Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

This book was set by Pine Tree Composition (Michelle Gardner, CSR).
The editors were Isabel Nogueira, Harriet Lebowitz, Jim Ransom, and Barbara Holton.
The production supervisor was Phil Galea.
The illustration manager was Charissa Baker.
The book designer was Eve Siegel.
The illustrator was Linda F. Harris.
The index was prepared by Kathy Pitcoff.

RR Donnelley was printer and binder.

This book is printed on acid-free paper.

Contents

Authors xiii
Preface xix

1. General Approach to the Patient; Health Maintenance & Disease Prevention 1
Stephen J. McPhee, MD, & Michael Pignone, MD, MPH

General Approach to the Patient 1
Health Maintenance & Disease Prevention 2
Prevention of Infectious Diseases 3

Prevention of Cardiovascular Disease 5
Prevention of Physical Inactivity & Sedentary Lifestyle 12
Cancer Prevention 13
Prevention of Injuries & Violence 14
Substance Abuse: Alcohol & Illicit Drugs 16

2. Common Symptoms 19

Ralph Gonzales, MD, MSPH

Cough 19
Lower Extremity Edema 21
Fever & Hyperthermia 22
Involuntary Weight Loss 24
Fatigue & Chronic Fatigue Syndrome 25
Acute Headache 28

3. Preoperative Evaluation 30

Joshua S. Adler, MD, & Lee Goldman, MD, MPH

Physiologic Effects of Anesthesia & Surgery 30
Evaluation of the Asymptomatic Patient 30
Cardiac Risk Assessment 31
Pulmonary Evaluation in Non-Lung Resection Surgery 35
Evaluation of the Patient With Liver Disease 37
Preoperative Hematologic Evaluation 38
Neurologic Evaluation 38
Management of Endocrine Diseases 39
Renal Disease 40
Antibiotic Prophylaxis of Surgical Wound Infections 41

4. Geriatric Medicine 43

C. Bree Johnston, MD, MPH, William L. Lyons, MD, & Kenneth E. Covinsky, MD, MPH

General Principles of Geriatric Medicine 43
General Approach to the Older Patient 44
Assessment of Older Adults 46
Selected Preventive Measures in Geriatric Practice 47
Common Problems of the Frail Older Person 50
Dementia 50
Depression 52
Delirium 53
Immobility 53
Falls & Gait Disorders 54
Urinary Incontinence 56
Weight Loss & Malnutrition 58
Pharmacotherapy & Polypharmacy 59

5. Care at the End of Life 61

Michael W. Rabow, MD, & Steven Z. Pantilat, MD

The End of Life 61
Diagnosis of the End of Life 61
Expectations About the End of Life 61
Communication & the Role of the Clinician at the End of Life 62
Caring for the Family 62
The Limits of Care at the End of Life 62
The Setting & Structure of Care 63
Ethical & Legal Background 63
Advance Directives 64
DNAR Orders 64
Hospice & Other Palliative Care Institutions 65
Cultural Issues 65
Management of Pain & Other Common Symptoms 60
Pain at the End of Life 66
Dyspnea 75
Nausea & Vomiting 75
Constipation 75
Delirium & Agitation 76
Other Specific Tasks of Caring 76
Nutrition & Hydration 76
Withdrawal of Curative Efforts 77
Psychologic, Social, & Spiritual Issues 77
Tasks After Death 79
The Pronouncement & Death Certificate 79
Autopsy & Organ Donation 79
Follow-Up & Grieving 79

6. Skin, Hair, & Nails 81

Timothy G. Berger, MD

Diagnosis of Skin Disorders 81
Principles of Dermatologic Therapy 81
Common Dermatoses 87
Pigmented Lesions 87
Scaling Disorders 90
Vesicular Dermatoses 103
Weeping or Encrusted Lesions 109
Pustular Disorders 111
Figurate Erythemas 117
Blistering Diseases 121
Papules 123
Violaceous to Purple Papules & Nodules 126

Pruritus (Itching) 128
Inflammatory Nodules 132
Photodermatitis 134
Ulcers 135
Miscellaneous Dermatologic Disorders 137
Pigmentary Disorders 137
Baldness (Alopecia) 138
Nail Disorders 139
Dermatitis Medicamentosa (Drug Eruption) 141

7. Eye 145

Paul Riordan-Eva, FRCOphth

Symptoms of Ocular Disease 145
Ocular Examination 146
Ophthalmologic Referrals 148
Refractive Errors 148
Disorders of the Lids & Lacrimal Apparatus 149
Conjunctivitis 150
Pinguecula & Pterygium 152
Corneal Ulcer 153
Acute (Angle-Closure) Glaucoma 154
Chronic Glaucoma 155
Uveitis 157
Cataract 158
Retinal Detachment 158
Vitreous Hemorrhage 159
Age-Related Macular Degeneration 159
Central & Branch Retinal Vein Occlusions 160
Central & Branch Retinal Artery Occlusions 161
Amaurosis Fugax 161
Retinal Disorders Associated With Systemic Diseases 161
AIDS 163
Anterior Ischemic Optic Neuropathy 163
Optic Neuritis 164
Optic Disk Swelling 164
Ocular Motor Palsies 164
Dysthyroid Eye Disease 165
Orbital Cellulitis 165
Ocular Trauma 165
Principles of Treatment of Ocular Infections 167
Techniques Used in the Treatment of Ocular Disorders 167
Precautions in Management of Ocular Disorders 172
Adverse Ocular Effects of Systemic Drugs 174
BR>**8. Ear, Nose, & Throat 175**

Robert K. Jackler, MD, & Michael J. Kaplan, MD

Diseases of the Ear 175
Diseases of the Nose & Paranasal Sinuses 189
Diseases of the Oral Cavity & Pharynx 196
Diseases of the Salivary Glands 202
Diseases of the Larynx 203
Tracheostomy & Cricothyrotomy 206
Foreign Bodies in the Upper Aerodigestive Tract 207
Diseases Presenting as Neck Masses 207
Otolaryngologic Manifestations of HIV Infection 209

9. Lung 212

Mark S. Chesnutt, MD, & Thomas J. Prendergast, MD

Common Manifestations of Lung Disease 212
Dyspnea 212
Cough 213
Hemoptysis 214
Approach to the Patient 214
Physical Examination 214
Pulmonary Function Tests 216
Disorders of the Airways 219
Pulmonary Infections 241
Pulmonary Neoplasms 259
Interstitial Lung Disease 269
Disorders of the Pulmonary Circulation 274
Environmental & Occupational Lung Disorders 287
Pleural Diseases 293
Disorders of Control of Ventilation 298
Acute Respiratory Failure 300
Acute Respiratory Distress Syndrome (ARDS) 303

10. Heart 306

Barry M. Massie, MD, & Thomas M. Amidon, MD

Symptoms & Signs 306
Diagnostic Testing 309
Congenital Heart Disease 310
Valvular Heart Disease 315
Coronary Heart Disease 326
Disturbances of Rate & Rhythm 352
Bradycardias & Conduction Disturbances 368
Cardiac Failure 371
Myocarditis & the Cardiomyopathies 384
Acute Rheumatic Fever & Rheumatic Heart Disease 389
Diseases of the Pericardium 391
Pulmonary Hypertension & Heart Disease 393
Neoplastic Diseases of the Heart 395
Cardiac Involvement in Miscellaneous Systemic Diseases 395
Traumatic Heart Disease 396
The Cardiac Patient & Surgery 397
The Cardiac Patient & Pregnancy 398

11. Systemic Hypertension 401

Barry M. Massie, MD

Approach to Hypertension 401
Drug Therapy 408
Hypertensive Urgencies & Emergencies 424

12. Blood Vessels & Lymphatics 428

Louis M. Messina, MD, Laura K. Pak, MD, & Lawrence M. Tierney, Jr., MD

Arterial Aneurysms 428
Lower Extremity Occlusive Disease 434
Other Arteriopathies 444
Vasomotor Disorders 446
Venous Diseases 450
Diseases of the Lymphatic Channels 457
Hypotension & Shock 458

13. Blood 462

Charles A. Linker, MD

Anemias 462
Neutropenia 479
Leukemias & Other Myeloproliferative Disorders 480
Lymphomas 492
Disorders of Hemostasis 498
Hypercoagulable States 510
Blood Transfusions 512

14. Alimentary Tract 515

Kenneth R. McQuaid, MD

Symptoms & Signs of Gastrointestinal Disease 515
Diseases of the Peritoneum 537
Diseases of the Esophagus 542
Diseases of the Stomach & Duodenum 560
Diseases of the Small Intestine 578
Diseases of the Colon & Rectum 592
Anorectal Diseases 618

15. Liver, Biliary Tract, & Pancreas 623

Lawrence S. Friedman, MD

Jaundice (Icterus) 623
Diseases of the Liver 626
Diseases of the Biliary Tract 652
Diseases of the Pancreas 661

16. Breast 669

Armando E. Giuliano, MD

Benign Breast Disorders 669
Fibrocystic Disease 669
Fibroadenoma of the Breast 670
Nipple Discharge 670
Fat Necrosis 671
Breast Abscess 671
Disorders of the Augmented Breast 671
Carcinoma of the Female Breast 672
Incidence & Risk Factors 672
Early Detection of Breast Cancer 674
Differential Diagnosis 679
Staging 679
Pathologic Types 681
Special Clinical Forms of Breast Cancer 682
Hormone Receptor Sites 683
Curative Treatment 683
Palliative Treatment 687
Prognosis 690
Follow-up Care 691
Carcinoma of the Male Breast 692

17. Gynecology 694

H. Trent MacKay, MD, MPH

Abnormal Premenopausal Bleeding 694
Postmenopausal Vaginal Bleeding 695
Premenstrual Syndrome (Premenstrual Tension) 696
Dysmenorrhea 696
Vaginitis 697
Cervicitis 699
Cervical Polyps 699
Cyst & Abscess of Bartholin's Duct 699
Effects of Exposure to Diethylstilbestrol in Utero 699
Cervical Intraepithelial Neoplasia 700
Carcinoma of the Cervix 701
Leiomyoma of the Uterus 703
Carcinoma of the Endometrium 704
Carcinoma of the Vulva 705
Endometriosis 705
Genital Prolapse 706
Uterine Prolapse 707
Pelvic Inflammatory Disease 707
Ovarian Tumors 708
Persistent Anovulation 712
Painful Intercourse (Dyspareunia) 713
Infertility 714
Contraception 716
Rape 724
Menopausal Syndrome 725

18. Obstetrics 728

William R. Crombleholme, MD

Diagnosis & Differential Diagnosis of Pregnancy 728
Essentials of Prenatal Care 728
Nutrition in Pregnancy 731
Travel & Immunizations During Pregnancy 732
Vomiting of Pregnancy & Hyperemesis Gravidarum 732
Spontaneous Abortion 732
Recurrent (Habitual) Abortion 734
Ectopic Pregnancy 734
Preeclampsia-Eclampsia 736
Gestational Trophoblastic Neoplasia 738
Third-Trimester Bleeding 739
Medical Conditions Complicating Pregnancy 740
Surgical Complications During Pregnancy 747
Prevention of Hemolytic Disease of the Newborn 748
Prevention of Preterm (Premature) Labor 749
Lactation 751
Puerperal Mastitis 752

19. Allergic & Immunologic Disorders 753

Jeffrey L. Kishiyama, MD, & Daniel C. Adelman, MD

Allergic Diseases 753
Atopic Disease 755
Allergic Rhinitis 756
Anaphylaxis, Urticaria, & Angioedema 759
Drug Allergy 760
Immune Complex Disease (Serum Sickness) 761
Pseudoallergic Reactions 762
Clinical Immunology 762
Cells Involved in Immunity 762
Tests for Cellular Immunity 764
Immunoglobulin Structure & Function 765
Immunodeficiency Disorders 767
Selective Immunoglobulin A Deficiency 767
Common Variable Immunodeficiency 767
Diseases of Immunoglobulin Over-production 768
Autoimmunity 770
Autoimmune Diseases 770
Tests for Autoantibodies Associated With Autoimmune Disease 770
Immunogenetics & Transplantation 772
Genetic Control of the Immune Response 772
Associations Between HLA Antigens & Specific Diseases 772
Clinical Transplantation 774
Mechanism of Action of Immunosuppressive Drugs 775
Immunomodulating Therapies 777

20. Arthritis & Musculoskeletal Disorders 778

David B. Hellmann, MD, FACP, & John H. Stone, MD, MPH

Diagnosis & Evaluation 778
Degenerative & Crystal-Induced Arthritis 778
Pain Syndromes 786
Autoimmune Diseases 797
Vasculitis Syndromes 812
Seronegative Spondyloarthropathies 819
Infectious Arthritis 823
Infections of Bones 825
Tumors & Tumor-Like Lesions of Bone 829
Other Rheumatic Disorders 830
Some Orthopedic Procedures for Arthritic Joints 831

21. Fluid & Electrolyte Disorders 833

Masafumi Fukagawa, MD, PhD, FJSIM, Kiyoshi Kurokawa, MD, MACP, & Maxine A. Papadakis, MD

Disorders of Sodium Concentration 834
Disorders of Potassium Concentration 840
Disorders of Calcium Concentration 845
Disorders of Phosphorus Concentration 847
Disorders of Magnesium Concentration 850
Hyperosmolar Disorders & Osmolar Gaps 852
Acid-Base Disorders 852
Fluid Management 862

22. Kidney 863

Suzanne Watnick, MD, & Gail Morrison, MD, FACP

Approach to Renal Disease 863
Acute Renal Failure 867
Chronic Kidney Disease 873
Glomerulonephropathies 882
Nephrotic Disease in Primary Renal Disorders 889
Nephrotic Disease from Systemic Disorders 890
Diseases Demonstrating Nephritic & Nephrotic Components 891
Tubulointerstitial Diseases 892
Cystic Diseases of the Kidney 894
Medullary Sponge Kidney 896
Multisystem Diseases with Variable Kidney Involvement 897
The Kidney & Aging 897

23. Urology 899

Marshall L. Stoller, MD, & Peter R. Carroll, MD, FACS

Urologic Evaluation 899
Evaluation of Hematuria 904
Genitourinary Tract Infections 904
Acute Cystitis 905

Acute Pyelonephritis 906
Acute Bacterial Prostatitis 908
Chronic Bacterial Prostatitis 908
Nonbacterial Prostatitis 909
Prostatodynia 910
Acute Epididymitis 910
Urinary Stone Disease 911
Urinary Incontinence 915
Male Erectile Dysfunction & Sexual Dysfunction 918
Male Infertility 920
Benign Prostatic Hyperplasia 921
Malignant Genitourinary Tract Disorders 928
Prostate Cancer 928
Bladder Cancer 933
Cancers of the Ureter & Renal Pelvis 936
Primary Tumors of the Kidney 936
Secondary Tumors of the Kidney 938
Primary Tumors of the Testis 938
Secondary Tumors of the Testis 940

24. Nervous System 941

Michael J. Aminoff, DSc, MD, FRCP

Headache 941
Facial Pain 945
Epilepsy 947
Syncope & Dysautonomia 952
Sensory Disturbances 953
Weakness & Paralysis 954
Transient Ischemic Attacks 954
Stroke 956
Intracranial & Spinal Space-Occupying Lesions 964
Nonmetastatic Neurologic Complications of Malignant Disease 968
Pseudotumor Cerebri 969
Selected Neurocutaneous Diseases 970
Movement Disorders 971
Dementia 978
Multiple Sclerosis 978
Vitamin E Deficiency 979
Spasticity 979
Myelopathies in AIDS 980
Myelopathy of Human T Cell Leukemia Virus 980
Subacute Combined Degeneration of the Spinal Cord 980
Wernicke's Encephalopathy 980
Stupor & Coma 980
Head Injury 983
Spinal Trauma 984
Syringomyelia 985
Motor Neuron Diseases 985
Peripheral Neuropathies 986
Discogenic Neck Pain 993
Brachial & Lumbar Plexus Lesions 996
Disorders of Neuromuscular Transmission 996
Myopathic Disorders 998
Periodic Paralysis Syndrome 1000

25. Psychiatric Disorders 1001

Stuart J. Eisendrath, MD, & Jonathan E. Lichtmacher, MD

Psychiatric Assessment 1001
Treatment Approaches 1004
Common Psychiatric Disorders 1005
Substance Use Disorders 1046
Delirium, Dementia, & Other Cognitive Disorders 1054
Geriatric Psychiatric Disorders 1057
Psychiatric Problems Associated with Hospitalization & Medical & Surgical Disorders 1059

26. Endocrinology 1062

Paul A. Fitzgerald, MD

Common Presentations in Endocrinology 1062
Diseases of the Hypothalamus & Pituitary Gland 1066
Diseases of the Thyroid Gland 1077
The Parathyroids 1103
Metabolic Bone Disease 1110
Diseases of the Adrenal Cortex 1116
Diseases of the Adrenal Medulla 1127
Pancreatic & Duodenal Neuroendocrine Tumors 1131
Diseases of the Testes 1132
Amenorrhea & Menopause 1135
Multiple Endocrine Neoplasia 1142
Clinical Use of Glucocorticoids 1144

27. Diabetes Mellitus & Hypoglycemia 1146

Umesh Masharani, MB, BS; MRCP(UK)

Diabetes Mellitus 1146
Diabetic Coma 1179
The Hypoglycemic States 1185

28. Lipid Abnormalities 1191

Robert B. Baron, MD, MS

Lipids & Lipoproteins 1191
Lipoproteins & Atherogenesis 1191
Lipid Fractions & the Risk of Coronary Heart Disease 1192
Therapeutic Effects of Lowering Cholesterol 1193
Secondary Conditions That Affect Lipid Metabolism 1194
Clinical Presentations 1194
Screening for High Blood Cholesterol 1195

Treatment of High LDL Cholesterol 1198
High Blood Triglycerides 1202

29. Nutrition 1203

Robert B. Baron, MD, MS

Nutritional Requirements 1203
Assessment of Nutritional Status 1210
Nutritional Disorders 1212
Eating Disorders 1218
Disorders of Vitamin Metabolism 1220
Diet Therapy 1226
Nutritional Support 1228

30. General Problems in Infectious Diseases 1235

Richard A. Jacobs, MD, PhD

Fever of Unknown Origin (FUO) 1235
Infections in the Immunocompromised Patient 1237
Nosocomial Infections 1240
Infections of the Central Nervous System 1242
Animal & Human Bite Wounds 1244
Sexually Transmitted Diseases 1245
Infections in Drug Users 1246
Acute Infectious Diarrhea 1248
Traveler's Diarrhea 1251
Active Immunization Against Infectious Diseases 1251
Recommended Immunization of Infants, Children, & Adolescents 1251
Recommended Immunization of Adults 1253
Recommended Immunizations for Travelers 1259
Hypersensitivity Tests & Desensitization 1261

31. HIV Infection 1263

Mitchell H. Katz, MD, & Harry Hollander, MD

Epidemiology 1264
Etiology 1266
Pathogenesis 1266
Pathophysiology 1266
Clinical Findings 1267
Differential Diagnosis 1276
Prevention 1276
Treatment 1279
Course & Prognosis 1292

32. Infectious Diseases: Viral & Rickettsial 1293

Samuel A. Shelburne, III, MD, & Wayne X. Shandera, MD

Viral Diseases 1293
Human Herpesviruses 1294
Major Vaccine-Preventable Viral Infections 1304
Other Neurotrophic Viruses 1311
Other Systemic Viral Diseases 1317
Common Viral Respiratory Infections 1320
Adenovirus Infections 1324
Other Exanthematous Viral Infections 1325
Viruses & Gastroenteritis 1326
Enteroviruses That Produce Several Syndromes 1327
Rickettsial Diseases 1328
Typhus Group 1329
Spotted Fevers 1332
Other Rickettsial & Rickettsial-Like Diseases 1333

33. Infectious Diseases: Bacterial & Chlamydial 1337

Henry F. Chambers, MD

Infections Caused by Gram-Positive Bacteria 1337
Infective Endocarditis 1351
Infections Caused by Gram-Negative Bacteria 1357
Actinomycosis 1373
Nocardiosis 1373
Infections Caused by Mycobacteria 1374
Infections Caused by Chlamydiae 1377

34. Infectious Diseases: Spirochetal 1380

Richard A. Jacobs, MD, PhD

Syphilis 1380
Non-Sexually Transmitted Treponematoses 1390
Miscellaneous Spirochetal Diseases 1391
Relapsing Fever 1391
Rat-Bite Fever 1392
Leptospirosis 1392
Lyme Disease 1393

35. Infectious Diseases: Protozoal & Helminthic 1400

Robert S. Goldsmith, MD, MPH, DTM&H

Protozoal Infections 1400
African Trypanosomiasis (Sleeping Sickness) 1400
American Trypanosomiasis (Chagas' Disease) 1402
Amebiasis 1404
Infections With Pathogenic Free-Living Amebas 1409
Babesiosis (Piroplasmosis) 1411
Balantidiasis 1412
Coccidial & Microsporidial Infections: Cryptosporidiosis, Isosporiasis, Cyclosporiasis, & Sarcocystosis 1412
Giardiasis 1415
Leishmaniasis 1417
Malaria 1422
Toxoplasmosis 1434

Helminthic Infections 1437
Trematode (Fluke) Infections 1437
Schistosomiasis 1437
Cestode Infections 1444
Nematode (Roundworm) Infections 1451

36. Infectious Diseases: Mycotic 1471

Richard J. Hamill, MD

Candidiasis 1471
Histoplasmosis 1473
Coccidioidomycosis 1474
Pneumocystosis 1475
Cryptococcosis 1477
Aspergillosis 1479
Mucormycosis 1480
Blastomycosis 1480
Paracoccidioidomycosis 1481
Sporotrichosis 1481
*Penicillium marneffe*i Infections 1481
Chromomblastomycosis 1482
Mycetoma 1482
Other Opportunistic Mold Infections 1482
Antifungal Therapy 1485

37. Anti-infective Chemotherapeutic & Antibiotic Agents 1486

Richard A. Jacobs, MD, PhD, & B. Joseph Guglielmo, PharmD

Some Principles of Antimicrobial Therapy 1486
Penicillins 1495
Cephalosporins 1501
Other β -Lactam Drugs 1504
Erythromycin Group (Macrolides) 1505
Azalides 1505
Ketolides 1506
Tetracycline Group 1507
Chloramphenicol 1508
Aminoglycosides 1508
Polymyxins 1510
Antituberculous Drugs 1511
Alternative Drugs in Tuberculosis Treatment 1511
Sulfonamides & Antifolate Drugs 1511
Sulfones Used in the Treatment of Leprosy 1513
Specialized Drugs Used Against Bacteria 1513
Streptogramins 1515
Oxazolidinones 1515
Quinolones 1515
Pentamidine & Atovaquone 1518
Antifungal Drugs 1518
Antiviral Chemotherapy 1522

38. Disorders Due to Physical Agents 1527

Richard Cohen, MD, MPH, & Brent R. W. Moelleken, MD, FACS

Disorders Due to Cold 1527
Disorders Due to Heat 1531
Burns 1534
Electric Shock 1538
Ionizing Radiation Reactions 1538
Drowning 1540
Other Disorders Due to Physical Agents 1542

39. Poisoning 1546

Kent R. Olson, MD

Initial Evaluation of the Patient With Poisoning or Drug Overdose 1546
The Symptomatic Patient 1546
Antidotes & Other Treatment 1549
Diagnosis of Poisoning 1552
Clinical Laboratory Tests in Management of Poisoning 1553
Treatment of Common Specific Poisonings (Alphabetical Order) 1555

40. Cancer 1577

Hope S. Rugo, MD

Incidence & Etiology 1577
Prevention of Cancer 1583
Primary Prevention 1583
Secondary Prevention 1591
Special Topics in Prevention 1593
Staging of Cancer 1594
Primary Cancer Treatment 1594
Surgery & Radiation Therapy 1594
Systemic Cancer Therapy 1597
Adjuvant Chemotherapy for Micrometastases 1606
Toxicity & Dose Modification of Chemotherapeutic Agents 1614
Evaluation of Tumor Response 1619
Tumor Size 1619
Tumor Markers 1620
General Well-Being, Performance Status, & Supportive Care 1621
Cancer Complications: Diagnosis & Management 1622
Oncologic Emergencies 1622
Other Complications 1625
The Paraneoplastic Syndromes 1628
Novel Therapies for Cancer Treatment 1631
Alternative & Complementary Therapies for Cancer Treatment 1634

41. Medical Genetics 1636

Reed E. Pyeritz, MD, PhD

Introduction to Medical Genetics 1636
Genes & Chromosomes 1637
Mutation 1638
Genes in Individuals 1639
Genes in Families 1640
Disorders of Multifactorial Causation 1643
Chromosomal Aberrations 1643
The Techniques of Medical Genetics 1644
Family History & Pedigree Analysis 1644
Cytogenetics 1644
Biochemical Genetics 1646
DNA Analysis 1648
Prenatal Diagnosis 1650
Neoplasia: Chromosomal & DNA Analysis 1651
Selected Genetic Disorders 1653
Acute Intermittent Porphyria 1653
Alkaptonuria 1654
Down's Syndrome 1655
Fragile X Mental Retardation 1655
Gaucher's Disease 1656
Homocystinuria 1656
Homocysteine & Arterial Occlusive Disease 1657
Klinefelter's Syndrome 1657
Marfan's Syndrome 1658

42. Diagnostic Testing & Medical Decision Making 1659

C. Diana Nicoll, MD, PhD, MPA, & Michael Pignone, MD, MPH

Benefits; Costs & Risks 1659
Performance of Diagnostic Tests 1659
Test Characteristics 1660
Use of Tests in Diagnosis & Management 1663
Odds-Likelihood Ratios 1664

43. Information Technology in Patient Care: The Internet, Telemedicine, & Clinical Decision Support 1670

Justin Graham, MD, MS, & Rick Kulkarni, MD

The Internet in Clinical Practice 1670
Information Reliability & Quality Assessment 1671
Legal Aspects of Medical Informatics 1672
Patient-Clinician Electronic Communication 1673
Interactive Forums 1674
Telemedicine 1675
Clinical Decision Support Systems 1676
Personal Digital Assistants (Handhelds) 1677
Medical Coding & Terminology 1678

44. Complementary & Alternative Medicine 1681

Ellen F. Hughes, MD, PhD, Bradly P. Jacobs, MD, MPH, & Brian M. Berman, MD

Herbal Medicines 1682
Dietary Supplements 1690
Acupuncture 1694
Homeopathy 1701

Appendix: Therapeutic Drug Monitoring & Laboratory Reference Ranges 1704

C. Diana Nicoll, MD, PhD, MPA

Preface

Current Medical Diagnosis & Treatment 2004 is the 43rd annual volume of this single-source reference for practitioners in both hospital and ambulatory settings. It emphasizes the practical features of clinical diagnosis and patient management in all fields of internal medicine and in specialties of interest to primary care practitioners and subspecialists who provide generalist care.

OUTSTANDING FEATURES

- Medical advances up to time of publication
- Detailed presentation of all primary care topics, including gynecology, obstetrics, dermatology, ophthalmology, otolaryngology, psychiatry, neurology, toxicology, and urology
- Concise format, facilitating efficient use in any practice setting
- More than 1000 diseases and disorders
- Only text with annual update of HIV infection
- Prevention and cost information
- Easy access to drug dosages, with trade names indexed and prices updated in each edition
- Annotated recent references, with unique identifiers (PubMed, PMID numbers)
- Companion Web site featuring direct links to more than 450 selected Web sites
- Inexpensive

INTENDED AUDIENCE

House officers and all students of the healing arts will find the descriptions of diagnostic and therapeutic modalities, with citations to the current literature, of everyday usefulness in patient care.

Internists, family physicians, nurse practitioners, and other primary care providers will appreciate *CMDT* as a ready reference and refresher text. Physicians in other specialties, surgeons, pharmacists, and dentists will find the book a basic internal medicine reference. Nurses, nurse-practitioners and physicians' assistants will welcome the format and scope of the book as a means of learning medical diagnosis and treatment. Those who are not involved in health care, including patients, who seek information about the nature of specific diseases and their diagnosis and treatment may also find this book to be a valuable resource.

SPECIAL TO THIS EDITION<

- Information on emerging infectious diseases such as severe acute respiratory syndrome (SARS), West Nile virus, and monkeypox
- Expansion of the chapter on common symptoms, to include cough, lower extremity edema, fever, involuntary weight loss, fatigue, and acute headache
- Enhanced coverage of psychiatric disorders, including posttraumatic stress disorder (PTSD)
- End-of-life care information integrated throughout the text
- Developments in thyroid disease, diabetes mellitus, asthma, and HIV infection, such as new nomenclature for pneumocystosis pneumonia (*Pneumocystis jiroveci*)
- New information on alternative medicine and complementary therapies
- Major revisions of chapters on cancer, blood vessels, and lymphatics, and genetics, including immunologic therapy for cancer, and adult-onset debilities due to mitochondrial mutations
- Drug information, bibliographies, and Web sites updated through June 2003
- Update on antibiotics, including new antiviral and antifungal agents
- Expanded information on the clinical presentation and treatment of bioterrorism-related diseases such as anthrax and smallpox
- List of key Internet addresses for current peer-reviewed medical information, including:
 - Centers for Disease Control and Prevention traveler's and immunization information
 - National Institutes of Health Consensus Statements
 - Agency for Healthcare Research and Quality of the United States Public Health Service Clinical Guidelines

COMPANION WEB SITE

CMDT's companion Web site, www.cmdtlinks.com, contains an annotated list of Web sites selected and revised throughout the year. The entries provide descriptions

of sites as well as ratings of them on a six-category scale. All linked Internet addresses are updated regularly.

CMDT IS ONLINE

An online version of *CMDT* is now available at www.cmdtonline.com. It includes the content in the book version as well as these additional valuable features:

- New diagnostic test information from *Pocket Guide to Diagnostic Tests*
- Up-to-date clinical guidelines for screening, prevention, and disease management from *Practice Guidelines in Primary Care*
- Hundreds of new color images, graphs, algorithms, and tables
- Patient education materials (printable), including direct links to the *Journal of the American Medical Association's* weekly patient pages
- Relevant Web sites keyed to chapter content
- Web Site of the Week, which features a site of special interest
- Direct PubMed links to abstracts of all references for immediate access to evidence
- Prevention and cost information
- Clinical vignettes linked to chapter content and Internet resources
- An integrated drug database
- Puzzles (What's This?), updated daily, to improve learners' pattern recognition
- In the News, updated daily and linked to related chapter content

ORDER OR SUBSCRIBE TO CMDT AND CMDTONLINE.COM)

It is now possible to receive each year's edition of the only annually updated textbook of medicine automatically upon publication simply by returning the enclosed postcard to McGraw-Hill. You can order *Current Medical Diagnosis & Treatment* 2004 and the online version by visiting the McGraw-Hill Web site, www.cmdtonline.com, or calling 1-800-262-4729.

ACKNOWLEDGMENTS

We wish to thank our associate authors for participating once again in the annual updating of this important book. Many students and physicians also have contributed useful suggestions to this and previous editions, and we are grateful. We continue to welcome comments and recommendations for future editions in writing or via electronic mail. The editors' and authors' institutional and Internet e-mail addresses are given in the Authors section.

Lawrence M. Tierney, Jr., MD
Stephen J. McPhee, MD
Maxine A. Papadakis, MD

San Francisco, California
September 2003

From inability to let alone; from too much zeal for the new and contempt for what is old; from putting knowledge before wisdom, and science before art and cleverness before common sense; from treating patients as cases; and from making the cure of the disease more grievous than the endurance of the same, Good Lord, deliver us.

—Sir Robert Hutchison

1. General Approach to the Patient; Health Maintenance & Disease Prevention - *Stephen J. McPhee, MD, & Michael Pignone, MD, MPH*

■ GENERAL APPROACH TO THE PATIENT

The approach to diagnosis begins with the history and pertinent physical examination—both susceptible to errors of omission and commission. The medical interview serves several functions. It is used to collect information of help in diagnosis (the "history" of the present illness), to assess and communicate prognosis, to provide emotional support, and to reach agreement with the patient about further diagnostic procedures and therapeutic options. It also serves as an opportunity to influence patient behavior, such as in motivational discussions about smoking cessation. Interviewing techniques that avoid domination by the physician increase patient satisfaction. Effective physician-patient communication can improve health outcomes.

Patient Compliance

For many illnesses, treatment depends on difficult fundamental behavioral changes, including alterations in diet, taking up exercise, giving up smoking, and cutting down drinking. Compliance is a problem in every practice; up to 50% of patients fail to achieve full compliance, and a third never take their medicines. Many patients with medical problems do not seek appropriate care or may drop out of care prematurely. Compliance rates for short-term, self-administered therapies are higher than for long-term therapies and are inversely correlated with the number of interventions, their complexity and cost, and the patient's perception of overmedication. As an example, in HIV-infected patients, adherence to antiretroviral therapy is a crucial determinant of treatment success. Studies have unequivocally demonstrated a close relationship between patient compliance and plasma HIV RNA levels, CD4 cell counts, and mortality. Adherence levels of > 95% are needed to maintain virologic suppression. However, studies show that 40-60% of patients are < 90% adherent and that adherence tends to decrease over time. Patient reasons for nonadherence include simple forgetfulness, being away from home, being busy, and changes in daily routine. Other reasons include psychiatric disorders (depression or substance abuse), uncertainty about the effectiveness of treatment, lack of knowledge about the consequences of poor adherence, regimen complexity, and treatment side effects.

Patients seem better able to take prescribed medications than to comply with recommendations to follow a diet, exercise regularly, reduce alcohol intake, or perform various self-care activities (such as monitoring blood glucose levels at home). For short-term regimens, adherence to medications can be improved by giving clear instructions. Writing out advice to patients, including changes in medication, may be helpful. Because functional health illiteracy is common, with almost half of English-speaking patients unable to read and understand basic written instructions, other forms of communication, such as videotape or oral instructions, may be more effective.

To help improve adherence to long-term regimens, clinicians can work with patients to reach agreement on the goals for therapy, provide information about the regimen, counsel about the importance of adherence and how to organize medication-taking, reinforce self-monitoring, provide more convenient care, prescribe a simple dosage regimen for all medications (preferably one or two doses daily), suggest ways to help in remembering to take doses (time of day, mealtime, alarms) and to keep appointments, and provide ways to simplify dosing (medication boxes). Single-unit doses supplied in foil-backed wrappers should be avoided for patients who have difficulty opening them. Medication boxes with compartments (eg, Medisets) that are filled weekly are useful. Microelectronic devices can provide feedback to show patients whether they have taken doses as scheduled or to notify patients within a day if doses are skipped. The clinician can also enlist social support from family and friends, recruit an adherence monitor, and provide rewards and recognition for the patient's efforts to follow the regimen.

Compliance is also improved when a trusting doctor-patient relationship has been established. Clinicians can improve patient compliance by inquiring specifically about the behaviors in question. When asked, many patients admit to incomplete compliance with medication regimens, with advice about giving up cigarettes, or with engaging only in "safe sex" practices. Although difficult, sufficient time must be made available for communication of health messages. Other ways of assessing medication compliance include pill counts and refill records; monitoring serum, urine, or saliva levels of drugs or metabolites; watching for appointment nonattendance and treatment nonresponse; and assessing predictable drug effects such as weight changes with diuretics or bradycardia from beta-blockers. Even partial compliance, as with drug treatment of hypertension and diabetes mellitus, improves outcomes compared with noncompliance.

Guiding Principles of Care

Ethical decisions are often called for in medical practice, at both the "micro" level of the individual patient-physician relationship and at the "macro" level of the allocation of resources. Ethical principles that guide the successful approach to diagnosis and treatment are honesty, beneficence, justice, avoidance of conflict of interest, and the pledge to do no harm. Increasingly, Western medicine involves patients in important decisions about medical care, including how far to proceed with treatment of patients who have terminal illnesses (see [Chapter 5](#)).

The physician's role does not end with diagnosis and treatment. The importance of the empathic clinician in helping patients and their families bear the burden of serious illness and death cannot be overemphasized. "To cure sometimes, to relieve often, and to comfort always" is a French saying as apt today as it was five centuries ago—as is Francis Peabody's admonition: "The secret of the care of the patient is in caring for the patient."

■ HEALTH MAINTENANCE & DISEASE PREVENTION

Preventive medicine is categorized as primary, secondary, or tertiary. Primary prevention aims to remove or reduce disease risk factors (eg, immunization, giving up or not starting smoking). Secondary prevention techniques promote early detection of disease or precursor states (eg, routine cervical Papanicolaou screening to detect carcinoma or dysplasia of the cervix). Tertiary prevention measures are aimed at limiting the impact of established disease (eg, partial mastectomy and radiation therapy to remove and control localized breast cancer). [Table 1-1](#) lists deaths from preventable causes in the United States—diseases that in 1990 accounted for 50% of all fatalities. [Table 1-2](#) compares recommendations for periodic health examinations as developed by the United States Preventive Services Task Force, the American College of Physicians, and the Canadian Task Force on the Periodic Health Examination. Despite emerging consensus on many of the services, controversy persists for others. Many effective preventive services are underutilized. A recent analysis found the following services had the most potential for improvement, based on their effectiveness and underuse: counseling about smoking cessation; screening older adults for vision impairment; screening and counseling adults and adolescents about alcohol abuse; screening older adults for colorectal cancer; screening young women for chlamydia infection; and vaccinating older adults against pneumococcal disease.

Walsh JM et al: Prevention in the year 2002: some news, some issues. *Prim Care Clin North Am* 2002;29:727. [\[PMID: 12529906\]](#)

PREVENTION OF INFECTIOUS DISEASES

Much of the decline in the incidence and fatality rates of infectious diseases is attributable to public health measures—especially immunization, improved sanitation, and better nutrition.

Immunization remains the best means of preventing many infectious diseases. In the United States, childhood immunization has resulted in near elimination of measles, mumps, rubella, poliomyelitis, diphtheria, pertussis, and tetanus. *Haemophilus influenzae* type b invasive disease has been reduced by more than 95% since introduction of the first conjugate vaccines. However, substantial vaccine-preventable morbidity and mortality continue to occur among adults from vaccine-preventable

diseases such as hepatitis A, hepatitis B, influenza, and pneumococcal infections. For example, in adults in the United States, there are an estimated 50,000-70,000 deaths annually from influenza, hepatitis B, and invasive pneumococcal disease. Yet in 1999, only 67% and 55% of elderly persons reported receiving influenza and pneumococcal vaccines (respectively). The American College of Physicians recommends that clinicians should review each adult's immunization status at age 50; assess risk factors that would indicate a need for pneumococcal vaccination and annual influenza immunizations; reimmunize at age 65 those who received an immunization against pneumococcus more than 6 years before; ensure that all adults have completed a primary diphtheria-tetanus immunization series, and administer a single booster at age 50; and assess the postvaccination serologic response to hepatitis B vaccination in all recipients who have ongoing risks of exposure to blood or body fluids (eg, sharp injuries, blood splashes).

In 2002, the Advisory Committee on Immunization Practices (ACIP) approved a schedule for the routine vaccination of persons aged 19 years and older.

Recently, needle-free jet injectors have been used successfully in administering trivalent inactivated influenza vaccine. In randomized, controlled trials, a novel triple-antigen (S, pre-S1, and pre-S2) recombinant hepatitis B vaccine (Hepacare) appears to be more effective than currently available single-antigen (S only) vaccine (Engerix B, Recombivax-HB). The new triple-antigen vaccine is also effective in more than three-quarters of inadequate responders to current single-antigen vaccines.

Recommended immunization schedules for children and adults are set forth in [Chapter 30](#). Immunization registries—confidential, population-based, computerized information systems that collect vaccination data about all residents of a geographic area—can be used to increase and sustain high vaccination coverage. Currently, approximately half of United States children aged under 6 years are participating in a registry, and national health objectives aim to increase this figure to 95% by 2010.

Skin testing for tuberculosis and treating selected patients reduces the risk of reactivation tuberculosis (see [Chapter 31](#), as is multidrug-resistant tuberculosis.

HIV infection is now the major infectious disease problem in the world. Since sexual contact is a common mode of transmission, prevention relies on eliminating unsafe sexual behavior by promoting abstinence, later onset of first sexual activity, decreased number of partners, and use of latex condoms. Appropriately used, condoms can reduce the rate of HIV transmission by nearly 70%. Couples with one infected partner who used condoms inconsistently had a considerable risk of infection: the rate of seroconversion was 4.8 per 100 persons per year, leading to an estimated cumulative incidence of 12.7% after 24 months. No seroconversions were noted with consistent condom use. Unfortunately, as many as one-third of HIV-positive individuals continue unprotected sexual practices after learning that they are HIV-infected. Tailored group educational intervention focused on practicing "safer sex" can reduce their transmission-risk behaviors with partners who are not HIV-positive. Other approaches to prevent HIV infection include treatment of sexually transmitted diseases, development of vaginal microbicides, and vaccine development. Increasingly, cases of HIV infection are transmitted by intravenous drug use. HIV prevention activities should include provision of sterile injection equipment for these individuals.

In immunocompromised patients, live vaccines are contraindicated but many killed or component vaccines are safe and recommended. *Asymptomatic* HIV-infected patients have not shown adverse consequences when given live MMR and influenza vaccinations as well as tetanus, hepatitis B, *H influenzae* type b, and pneumococcal vaccinations—all should be given. However, if poliomyelitis immunization is required, the inactivated poliomyelitis vaccine is indicated. In *symptomatic* HIV-infected patients, live virus vaccines such as MMR should generally be avoided, but annual influenza vaccination is safe.

Whenever possible, immunizations should be completed before procedures that require or induce immunosuppression (organ transplantation or chemotherapy), or that reduce immunogenic responses (splenectomy). However, if this is not possible, the patient may mount only a partial immune response, yet even this partial response can be of benefit. Patients who undergo allogeneic bone marrow transplantation lose preexisting immunities and should be revaccinated. In many situations, family members should also be vaccinated to protect the immunocompromised patient, though oral live polio vaccine should be avoided because of the risk of infecting the patient.

New cases of poliomyelitis have been reported in Haiti recently, slowing its eradication in the Western Hemisphere.

The 2001 anthrax attacks in the United States have raised concern about the nation's vulnerability to a smallpox attack. Resumption of smallpox vaccination has been proposed and is now under way for health care workers, police and firemen, etc. However, smallpox vaccine has a higher complication rate than any other vaccine currently being used. Expected adverse events in a mass smallpox vaccination campaign include fever (less than one case per five vaccine recipients), rash (less than one case per 100 recipients), encephalitis (less than three cases per million), and death (less than two cases per million). Careful prevaccination exclusion of high-risk individuals (those with eczema or immunosuppression) and their close contacts would be essential to minimize such complications. It is estimated that about 25% of potential vaccine recipients would require such exclusion, and these individuals would remain susceptible to smallpox infection.

PREVENTION OF CARDIOVASCULAR DISEASE

Cardiovascular diseases, including coronary heart disease and stroke, represent two of the most important causes of morbidity and mortality in developed countries. Several risk factors increase the risk for coronary disease and stroke. They can be divided into those that are modifiable (eg, lipid disorders, hypertension, cigarette smoking) and those that are not (eg, gender, age, family history of early coronary disease). This section considers the role of screening for and treating the former.

Impressive declines in age-specific mortality rates from heart disease and stroke have been achieved in all age groups in North America during the past 2 decades. The chief reasons for this favorable trend appear to be modification of risk factors, especially cigarette smoking and hypercholesterolemia, plus more aggressive detection and treatment of hypertension and better care for patients with heart disease.

Cigarette Smoking

Cigarette smoking remains the most important cause of preventable morbidity and early mortality in developed countries. In the United States, it is estimated that annually during 1995-1999 smoking caused approximately 440,000 premature deaths and cost approximately \$157 billion in health-related economic losses. Nicotine is highly addictive, raises brain levels of dopamine, and produces withdrawal symptoms on discontinuation. Cigarettes are responsible for one in every five deaths in the USA, yet smoking prevalence rates have been increasing among high school and college students. Cigar smoking has also increased; there is also continued use of smokeless tobacco (chewing tobacco and snuff), particularly among young people. Tobacco dependence may have a genetic component.

Smokers have twice the risk of fatal heart disease, 10 times the risk of lung cancer, and several times the risk of cancers of the mouth, throat, esophagus, pancreas, kidney, bladder, and cervix; a two- to threefold higher incidence of stroke and peptic ulcers (which heal less well than in nonsmokers); a two- to fourfold greater risk of fractures of the hip, wrist, and vertebrae; four times the risk of invasive pneumococcal disease; and a twofold increase in cataracts. In the United States, over 90% of cases of chronic obstructive pulmonary disease (COPD) occur among current or former smokers. Both active smoking and passive smoking are associated with deterioration of the elastic properties of the aorta and with progression of carotid artery atherosclerosis. Smoking has also been associated with increased risks of leukemia, of colon and prostate cancers, of breast cancer among postmenopausal women who are slow acetylators of *N*-acetyltransferase-2 enzymes, of osteoporosis, and of Alzheimer's disease. In cancers of the head and neck, lung, esophagus, and bladder, smoking is linked to mutations of the *P53* gene, the most common genetic change in human cancer. Patients with head and neck cancer who continue to smoke during radiation therapy have lower rates of response than those who do not smoke. Olfaction and taste are impaired in smokers, and facial wrinkles are increased. Heavy smokers have a 2.5 greater risk of age-related macular degeneration. Smokers die 5-8 years earlier than never-smokers.

The children of smokers have lower birth weights, are more likely to be mentally retarded, have more frequent respiratory infections and less efficient pulmonary function, have a higher incidence of chronic ear infections than children of nonsmokers, and are more likely to become smokers themselves.

In addition, exposure to environmental tobacco smoke has been shown to increase the risk of cervical cancer, lung cancer, invasive pneumococcal disease, and heart disease; to promote endothelial damage and platelet aggregation; and to increase urinary excretion of tobacco-specific lung carcinogens. The incidence of breast cancer may be increased as well. Of approximately 450,000 smoking-related deaths in the United States annually, as many as 53,000 are attributable to passive smoking.

Smoking cessation lessens the risks of death and of myocardial infarction in people with coronary artery disease; reduces the rate of death and acute myocardial infarction in patients who have undergone percutaneous coronary revascularization; lessens the risk of stroke; slows the rate of progression of carotid atherosclerosis; and is associated with reversal of chronic bronchitis and improved pulmonary function. On average, women smokers who quit smoking by age 35 add about 3 years to their life expectancy, and men add more than 2 years to theirs. Smoking cessation can increase life expectancy even for those who stop after the age of 65.

Fortunately, adult rates in the United States are now at an all-time low—23%—but rates are climbing for young people.

Although tobacco use constitutes the most serious common medical problem, it is undertreated. Over 70% of smokers see a physician each year, but only 20% of them receive any medical quitting advice or assistance. (Persons whose physicians advise them to quit are 1.6 times as likely to attempt quitting.) About 4% of smokers are able to quit each year.

The five steps for helping smokers quit are summarized in [Table 1-3](#). Common elements of supportive smoking cessation treatments are reviewed in [Table 1-4](#). A system should be implemented to identify smokers, and advice to quit should be tailored to the patient's level of readiness to change. All patients trying to quit should be offered pharmacotherapy except those with medical contraindications, those smoking fewer than 10 cigarettes per day, women who are pregnant or breast feeding, and adolescents. Nicotine replacement therapy doubles the chance of successful quitting. Guidelines for its use are presented in [Table 1-5](#). Suggestions for the nicotine patch are listed in [Table 1-6](#) and for nicotine gum in [Table 1-7](#). Both patch and gum are now available over-the-counter, and nicotine nasal spray by prescription. When the spray is combined with the patch, cessation rates are substantially higher. A new nicotine polacrilex lozenge has been found to be safe and effective for smoking cessation in both low- and high-dependence smokers. Adverse events resemble those seen with nicotine gum. Nicotine replacement to reduce cigarette consumption is ineffective in smokers who are unwilling to quit. The sustained-release antidepressant drug bupropion (150-300 mg/d) is an effective smoking cessation agent and is associated with minimal weight gain. It acts by boosting brain levels of dopamine and norepinephrine, mimicking the effect of nicotine. Bupropion, either alone or in combination with a nicotine patch, has been shown to produce significantly higher abstinence rates (30-35% at 1 year) than either a patch alone or placebo. Weight gain was less in the combined program. (See [Table 1-8](#).)

Weight gain occurs in most patients (80%) following smoking cessation. For many it averages 2 kg, but for others (10-15%) major weight gain—over 13 kg—may occur.

Clinicians should not show disapproval of patients who cannot stop smoking. Thoughtful advice that emphasizes the benefits of cessation and recognizes common barriers to success can increase quit rates. An intercurrent illness such as acute bronchitis or acute myocardial infarction may motivate even the most addicted smoker to quit. Individualized or group counseling is very cost-effective, even more so than treating hypertension. Smoking cessation counseling by telephone ("quitlines") has proved effective. An additional strategy is to recommend that any smoking take place out of doors to limit the effects of passive smoke on housemates and coworkers. This can lead to smoking reduction and quitting. The clinician's role in smoking cessation is summarized in [Table 1-4](#).

Lipid Disorders

Lower LDL cholesterol concentrations and higher HDL levels are associated with a reduced risk of coronary heart disease. Elevated plasma lipoprotein(a) is an independent risk factor for early onset of coronary heart disease in men but has not yet been evaluated clinically. The absolute benefits of screening for—and treating—abnormal lipid levels depend on the presence of other cardiovascular risk factors. If other risk factors are present, cardiovascular risk is higher and the benefits of therapy are greater. Patients with known cardiovascular disease are at still higher risk and benefit from treatment even when lipid levels are only modestly elevated.

Compliance with statin-type drugs is better than for the other classes of lipid-lowering agents. Multiple large randomized, placebo-controlled trials have convincingly demonstrated significant reductions in total mortality and major coronary events with lowering levels of low-density lipoprotein cholesterol by statin therapy including both middle-aged and elderly individuals. These results were achieved in a broad range of patients including those with or without a history of coronary artery disease, those with elevated or average LDL-C levels, and those undergoing successful percutaneous transluminal coronary angioplasty. Statins also appear to reduce the risk of stroke and, in the case of high-potency statins, marked LDL-C reductions (< 100 mg/dL) produce regression of carotid artery atherosclerosis.

Recently, a new lipid-lowering drug, ezetimibe, has been evaluated in patients with primary hypercholesterolemia. Ezetimibe inhibits the absorption of dietary and biliary cholesterol by blocking its passage across the intestinal wall. In patients with primary hypercholesterolemia, the drug has been found to be both safe and efficacious when used both alone and in combination with statins in lowering LDL-C, total cholesterol, and triglycerides, and increasing HDL-C.

In addition, high-amount high-intensity physical exercise leads to significant improvements in lipoprotein profiles.

Guidelines for therapy are discussed in [Chapter 28](#).

Hyperhomocysteinemia

Elevated plasma homocysteine may be an independent risk factor for coronary artery disease and may impart a risk similar to that associated with cigarette smoking or hyperlipidemia. At this time, there is insufficient evidence to justify screening for elevated serum homocysteine, but patients should be encouraged to maintain an adequate intake of folate, pyridoxine (vitamin B₆), and vitamin B₁₂. Elevated levels can be reduced with folate and pyridoxine treatment and with smoking cessation (though not smoking reduction), but their clinical significance is unknown. One randomized trial found that such pharmacologic therapy significantly reduced homocysteine levels and decreased the rate of coronary restenosis and the need for revascularization after percutaneous transluminal coronary angioplasty.

Booth GL et al: Preventive health care, 2000 update: screening and management of hyperhomocysteinemia for the prevention of coronary artery disease events. Canadian Task Force on Preventive Health Care. CMAJ 2000;163:21. [\[PMID: 10920726\]](#)

Hypertension

Over 43 million adults in the United States have hypertension, but 31% are unaware of their elevated blood pressure; 17% are aware but untreated; 29% are being treated but have not controlled their blood pressure (still greater than 140/90 mm Hg); and only 23% are well controlled. In every adult age group, higher values of systolic and diastolic blood pressure carry greater risks of stroke and congestive heart failure. Systolic blood pressure is a better predictor of morbid events than is diastolic blood pressure. Clinicians can apply specific blood pressure criteria, such as those of the Joint National Committee, to decide at what levels treatment should be considered in individual cases. [Chapter 11.](#)

Chemoprevention

As discussed in [Chapters 10](#) and [24](#), regular use of low-dose aspirin (81-325 mg) can reduce the incidence of myocardial infarction in patients at increased risk for heart disease. However, a recent randomized, controlled trial found that antioxidant vitamin (vitamin E, vitamin C, and beta-carotene) supplementation produced no significant reductions in the 5-year incidence of—or mortality from—vascular disease, cancer, or other major outcomes in high-risk individuals with coronary artery disease, other occlusive arterial disease, or diabetes mellitus.

PREVENTION OF PHYSICAL INACTIVITY & SEDENTARY LIFESTYLE

Dietary factors and the lack of sufficient physical activity are the second most important contributors to preventable deaths, trailing only tobacco use. The prevalence of obesity is increasing in both children and adults in the United States. Reversing these trends will require regular physical activity as well as modification of diet. A sedentary lifestyle has been linked to 28% of deaths from leading chronic diseases. The CDC has recommended that every adult in the United States should engage in 30 minutes or more of moderate-intensity physical activity on most days of the week. This new guideline complements previous advice urging at least 20-30 minutes of more vigorous aerobic exercise three to five times a week.

Patients who engage in regular moderate to vigorous exercise have a lower risk of myocardial infarction, stroke, hypertension, hyperlipidemia, type 2 diabetes mellitus, diverticular disease, and osteoporosis. The benefits of exercise appear to be dose-dependent, with a major difference in benefit between no and mild to moderate exercise and a smaller difference in benefit between moderate and vigorous exercise. Persons who engage in regular exercise have a lower long-term risk of coronary events, including fatal myocardial infarctions (in both men and women), and in middle-aged and older individuals exercise improves coronary and endothelial and smooth muscle function and reduces the risk of hypertension. In older nonsmoking men, walking 2 miles or more per day is associated with an almost 50% lower mortality. The relative risk of stroke was found to be less than one-sixth in men who exercised vigorously compared with those who were inactive; the risk of type 2 diabetes mellitus was about half among men who exercised five or more times weekly compared with those who exercised once a week. Glucose control is improved in diabetics who exercise regularly, even at a modest level. In sedentary individuals with dyslipidemia, high amounts of high-intensity exercise produce significant beneficial effects on serum lipoprotein profiles. Physical activity is associated with a lower risk of colon cancer (though not rectal cancer) in men and women and of breast and reproductive organ cancer in women. Finally, weight-bearing exercise (especially resistance and high-impact activities) increases bone mineral content and retards development of osteoporosis in women and contributes to a reduced risk of falls in older persons.

Exercise may also confer benefits on those with chronic illness. Men and women with chronic symptomatic osteoarthritis of one or both knees benefited from a supervised walking program, with improved self-reported functional status and decreased pain and use of pain medication. Exercise produces sustained lowering of both systolic and diastolic blood pressure in patients with mild hypertension. In addition, physical activity can help patients maintain ideal body weight. Individuals who

maintain ideal body weight have a 35-55% lower risk for myocardial infarction than with those who are obese. Physical activity reduces depression and anxiety, improves adaptation to stress, improves sleep quality, and enhances mood, self-esteem, and overall performance.

However, physical exertion can rarely trigger the onset of acute myocardial infarction, particularly in persons who are habitually sedentary. Increased activity increases the risk of musculoskeletal injuries, which can be minimized by proper warm-up and stretching, and by gradual rather than sudden increase in activity. Other potential complications of exercise include angina pectoris, arrhythmias, sudden death, and asthma. In insulin-requiring diabetics who undertake vigorous exercise, the need for insulin is reduced; hypoglycemia may be a consequence.

Only about 20% of adults in the United States are active at the moderate level—and only 8% currently exercise at the more vigorous level—recommended for health benefits. Instead, 60% report irregular or no leisure time physical activity.

Clinicians should advise patients about the benefits and risks of exercise, prescribe an exercise program appropriate for each patient, and provide advice that will help to prevent injuries or cardiovascular complications. The value of routine electrocardiography stress testing prior to initiation of an exercise program in middle-aged or older adults remains controversial. Patients with ischemic heart disease or other cardiovascular disease require medically supervised, graded exercise programs. Exercise should not be prescribed for patients with decompensated congestive heart failure, complex ventricular arrhythmias, unstable angina pectoris, hemodynamically significant aortic stenosis, aortic aneurysm, or uncontrolled diabetes mellitus. Five- to 10-minute warm-up and cool-down periods, stretching exercises, and gradual increases in exercise intensity help to prevent musculoskeletal and cardiovascular complications.

Physical activity can be incorporated into any person's daily routine. For example, the clinician can advise a patient to take the stairs instead of the elevator, to walk or bike instead of driving, to do housework or yard work, to get off the bus one or two stops earlier and walk the rest of the way, to park at the far end of the parking lot, or to walk during the lunch hour. [Table 29-2](#) shows energy expenditures associated with selected physical activities. The basic message must be: the more the better, and anything is better than nothing.

CANCER PREVENTION

Primary Prevention

Cigarette smoking is the most important preventable cause of cancer. Primary prevention of skin cancer consists of restricting exposure to ultraviolet light by wearing appropriate clothing and use of sunscreens. In the past 2 decades, there has been a threefold increase in the incidence of squamous cell carcinoma and a fourfold increase in melanoma in the United States. Individuals who engage in regular physical exercise and avoid obesity have lower rates of breast and colon cancer. Prevention of occupationally induced cancers involves minimizing exposure to carcinogenic substances such as asbestos, ionizing radiation, and benzene compounds. Chemoprevention may be an important part of primary cancer prevention (see [Chapter 40](#)). Tamoxifen for breast cancer prevention is discussed in [Chapters 16](#) and [40](#).

Screening & Early Detection

Screening has been shown to prevent death from cancers of the breast, colon, and cervix through cancer screening procedures. Current cancer screening recommendations from the American Cancer Society, the Canadian Task Force on Preventive Health Care, and the United States Preventive Services Task Force are shown in [Table 1-9](#).

The appropriate form and frequency of screening for breast cancer is controversial. A recent large randomized trial of breast self-examination conducted among factory workers in Shanghai found no benefit. A systematic review performed for the United States Preventive Services Task Force found that mammography was moderately effective in reducing breast cancer mortality for women 40-74 years of age. The absolute benefit was greater for older women, and the risk of false-positive results was high for all women.

All current recommendations call for cervical and colorectal cancer screening. Prostate cancer screening, however, is controversial, as no completed studies have answered the question whether early detection and treatment after screen detection produces sufficient benefits to outweigh harms of treatment. Providers and patients are advised to discuss how to proceed in light of this uncertainty.

Single serum PSA measurements appear to offer relatively high sensitivity and specificity to detect prostate cancer. The sensitivity is about 65%, the specificity about 80%, and the positive predictive value for prostate cancer is about 45%. When both the digital rectal examination and serum PSA are abnormal, PSA specificity increases, but sensitivity falls (to 30%) and predictive value rises only slightly. Whether early detection and treatment alters the natural course of the disease remains to be seen. There are still no data on the morbidity and mortality benefits of such screening. Unlike the American College of Physicians, the American Cancer Society recommends that providers offer annual PSA testing for men over age 50. Screening is not recommended for any group for men who have estimated life expectancies of less than 10 years. Decision aids have been developed to help men weigh the arguments for and against PSA screening.

Annual or biennial fecal occult blood testing reduces mortality from colorectal cancer by 16-33%. The risk of death from colon cancer among patients undergoing at least one sigmoidoscopic examination is reduced by 60-80% compared with that among those not having sigmoidoscopy. Colonoscopy has been recently advocated as a screening examination. While it is more accurate than flexible sigmoidoscopy for detecting cancer and polyps, its value in reducing colon cancer mortality has not been studied.

Screening for cervical cancer with a Papanicolaou smear is indicated in sexually active adolescents and in adult women every 1-3 years. Screening for vaginal cancer with a Pap smear is not indicated in women who have undergone hysterectomies for benign disease with removal of the cervix—except in DES-exposed women (see [Chapter 17](#)). Women over age 70 who have had normal results on three or more previous Pap smears may elect to stop screening.

PREVENTION OF INJURIES & VIOLENCE

Injuries remain the most important cause of loss of potential years of life before age 65. Road traffic injuries, self-inflicted injuries, falls, and interpersonal violence are the major sources of injuries. Injuries affect mostly young people, often causing long-term disability. In 1997, about 107,000 preventable bicycle-related head injuries occurred in the United States.

Though there has been a steady decline in motor vehicle accident deaths per miles driven, road traffic injuries remain the tenth leading cause of death and the ninth leading cause of the burden of disease. Although seat belt use protects against serious injury and death in motor vehicle accidents, at least one-fourth of adults do not use seat belts routinely. Air bags are protective for adults but not for small children. In 1996, 64% of motorcyclists used helmets, an improvement over previous years. The rate of helmet use by bicyclists and motorcyclists is significantly increased in states with helmet laws. Recent data for bicyclists are not available. Young men appear most likely to resist wearing helmets. Clinicians should try to educate their patients about seat belts, safety helmets, the risks of using cellular telephones while driving, drinking and driving—or using other intoxicants or long-acting benzodiazepines and then driving—and the risks of having guns in the home. Chronic alcohol abuse adversely affects outcome from trauma and increases the risk of readmission for new trauma. Males aged 16-35 are at especially high risk for serious injury and death from accidents and violence, with blacks and Latinos at greatest risk. For 16- and 17-year-old drivers, the risk of fatal crashes increases with the number of passengers. Deaths from firearms have reached epidemic levels in the United States and will soon surpass in numbers deaths from motor vehicle accidents. Having a gun in the home increases the likelihood of homicide nearly threefold and of suicide fivefold. Alcohol and illicit drug use are associated with an increased risk of violent death. Physicians should be alert to signs of depression and suicidal ideation and should initiate interventions to prevent suicide.

Finally, clinicians have a critical role in detection, prevention, and management of physical or sexual abuse—in particular, routine assessment of women for risk of domestic violence. Inclusion of a single question about domestic violence in the medical history—"At any time, has a partner ever hit you, kicked you, or otherwise physically hurt you?"—increased identification of this common problem from nil to 11.6%. Another screening device consists of three questions: (1) "Have you ever been hit, kicked, punched, or otherwise hurt by someone within the past year? If so, by whom?" (2) "Do you feel safe in your current relationship?" (3) "Is there a partner from a previous relationship who is making you feel unsafe now?" Use of these questions increased identification of domestic violence to 29.5% of women in an emergency department.

Physical and psychologic abuse, exploitation, and neglect of older adults are serious underrecognized problems. Clues to elder mistreatment include the patient's appearance, recurrent urgent-care visits, missed appointments, suspicious physical findings, and implausible explanations for injuries.

SUBSTANCE ABUSE: ALCOHOL & ILLICIT DRUGS

Common brain neurotransmitter changes follow regular use of addictive substances such as alcohol, tobacco, and illicit drugs. Substance abuse is a major public health problem in the United States and is estimated to be a factor in 41% of highway fatality accidents. Approximately two-thirds of high school seniors are regular users of alcohol, and the lifetime prevalence of alcoholism is estimated to be between 12% and 16%. Underdiagnosis is substantial, both because of patient denial and lack of detection of clinical clues. A substantial decline in alcohol-related fatalities testifies to the success of educational and law-enforcement efforts to stop drinking and driving. Even so, alcohol-impaired driving remains prevalent, especially among men aged 18-34 years. Binge drinking among college students has recently increased.

As with cigarette use, clinician identification and counseling about alcoholism may improve the chances of recovery. About 10% of all adults seen in medical practices are problem drinkers. An estimated 15-30% of hospitalized patients have problems with alcohol abuse or dependence, but the connection between patients' presenting complaints and their alcohol abuse is often missed. The CAGE test (see [Chapter 25](#)) can produce a 10-30% reduction in long-term alcohol use and alcohol-related problems. However, brief advice and counseling without regular follow-up and reinforcement cannot sustain significant long-term reductions in unhealthy drinking behaviors. Several pharmacologic agents are effective in reducing alcohol consumption. For example, naltrexone may be effective in preventing relapse to drinking when combined with psychosocial treatment.

Use of illegal drugs—including cocaine, methamphetamine, and so-called "designer drugs"—either sporadically or episodically remains an important problem. A disturbing trend is the recent increase in use of marijuana and inhalants among eighth graders and high school students. Many drug users are employed, and many use drugs during pregnancy. Cocaine or tobacco use during early pregnancy substantially increases the risk of miscarriage. Abuse of anabolic-androgenic steroids has been associated with use of other illicit drugs, alcohol, and cigarettes and with violence and criminal behavior. As with alcohol abuse, the recognition of drug abuse presents special problems and requires that the clinician actively consider the diagnosis.

Currently, evidence does not support the use of carbamazepine, disulfiram, mazindol, phenytoin, nimodipine, lithium, antidepressants, or dopamine agonists in the treatment of cocaine dependence. Buprenorphine has potential as a medication to ameliorate the signs and symptoms of withdrawal from heroin. Slow tapering with temporary substitution of methadone and buprenorphine—accompanied by medical supervision and ancillary medications—can reduce withdrawal severity, but most patients relapse to heroin use. Evidence does not support the use of naltrexone in maintenance treatment of opioid addiction.

Clinical aspects of substance abuse and treatment issues are discussed in [Chapter 25](#).

Table 1-3. Actions and strategies for the primary care clinician to help patients quit smoking.¹

Action	Strategies for Implementation
	Step 1. Ask—Systematically Identify All Tobacco Users at Every Visit
Implement an officewide system that ensures that for every patient at every clinic visit, tobacco-use status is queried and documented ²	Expand the vital signs to include tobacco use. Data should be collected by the health care team. The action should be implemented using preprinted progress note paper that includes the assessing tobacco-use status. Alternatives to the vital signs stamp are to place tobacco-use status stickers on all patients' charts or to indicate smoking status using computerized reminder systems.
	Step 2. Advise—Strongly Urge All Smokers to Quit
In a <i>clear, strong</i> , and <i>personalized</i> manner, urge every smoker to quit	Advice should be Clear: "I think it is important for you to quit smoking now, and I will help you. Cutting down while you are ill is not enough." Strong: "As your clinician, I need you to know that quitting smoking is the most important thing you can do to protect your current and future health." Personalized: Tie smoking to current health or illness and/or the social and economic costs of tobacco use, motivational level/readiness to quit, and the impact of smoking on children and others in the household. Encourage clinic staff to reinforce the cessation message and support the patients quit attempt.
	Step 3. Attempt—Identify Smokers Willing to Make a Quit Attempt
Ask every smoker if he or she is willing to make a quit attempt at this time	If the patient is willing to make a quit attempt at this time, provide assistance (see step 4). If the patient prefers a more intensive treatment or the clinician believes more intensive treatment is appropriate, refer the patient to interventions administered by a smoking cessation specialist and follow up with him or her regarding quitting (see step 5). If the patient clearly states he or she is not willing to make a quit attempt at this time, provide a motivational intervention.
	Step 4. Assist—Aid the Patient in Quitting
A. Help the patient with a quit plan	<i>Set a quit date.</i> Ideally, the quit date should be within 2 weeks, taking patient preference into account. <i>Help the patient prepare for quitting.</i> The patient must: <i>Inform</i> family, friends, and coworkers of quitting and request understanding and support. <i>Prepare the environment</i> by removing cigarettes from it. Prior to quitting, the patient should avoid smoking in places where he or she spends a lot of time (eg, home, car). <i>Review</i> previous quit attempts. What helped? What led to relapse? <i>Anticipate</i> challenges to the planned quit attempt, particularly during the critical first few weeks.
B. Encourage nicotine replacement therapy except in special circumstances	Encourage the use of the nicotine patch or nicotine gum therapy for smoking cessation (see Tables 1-5 to 1-7 for specific instructions and precautions).
C. Give key advice on successful quitting	Abstinence: Total abstinence is essential. Not even a single puff after the quit date. Alcohol: Drinking alcohol is highly associated with relapse. Those who stop smoking should review their alcohol use and consider limiting or abstaining from alcohol use during the quit process. Other smokers in the household: The presence of other smokers in the household, particularly a spouse, is associated with lower success rates. Patients should consider quitting with their significant others and/or developing specific plans to maintain abstinence in a household where others still smoke.
D. Provide supplementary materials	Source: Federal agencies, including the National Cancer Institute and the Agency for Health Care Policy and Research; nonprofit agencies (American Cancer Society, American Lung Association, American Heart Association); or local or state health departments. Selection concerns: The material must be culturally, racially, educationally, and age appropriate for the patient. Location: Readily available in every clinic office.
	Step 5. Arrange—Schedule Follow-Up Contact
Schedule follow-up contact, either in person or via telephone ²	Timing: Follow-up contact should occur soon after the quit date, preferably during the first week. A second follow-up contact is recommended within the first month. Schedule further follow-up contacts as indicated. Actions during follow-up: Congratulate success. If smoking occurred, review the circumstances and elicit recommitment to total abstinence. Remind the patient that a lapse can be used as a learning experience and is not a sign of failure. Identify the problems already encountered and anticipate challenges in the immediate future. Assess nicotine replacement therapy use and problems. Consider referral to a more intense or specialized program.

Table 1-4. Common elements of supportive smoking treatments.¹

Component	Examples
Encouragement of the patient in the quit attempt	Note that effective cessation treatments are now available. Note that half the people who have ever smoked have now quit. Communicate belief in the patient's ability to quit.
Communication of caring and concern	Ask how the patient feels about quitting. Directly express concern and a willingness to help. Be open to the patient's expression of fears of quitting, difficulties experienced, and ambivalent feelings.
Encouragement of the patient to talk about the quitting process	Ask about Reasons that the patient wants to quit. Difficulties encountered while quitting. Success the patient has achieved. Concerns or worries about quitting.
Provision of basic information about smoking and successful quitting	Inform the patient about The nature and time course of withdrawal. The addictive nature of smoking. The fact that any smoking (even a single puff) increases the likelihood of full relapse.

Table 1-5. Clinical guidelines for prescribing nicotine replacement products.¹

1. Who should receive nicotine replacement therapy?

Available research shows that nicotine replacement therapy generally increases rates of smoking cessation. Therefore, except in special circumstances, the clinician should encourage the use of nicotine replacement with patients who smoke. Little research is available on the use of nicotine replacement with light smokers (ie, those smoking = 10-15 cigarettes/d). If nicotine replacement is to be used with light smokers, a lower starting dose of the nicotine patch or nicotine gum should be considered.

2. Should nicotine replacement therapy be tailored to the individual smoker?

Research does not support the tailoring of nicotine patch therapy (except with light smokers as noted above). Patients should be prescribed the patch dosages outlined in Table 1-6.

Research supports tailoring nicotine gum treatment. Specifically, research suggests that 4-mg gum rather than 2-mg gum be used with patients who are highly dependent on nicotine (eg, those smoking > 20 cigarettes/d, those who smoke immediately upon awakening, and those who report histories of severe nicotine withdrawal symptoms). Clinicians may also recommend the higher gum dose if patients request it or have failed to quit using the 2-mg gum.

Table 1-6. Suggestions for the clinical use of the nicotine patch.¹

Parameter of Clinical Use	Suggestions																						
Patient selection	Appropriate as a primary pharmacotherapy for smoking cessation.																						
Precautions	<i>Pregnancy:</i> Pregnant smokers should first be encouraged to attempt cessation without pharmacologic treatment. The nicotine patch should be used during pregnancy only if the increased likelihood of smoking cessation, with its potential benefits, outweighs the risk of nicotine replacement and potential concomitant smoking. Similar factors should be considered in lactating women. <i>Cardiovascular diseases:</i> While not an independent risk factor for acute myocardial events, the nicotine patch should be used only after consideration of risks and benefits among particular cardiovascular patient groups: those in the immediate (within 2 weeks) post-myocardial infarction period, those with serious arrhythmias, and those with severe or worsening angina pectoris. <i>Skin reactions:</i> Up to 50% of patients using the nicotine patch will have a local skin reaction. Skin reactions are usually mild and self-limiting but may worsen over the course of therapy. Local treatment with hydrocortisone cream (2.5%) or triamcinolone cream (0.5%) and rotating patch sites may ameliorate such local reactions. In fewer than 5% of patients do such reactions require the discontinuation of nicotine patch treatment.																						
Dosage ²	Treatment of 8 weeks or less has been shown to be as efficacious as longer treatment periods. Based on this finding, we suggest the following treatment schedules as reasonable for most smokers. Clinicians should consult the package insert for other treatment suggestions. Finally, clinicians should consider individualizing treatment based on specific patient characteristics such as previous experience with the patch, number of cigarettes smoked, and degree of addiction. <table><tr><th>Brand</th><th>Duration (weeks)</th><th>Dosage (mg/h)</th></tr><tr><td rowspan="3">Nicoderm and Habitrol</td><td>4</td><td>21/24</td></tr><tr><td>then 2</td><td>14/24</td></tr><tr><td>then 2</td><td>7/24</td></tr><tr><td rowspan="2">Prostep</td><td>4</td><td>22/24</td></tr><tr><td>then 4</td><td>11/24</td></tr><tr><td rowspan="3">Nicotrol</td><td>4</td><td>15/16</td></tr><tr><td>then 2</td><td>10/16</td></tr><tr><td>then 2</td><td>5/16</td></tr></table>	Brand	Duration (weeks)	Dosage (mg/h)	Nicoderm and Habitrol	4	21/24	then 2	14/24	then 2	7/24	Prostep	4	22/24	then 4	11/24	Nicotrol	4	15/16	then 2	10/16	then 2	5/16
Brand	Duration (weeks)	Dosage (mg/h)																					
Nicoderm and Habitrol	4	21/24																					
	then 2	14/24																					
	then 2	7/24																					
Prostep	4	22/24																					
	then 4	11/24																					
Nicotrol	4	15/16																					
	then 2	10/16																					
	then 2	5/16																					
Prescribing instructions	Abstinence from smoking: The patient should refrain from smoking while using the patch. Location: At the start of each day, the patient should place a new patch on a relatively hairless location between the neck and the waist. Activities: There are no restrictions while using the patch. Time: Patches should be applied as soon as patients awaken on their quit day.

-

Table 1-7. Suggestions for the clinical use of nicotine gum.¹

Parameter of Clinical Use	Suggestions
Patient selection	Appropriate as a primary pharmacotherapy for smoking cessation.
Precautions	<i>Pregnancy:</i> Pregnant smokers should first be encouraged to attempt cessation without pharmacologic treatment. Nicotine gum should be used during pregnancy only if the increased likelihood of smoking cessation, with its potential benefits, outweighs the risk of nicotine replacement and potential concomitant smoking. <i>Cardiovascular diseases:</i> Although not an independent risk factor for acute myocardial events, nicotine gum should be used only after consideration of risks and benefits among particular cardiovascular patient groups: those in the immediate (within 2 weeks) post-myocardial infarction period, those with serious arrhythmias, and those with serious or worsening angina pectoris. <i>Adverse effects:</i> Common adverse effects of nicotine chewing gum include mouth soreness, hiccups, dyspepsia, and jaw ache. These effects are generally mild and transient and can often be alleviated by correcting the patient's chewing technique (see "Prescribing instructions" below).
Dosage	<i>Dosage:</i> Nicotine gum is available in doses of 2 mg and 4 mg per piece. Patients who smoke less than 25 cigarettes per day should be prescribed the 2-mg gum initially. The 4-mg gum should be prescribed to patients who express a preference for it, have failed with the 2-mg gum but remain motivated to quit, and/or smoke greater than 25 cigarettes per day. The gum is most commonly prescribed for the first few months of a quit attempt. Clinicians should tailor the duration of therapy to fit the needs of each patient. Patients using the 2-mg strength should use not more than 30 pieces per day, whereas those using the 4-mg strength should not exceed 20 pieces per day.
Prescribing instructions	<i>Abstinence from smoking:</i> The patient should refrain from smoking while using the gum. <i>Chewing technique:</i> The gum should be chewed slowly until a "peppery" taste emerges, then "parked" between cheek and gum to facilitate nicotine absorption through the oral mucosa. Gum should be slowly and intermittently chewed and parked for about 30 minutes. <i>Absorption:</i> Acidic beverages (eg, coffee, juices, soft drinks) interfere with the buccal absorption of nicotine, so eating and drinking anything except water should be avoided for 15 minutes before and during chewing. <i>Scheduling of dose:</i> A common problem is that patients do not use enough gum to get the maximum benefit: they chew too few pieces per day and do not use the gum for a sufficient number of weeks. Instructions to chew the gum on a fixed schedule (at least 1 piece every 1 to 2 hours) for at least 1 to 3 months may be more beneficial than ad lib use.

-

Table 1-8. Suggestions for the clinical use of bupropion SR.

Parameter of Clinical Use	Suggestions
Patient selection	Appropriate as a first-line pharmacotherapy for smoking cessation.
Precautions	<i>Pregnancy</i>—Pregnant smokers should be encouraged to quit first without pharmacologic treatment. Bupropion SR should be used during pregnancy only if the increased likelihood of smoking abstinence, with its potential benefits, outweighs the risk of bupropion SR treatment and potential concomitant smoking. Similar factors should be considered in lactating women. (FDA Class B) <i>Cardiovascular diseases</i>—Generally well tolerated; infrequent reports of hypertension. <i>Side effects</i>—The most common side effects reported by bupropion SR users were insomnia (35-40%) and dry mouth (10%). <i>Contraindications</i>—Bupropion SR is contraindicated in individuals with a history of seizure disorder, a history of an eating disorder, who are using another form of bupropion (Wellbutrin or Wellbutrin SR), or who have used an MAO inhibitor in the past 14 days.
Dosage	Patients should begin with a dose of 150 mg q AM for 3 days, then increase to 150 mg bid Dosing at 150 mg bid should continue for 7-12 weeks following the quit date. Unlike nicotine replacement products, patients should begin bupropion SR treatment 1-2 weeks <i>before</i> they quit smoking. For maintenance therapy, consider bupropion SR 150 mg b.i.d. for up to 6 months.
Prescribing	<i>Cessation prior to quit date</i>—Recognize that some patients will lose their desire to smoke prior to their quit date, or will spontaneously reduce the amount they smoke. <i>Scheduling of dose</i>—If insomnia is marked, taking the PM dose earlier (in the afternoon, at least 8 hours after the first dose) may provide some relief. <i>Alcohol</i>—Use alcohol only in moderation.

Table 1-9. Cancer screening recommendations for average-risk adults, 2003.

	Test	ACS ¹	CTF ²	USPSTF ³
Breast	Self-examination (BSE)	Monthly for women over age 20.	Fair evidence that BSE <i>should not</i> be used.	Insufficient evidence to recommend for or against.
	Clinical breast examination	Every 3 years age 20-40 and annually thereafter.	Every 1-2 years in age women 40-59.	Insufficient evidence to recommend for or against.
	Mammography	Annually age 40 and older.	Every 1-2 years in age women 40-59. Current evidence does not support the recommendation that screening mammography be included in or excluded from the periodic health examination of women aged 40-49.	Recommended every 1-2 years for women age 40 and over (B).
Cervix	Papanicolaou test	Annually beginning within 3 years after first vaginal intercourse or no later than age 21. After age 30, women with three normal tests may be screened every 2-3 years. Women may choose to stop screening after age 70 if they have had three normal (and no abnormal) results within the last 10 years.	Annually at age of first intercourse or by age 18; can move to every-2-year screening after two normal results.	Every 3 years beginning at onset of sexual activity.
Colon	Stool test for occult blood*	Screening recommended, with the combination of fecal occult blood test (FOBT) and sigmoidoscopy preferred over stool test or sigmoidoscopy alone. Barium enema and colonoscopy also considered reasonable alternatives.	Good evidence for screening every 1-2 years over age 50.	Screening strongly recommended (A), but insufficient evidence to determine best test.
	Sigmoidoscopy		Fair evidence for screening over age 50 (insufficient evidence about combining stool test and sigmoidoscopy).	
	Double-constrast barium enema		Not addressed.	
	Colonoscopy		Insufficient evidence for or against use in screening.	
Prostate	Digital rectal exam (DRE)	Not recommended.	No recommendation.	Not recommended.
	Digital rectal exam (DRE)	DRE and PSA should be offered annually to men age 50 and older who have at least a 10- year life expectancy. Information should be provided to men about the benefits and risks, and they should be allowed to participate in the decision. Men without a clear preference should be screened.	Insufficient evidence for or against including in routine care.	Insufficient evidence to recommend for or against.
	PSA blood test		Fair evidence <i>against</i> including in routine care.	
Other	Cancer-related checkup	Every 3 years for men 20-40 and annually thereafter; should include counseling and perhaps oral cavity, thyroid, lymph node, or testicular examinations.	Not assessed.	Not assessed.

*Home test with three samples.

Table 1-10. Screening for alcohol abuse.

1. CAGE screening test¹

Have you ever felt the need to	Cut down on drinking?
Have you ever felt	Annoyed by criticism of your drinking?
Have you ever felt	Guilty about your drinking?
Have you ever taken a morning	Eye opener?

INTERPRETATION: Two "yes" answers are considered a positive screen. One "yes" answer should arouse a suspicion of alcohol abuse.

2. The Alcohol Use Disorder Identification Test (AUDIT).² (Scores for response categories are given in parentheses. Scores range from 0 to 40, with a cutoff score of = 5 indicating hazardous drinking, harmful drinking, or alcohol dependence.)

1. How often do you have a drink containing alcohol?	(0) Never	(1) Monthly or less	(2) Two to four times a week	(3) Two or three times a week	(4) Four or more times a month
2. How many drinks containing alcohol do you have on a typical day when you are drinking?	(0) 1 or 2	(1) 3 or 4	(2) 5 or 6	(3) 7 to 9	(4) 10 or more
3. How often do you have six or more drinks on one occasion?	(0) Never	(1) Less than monthly	(2) Monthly	(3) Weekly	(4) Daily or almost daily
4. How often during the past year have you found that you were not able to stop drinking once you had started?	(0) Never	(1) Less than monthly	(2) Monthly	(3) Weekly	(4) Daily or almost daily
5. How often during the past year have you failed to do what was normally expected of you because of drinking?	(0) Never	(1) Less than monthly	(2) Monthly	(3) Weekly	(4) Daily or almost daily
6. How often during the past year have you needed a first drink in the morning to get yourself going after a heavy drinking session?	(0) Never	(1) Less than monthly	(2) Monthly	(3) Weekly	(4) Daily or almost daily
7. How often during the past year have you had a feeling of guilt or remorse after drinking?	(0) Never	(1) Less than monthly	(2) Monthly	(3) Weekly	(4) Daily or almost daily
8. How often during the past year have you been unable to remember what happened the night before because you had been drinking?	(0) Never	(1) Less than monthly	(2) Monthly	(3) Weekly	(4) Daily or almost daily
9. Have you or has someone else been injured as a result of your drinking?	(0) No	(4) Yes, during the past year			
10. Has a relative or friend or a doctor or other health worker been concerned about your drinking or suggested you cut down?	(0) No	(2) Yes, but not in the past year	(4) Yes, during the past year

INTRODUCTION

New or unexplained symptoms account for about half of all office visits; the remainder are for ongoing care of established medical conditions. The evidence-based medicine movement of the last decade has reshaped how illness is diagnosed and treated, and promises to improve the cost and quality of health care delivery and patient outcomes.

Evidence-based symptom evaluation combines knowledge of a symptom's clinical epidemiology with disease candidates according to Bayesian principles (see [Chapter 42](#)), such that the likelihood of a specific disease is a function of patient demographics, comorbidities, and clinical features. This knowledge can help support decisions about further testing or treatment or whether to perform additional testing before treatment, or to treat without further testing.

In addition to epidemiologic factors, clinicians should recognize that biological, psychological and social factors affect how their patients process and filter symptoms. Thus, patients vary in deciding when symptoms are sufficiently bothersome or worrisome to cause them to seek medical attention, and interpret symptoms within a particular social and cultural context. Patients also vary in what they expect from the office visit and how much they will tolerate unexplained symptoms.

Many symptoms defy diagnosis. If symptom relief is not easily achieved, management of these patients becomes challenging. The shift toward evidence-based medicine principles, which encourage narrow study questions in homogeneous study populations, inadvertently results in syndromes not readily explained by current biomedical models of disease, such as chronic fatigue syndrome. Clinical syndromes due to common respiratory viruses illustrate the complexity of how symptoms are manifested, even when the cause is known. Using this example, in 1967, Evans proposed five "realities" about respiratory infections: (1) The same clinical syndrome may be produced by a variety of infectious agents; (2) the same agent may produce a variety of syndromes; (3) the most likely cause of a syndrome may vary by patient age, year, geography, and setting; (4) diagnosis of the agent is frequently impossible on the basis of clinical findings alone; and (5) the causes of a large proportion of infectious disease syndromes are still unknown.

COUGH

Essential Inquiries

- Duration of cough.
- Dyspnea (at rest or with exertion).
- Constitutional symptoms.
- Tobacco use history.
- Vital signs (heart rate, respiratory rate, body temperature).
- Chest examination.
- Chest radiography when unexplained cough lasts more than 3-6 weeks.

General Considerations

Cough adversely affects personal and work-related interactions, disrupts sleep, and often causes discomfort of the throat and chest wall. Most people seeking medical attention for acute cough desire symptom relief; few are worried about serious illness. Cough results from stimulation of mechanical or chemical afferent nerve receptors in the bronchial tree. Effective cough depends on an intact afferent-efferent reflex arc, adequate expiratory and chest wall muscle strength, and normal mucociliary production and clearance.

Clinical Findings

A. Symptoms

Distinguishing acute (< 3 weeks) and persistent (> 3 weeks) cough illness syndromes is a useful first step in evaluation. In healthy adults, most acute cough syndromes are due to viral respiratory tract infections. Additional features of infection such as fever, nasal congestion, and sore throat help confirm the diagnosis. Dyspnea (at rest or with exertion) may reflect a more serious condition, and further evaluation should include assessment of oxygenation (pulse oximetry or arterial blood gas measurement), airflow (peak flow or spirometry), and pulmonary parenchymal disease (chest radiography). The timing and character of the cough have not been found to be useful in establishing the cause of acute or persistent cough syndromes, although cough variant asthma should be considered in adults with prominent nocturnal cough. Uncommon causes of acute cough illness should be suspected in those with heart disease (congestive heart failure) or hay fever (allergic rhinitis) and those with environmental risk factors.

Cough lasting more than 3 weeks is less likely due to respiratory tract infection. Still, in patients with cough persisting 3-6 weeks following a typical acute respiratory tract infection, it is the most likely cause, and additional evaluation is usually not necessary. Conversely, any of the conditions that cause persistent cough can contribute to or cause acute cough.

When ACE inhibitor therapy, antecedent upper respiratory tract infection, and chest radiograph abnormalities are absent, up to 90% of cases of persistent cough are due to postnasal drip, asthma, or gastroesophageal reflux disease (GERD). A history of nasal or sinus congestion, wheezing, or heartburn should direct subsequent evaluation and treatment, though these conditions frequently cause persistent cough in the absence of typical symptoms. Bronchogenic carcinoma is suspected when cough is accompanied by unexplained weight loss and fevers with night sweats, particularly in persons with significant tobacco or occupational exposures. Persistent cough accompanied by excessive secretions suggests chronic bronchitis in a smoker, or bronchiectasis in a patient with a history of recurrent or complicated pneumonia; chest x-rays are helpful in diagnosis. Dyspnea at rest or with exertion is not commonly reported among patients with persistent cough. The report of dyspnea requires assessment for other evidence of chronic lung disease or congestive heart failure.

B. Physical Examination

Examination can direct subsequent diagnostic testing for acute and persistent cough. Pneumonia is suspected when acute cough is accompanied by vital sign abnormalities (tachycardia, tachypnea, fever) or findings suggestive of airspace consolidation (rales, decreased breath sounds, fremitus, egophony). Purulent sputum predicts neither bacterial bronchitis nor radiographic pneumonia in the otherwise healthy adult. While purulent sputum is a statistically significant risk factor for pneumonia (relative risk about 2.0), this means only that the rate of pneumonia in patients with purulent sputum is 4% compared with 2% among those without purulent sputum (ie, 95 out of 100 adults with purulent sputum do not have radiographic pneumonia). In addition, antibiotic treatment of adults with purulent sputum production shows no benefit. Wheezing and rhonchi are frequent findings in adults with acute bronchitis, and do not represent adult-onset asthma in most cases.

Physical examination of adults with persistent cough may also reveal evidence of chronic sinusitis, contributing to postnasal drip syndrome or asthma. Chest and cardiac signs may distinguish COPD from congestive heart failure. In patients with cough and dyspnea, a normal match test (ability to blow out a match from 25 cm away) and maximum laryngeal height > 4 cm (measured from the sternal notch to the cricoid cartilage at end-expiration) substantially decreases the likelihood of COPD. Similarly, normal jugular venous pressure and negative hepatojugular reflux decrease the likelihood of biventricular congestive heart failure.

Differential Diagnosis

A. Acute Cough

Acute cough may be a symptom of acute respiratory tract infection, asthma, allergic rhinitis, and congestive heart failure.

B. Persistent Cough

Causes include postnasal drip syndrome, asthma, gastroesophageal reflux disease, chronic bronchitis, bronchiectasis, tuberculosis or other chronic infection, interstitial lung disease, and bronchogenic carcinoma. Persistent cough may also be psychogenic.

Diagnostic Studies

A. Acute Cough

Chest radiography should be considered for any adult with acute cough who shows abnormal vital signs or in whom the chest examination is suggestive of pneumonia. The relationship between specific clinical findings and the probability of pneumonia is shown in [Figure 2-1](#). In patients with dyspnea, pulse oximetry and peak flow exclude hypoxemia or obstructive airway disease. However, a normal pulse oximetry value (eg, > 93%) does not rule out a significant A-a gradient when patients have effective respiratory compensation.

B. Persistent Cough

Chest radiography is indicated if ACE inhibitor therapy-related and postinfectious cough are excluded by history. When the chest film is normal, evaluation for postnasal drip, asthma, and GERD should be initiated. The presence of typical symptoms of these conditions directs further evaluation or empiric therapy, though typical symptoms are often absent. Definitive procedures for determining the presence of each are available (see [Table 2-1](#)). However, empiric treatment with a maximum-strength regimen for postnasal drip, asthma, or GERD for 2-4 weeks is the recommended approach since documenting the presence of postnasal drip, asthma, and GERD does not mean they are the cause of the cough illness. In about 25% of cases, persistent cough has multiple contributors.

LOWER EXTREMITY EDEMA

Essential Inquiries

- History of venous thromboembolism.
- Symmetry.
- Pain.
- Dependence.

General Considerations

Acute and chronic lower extremity edema present important diagnostic and treatment challenges. Lower extremities can swell in response to increased venous or lymphatic pressures, decreased intravascular oncotic pressure, increased capillary leak, and local injury or infection. Chronic venous insufficiency is by far the most common cause, affecting up to 2% of the population. The incidence of venous insufficiency has not changed during the past 25 years, suggesting that preventive strategies are needed. Venous insufficiency is a common complication of deep venous thrombosis; however, only a minority of patients with chronic venous insufficiency report a history of this disorder. Venous ulcer formation commonly affects patients with chronic venous insufficiency, and management of venous ulceration is both labor-intensive and expensive.

Clinical Findings

A. Symptoms and Signs

Normal lower extremity venous pressure (in the erect position: 80 mm Hg in deep veins, 20-30 mm Hg in superficial veins) and cephalad venous blood flow require competent bicuspid venous valves, effective muscle contractions, and normal respirations. When one or more of these components fail, venous hypertension may result. Chronic exposure to elevated venous pressure by the postcapillary venules in the legs leads to leakage of fibrinogen and growth factors into the interstitial space, leukocyte aggregation and activation, and obliteration of the cutaneous lymphatic network. These changes account for the brawny, fibrotic skin changes observed in patients with chronic venous insufficiency, and the predisposition toward skin ulceration, particularly in the medial malleolar area.

Among common causes of lower extremity swelling, deep venous thrombosis (DVT) is the most life-threatening. Historical clues suggesting DVT include a history of cancer, recent limb immobilization, or confinement to bed for at least 3 days following major surgery within the past month ([Table 2-2](#)). A search for alternative explanations is equally important in excluding DVT. Bilateral involvement and significant improvement upon awakening favor systemic causes (eg, venous insufficiency, congestive heart failure, and cirrhosis). Pain, particularly if severe, is uncommon in uncomplicated venous insufficiency. Lower extremity swelling and inflammation in a limb previously affected by DVT could represent anticoagulation failure and thrombus recurrence but more often is caused by postphlebotic syndrome with valvular incompetence. Other causes of a painful, swollen calf include ruptured popliteal cyst, calf strain or trauma, and cellulitis. Lower extremity swelling is a familiar complication of therapy with calcium channel blockers (particularly felodipine and amlodipine), thiazolidinediones, and minoxidil.

B. Physical Examination

Physical examination should include assessment of the heart, lungs, and abdomen for evidence of pulmonary hypertension (primary, or secondary to chronic lung disease), congestive heart failure, or cirrhosis. Some patients with the latter have pulmonary hypertension without lung disease. There is a spectrum of skin findings related to chronic venous insufficiency that depend on the severity and chronicity of the disease, ranging from hyperpigmentation and stasis dermatitis to abnormalities highly specific for chronic venous insufficiency: lipodermatosclerosis (thick brawny skin; in advanced cases, the lower leg resembles an inverted champagne bottle) and atrophie blanche (small depigmented macules within areas of heavy pigmentation). The size of both calves should be measured 10 cm below the tibial tuberosity and elicitation of pitting and tenderness performed. Swelling of the entire leg or swelling of one leg greater than 3 cm more than the other suggests deep venous obstruction. In normal persons, the left calf is slightly larger than the right as a result of the left common iliac vein coursing under the aorta.

An ulcer located over the medial malleolus is a hallmark of chronic venous insufficiency but can be due to other causes. Shallow, large, modestly painful ulcers are characteristic of venous insufficiency, whereas small, deep, and more painful ulcers are more apt to be due to arterial insufficiency, vasculitis, or infection (including cutaneous diphtheria). Diabetic vascular ulcers, however, may be painless. When an ulcer is on the foot or above the mid calf, causes other than venous insufficiency should be considered.

C. Diagnostic Studies

Most causes of lower extremity swelling can be demonstrated with color duplex ultrasonography. Patients without an obvious cause of acute lower extremity swelling (eg, calf strain) should have an ultrasound performed, since DVT is difficult to exclude on clinical grounds. Assessment of the ankle-brachial pressure index (ABPI) is important in the management of chronic venous insufficiency, since peripheral arterial disease may be exacerbated by compression therapy. This can be performed at the same time as ultrasound. Caution is required in interpreting the results of ABPI in older patients and diabetics due to decreased compressibility of their arteries.

Differential Diagnosis

Possible causes include chronic venous insufficiency, deep venous thrombosis, cellulitis, musculoskeletal disorders (Baker's cyst rupture, gastrocnemius tear or rupture), lymphedema, congestive heart failure, cirrhosis, nephrotic syndrome, and calcium channel blocker, thiazolidinedione or minoxidil side effect.

Treatment

In patients with chronic venous insufficiency without a comorbid volume overload state (eg, congestive heart failure), it is best to avoid diuretic therapy. These patients have relatively decreased intravascular volume, and administration of diuretics may result in acute renal insufficiency and oliguria. The most effective treatment involves (1) leg elevation, above the level of the heart, for 30 minutes three to four times daily, and during sleep; and (2) compression therapy. A wide variety of stockings and devices are effective in decreasing swelling and preventing ulcer formation. They should be put on with awakening, before hydration forces result in edema. Patients with decreased ABPI should be managed in concert with a vascular surgeon.

Valencia IC et al: Chronic venous insufficiency and venous leg ulceration. J Am Acad Dermatol 2001;44:401. [\[PMID: 11209109\]](#)

FEVER & HYPERTHERMIA

Essential Inquiries

- Localizing symptoms.
- Weight loss.
- Joint pain.
- Intravenous substance use.
- Immunosuppression or neutropenia.
- History of cancer.

- Medications.
- Travel.

General Considerations

The average normal oral body temperature taken in mid-morning is 36.7 °C (range 36-37.4 °C). This spectrum includes a mean and 2 standard deviations, thus encompassing 95% of a normal population, measured in mid-morning. The normal rectal or vaginal temperature is 0.5 °C higher than the oral temperature, and the axillary temperature is correspondingly lower. Rectal temperature is more reliable than oral temperature, particularly in mouth breathers or in tachypneic states.

The normal diurnal temperature variation is 0.5- 1°C, being lowest in the early morning and highest in the evening. There is a slight sustained temperature rise following ovulation, during the menstrual cycle, and in the first trimester of pregnancy.

Fever is a regulated rise to a new "set point" of body temperature. When proper stimuli act on appropriate monocyte-macrophages, these cells elaborate pyrogenic cytokines, causing elevation of the set point through effects in the hypothalamus. These cytokines include interleukin-1 (IL-1), tumor necrosis factor (TNF), interferon-gamma, and interleukin-6 (IL-6). The elevation in temperature results from either increased heat production (eg, shivering) or decreased loss (eg, peripheral vasoconstriction). Body temperature in cytokine-induced fever seldom exceeds 41.1 °C unless there is structural damage to hypothalamic regulatory centers.

Hyperthermia

Hyperthermia—not mediated by cytokines—occurs when body metabolic heat production or environmental heat load exceeds normal heat loss capacity or when there is impaired heat loss; heat stroke is an example. Body temperature may rise to levels (> 41.1 °C) capable of producing irreversible protein denaturation and resultant brain damage; no diurnal variation is observed.

Neuroleptic malignant syndrome is a rare and potentially lethal idiosyncratic reaction to major tranquilizers, particularly haloperidol and fluphenazine. It has clinical and pathophysiologic similarities to malignant hyperthermia of anesthesia (see [Chapters 25](#) and [39](#)).

Fever as a symptom provides important information about the presence of illness—particularly infections—and about changes in the clinical status of the patient. The fever pattern, however, is of marginal value for most specific diagnoses except for the relapsing fever of malaria, borreliosis, and occasional cases of lymphoma, especially Hodgkin's disease. Furthermore, the degree of temperature elevation does not necessarily correspond to the severity of the illness. In general, the febrile response tends to be greater in children than in adults; in older persons and neonates and in those receiving certain medications (eg, NSAIDs or corticosteroids), a normal temperature or even hypothermia may be observed.

Markedly elevated body temperature may result in profound metabolic disturbances. High temperature during the first trimester of pregnancy may cause birth defects, such as anencephaly. Fever increases insulin requirements and alters the metabolism and disposition of drugs used for the treatment of the diverse diseases associated with fever.

Prolonged Fever

Most febrile illnesses are due to common infections, are short-lived, and are relatively easy to diagnose. In certain instances, however, the origin of the fever may remain obscure ("fever of undetermined origin"; FVO) even after protracted diagnostic examination. The term FVO has traditionally been reserved for unexplained cases of fever exceeding 38.3 °C on several occasions for at least 3 weeks in patients without neutropenia or immunosuppression (see [Chapter 30](#)).

After extensive evaluation, one-fourth of these patients are judged to have chronic or indolent infection, about one-fourth autoimmune diseases, and about one-tenth a malignancy; the remainder have miscellaneous other disorders or no diagnosis is reached. Long-term follow-up of patients with initially undiagnosed FVO demonstrates that half become symptom-free during evaluation. In the remainder, a definitive diagnosis is established in 20%, usually within 2 months after investigation, and 30% have persistent or recurring fever for months or even years.

Approach to the Patient with FVO

Standardized algorithms for FVO are difficult to extrapolate to the individual patient. Nevertheless, the results of a history, physical examination, routine laboratory tests, and blood cultures provide important diagnostic clues that lead to a definitive diagnosis in most cases. In patients without a diagnosis or clues to one, staged diagnostic approaches have been employed for research purposes. Chest radiography and abdominal ultrasound and CT scans, often repeated after previous nondiagnostic studies, are most helpful. Radionuclide agents include labeled leukocytes, gallium-67, and radiolabeled human immunoglobulin; however, these tests appear to be most useful in patients with localizing signs of inflammation. There is little or no value to be derived from undirected immunologic, microbiologic, serologic, or endocrinologic studies. In older patients, a temporal artery biopsy is occasionally of use.

Fever of unknown origin is commonly associated with AIDS and HIV-related infections, though uncomplicated HIV infection is not a cause of prolonged fever. When FVO is observed in HIV-infected individuals, it usually occurs in the late stages. The most common causes are disseminated *Mycobacterium avium* infection, *Pneumocystis jiroveci* (formerly *P carinii*) pneumonia, cytomegalovirus infection, disseminated histoplasmosis, and lymphoma.

The differential diagnosis of a febrile illness in the returned traveler is extensive but most commonly includes tropical infections such as malaria, dysentery, hepatitis, and dengue fever. A substantial number of febrile illnesses in travelers are never diagnosed.

Differential Diagnosis

See [Table 2-3](#).

Treatment

Most fever is well tolerated. When the temperature is greater than 40 °C, symptomatic treatment may be required. A reading over 41 °C is likely to be hyperthermia and thus not cytokine-mediated, and emergent management is indicated. (See Heat Stroke, [Chapter 38](#).)

A. Measures for Removal of Heat

Alcohol sponges, cold sponges, ice bags, ice-water enemas, and ice baths will lower body temperature. They are more useful in hyperthermia, since patients with cytokine-related fever will attempt to override these therapies.

B. Antipyretic Drugs

Antipyretic therapy is not needed except for patients with marginal hemodynamic status. Aspirin or acetaminophen, 325-650 mg every 4 hours, is effective in reducing fever. These drugs are best administered continuously rather than as needed, since "prn" dosing results in periodic chills and sweats due to fluctuations in temperature caused by varying levels of drug.

C. Antimicrobial Therapy

In most febrile patients, empirical antibiotic therapy should be deferred pending further evaluation. However, persons in whom a clinically significant infection is likely should be started on appropriate antibiotic therapy. Prompt broad-spectrum antimicrobials are also indicated for febrile patients who are clinically unstable, even before infection can be documented. These include patients with hemodynamic instability, those with neutropenia (neutrophils less than 500/uL), others who are asplenic (surgically or secondary to sickle cell disease) or immunosuppressed (including individuals taking systemic corticosteroids, azathioprine, cyclosporine, or other immunosuppressive medications), and those who are HIV-infected (see [Chapter 31](#)). For treatment of fever during neutropenia following chemotherapy, outpatient parenteral antimicrobial therapy with an agent such as ceftriaxone can be provided effectively and safely. If a fungal infection is suspected in patients with prolonged fever and neutropenia, fluconazole is an equally effective but less toxic alternative to amphotericin B.

INVOLUNTARY WEIGHT LOSS

Essential Inquiries

- Age.
- Caloric intake.
- Fever.
- Change in bowel habits.
- Secondary confirmation (eg, changes in clothing size).
- Substance use.
- Age-appropriate cancer screening history.

General Considerations

Body weight is determined by a person's caloric intake, absorptive capacity, metabolic rate, and energy losses. The metabolic rate can be affected by a multitude of medical conditions through the release of various cytokines such as cachectin and interleukins. Body weight normally peaks by the fifth or sixth decade and then gradually declines at a rate of 1-2 kg per decade.

Clinical Findings

Involuntary weight loss is regarded as clinically significant when it exceeds 5% or more of usual body weight over a 6- to 12-month period and often indicates serious physical or psychologic illness. Physical causes are usually evident during the initial evaluation. Cancer (about 30%), gastrointestinal disorders (about 15%), and dementia or depression (about 15%) are the most common causes. When an adequately nourished-appearing patient complains of weight loss, inquiry should be made about exact weight changes (with approximate dates) and about changes in clothing size. Family members may provide confirmation of weight loss, as may old documents such as driver's licenses.

Once the weight loss is established, the history, medication profile, physical examination, and conventional laboratory and radiologic investigations such as complete blood count, serologic tests, TSH level, urinalysis, fecal occult blood test, chest x-ray, and upper gastrointestinal series usually reveal the cause. When these tests are normal, the second phase of evaluation should focus on more definitive gastrointestinal investigation (eg, tests for malabsorption; endoscopy) and cancer screening (eg, Pap smear, mammography, PSA).

If the initial evaluation is unrevealing, follow-up is preferable to further diagnostic testing. Death at 2-year follow-up was not nearly as high in patients with unexplained involuntary weight loss (8%) as in those with weight loss due to malignant (79%) and established nonmalignant diseases (19%). Psychiatric consultation should be considered when there is evidence of depression, dementia, anorexia nervosa, or other emotional problems. Ultimately, in approximately 15-25% of cases, no cause for the weight loss can be found.

A mild, gradual weight loss occurs in some older individuals. It is due to changes in body composition, including loss of height and lean body mass and lower basal metabolic rate, leading to decreased energy requirements. However, rapid unintentional weight loss is predictive of morbidity and mortality in any population. In addition to various disease states, causes in older individuals include loss of teeth and consequent difficulty with chewing, alcoholism, and social isolation.

Differential Diagnosis

Malignancy, gastrointestinal disorders (eg, malabsorption, pancreatic insufficiency), dementia, depression, anorexia nervosa, hyperthyroidism, alcoholism, and social isolation are all established causes.

Treatment

Weight stabilization occurs in the majority of surviving patients with both established and unknown causes of weight loss through treatment of the underlying disorder and caloric supplementation. Nutrient intake goals are established in relation to the severity of weight loss, in general ranging from 30 to 40 kcal/kg per day. In order of preference, route of administration options include oral, temporary nasojejun tube, or percutaneous gastric or jejunal tube. Parenteral nutrition is reserved for patients with serious associated problems. A variety of pharmacologic agents have been proposed for the treatment of weight loss. These can be categorized into appetite stimulants (corticosteroids, progestational agents, dronabinol and serotonin antagonists); anabolic agents (growth hormone and testosterone derivatives); and anticatabolic agents (omega-3 fatty acids, pentoxifylline, hydrazine sulfate, and thalidomide).

FATIGUE & CHRONIC FATIGUE SYNDROME

Essential Inquiries

- Weight loss.
- Fever.
- Sleep-disordered breathing.
- Medications.
- Substance use.

General Considerations

As an isolated symptom, fatigue accounts for 1-3% of visits to generalists. The symptom of fatigue may be less well defined and explained by patients than symptoms associated with specific functions. Fatigue or lassitude and the closely related complaints of weakness, tiredness, and lethargy are often attributed to overexertion, poor physical conditioning, sleep disturbance, obesity, undernutrition, and emotional problems. A history of the patient's daily living and working habits may obviate the need for extensive and unproductive diagnostic studies.

Clinical Findings

Important diseases that can cause fatigue include hyperthyroidism and hypothyroidism, congestive heart failure, infections (endocarditis, hepatitis), COPD, sleep apnea, anemia, autoimmune disorders, and cancer. Alcoholism, drug side effects such as from sedatives and beta-blockers, and psychologic conditions such as insomnia, depression, and somatization disorder are other causes. The lifetime prevalence of significant fatigue (present for at least 2 weeks) is about 25%. Fatigue of unknown cause or related to psychiatric illness exceeds that due to physical illness, injury, medications, drugs, or alcohol. Psychiatric disorders associated with fatigue include depression, dysthymia, somatoform disorders, panic attack, and alcohol abuse. Prolonged fatigue is a central feature of several syndromes, such as irritable bowel syndrome and anxiety ([Figure 2-2](#)).

Chronic Fatigue Syndrome

A working case definition of chronic fatigue syndrome ([Figure 2-3](#)) indicates that it is not a homogeneous abnormality, and there is no single pathogenic mechanism. No physical finding or laboratory test can be used to confirm the diagnosis of this disorder.

Early theories postulated an infectious or immune dysregulation mechanism, and it appears that neurologic, affective, and cognitive symptoms also occur frequently. Neuropsychologic, neuroendocrine, and brain imaging studies have confirmed the occurrence of neurobiologic abnormalities in most patients. Sleep disorders have been reported in 40-80% of patients with chronic fatigue syndrome, but their treatment has provided only modest benefit, suggesting that it is an effect rather than a cause of the fatigue. Magnetic resonance imaging may show brain abnormalities on T2-weighted images—chiefly small, punctate, subcortical white matter hyperintensities, predominantly in the frontal lobes.

After the history and physical examination process is completed, standard investigation of chronic fatigue should include complete blood count, erythrocyte sedimentation rate, serum chemistries—BUN, electrolytes, glucose, creatinine, calcium; liver and thyroid function tests—antinuclear antibody, urinalysis, and tuberculin skin test; and screening questionnaires for psychiatric disorders. Other tests to be performed as clinically indicated are serum cortisol, rheumatoid factor, immunoglobulin levels, Lyme serology in endemic areas, and tests for HIV antibody. More extensive testing is usually unhelpful, including antibody to Epstein-Barr virus. There may be an abnormally high rate of postural hypotension; some of these patients report response to increases in dietary sodium as well as antihypotensive agents such as fludrocortisone, 0.1 mg/d.

A variety of treatments have been tried. Acyclovir, intravenous immunoglobulin, nystatin, and low-dose hydrocortisone do not improve symptoms. There is a greater prevalence of past and current psychiatric diagnoses in patients with this syndrome. Affective disorders are especially common, but fluoxetine alone, 20 mg daily, is not beneficial. Patients with chronic fatigue syndrome have benefited from a comprehensive multidisciplinary intervention, including optimal medical management, treating any ongoing affective or anxiety disorder pharmacologically, and implementing a comprehensive cognitive-behavioral treatment program. Cognitive behavior therapy, a form of nonpharmacologic treatment emphasizing self-help and aiming to change perceptions and behaviors that may perpetuate symptoms and disability, is helpful. Although few patients are cured, the treatment effect is substantial. Response to cognitive behavioral therapy is not predictable on the basis of severity or duration of chronic fatigue syndrome. Graded exercise has also been shown to improve functional work capacity and physical function. At present, intensive individual cognitive behavioral therapy administered by a skilled therapist and graded exercise is the treatment of choice for patients with chronic fatigue syndrome.

In addition, the clinician's sympathetic listening and explanatory responses can help overcome the patient's frustrations and debilitation by this still mysterious illness. All patients should be encouraged to engage in normal activities to the extent possible and should be reassured that full recovery is eventually possible in most cases.

ACUTE HEADACHE

Essential Inquiries

- Age > 50 years.
- Rapid onset and severe intensity.
- Fever.
- Trauma.
- Vision changes.
- Past medical history of hypertension or HIV infection.
- Hypertension.
- Neurologic findings (mental status changes, motor or sensory deficits).

General Considerations

Headache is a common reason that adults seek medical care, accounting for approximately 13 million visits each year in the United States to physicians' offices, urgent care clinics, and emergency departments. A broad range of disorders can lead to headache. This chapter will deal only with the approach to a new acute headache—not due to trauma—in adolescents and adults. The challenge in the initial evaluation of acute headache is to identify those conditions that are life-threatening. In the emergency department setting, approximately 1% of patients presenting with acute headache will have a life-threatening condition, whereas the prevalence of life-threatening conditions in the office practice setting is likely to be much lower.

Regardless of the underlying cause, headache is currently believed to occur as a result of the release of neuropeptides from trigeminal nerve endings that encapsulate the blood vessels of the pia mater and dura mater, resulting in neurogenic inflammation. Because this represents a final common pathway, diminution of headache in response to typical migraine therapies (such as serotonin receptor antagonists or ketorolac tromethamine) does not rule out critical conditions such as subarachnoid hemorrhage or meningitis as the underlying cause.

Clinical Findings

A careful history and physical examination should be aimed at identifying causes of acute headache that require immediate treatment. These causes can be broadly classified as imminent or completed **vascular events** (intracranial hemorrhage, thrombosis, vasculitis, malignant hypertension, arterial dissection, or aneurysm), **infections** (abscess, encephalitis, meningitis), **intracranial masses** causing intracranial hypertension, **preeclampsia**, and **carbon monoxide poisoning**. The natural history of the onset of headache can be helpful. Report of a sudden-onset headache that reaches maximal and severe intensity within seconds or a few minutes is the classic description of a "thunderclap headache" and should precipitate workup for subarachnoid hemorrhage. A new headache in a patient of advanced age or with a history of HIV disease under most circumstances (including a normal neurologic examination) warrants neuroimaging immediately or soon. When the patient has a medical history of hypertension—particularly uncontrolled hypertension—a complete search for criteria satisfying a diagnosis of "malignant hypertension" is appropriate in order to determine the correct urgency level of hypertension management (see [Chapter 11](#)). Headache and hypertension associated with pregnancy may be due to preeclampsia. Episodic headache associated with the triad of hypertension, heart palpitations, and sweats should suggest the possibility of pheochromocytoma. In the absence of thunderclap headache, advanced age, and HIV disease, findings on physical examination will usually determine the time course and need for further diagnostic testing.

Critical components of physical examination of the patient with acute headache include vital sign measurements, neurologic examination, and vision testing with funduscopic examination. The finding of fever with acute headache should suggest additional maneuvers to elicit evidence of meningeal inflammation, such as Kernig and Brudzinski signs. Besides malignant hypertension, significant hypertension can also be a sign of intracranial hemorrhage, preeclampsia, and pheochromocytoma. Patients over 60 years of age should be examined for scalp or temporal artery tenderness.

Careful assessment of visual acuity, ocular gaze, visual fields, pupillary defects, the optic disk, and retinal vein pulsations is crucial. Diminished visual acuity is suggestive of glaucoma, temporal arteritis, or optic neuritis. Ophthalmoplegia or visual field defects may be signs of venous sinus thrombosis, tumor, or aneurysm. Afferent pupillary defects can be due to intracranial masses or optic neuritis. Ipsilateral ptosis and miosis suggest Horner's syndrome and in conjunction with acute headache may signify carotid artery dissection. Finally, papilledema or absent retinal venous pulsations are signs of elevated intracranial pressure—findings that should be followed by neuroimaging prior to performing lumbar puncture.

Mental status and complete neurologic evaluations are also critical and should include assessment of motor and sensory systems, reflexes, gait, cerebellar function, and pronator drift. Any abnormality on mental status or neurologic evaluation warrants emergent neuroimaging.

Diagnostic Studies ([Table 2-4](#))

Under most circumstances, a noncontrast head CT is sufficient to exclude intracranial hypertension with impending herniation, intracranial hemorrhage, and many types of intracranial masses (notable exceptions include lymphoma and toxoplasmosis in HIV-positive patients, herpes simplex encephalitis, and brain abscess). When appropriate, a contrast study can often be ordered to follow a normal noncontrast study. A normal neuroimaging study does not sufficiently exclude subarachnoid hemorrhage and should be followed by lumbar puncture. In patients for whom there is a high level of suspicion for subarachnoid hemorrhage or aneurysm, a normal CT and lumbar puncture should be followed by angiography within the next few days (provided the patient is medically stable). Lumbar puncture is also indicated to exclude infectious causes of acute headache, particularly in patients with fever or meningeal signs. Cerebrospinal fluid tests should routinely include Gram stain, white blood cell count with differential, red blood cell count, glucose, total protein, and bacterial culture. In appropriate patients, one should also consider testing cerebrospinal fluid for VDRL (syphilis), cryptococcal antigen (HIV-positive patients), acid-fast bacillus stain and culture, and complement fixation and culture for coccidioidomycosis. Storage of an extra tube with 5 mL of cerebrospinal fluid is also prudent for conducting unanticipated tests in the immediate future. Consultation with infectious disease experts regarding local availability of newer polymerase chain reaction tests for specific infectious pathogens (eg, herpes simplex 2) should also be considered in patients with evidence of central nervous system infection but no identifiable pathogen.

In addition to neuroimaging and lumbar puncture, additional diagnostic tests for exclusion of life-threatening causes of acute headache include erythrocyte sedimentation rate (temporal arteritis; endocarditis), urinalysis (malignant hypertension; preeclampsia), and sinus CT or x-ray (bacterial sinusitis, independently or as a

cause of venous sinus thrombosis).

Treatment

Treatment should be based on determination of the cause of acute headache.

INTRODUCTION

Each year, tens of millions of patients in the United States undergo a surgical procedure requiring general or spinal-epidural anesthesia. A disproportionate and increasing number of these patients are over age 65. Most patients do not suffer significant morbidity as a result of the surgical procedure or the anesthetic. The rate of major complications varies from 3% to 15% depending on the patient's age, the presence of underlying disease, and the type of surgery. Cardiac, pulmonary, and neurologic complications account for most of the perioperative morbidity and mortality.

The role of the medical consultant includes clearly defining the patient's medical conditions, evaluating the severity and stability of these conditions, providing a surgical risk assessment, and recommending perioperative measures to reduce surgical risk.

Leung JM et al: Relative importance of preoperative health status versus intraoperative factors in predicting postoperative adverse outcomes in geriatric patients. J Am Geriatr Soc 2001;49:1080. [\[PMID: 11555070\]](#)

Polanczyk CA et al: Impact of age on perioperative complications and length of stay in patients undergoing noncardiac surgery. Ann Intern Med 2001;134:637. [\[PMID: 11304103\]](#)

PHYSIOLOGIC EFFECTS OF ANESTHESIA & SURGERY

The complications of anesthesia and surgery are, for the most part, logical results of their known physiologic effects. Both general and spinal or epidural anesthetic agents usually cause peripheral vasodilation, and most of the commonly used general anesthetic regimens also decrease myocardial contractility. These effects often result in transient mild hypotension or, less frequently, prolonged or more severe hypotension. The decrease in tidal volume caused by general and spinal-epidural anesthesia can close small airways and lead to atelectasis. Epinephrine, norepinephrine, and cortisol levels increase during surgery and remain elevated for 1-3 days. Serum antidiuretic hormone levels may be elevated for up to 1 week postoperatively. There is some evidence that general anesthesia may be associated with a relative hypercoagulable state during the perioperative period. This does not occur with spinal or epidural anesthesia. The degree to which this hypercoagulability contributes to perioperative morbidity is not known.

There is no evidence that spinal or epidural anesthesia is preferable to general anesthesia in terms of cardiac outcomes or overall surgical outcomes. Similarly, there is no conclusive evidence that the routine use of invasive hemodynamic monitoring with pulmonary artery catheters improves surgical outcomes. In general, the choice of anesthetic technique or agent and the decision to use invasive hemodynamic monitoring should be left to the anesthesiologist.

EVALUATION OF THE ASYMPTOMATIC PATIENT

Patients without significant medical problems—especially those under age 50—are at very low risk for perioperative complications. The preoperative evaluation of these patients should include a complete history and physical examination. Special emphasis is placed on the assessment of functional status, exercise tolerance, and cardiopulmonary symptoms and signs in an effort to reveal previously unrecognized disease (especially cardiopulmonary disease) that may require further evaluation prior to surgery. Additionally, a directed bleeding history ([Table 3-1](#)) should be taken to uncover disorders of hemostasis that could contribute to excessive surgical blood loss.

Routine testing of asymptomatic healthy patients should include a 12-lead ECG for those over 50 years of age and for any patient with risk factors for coronary artery disease—specifically, to look for evidence of clinically silent coronary artery disease that would prompt further cardiac evaluation. Minor ECG abnormalities such as bundle branch block, T wave changes, and premature ventricular contractions do not predict adverse postoperative outcomes. Additional testing of asymptomatic healthy patients has not been found to be helpful and is not recommended. However, the preoperative evaluation may provide an opportunity to perform other tests that are recommended as part of routine health maintenance (see [Chapter 1](#)).

Schein OD et al: The value of routine preoperative medical testing before cataract surgery. Study of Medical Testing for Cataract Surgery. N Engl J Med 2000;342:168. [\[PMID: 10639542\]](#)

CARDIAC RISK ASSESSMENT

The cardiac complications of noncardiac surgery are perhaps the major cause of perioperative morbidity and mortality. As such, this has been the most extensively studied area of perioperative medicine. The most important perioperative cardiac complications are myocardial infarction, congestive heart failure, and cardiac death. Older age, preexisting coronary artery disease, and congestive heart failure are the principal risk factors for development of these complications.

Major abdominal, thoracic, and vascular surgical procedures (especially abdominal aortic aneurysm repair) tend to carry a higher risk of postoperative cardiac complications than other procedures. Emergency operations are generally associated with more cardiac complications than elective operations. These high-risk procedures are more often associated with major fluid shifts, hemorrhage, and hypoxemia, which may predispose to cardiac complications.

Coronary Artery Disease

Approximately 50,000 patients undergoing surgery each year suffer a perioperative myocardial infarction. Patients without coronary artery disease are at extremely low risk (< 0.5%) for perioperative ischemic cardiac complications. Patients with known or suspected coronary artery disease, as defined in [Table 3-2](#), have a fivefold to 50-fold increased risk of perioperative cardiac complications.

The estimated risk of cardiac complications in patients with coronary artery disease can be further refined through an assessment of the severity of anginal symptoms, the use of multifactorial indices, and the judicious use of noninvasive tests for ischemia. The severity of anginal symptoms is most accurately assessed using a standardized scale such as that shown in [Table 3-3](#). Multifactorial indices combine several clinical parameters to estimate an overall risk of cardiac complications. An updated risk index is presented in [Table 3-4](#). This index more accurately predicts perioperative outcomes using modern surgical techniques.

Preoperative Noninvasive Ischemia Testing

Noninvasive tests for myocardial ischemia such as exercise treadmill testing, dipyridamole-thallium scintigraphy, and dobutamine stress echocardiography have been shown to improve upon the clinical risk assessment and help to optimize perioperative management in selected patients. Most patients can be accurately stratified through an assessment of anginal symptoms. Patients who have mild symptoms, defined as Canadian Cardiovascular Society (CCS) class 1 or 2 angina, and a low or intermediate multifactorial index score are at low risk for cardiac complications. Noninvasive testing in these patients is generally unnecessary. Patients with severe symptoms, CCS class 3 or 4 angina, or a high multifactorial index score are likely to be at high risk for cardiac complications. Stress echocardiography in this group of patients may be able to identify a low-risk subgroup. In the case of high-clinical-risk vascular surgery patients, the absence of a regional wall motion abnormality on stress echocardiography predicts a low risk of perioperative cardiac death or myocardial infarction.

Noninvasive cardiac testing may also be useful in patients with known or suspected coronary artery disease and an unknown functional status. In patients who are able to walk, jog, or use a supine bicycle, the absence of ischemia at or above 85% of their maximal predicted heart rate on exercise electrocardiography predicts a low risk for perioperative cardiac complications.

In patients who cannot exercise, a normal dipyridamole-thallium scan or stress echocardiogram predicts a low risk of complications (comparable to that of patients with a low-risk clinical assessment), whereas evidence of thallium redistribution—or stress-induced echocardiographic wall motion abnormalities—predicts a much higher risk (comparable to that of patients with a high-risk clinical assessment).

Of note—in patients with known coronary artery disease who cannot exercise but have other clinical indicators predicting a high risk of cardiac complications (such as a high multifactorial index score), dobutamine stress echocardiography is the preferred noninvasive test.

Any patient who is considered a candidate for noninvasive ischemia testing independent of the planned noncardiac surgery should generally have such testing prior to surgery if the test result may lead to coronary revascularization. This is particularly true for patients found to be at high risk on clinical assessment.

Evidence of ischemia on preoperative continuous electrocardiographic monitoring has been associated with perioperative cardiac complications. However, the practical use of this test is limited by the need for a normal baseline ECG and the minimum 24-hour testing period.

Left ventricular systolic dysfunction, moderate or severe left ventricular hypertrophy, and a peak aortic gradient greater than 40 mm Hg on resting echocardiography are associated with an increased risk of cardiac complications in selected patients. Resting echocardiography, however, is not recommended for routine perioperative risk assessment.

Preoperative Management of Patients with Coronary Artery Disease

A. Low-Risk Patients with Coronary Artery Disease

Patients in this group have roughly a 4% risk of myocardial infarction and about a 1% mortality rate. Results from the Coronary Artery Surgery Study trial registry indicate that patients who have undergone prior coronary artery bypass graft surgery—particularly if within the last 2 years—are at lower risk for cardiac complications with subsequent noncardiac surgery compared with similar patients treated medically. Patients who have undergone percutaneous transluminal coronary angioplasty (PTCA) within 6 months of noncardiac surgery also seem to be at relatively low risk for complications. However, this should not be interpreted as a prescription for the use of prophylactic revascularization. The use of coronary angiography and revascularization in these patients depends on two factors: the urgency of the surgery and whether the patient has indications for such evaluation regardless of the planned surgery. The mortality rate for coronary artery bypass surgery is roughly 1.5% and that for PTCA ranges from 0.5% to 1.5%; thus, the routine prophylactic use of these procedures prior to elective noncardiac surgery is unlikely to decrease total morbidity or mortality rates. However, in patients who are candidates for coronary angiography and subsequent revascularization independent of the planned surgery, it seems prudent to proceed with these prior to elective noncardiac surgery when feasible.

Preoperative antianginal medications, including beta-blockers, calcium channel blockers, and nitrates, should be continued preoperatively and during the postoperative period. The institution of prophylactic beta-blockers in the immediate preoperative period has been shown to reduce intraoperative myocardial ischemia and may reduce the incidence of perioperative myocardial infarction. In the first large clinical trial, prophylactic atenolol reduced cardiac morbidity at 6, 12, and 24 months after noncardiac surgery in patients with known or suspected coronary artery disease. The most dramatic results of perioperative beta blockade have been demonstrated in a randomized controlled trial of prophylactic bisoprolol in patients who had known coronary artery disease and abnormal stress echocardiograms and who underwent major noncardiac surgery. The risk of nonfatal myocardial infarction or cardiac death was reduced from 34% to 3.4% in the bisoprolol group compared with the placebo group. Thus, perioperative prophylactic beta blockade is recommended for patients with known or suspected coronary artery disease undergoing major surgery. The dosing schedules for atenolol and bisoprolol are set forth in [Table 3-5](#).

Prophylactic intraoperative intravenous nitroglycerin may decrease the frequency of ischemia but has not been shown to reduce the rate of postoperative complications. This may be considered for high-risk patients. Too little is known about the effects of the prophylactic use of calcium channel blockers to make any recommendations. A clinical trial of the prophylactic use of the α_2 -adrenergic agonist mivazerol in patients with coronary artery disease found no significant benefit overall.

B. High-Risk Patients with Coronary Artery Disease

In this group surgery should be postponed, except in emergency situations, to allow for stabilization of ischemic symptoms. For patients with a recent myocardial infarction and evidence of ongoing ischemia, delaying surgery for 3-6 months postinfarction to allow for appropriate stabilization and therapy may significantly reduce perioperative mortality and morbidity rates. Patients with unstable angina should be evaluated and treated as indicated by their cardiac status prior to surgery and then reevaluated with respect to severity of symptoms and functional status. Patients with severe stable angina or worsening angina may be managed in a variety of ways. Like patients with less severe angina, those who are potential candidates for coronary revascularization independent of the planned noncardiac surgery should certainly proceed with this evaluation prior to noncardiac surgery. For patients who are not obvious candidates for revascularization, one approach is to optimize their antianginal medications and reevaluate their symptoms. This approach assumes that an improvement in symptoms correlates with a reduction in perioperative cardiac complication rates—an assumption that is without clear validation at present. All high-risk patients should be treated with prophylactic atenolol or bisoprolol if they are not already taking a beta-blocking agent and if it is not otherwise contraindicated. An alternative approach is preoperative PTCA. However, it is not known if such a strategy effectively reduces surgical risk. In a cohort analysis from the BARI (Bypass Angioplasty Revascularization Investigation) trial, patients who underwent multivessel angioplasty (without intracoronary stent placement) for stable coronary artery disease had a 1.6% cardiac complication rate with subsequent noncardiac surgery. It is of note that the complication rate was 0.8% when the interval between the PTCA and noncardiac surgery was less than 4 years compared with a rate of 3.6% when surgery was done more than 4 years following PTCA.

The use of intracoronary stents in the immediate preoperative period, however, may increase the risk of perioperative cardiac complications. In a recent retrospective study, patients who underwent noncardiac surgery within 14 days after intracoronary stenting had extremely high total morbidity and mortality (32%) rates. The complication rates were substantially lower in patients who underwent noncardiac surgery 15-39 days after stenting. The presumed mechanism of this very high mortality is acute stent thrombosis that results from discontinuation of anticoagulant therapy prior to the standard 4 weeks. Therefore, it is prudent to delay elective surgery for at least 4 weeks after intracoronary stenting.

An approach to the assessment and management of patients with known or suspected coronary artery disease is set forth in [Figure 3-1](#).

Congestive Heart Failure & Left Ventricular Dysfunction

Decompensated congestive heart failure, manifested by an elevated jugular venous pressure, an audible third heart sound, or evidence of pulmonary edema on physical examination or chest radiography, significantly increases the risk of perioperative pulmonary edema (roughly 15%) and cardiac death (2-10%). Preoperative control of congestive heart failure, including the use of diuretics and afterload reducing agents, is likely to reduce the perioperative risk. One must be cautious not to give too much diuretic, since the volume-depleted patient will be much more susceptible to intraoperative hypotension. Although spironolactone, beta-adrenergic blocking agents, and angiotensin receptor-blocking agents have been shown to reduce long-term mortality in patients with heart failure, institution of these agents in the immediate preoperative period has not been studied and is not recommended as routine practice.

Patients with compensated left ventricular dysfunction are at increased risk for developing perioperative pulmonary edema but are not at excess risk for other cardiac complications. One large study found that patients with a left ventricular ejection fraction of less than 50% had an absolute risk of 12% for postoperative congestive heart failure compared with 3% for patients with an ejection fraction greater than 50%. Such patients should be maintained on all chronic heart failure medications up to and including the day of surgery. Patients receiving digoxin and diuretics should routinely have serum electrolyte and digoxin levels measured prior to surgery because abnormalities in these levels may increase the risk of perioperative arrhythmias. Preoperative echocardiography or radionuclide angiography to assess left ventricular function should be considered for patients with evidence of left ventricular dysfunction who have not had an objective assessment of left ventricular function, and in patients for whom the cause of left ventricular dysfunction is in question. The surgeon and anesthesiologist should be made aware of the presence and severity of left ventricular dysfunction so that appropriate decisions can be made regarding perioperative fluid management and intraoperative monitoring.

Valvular Heart Disease

There are few data available regarding the perioperative risks of valvular heart disease independent of associated coronary artery disease or congestive heart failure. Patients with severe symptomatic aortic stenosis are clearly at increased risk for cardiac complications. Such patients who are candidates for valve replacement surgery or, if only short-term relief is needed, for balloon valvuloplasty independent of the planned noncardiac surgery should have the corrective procedure performed prior to noncardiac surgery. In the largest recent series of patients with severe aortic stenosis who underwent noncardiac surgery, the mortality rate was less than 5% and the cardiac morbidity rate was approximately 10%. It is noteworthy that all patients had normal or near-normal preoperative left ventricular systolic function and that patients with asymptomatic aortic stenosis appeared to be at lower risk than patients with symptomatic aortic stenosis. The relatively low morbidity and mortality in this series may be due to the recent use of invasive intraoperative monitoring, including pulmonary artery catheterization and transesophageal echocardiography. Nevertheless, noncardiac surgery in patients with severe aortic stenosis must be approached with great caution and requires close consultation with the anesthesiologist.

The severity of valvular lesions should be defined prior to surgery to allow for appropriate fluid management and consideration of invasive intraoperative monitoring. Echocardiography should also be considered in patients with a previously unexplained heart murmur for those procedures in which a valvular abnormality would require antibiotic prophylaxis. For specific recommendations regarding antibiotic prophylaxis, see [Chapter 33](#).

Arrhythmias

Several early studies on cardiac risk factors reported that both atrial and ventricular arrhythmias were independent predictors of an increased risk of perioperative complications. Recent data have shown these rhythm disturbances to be frequently associated with underlying structural heart disease, especially coronary artery disease and left ventricular dysfunction. The finding of a rhythm disturbance on preoperative evaluation should prompt consideration of further cardiac evaluation, particularly when the finding of structural heart disease would alter perioperative management. Patients found to have a rhythm disturbance without evidence of underlying heart disease are at very low risk for perioperative cardiac complications.

Management of patients with arrhythmias in the preoperative period should be guided by factors independent of the planned surgery. In patients with atrial fibrillation,

adequate rate control should be established. Symptomatic supraventricular and ventricular tachycardia must be controlled prior to surgery. There is no evidence that the use of antiarrhythmic medications to suppress an asymptomatic arrhythmia alters perioperative risk.

It seems prudent for patients who have indications for a permanent pacemaker to have it placed prior to noncardiac surgery. When surgery is urgent, these patients may be managed perioperatively with temporary transvenous pacing. Patients with bundle branch block who do not meet recognized criteria for a permanent pacemaker do not require pacing during surgery.

Hypertension

Severe hypertension, defined as a systolic pressure greater than 180 mm Hg or diastolic pressure greater than 110 mm Hg, appears to be an independent predictor of perioperative cardiac complications, including myocardial infarction and congestive heart failure. Mild to moderate hypertension immediately preoperatively is associated with intraoperative blood pressure lability and asymptomatic myocardial ischemia but does not appear to be an independent risk factor for adverse cardiac outcomes. It seems wise to delay surgery in patients with severe hypertension until blood pressure can be controlled, though it is not known whether the risk of cardiac complications is reduced with this approach. It is unlikely that treatment of mild to moderate hypertension in the immediate preoperative period will significantly reduce the risk of cardiac complications. However, chronic medications for hypertension should be continued up to and including the day of surgery.

PULMONARY EVALUATION IN NON-LUNG RESECTION SURGERY

Pneumonia and respiratory failure requiring prolonged mechanical ventilation are the most important postoperative pulmonary complications and occur in 2-19% of surgical procedures.

Risk Factors for the Development of Postoperative Pulmonary Complications

Numerous series have investigated the risk factors for the development of postoperative pulmonary complications. The risk of developing a pulmonary complication is highest in patients undergoing cardiac, thoracic, and upper abdominal surgery, with reported complication rates ranging from 9% to 19%. The risk in patients undergoing lower abdominal or pelvic procedures ranges from 2% to 5%, and for extremity procedures the range is less than 1-3%. The pulmonary complication rate for laparoscopic procedures appears to be much lower than that for open procedures. In one series of over 1500 patients who underwent laparoscopic cholecystectomy, the pulmonary complication rate was less than 1%.

Three patient-specific factors have been repeatedly found to increase the risk of postoperative pulmonary complications: chronic lung disease, morbid obesity, and tobacco use. Patients with chronic obstructive pulmonary disease (COPD) have a twofold to fourfold increased risk compared with patients without COPD. Assessment of the severity of COPD using pulmonary function tests has not been shown to improve upon the clinical risk assessment with the exception that patients with an FEV₁ under 500 mL or an FEV₁ below 50% of the predicted value appear to be at particularly high risk. In a single large prospective cohort of US military veterans, additional risk factors for the development of postoperative pneumonia included age over 60 years, dependent functional status, impaired sensorium, and prior stroke. In addition, two studies found that placement of a nasogastric tube postoperatively increases the risk of pneumonia.

Patients with asthma are at increased risk for bronchospasm during tracheal intubation and extubation and during the postoperative period. However, if patients are at their optimal pulmonary function (as determined by symptoms, physical examination, or spirometry) at the time of surgery, they do not appear to be at increased risk for other pulmonary complications.

Morbidly obese patients—those weighing over 113 kg (250 lb)—are approximately twice as likely to develop postoperative pneumonia as patients weighing less. Mild obesity does not appear to increase the risk of clinically important pulmonary complications.

Several studies have shown that current cigarette smoking is associated with an increased risk for developing postoperative atelectasis. In a single study, cigarette smoking was also found to double the risk of developing postoperative pneumonia, even when controlling for underlying lung disease. A summary of the known risk factors for pulmonary complications is presented in [Table 3-6](#).

Pulmonary Function Testing & Arterial Blood Gas Analysis

The vast majority of studies have shown that preoperative pulmonary function testing in unselected patients is not helpful in predicting postoperative pulmonary complications. The data are conflicting regarding the utility of preoperative pulmonary function testing in certain selected groups of patients: the morbidly obese, those with COPD, and those undergoing upper abdominal or cardiothoracic surgery. No single pulmonary function test value places a patient at prohibitive risk for non-lung resection surgery. At present, definitive recommendations regarding the indications for preoperative pulmonary function testing cannot be made. In general terms, such testing may be helpful to confirm the diagnosis of COPD or asthma, to assess the severity of known pulmonary disease, and perhaps as part of the risk assessment for patients undergoing upper abdominal surgery, cardiac surgery, or thoracic surgery.

Arterial blood gas measurement is not routinely recommended except in patients with known lung disease and suspected hypoxemia or hypercapnia.

Perioperative Management

The goal of perioperative management is to reduce the likelihood of postoperative pulmonary complications. Smoking cessation for at least 4 weeks prior to thoracic surgery reduced the incidence of pulmonary complications by 25%. Incentive spirometry (IS), continuous positive airway pressure (CPAP), intermittent positive-pressure breathing (IPPB), and deep breathing exercises (DBE) have all been shown to reduce the incidence of postoperative atelectasis and, in a small number of studies, to reduce the incidence of postoperative pulmonary complications. In most comparative trials, these methods were equally effective. However, in a randomized trial of patients undergoing resection of the esophagus or stomach, those who received postoperative CPAP had a lower risk of prolonged mechanical ventilation or reintubation compared with those who did IS or DBE. Given the higher cost of CPAP and IPPB, IS and DBE are the preferred methods for most patients. CPAP may be preferable for patients undergoing esophageal or gastric resection. IS must be performed for 15 minutes every 2 hours. DBE must be performed hourly and consist of 3-second breath-holding, pursed lip breathing, and coughing. These measures should be started preoperatively and be continued for 1-2 days postoperatively.

There has been recent enthusiasm for the use of postoperative epidural analgesia to improve pain control and perhaps to reduce pulmonary complications. Most studies suggest that postoperative epidural opioid and local anesthetic agents provide excellent pain control but do not appreciably reduce pulmonary complication rates.

There is some evidence that the incidence of postoperative pulmonary complications in patients with COPD or asthma may be reduced by preoperative optimization of pulmonary function. Patients who are wheezing will probably benefit from therapy with bronchodilators and, in certain cases, corticosteroids preoperatively. Antibiotics may be of benefit for patients who cough with purulent sputum if the sputum can be cleared prior to surgery. Patients who take oral theophylline should be maintained on it during the intraoperative and postoperative periods, using intravenous theophylline when necessary.

EVALUATION OF THE PATIENT WITH LIVER DISEASE

Patients with serious liver disease are generally thought to be at increased risk for perioperative morbidity and demise. Appropriate preoperative evaluation requires consideration of the effects of anesthesia and surgery on postoperative liver function and of the complications associated with anesthesia and surgery in patients with preexisting liver disease.

The Effects of Anesthesia & Surgery on Liver Function

Postoperative elevation of serum aminotransferase levels is a relatively common finding after major surgery. Most of these elevations are transient and not associated with hepatic dysfunction. Studies in the 1960s and early 1970s showed that patients with liver disease are at increased relative risk for postoperative deterioration in hepatic function, though the absolute risk is not known. General anesthetic agents may cause deterioration of hepatic function via intraoperative reduction in hepatic blood flow leading to ischemic injury. It is important to remember that agents used for spinal and epidural anesthesia produce similar reductions in hepatic blood flow and thus may be equally likely to lead to ischemic liver injury. Intraoperative hypotension, hemorrhage, and hypoxemia may also contribute to liver injury.

Risk Factors for Surgical Complications

Surgery in the patient with serious liver disease has been associated in several series with a variety of significant complications, including hemorrhage, infection, renal failure, and encephalopathy, and with a substantial mortality rate. A key limitation in interpreting these data is our inability to determine the contribution of the liver disease to the observed complications independent of the surgical procedure.

In three small series of patients with acute viral hepatitis who underwent abdominal surgery, the mortality rate was roughly 10%. Patients undergoing portosystemic shunt surgery who have evidence of alcoholic hepatitis on the preoperative liver biopsy have a significantly increased surgical mortality rate. Although data are quite limited, it seems reasonable to delay elective surgery in patients with acute viral or alcoholic hepatitis, at least until the acute episode has resolved. These data are not sufficient to warrant substantial delays in urgent or emergent surgery.

There are few data regarding the risks of surgery in patients with chronic hepatitis. In a series of 272 patients with chronic hepatitis undergoing a variety of surgical procedures for variceal hemorrhage, the in-hospital mortality rate was less than 2%. It is of note that patients with Child-Pugh class C cirrhosis (see [Chapter 15](#)) or with serum aminotransferase levels over 150 units/L were excluded. In a study of patients undergoing hepatectomy for hepatocellular carcinoma, patients with both cirrhosis and active hepatitis on the preoperative liver biopsy had a fourfold increase in mortality (8.7%) compared with patients with cirrhosis alone or active hepatitis alone.

Substantial data exist regarding surgery in patients with cirrhosis. In several series from the 1960s and 1970s, patients with cirrhosis undergoing abdominal surgery had substantial mortality rates. Biliary surgery was especially risky. Patients with Childs-Pugh class A or B cirrhosis who underwent abdominal surgery during the 1990s, however, had relatively low mortality rates (hepatectomy 0-8%, open cholecystectomy 0-1%, laparoscopic cholecystectomy 0-1%). Three recent studies investigated the risk factors for morbidity and mortality in patients with hepatocellular carcinoma and underlying Child-Pugh class A or B cirrhosis who underwent liver resection. An elevation of serum alanine aminotransferase (ALT) above twice-normal, an abnormal indocyanine green test, and an abnormal result on technetium-99m galactosyl-human serum albumin liver scintigraphy all were associated with increased perioperative morbidity or mortality. Patients with Childs-Pugh class C cirrhosis who underwent portosystemic shunt surgery, biliary surgery, or trauma surgery during the 1970s and 1980s had a 50-85% mortality rate. More recent surgical data in these patients are lacking. A conservative approach would be to avoid elective surgery in patients with class C cirrhosis or those with class A or B cirrhosis and concomitant active hepatitis.

PREOPERATIVE HEMATOLOGIC EVALUATION

Several hematologic disorders may have an impact on the outcomes of surgery. A detailed discussion of the preoperative management of patients with complicated hematologic disorders is beyond the scope of this section. Two of the more common clinical situations faced by the medical consultant are the patient with preexisting anemia and the assessment of bleeding risk.

The key issues in the anemic patient are to determine the need for preoperative diagnostic evaluation and the need for transfusion. When feasible, the diagnostic evaluation of the patient with previously unrecognized anemia should be done prior to surgery because certain types of anemia (particularly sickle cell disease and immune hemolytic anemias) may have implications for perioperative management. Most data suggest that morbidity and mortality increase as the preoperative hemoglobin level decreases, though none of these data were corrected for the presence of preexisting diseases. Hemoglobin levels below 8 or 9 g/dL appear to be associated with significantly more perioperative complications than higher levels. In patients with ischemic heart disease, a preoperative hemoglobin level below 10 g/dL has been associated with an increased perioperative mortality rate. It is not known, however, whether preoperative transfusion reduces the risk for perioperative complications. Determination of the need for preoperative transfusion in an individual patient must consider factors other than the absolute hemoglobin level, including the presence of cardiopulmonary disease, the type of surgery, and the likelihood of surgical blood loss.

The most important component of the bleeding risk assessment is a directed bleeding history ([Table 3-1](#)). Patients who are reliable historians and who reveal no suggestion of abnormal bleeding on directed bleeding history and physical examination are at very low risk for having an occult bleeding disorder. Laboratory tests of hemostatic parameters in these patients are generally not needed. When the directed bleeding history is unreliable or incomplete or when abnormal bleeding is suggested, a formal evaluation of hemostasis should be done prior to surgery and should include measurement of the prothrombin time, the activated partial thromboplastin time, the platelet count, and the bleeding time.

Baker R: Pre-operative hemostatic assessment and management. Transfus Apheresis Sci 2002;27:45. [\[PMID: 12201470\]](#)

NEUROLOGIC EVALUATION

Delirium occurs after major surgery in approximately 9% of patients over the age of 50 years. Postoperative delirium has been associated with higher rates of major postoperative cardiac and pulmonary complications, poor functional recovery, and increased length of hospital stay. Several preoperative and postoperative factors have been associated with the development of postoperative delirium ([Table 3-7](#)). Patients with multiple risk factors are at especially high risk.

Delirium is particularly common after hip fracture repair, occurring in 35-65% of patients. In a randomized controlled trial of hip fracture surgery patients, those who received daily visits and targeted recommendations from a geriatrician had a lower risk of postoperative delirium (32%) than the control patients (50%). The most frequent interventions to prevent delirium were maintenance of the hematocrit greater than 30%; minimizing the use of benzodiazepines, anticholinergic, and antihistamine medications; maintenance of regular bowel function; and early discontinuation of urinary catheters.

Stroke may occur in 1-6% of patients undergoing cardiac, carotid artery, or peripheral vascular surgery, but it occurs in less than 1% of all other surgical procedures. Most of the available data on postoperative stroke are in cardiac surgery patients. Stroke after cardiac surgery is associated with significantly increased mortality, up to 22% in some studies. The risk factors for stroke after cardiac surgery include age > 60 years, a calcified aorta, prior stroke, carotid stenosis > 50%, peripheral vascular disease, cigarette smoking, diabetes mellitus, and renal failure. Most studies suggest that asymptomatic carotid bruits are associated with little or no increased risk of stroke in noncardiac, noncarotid surgery. The importance of asymptomatic carotid artery stenoses > 50% is not known.

Prophylactic carotid endarterectomy in most patients with asymptomatic carotid artery disease is unlikely to be beneficial. On the other hand, patients with carotid disease who are candidates for carotid endarterectomy anyway ([Chapter 12](#)) should probably have the carotid surgery prior to the elective surgery. Some patients

require both cardiac and carotid surgery. The ideal timing of these two procedures is not certain and must be decided individually for each patient. In general, the more symptomatic and threatening condition should be addressed first. Nonstroke neurologic complications including coma, seizures, memory loss, and diminished intellectual function occur in up to 7% of patients after cardiac surgery. The risk factors for these complications include a calcified aorta, age > 70 years, pulmonary disease, diabetes, and neurologic disease.

MANAGEMENT OF ENDOCRINE DISEASES

Diabetes Mellitus

Patients with diabetes are at increased risk for postoperative infections. Furthermore, diabetic patients are more likely to have cardiovascular disease and thus are at increased risk for postoperative cardiac complications. The most challenging issue in diabetics, however, is the maintenance of glucose control during the perioperative period.

The increased secretion of cortisol, epinephrine, glucagon, and growth hormone during surgery is associated with insulin resistance and hyperglycemia in diabetic patients. The goal of management is the prevention of severe hyperglycemia or hypoglycemia in the perioperative period.

The ideal blood glucose level during surgery is not known. In vitro studies have shown that cellular immunity may be impaired when the blood glucose level exceeds 250 mg/dL. In three trials of patients undergoing cardiac surgery, patients with mean postoperative glucose levels < 200 mg/dL had fewer serious wound infections than patients with higher mean levels. Based on these data, it is advisable to maintain perioperative glucose levels between 100 mg/dL and 200 mg/dL.

All diabetic patients should have serum electrolyte levels measured and abnormalities in any of these levels corrected prior to surgery. Serum creatinine and urea nitrogen levels should also be measured to assess renal function. The specific pharmacologic management of diabetes during the perioperative period depends on the type of diabetes (insulin-dependent or not), the level of glycemic control, and the type and length of surgery. In general, type 1 patients and type 2 patients requiring insulin will need intraoperative insulin with any surgical procedure. Type 2 patients taking oral agents generally require insulin during major or prolonged surgery.

Perioperative management of all diabetic patients requires frequent blood glucose monitoring to prevent hypoglycemia and to ensure prompt treatment of hyperglycemia ([Tables 3-8](#) and [3-9](#)). Specific recommendations for glycemic control in patients who do not need intraoperative insulin are shown in [Table 3-8](#). For patients who require intraoperative insulin, no single regimen has been found to be superior in comparative trials. Three commonly used insulin administration methods are shown in [Table 3-9](#). The subcutaneous route is used most often because it is easier to access and is less expensive. Intravenous insulin, which offers more rapid onset, shorter duration of action, and ease of dose titration, may be preferable in patients with poorly controlled diabetes and in those undergoing cardiac surgery.

Glucocorticoid Replacement

Perioperative complications (predominantly hypotension) resulting from primary or secondary adrenocortical insufficiency are rare. It is not known whether the administration of high-dose glucocorticoids during the perioperative period in patients at risk for adrenocortical insufficiency decreases the risk of these complications. In a trial comparing high-dose glucocorticoid therapy with simply administering chronic glucocorticoid medications in patients with secondary adrenal suppression, there were no differences in perioperative complications. Therefore, definitive recommendations regarding perioperative glucocorticoid therapy cannot be made. The most conservative approach would be to consider any patient to be at risk for having adrenocortical insufficiency who has received either the equivalent of 20 mg of prednisone daily for 1 week or the equivalent of 7.5 mg of prednisone daily for 1 month within the past year. A commonly used regimen is 100 mg of hydrocortisone given intravenously every 8 hours beginning on the morning of surgery and continuing for 48-72 hours. Tapering the dose is not necessary. Patients being maintained on chronic corticosteroids should then resume their usual dose.

Hypothyroidism

Severe symptomatic hypothyroidism has been associated with several perioperative complications, including intraoperative hypotension, congestive heart failure, cardiac arrest, and death. Elective surgery should be delayed in patients with severe hypothyroidism until adequate thyroid hormone replacement can be achieved. Conversely, patients with asymptomatic or mild hypothyroidism generally tolerate surgery well, with only a slight increase in the incidence of intraoperative hypotension; surgery need not be delayed for the month or more required to ensure adequate thyroid hormone replacement.

Inzucchi SE: Glycemic management of diabetes in the perioperative setting. Int Anesthesiol Clin 2002;40:77. [\[PMID: 11897937\]](#)

RENAL DISEASE

The risk for development of a significant reduction in renal function, including dialysis-requiring acute renal failure, after major surgery has been estimated to be between 2% and 20%. The mortality associated with the development of postoperative acute renal failure that requires dialysis after general, vascular, or cardiac surgery exceeds 50%. Risk factors that have been associated with postoperative deterioration in renal function are shown in [Table 3-10](#). Several medications, including "renal dose" dopamine, mannitol, and furosemide, have been evaluated in an attempt to preserve renal function during the perioperative period. None of these, however, have been proved effective in clinical trials. Maintenance of adequate intravascular volume is likely to be the most effective method to reduce the risk of perioperative deterioration in renal function.

Although the mortality rate for elective major surgery is low (1-4%) in patients with dialysis-dependent chronic renal failure, the risk for perioperative complications, including postoperative hyperkalemia, pneumonia, fluid overload, and bleeding, is substantially increased. Postoperative hyperkalemia requiring emergent hemodialysis has been reported to occur in 20-30% of patients, and postoperative pneumonia may occur in up to 20% of patients. Patients should be dialyzed preoperatively within 24 hours before surgery, and their serum electrolyte levels should be measured just prior to surgery and monitored closely during the postoperative period.

ANTIBIOTIC PROPHYLAXIS OF SURGICAL WOUND INFECTIONS

The development of a postoperative wound infection is a common and extremely important cause of morbidity and prolonged hospital stays. There are an estimated 0.5-1 million postoperative wound infections annually in the United States. For most major procedures, the use of prophylactic antibiotics has been demonstrated to reduce the incidence of postoperative wound infections significantly. For example, antibiotic prophylaxis in colorectal surgery reduces the incidence of wound infection from 25-50% to below 9%. Prophylactic antibiotics are considered standard care for all but "clean" surgical procedures. Clean procedures are those that are elective, nontraumatic, and not associated with acute inflammation and that do not enter the respiratory, gastrointestinal, biliary, or genitourinary tract. The postoperative wound infection rate for clean procedures is thought to be roughly 2%. However, in certain clean procedures, such as those that involve the insertion of a foreign body, antibiotic prophylaxis is still recommended because the consequences of infection are serious.

Multiple studies have evaluated the effectiveness of different antibiotic regimens for various surgical procedures. In most cases, no single antibiotic regimen has been shown to be superior. Several general conclusions can be drawn from these data. First, there is substantial evidence to suggest that a single dose of an appropriate intravenous antibiotic—or combination of antibiotics—is as effective as multiple-dose regimens that extend into the postoperative period. For longer procedures, the dose should be repeated every 3-4 hours to ensure maintenance of a therapeutic serum level. One important exception is cardiac surgery, in which at least 24 hours of postoperative therapy is recommended. Second, for most procedures, a first-generation cephalosporin is as effective as later-generation agents. Third, with the exception of colorectal surgery, all prophylactic antibiotics should be given intravenously at induction of anesthesia or roughly 30 minutes prior to the skin incision. Although the type of procedure is the main factor determining the risk of developing a postoperative wound infection, certain patient factors have been associated with increased risk, including diabetes, older age, and multiple medical comorbidities. Current antibiotic prophylaxis recommendations for a variety of procedures are shown in [Table 3-11](#).

The most promising intervention to reduce the occurrence of postoperative wound infection may be the administration of supplemental oxygen during and immediately

after surgery. In a recent study of patients undergoing colorectal surgery, the administration of 80% oxygen during and for 2 hours after surgery was associated with a 50% reduction in the development of postoperative wound infections compared with the use of 30% oxygen.

Table 3-3. Canadian Cardiovascular Society angina class.¹

I. Ordinary physical activity, such as walking and climbing stairs, does not cause angina. Angina occurs with strenuous or rapid or prolonged exertion at work or recreation.

II. Slight limitation of ordinary activity. Angina occurs with walking or climbing stairs rapidly, walking uphill, walking or stair climbing after meals, or only during the few hours after awakening. Angina occurs when walking more than two blocks on the level or climbing more than one flight of stairs at a normal pace and in normal conditions.

III. Marked limitation of ordinary physical activity. Angina occurs with walking one to two blocks on the level and climbing one flight of stairs in normal conditions and at a normal pace.

IV. Inability to carry on any physical activity without discomfort; angina may be present at rest.

GENERAL PRINCIPLES OF GERIATRIC MEDICINE

Human biologic aging is best characterized as the progressive constriction of each organ system's homeostatic reserve. This decline ("homeostenosis") begins around the fifth decade, is progressive, and varies among individuals. Each organ system's decline is influenced by genetic factors, diet, environment, and personal habits.

Several principles follow from these observations. Individuals become more dissimilar as they age, rejecting any stereotype of aging; an abrupt decline in any system or function is almost certainly due to disease and not to "normal (or usual) aging"; "normal aging" can be attenuated to some extent by modification of risk factors (eg, increased blood pressure, smoking, sedentary lifestyle); and "healthy old age" is not an oxymoron. In the absence of stressors (eg, extreme heat, high altitude, disease), the decline in homeostatic reserve should not cause symptoms or impose restrictions on activities of daily living.

These facts may make it easier to understand the striking increases that have occurred in longevity ([Table 4-1](#)). While only 20% of people over age 85, for example, live in nursing homes, only about half of individuals in this age range are independent in their activities of self-care. This has substantial implications for disease screening, patient counseling, and medical decision-making.

Still, as individuals age, they are more likely to suffer from disease, disability, and treatment side effects. Combined with the decrease in physiologic reserve, these added burdens (if present) make the older person more vulnerable to environmental, pathologic, or pharmacologic insults. Understanding these facts is crucial for optimal care of older patients.

Older Patients Differ from Younger Ones

The health problems and medical management of elderly patients differ from those of younger ones.

Disease presentation is often atypical in older adults. A disorder in one organ system may lead to symptoms in another, especially one compromised by preexisting disease. Because these organ systems are often the brain, the lower urinary tract, or the cardiovascular or musculoskeletal system, a limited number of presenting symptoms predominate—confusion, falling, incontinence, and functional decline—irrespective of the underlying disease. A 45-year-old may seek care for productive cough, fever, and dyspnea as manifestations of pneumonia, but the same disease may cause an 80-year-old to present with a new problem of falls and difficulty following a conversation. Thus, regardless of the presenting symptom in older people, the differential diagnosis is often the same. The corollary is equally important: The organ system usually associated with a particular symptom is less likely to be the source of that symptom in older individuals than in younger ones. Thus, compared with middle-aged individuals, acute confusion in older patients is less often due to a new brain lesion, or incontinence to a bladder disorder.

Because of impaired compensatory mechanisms, disease in older patients often presents at an earlier stage ([Figure 4-1](#)). Heart failure may be precipitated by slight hyperthyroidism, significant cognitive dysfunction by only mild hyperparathyroidism, urinary retention by only mild prostatic enlargement, and nonketotic hyperosmolar coma by only mild glucose intolerance. Similarly, drug side effects can occur with low doses of drugs that usually produce no side effects in younger people. For instance, a mild anticholinergic agent (eg, diphenhydramine) may cause confusion, diuretics may precipitate urinary incontinence, digoxin may induce anorexia even with normal serum levels, and over-the-counter sympathomimetics may result in urinary retention in older men with mild prostatic obstruction. The predisposition to develop symptoms at an earlier stage of disease is often offset by the change in illness behavior that occurs with age. The current cohort of elderly people may be less likely to seek attention until symptoms become disabling. Physicians must ask specific questions of their older patients in order to uncover problems in the early stages.

Since many compensatory mechanisms are often compromised concurrently, there are usually multiple abnormalities amenable to treatment. Small improvements in each may yield dramatic benefits overall. Cognitive impairment in patients with Alzheimer's disease may respond much better to interventions that address comorbidity than to prescription of donepezil, as comorbid conditions may interfere with the ability to compensate for cognitive loss. Similar approaches apply to most other common geriatric syndromes, including falls, incontinence, and dizziness.

Many abnormal findings in younger patients are relatively common in older people and may not be responsible for a particular symptom. Such findings include bacteriuria, premature ventricular contractions, impaired glucose tolerance, and reduced vibratory sense in the toes. These may be only incidental findings resulting in missed diagnoses and misdirected therapy. Bacteriuria should not end the search for a source of fever in an acutely ill older patient, nor should an elevated random blood sugar be incriminated as the cause of neuropathy. Some abnormalities must not be dismissed as due to old age. There is no anemia, erectile dysfunction, depression, or confusion of old age.

Symptoms in older people are often due to multiple causes, and the diagnostic "law of parsimony" often does not apply. Fever, anemia, Roth spots, and a heart murmur are almost diagnostic of endocarditis in a younger patient but are more apt to reflect a viral illness, aspirin-induced blood loss, a cholesterol embolus, and insignificant aortic sclerosis, in an older patient. Moreover, even when the diagnosis is correct, treatment of a single disease in an older patient is unlikely to result in cure. In a younger patient, incontinence due to involuntary bladder contractions is treated effectively with a bladder relaxant medication. In an older patient whose incontinence is associated with fecal impaction, who is taking medications that cloud the sensorium, and who has impaired dexterity due to arthritis, treatment of the bladder abnormality is unlikely to restore continence. Disimpaction, discontinuation of the offending medications, and treatment of the arthritis may restore continence without the need for a bladder relaxant.

Because the older patient is more likely than a younger one to suffer the adverse consequences of disease, treatment—and even prevention—may be equally effective. The benefits to survival of exercise, as well as beta-blocker therapy after myocardial infarction, appear to be at least as impressive in older patients as in younger ones; the relative value of immunization against influenza is even greater. Prevention in older patients must be viewed in a broader context. Although interventions to increase bone density may decrease fracture risk, this risk may be reduced further by strategies that improve balance, strengthen legs, ameliorate contributing medical conditions, replete nutritional deficits, and eliminate environmental hazards.

In contrast to the care of younger patients, for whom cure of disease and prolongation of life are usually of paramount concern, the goals of care for older patients may well differ. Although some may seek a focus on life extension, others clearly prefer improved function, comfort, and quality of life.

Rothschild JM et al: Preventable medical injuries in older patients. Arch Intern Med 2000;160:2717. [\[PMID: 11025781\]](#)

■ GENERAL APPROACH TO THE OLDER PATIENT

Understanding the Patient's Values & Goals

An effective therapeutic encounter calls for a clear understanding of the patient's goals and preferences. Knowing about the patient's goals early will help the health care provider focus the patient's visits appropriately. Some patients will not have clear-cut goals and are willing to be guided by the health care provider's judgment. Goals made explicit at the outset may change after discussion with a physician. The patient's wishes regarding end-of-life care and attempts at resuscitation should emerge from a frank discussion of these goals. When an advance directive has been executed, it should be reviewed and placed in the medical record. Even if the patient has not executed an advance directive or durable power of attorney for health care, he or she may be able to identify a preferred surrogate decision maker, and that individual's name and contact information should be recorded as well. Goals and values for care should be discussed with the surrogate as well as with the patient.

Fried TR et al: Understanding the treatment preferences of seriously ill patients. N Engl J Med 2002;346:1061. [\[PMID: 11932474\]](#)

Rosenfeld KE et al: End-of-life decision making: a qualitative study of elderly individuals. J Gen Intern Med 2000;15: 620. [\[PMID: 11029675\]](#)

Tulsky JA et al: Opening the black box: how do physicians communicate about advance directives? Ann Intern Med 1998;129:441. [\[PMID: 9735081\]](#)

Establishing Priorities

Optimal care for the older patient is facilitated when the clinician explicitly sets priorities, deciding what specific evaluations and therapies are most likely to provide benefit. Setting these priorities should be based upon the patient's goals for care and life expectancy, the prevalence of specific diseases, the performance characteristics of screening or diagnostic tests, and the effectiveness of therapeutic interventions. The concepts of "number needed to screen" and "number needed to treat" often help put diagnostic tests and interventions into perspective.

Interventions that are likely to help well elders may differ from those that will benefit frail elders or younger people. Tight glucose control in an elderly diabetic who values her independence might be sacrificed if it would require initiation of insulin therapy with placement in a nursing facility. Colon cancer screening might be advised in an 80-year-old man in good health who is highly motivated (number needed to screen to prevent one death over remaining life: about 200), but not for a man of the

same age with multiple comorbidities, a life expectancy of less than 5 years, or an aversion to medical care ([Table 4-1](#)). Some interventions produce almost immediate benefit, and those may be useful at any age. Even the oldest old people can benefit from beginning an exercise program. Likewise, an 80-year-old person with a limited life expectancy is likely to benefit from a screening for falls and a fall risk reduction program (number needed to screen to prevent one fall over 1 year: about 20).

Caregiver Issues

Providing primary care for a frail elderly person requires attention to the caregiver as well as the patient, since the health and well-being of the two are closely linked. High levels of functional dependency place an enormous burden on a caregiver. Burnout, neglect, and abuse are possible consequences, and stressed caregivers may suffer higher mortality. Likewise, an older patient's need for nursing home placement is often better predicted from assessment of the caregiver characteristics and stress than the severity of the patient's illness. For the stressed caregiver, a social worker may help identify programs such as caregiver support groups, respite programs, adult day care, or hired home health aids.

It is wise to observe and talk with every older person alone for at least part of a visit in order to question directly ([Table 4-2](#)) about possible abuse and neglect. Clues to the possibility of elder abuse include behavioral changes in the presence of the caregiver, delays between injuries and sought treatment, inconsistencies between an observed injury and associated explanation, lack of appropriate clothing or hygiene, and not filling prescriptions. The older patient who is also a caregiver is at risk for depression and should be screened for it.

Yaffe K et al: Patient and caregiver characteristics and nursing home placement in patients with dementia. JAMA 2002;287:2090. [\[PMID: 11966383\]](#)

Using Time Efficiently

Certain strategies can guide a physician in using time wisely with an elderly patient: (1) Identify the patient's goals and values for medical care early in your therapeutic relationship; (2) use brief assessment instruments when appropriate, and train nonphysician personnel in their performance; (3) employ portable amplifiers, large print information, and magnifying lenses; and (4) involve other professionals (nurses, social workers, dietitians, physical and occupational therapists, psychologists) in complex cases.

ASSESSMENT OF OLDER ADULTS

Functional Assessment

Functional assessment gauges a patient's ability to manage tasks of self-care, household management, and mobility.

About one-fourth of patients over 65 have impairments in their IADLs (instrumental activities of daily living: transportation, shopping, cooking, using the telephone, managing money, taking medications, housecleaning, laundry) or ADLs (activities of daily living: bathing, dressing, eating, transferring from bed to chair, continence, toileting). Half of those over 85 have these latter impairments. Persons who are unable to perform IADLs independently are far more likely to have dementia than their independent counterparts.

Information about function can be used in a number of ways: (1) as baseline information, (2) as a measure of the patient's need for support services or placement, (3) as an indicator of possible caregiver stress, (4) as a potential marker of specific disease activity; and (5) to determine the need for therapeutic interventions.

In general, persons who need help only with IADLs may be aided by a chore worker, a day program, or placement in a board-and-care home or assisted living situation. While many persons who need help with ADLs may require a nursing home level of care, most live at home with caregivers.

Screening for Vision Impairment

An appreciable minority of elders have severe visual loss. Visual impairment is an independent risk factor for falls; it also has a significant impact on quality of life. Direct visual testing with a Snellen chart or Jaeger card is the most sensitive and specific approach to visual screening, though the performance of these instruments in most primary care settings is uncertain. Referring all older people for a complete eye examination by an ophthalmologist or optometrist has the advantages of improving the quality of the examination and allowing for cataract and glaucoma screening.

Screening for Hearing Impairment

Over one-third of those over 65 and half of those over 85 have some hearing loss. This deficit is correlated with social isolation and depression. Although the optimal screening method for hearing loss in older adults is undetermined, the whispered voice test is easy to perform and has sensitivities and specificities ranging from 70% to 100%. To determine the degree to which the impairment interferes with functioning, the physician may ask if the patient becomes frustrated when conversing with family members, is embarrassed when meeting new people, has difficulty listening to the radio or watching TV, or has problems understanding conversations in noisy restaurants.

Compliance with hearing amplification can be a challenge because of the stigma associated with hearing aid use as well as the cost of such devices, which are not paid for under most Medicare plans. High compliance rates can be achieved with a proactive approach such as the use of loaner aids for low-income persons. In addition to standard hearing aids, pocket amplifiers as well as amplifiers to telephone, television, and radio may be useful.

Screening for Falls & Gait Impairment

Falls are the leading cause of nonfatal injuries in older persons, and their complications are the leading cause of death from injury in those over 65. Hip fractures are common precursors to functional impairment, nursing home placement, and death. Furthermore, fear of falling may lead some elders to restrict their activities. About one-third of people over 65 fall each year, and the frequency increases markedly with advancing age.

Every older person should be asked about falls; many will not volunteer such information. One should ask about home hazards that might be remediable. A thorough gait assessment should be performed in all older people. An abnormal gait may suggest a remediable risk factor for falls, eg, proximal muscle weakness, balance problems, pain, or other neurologic impairments.

Gait and balance can be readily assessed by the "Up and Go Test," in which the patient is asked to stand up from a sitting position without use of hands, walk 10 feet, turn around, walk back, and sit down. It can be supplemented with a Romberg test, a gentle push on the sternum, and a 360-degree turn if more information is needed. Is the patient able to rise from a chair without use of his or her arms in a single, smooth attempt? Is there stability immediately upon standing, or does the patient stagger? Is balance maintained when the patient is pushed lightly on the sternum? Is there steadiness when standing with eyes closed? How is walking initiated, and does each foot swing clear of the floor and pass the opposite foot? Are the steps equal? Is there stopping or discontinuity between steps, or sway of the trunk, flexion of knees or back, spreading out of the arms? Do the heels almost touch during the stride, or is there a wide-based gait? Is a walking aid (cane, walker) necessary or being used properly? Does the patient take more than 10-15 seconds for the Up and Go Test? Slower times—particularly if longer than 20 seconds—are often associated with other impairments of function.

Screening for Cognitive Impairment

The prevalence of dementia doubles every 5 years after age 60, so that by age 85 about 30-50% of individuals have some degree of impairment. Patients with mild or early dementia frequently remain undiagnosed because their social graces are retained.

Although there is no consensus at present on whether older patients should be screened for dementia, the benefits of early detection include identification of potentially reversible causes, planning for the future (including advance directives), providing support and counseling for the caregiver, modification of interventions for other diseases as appropriate (eg, simplifying drug regimens, minimizing anticholinergic drug use), and beginning anticholinesterase inhibitor drugs.

The combination of the "clock draw" (in which the patient is asked to sketch a clock face, with all the numerals placed properly, the two clock hands positioned at a specified time) and the "three-item recall" is fairly quick and has reasonable test characteristics. When the patient is able to recall all three items after 3 minutes, the

probability of dementia is greatly reduced. Conversely, an abnormally drawn clock markedly increases the probability of dementia. When patients fail either of these screening tests, further testing with the Mini-Mental State questionnaire ([Figure 25-1](#)), neuropsychologic testing, or other instruments is warranted.

Borson S et al: The mini-cog: a cognitive 'vital signs' measure for dementia screening in multi-lingual elderly. *Int J Geriatr Psychiatry* 2000;15:1021. [\[PMID: 11113982\]](#)

Manly JJ et al: Cognitive test performance among nondemented elderly African Americans and whites. *Neurology* 1998; 50:1238. [\[PMID: 9595969\]](#)

Screening for Incontinence

Incontinence in older adults is common, and interventions can improve most patients. Many patients fail to tell their providers about it. A simple question about involuntary leakage of urine is a reasonable screen: "Do you have a problem with urine leaks or accidents?"

Screening for Depression

Although major depressive disorder has a slightly lower prevalence in older adults than in younger populations, depressive symptomatology is actually more common. Its prevalence in ill and hospitalized elders is particularly high. A simple two-question screen ([Table 4-3](#)) has shown 96% sensitivity for detecting major depression in a general population and may have even higher sensitivity in those over age 65. Positive responses can be followed up with more comprehensive, structured interviews, eg, Yesavage's Geriatric Depression Scale ([Table 4-4](#)).

Steffens DC et al: Prevalence of depression and its treatment in an elderly population: the Cache County study. *Arch Gen Psychiatry* 2000;57:601. [\[PMID: 10839339\]](#)

Screening the High-Functioning Elder

Standard functional screening measures may not be useful in capturing subtle impairments in highly functional independent elders. One technique for these patients is to identify and regularly ask about a target activity, such as playing bridge, bowling, or practicing law. If the patient begins to have trouble with or discontinues such an "advanced activity of daily living," it may indicate early impairment, such as dementia, incontinence, or worsening hearing loss, which additional gentle questioning or assessment may uncover.

Assessment of Decision-Making Capacity

It is common for a cognitively impaired elder to face a serious medical decision and for the clinicians involved in his care to ascertain whether the capacity exists to make the choice. There are four components of a thorough assessment: (1) ability to express a choice; (2) understanding relevant information about the risks and benefits of planned therapy and the alternatives, including no treatment; (3) comprehension of the problem and its consequences; and (4) ability to reason. A patient's choice should follow rationally from an understanding of the consequences.

In performing such assessments, it is to be remembered that decision-making capacity varies over time: a delirious patient may regain his capacity after an infection is treated, and so reassessments are often appropriate. Furthermore, the capacity to make a decision is a function of the decision in question. A mildly demented woman may lack the capacity to consent to coronary artery bypass grafting yet retain the capacity to designate a surrogate decision maker or allow removal of a suspicious nevus.

Grisso T, Appelbaum PS: *Assessing Competence to Consent to Treatment: A Guide for Physicians and Other Health Professionals*. Oxford Univ Press, 1998.

Functional Screening Instrument

[Table 4-3](#) gives a simple functional screening list. In addition to ADL and IADL assessment, it looks for evidence of health problems that affect function: sensory impairment, limited upper extremity range of motion, mobility, falls, weight loss, incontinence, depressed mood, and cognitive impairment.

SELECTED PREVENTIVE MEASURES IN GERIATRIC PRACTICE

Exercise

Inactive elders are at greater risk of becoming functionally dependent than their more physically active counterparts. Higher levels of physical activity are associated with reduced risks of future disability, disease-related morbidity, and mortality. Even sedentary elders should be urged to increase their level of physical activity. By writing out an exercise prescription, a physician demonstrates the importance of the activity and may improve compliance. Components include strength training (isolated muscle group contractions), endurance training (walking, cycling, swimming), flexibility (static stretch of various muscle groups), and balance (tai chi, dance). Ideally, the patient should aim for a total of 30 minutes of activity daily, though any increase in exercise is likely to be beneficial. The type of physical activity prescribed should be geared to the patient's diagnoses and risk factors, eg, quadriceps strengthening for a man with osteoarthritis of the knee, tai chi for a woman with osteoporosis at risk for falls, and aerobic exercise for a man with cardiovascular risk factors.

Manson JE et al: Walking compared with vigorous exercise for the prevention of cardiovascular events in women. *N Engl J Med* 2002;347:716. [\[PMID: 12213942\]](#)

Hypertension

Treatment of hypertension is of substantial benefit in older adults, and the absolute benefit of treatment may be greater in older than in younger patients. Pulse pressure may be a useful marker of risk for heart failure and stroke among elders with systolic hypertension. Antihypertensive treatment of patients over 80—including treatment of isolated systolic hypertension—reduces the incidence of strokes and other cardiovascular events as well as heart failure. Lifestyle modifications (weight loss for overweight patients, alcohol and sodium limitation, increased aerobic physical activity) are reasonable to recommend for all hypertensive patients for whom treatment is appropriate. For those who require pharmacologic treatment, thiazides are the drugs of choice unless a comorbid condition makes another choice preferable.

Stroke Prevention

The incidence of stroke in older adults roughly doubles with each 10 years of age. The greatest risk factor is hypertension. Another is atrial fibrillation, the prevalence of which also increases with age. Many elderly patients with this arrhythmia are not anticoagulated because their physicians fear injuries due to falls. In most instances, the benefits of anticoagulation are likely to outweigh the increased risk of fall-related bleeding unless the patient has multiple falls, high-risk falls, or a low risk of stroke, such as a person under age 75 with lone atrial fibrillation.

Cancer Screening

Screening elderly men for prostate cancer is not necessary since it does not prolong life and given the risk of incontinence or erectile dysfunction that may accompany surgical therapy or radiation. An older woman is likely to benefit from breast cancer screening until her life expectancy falls below 5-10 years ([Table 4-1](#)). Screening for colon cancer can be stopped when a patient's life expectancy is less than 5-10 years. Cervical cancer is uncommon in older women, and screening can usually be discontinued at age 65 if the woman has had a history of regular screening and normal Pap smears.

Osteoporosis

Primary prevention of osteoporosis begins with identification of risk factors (older age, female gender, white or Asian race, low calcium intake, smoking, excessive alcohol use, and chronic glucocorticoid use). Calcium carbonate (500 mg once daily to three times daily at meals) and vitamin D (400-800 IU/d, contained in one or two multivitamin tablets) reduce the risk of osteoporotic fractures in both men and women. Measurement of bone mineral density (preferably using dual-energy x-ray absorptiometry of the proximal femur) of women with multiple risk factors may uncover asymptomatic osteoporosis; such women may be offered a bisphosphonate or other therapy. Screening strategies for men are controversial, but osteoporosis should be considered in men receiving hormonal treatment for prostate cancer. Other risk factors for men are hypogonadism, chronic glucocorticoid administration, high alcohol intake, and a history of previous fractures.

Immunizations

Individuals over age 65—and healthcare workers who are in contact with them—should receive annual influenza vaccinations. Similarly, persons over 65 should receive at least one pneumococcal immunization; some experts recommend revaccination in those over 75 or with severe chronic disease and who were vaccinated more than 5 years previously. A single booster dose of tetanus and diphtheria vaccine should be given at age 65 or older.

PPD for Congregate Living

Older adults are a significant reservoir of tuberculosis, both primary and reactivation. Over 20% of elderly patients who develop the disease live in nursing homes. Long-term care facilities should routinely perform a tuberculin skin test (PPD) on all entering patients, using the two-step approach in which a second dose is administered to persons whose first was negative. If the second reaction is also negative, the patient is uninfected or anergic; if positive, a boosted response is likely, signifying a tuberculin reactor but not a recent converter. Whether these reactors need treatment is controversial, but their positive-PPD status should be noted. Prophylaxis and treatment regimens are described in [Chapter 9](#). Skin testing is repeated annually in congregate settings or if an active case is identified in the group.

■ COMMON PROBLEMS OF THE FRAIL OLDER PERSON

DEMENTIA

Older individuals experience occasional difficulty retrieving items from memory (usually manifested as word-finding complaints) and experience a slowing in their rate of information processing. By contrast, dementia is an acquired persistent and progressive impairment in intellectual function, with compromise in multiple cognitive domains at least one of which is memory. The demented patient's deficits must represent a significant decline in function and must be severe enough to interfere with work or social life.

Intellectual impairments in older patients are frequently the result of two other syndromes, each of which frequently coexists with dementia: depression and delirium. Depression is a common concomitant of dementia, but it can also masquerade as dementia. Moreover, a patient with depression and cognitive impairment whose intellectual function improves with treatment of the mood disorder has an almost fivefold greater risk of suffering irreversible dementia later in life. Delirium, characterized by acute confusion, occurs much more commonly in patients with underlying dementia.

General Considerations

Dementia is the fourth leading cause of death in the United States and has a prevalence which doubles every 5 years in the older population, reaching 30-50% at age 85. Women suffer disproportionately, both as patients (even after age adjustment) and as caregivers. Alzheimer's disease accounts for roughly two-thirds of cases in the United States, with vascular dementia (either alone or combined with Alzheimer's disease) accounting for much of the rest. Risk factors for Alzheimer's disease are older age, family history, lower education level, and female gender. Some epidemiologic studies suggest that head injury, hypertension, higher homocysteine levels, and higher LDL cholesterol levels are risk factors for dementia, while NSAID use, HMG-CoA reductase inhibitor use, moderate alcohol intake, and strong social supports may decrease the risk. However, these studies should be viewed cautiously since each of these factors may be a marker for other unidentified factors. Risk factors for vascular dementia are those for stroke, ie, older age, male sex, black race, hypertension, cigarette use, previous myocardial infarction, atrial fibrillation, diabetes, and hyperlipidemia.

Causes of potentially reversible cognitive impairment include drug effect, depression, thyroid disease, vitamin B₁₂ deficiency, hypercalcemia, subdural hematoma, HIV infection, and normal pressure hydrocephalus. The prevalence of fully reversible dementias is well under 5%, and the correction of these suspected causes leads only to partial improvement.

Clinical Features

Demented patients have memory impairment and at least one or more of the following: language impairment (initially just word finding; later, difficulty following a conversation; finally, mutism), apraxia (inability to perform previously learned tasks, such as cutting a loaf of bread, despite intact sensory and motor function), agnosia (inability to recognize objects), and impaired executive function (poor abstraction, mental flexibility, planning, and judgment). Alzheimer's disease typically presents with early problems in memory and visuospatial abilities (eg, becoming lost in familiar surroundings, inability to copy a geometric design on paper), yet social graces may be retained despite advanced cognitive decline. Personality changes and behavioral difficulties (wandering, inappropriate sexual behavior, agitation) may develop as the disease progresses. Hallucinations are not typically observed except in moderate-to-severe dementia. End-stage disease is characterized by near-mutism; inability to sit up, hold up the head, or track objects with the eyes; difficulty with eating and swallowing; weight loss; bowel or bladder incontinence; and recurrent respiratory or urinary infections.

"Subcortical" dementias (eg, the dementia of Parkinson's disease, and most cases of vascular dementia) are characterized by psychomotor slowing, reduced attention, early loss of executive function, personality changes, and benefit from cuing in tests of memory.

Dementia with Lewy bodies may be confused with delirium, as fluctuating cognitive impairment is frequently observed. Rigidity and bradykinesia are primarily noted, and tremor is rare. Response to dopaminergic agonist therapy is poor. Hallucinations—classically visual and bizarre (eg, animals or mythologic creatures)—may occur as well. These patients demonstrate a hypersensitivity to neuroleptic therapy, and attempts to treat the hallucinations may lead to marked worsening of extrapyramidal symptoms.

Frontotemporal dementias are a group of diseases that include Pick's disease, dementia associated with amyotrophic lateral sclerosis, and others. Patients manifest personality change (euphoria, disinhibition, apathy) and compulsive behaviors (often peculiar eating habits or hyperorality). In contrast to Alzheimer's disease, visuospatial function is relatively preserved.

Dementia in association with motor findings, such as extrapyramidal features or ataxia, may represent a less common disorder (eg, progressive supranuclear palsy, corticobasal ganglionic degeneration, olivopontocerebellar atrophy).

Differential Diagnosis

In addition to depression and delirium, apparent cognitive impairment in older adults may be the result of drug effects or uncorrected sensory deficits; these problems more often exacerbate dementia than mimic it.

Many medications have been associated with diminished mentation in older patients. Anticholinergic agents, hypnotics, neuroleptics, and opioids are well-established causes, but NSAIDs, antihistamines (including H₂ antagonists), and corticosteroids have been implicated as well.

An elderly patient with intact cognition but with severe impairments in vision or hearing commonly becomes confused in an unfamiliar medical setting and consequently may be falsely labeled as demented. Cognitive testing is best performed after optimal correction of the sensory deficits.

Diagnosis

Historical questions in an evaluation for dementia include those directed at the rate of progression of the deficits, their nature (including any personality or behavioral change), motor problems, risk factors for HIV, family history, medication list, functional disabilities, and degree of social support.

The neurologic examination emphasizes assessment of mental status (see [Figure 25-1](#)) but should also include evaluation for deficits related to previous strokes, parkinsonism, or peripheral neuropathy. The remainder of the physical examination should focus on identifying comorbid conditions that may aggravate the individual's disability.

Laboratory studies for most patients are intended to uncover treatable causes of cognitive impairment and include a complete blood count, electrolytes, calcium, creatinine, glucose, TSH, and vitamin B₁₂ levels. HIV testing, RPR, heavy metal screen, and liver function tests may be informative in selected patients.

Although consensus is lacking with respect to which patients benefit from head CT or MRI, those who are younger and those who have focal neurologic symptoms or signs, seizures, gait abnormalities, and an acute or subacute onset are most likely to yield positive findings.

Referral for neuropsychologic testing may be helpful in the following circumstances: to distinguish dementia from depression, to diagnose dementia in persons of very poor education or very high premorbid intellect, and to aid diagnosis when impairment is mild.

Treatment

Soon after diagnosis, patients and families should be made aware of the Alzheimer's Association as well as the wealth of helpful publications available for advice in coping with behavioral problems, financial worries, and other matters. Caregiver support, education, and counseling can prevent or delay nursing home placement. Education includes the manifestations and natural history of dementia as well as the availability of local support services such as respite care. Even under the best of circumstances, caregiver stress can be substantial. Caregivers are at increased risk of depression, and physicians should be alert for signs of elder abuse when working with stressed caregivers.

Because demented patients have greatly diminished cognitive reserve, they are at high risk of experiencing acute cognitive or functional decline in the setting of new medical illness. Consequently, fragile cognitive status may be best maintained by ensuring that comorbid diseases such as congestive heart failure and infections are detected and treated.

Acetylcholinesterase inhibitors (eg, donepezil, galantamine, rivastigmine) produce statistically significant but clinically modest improvements in cognitive function when used to treat mildly to moderately demented patients. A minority show improvement, while a larger number may experience a less rapid decline in cognition or functional status. Starting doses, respectively, of donepezil, galantamine, and rivastigmine, are 5 mg orally daily (maximum 10 mg daily), 4 mg orally twice daily (maximum 12 mg twice daily), and 1.5 mg orally twice daily (maximum 6 mg twice daily). The doses are increased gradually as tolerated. The most bothersome side effects include diarrhea, nausea, anorexia, and weight loss. Recent data suggest that acetylcholinesterase inhibitors may exert a modest benefit on functional outcomes and may be beneficial also in patients with more advanced disease. When the drugs should be discontinued is unclear. Other agents have been studied. Ginkgo biloba has shown mixed results in clinical trials. Vitamin E demonstrated some efficacy in one randomized controlled trial, but the results are difficult to interpret. Estrogen has shown no benefit in randomized trials.

Behavioral problems in demented patients are often best managed with a nonpharmacologic approach. Initially, it should be established that the problem is not unrecognized delirium, pain, urinary obstruction, or fecal impaction. It also helps to inquire whether the caregiver can tolerate the behavior, as it is often easier to find ways to accommodate to the behavior than to modify it. If not, the caregiver is asked to keep a brief, informal journal in which the behavior is described along with antecedent events and consequences. Recurring precipitants of the behavior are often found to be present or it may be that the behavior is rewarded—for example, by increased attention. Caregivers are taught to use simple language when communicating with the patient, to break down activities into simple component tasks, and to employ a "distract, not confront" approach when the patient seems disturbed by a troublesome issue. Additional steps to address behavioral problems include the discontinuation of all medications except those considered absolutely necessary and correction, if possible, of sensory deficits.

There is no clear consensus about a pharmacologic approach to treatment of behavioral problems in patients who have not benefited from nonpharmacologic therapies. The target symptoms—depression, anxiety, psychosis—may suggest which class of medications might be most helpful in a given patient. Patients with depressive symptoms may show improvement with antidepressant therapy. Anxious behavior may respond to buspirone, starting at 5-7.5 mg twice daily and advancing to 30 mg daily if necessary; this generally requires several weeks to show efficacy.

The efficacy of acetylcholinesterase inhibitors for behavioral disturbances in Alzheimer's dementia is still undetermined, but a recent meta-analysis suggested that they may exert a modest benefit on neuropsychiatric outcomes. Patients with Lewy body dementia have shown clinically significant improvement in behavioral symptoms when treated with rivastigmine. Neuroleptics are commonly used for behavioral disturbances, but the literature on their efficacy is mixed. A recent review suggested that haloperidol may be modestly useful in reducing aggression—but not agitation—in dementia and that it is associated with significant adverse effects. The newer atypical agents (risperidone, olanzapine, quetiapine) are usually better tolerated than older agents, but they are considerably more expensive. Questions have been raised about a possible association between risperidone use in dementia and increased cerebrovascular events. Starting and target dosages of neuroleptics are much lower than those used in schizophrenia (eg, haloperidol, 0.5-2 mg; risperidone, 0.25-2 mg). Federal regulations require that if antipsychotic agents are employed in treatment of a nursing home patient, drug reduction efforts must be made at least every 6 months.

Other agents such as mood stabilizers and trazodone have also been used, but a recent trial of valproate showed no benefit for treating agitation in dementia. In one trial, haloperidol, trazodone, behavioral management techniques, and placebo produced comparable if modest reductions in agitation in patients with dementia.

Prognosis

Life expectancy after a diagnosis of Alzheimer's disease is typically 3-15 years; it may be shorter than previously reported. Other neurodegenerative dementias, such as dementia with Lewy bodies, show more rapid decline.

DEPRESSION

Geriatric patients with depression are more likely than younger ones to have somatic complaints, less likely to report depressed mood or feelings of guilt, and more likely to experience delusions.

Depressive syndromes that arise late in life are a heterogeneous collection, and a significant number may represent individuals with neurodegenerative disorders (eg, dementia). Consequently, close follow-up of a newly diagnosed patient, with frequent assessment of mental status and neurologic examination, may disclose an additional or alternative diagnosis.

Recognizing and treating depression in older adults is vital, as the syndrome is associated with disability, increased rates of hospitalization and nursing home admission, and higher mortality. Medical illness and disability—more common in older adults—are risk factors for depression. In particular, stroke and Parkinson's disease appear to predispose to depression. Suicide, the most dreaded complication of depression, has its highest risk in the geriatric age group. Although the presence of comorbid medical illnesses and cognitive disorders may interfere with diagnosis, use of the Geriatric Depression Scale ([Table 4-4](#)) with candidate cases may provide the data needed to make a treatment decision.

Elderly patients with depressive symptoms should be questioned about medication use, as many drugs (benzodiazepines, cimetidine, corticosteroids, and clonidine, to name a few) may contribute to the clinical picture. Similarly, several medical problems can cause fatigue, lethargy, or hypoactive delirium, all of which may be mistaken for depression. Laboratory requests should include a complete blood count; liver, thyroid, and renal function tests; and serum calcium. The workup to exclude an organic explanation calls for urinalysis and an electrocardiogram.

Many experts recommend longer trials of antidepressants (at least 9 weeks) in elderly patients than in younger ones.

DELIRIUM (SEE ALSO [CHAPTER 25](#))

Delirium is an acute, fluctuating disturbance of consciousness, associated with a change in cognition or the development of perceptual disturbances. It is the pathophysiologic consequence of an underlying general medical condition such as infection, coronary ischemia, hypoxemia, or metabolic derangement. Delirium is associated with worse clinical outcomes (higher in-hospital and postdischarge mortality, longer lengths of stay, greater probability of placement in a nursing facility), though it is unclear if delirium causes worse outcomes or is simply an ominous marker.

Although the acutely agitated, "sundowning" elderly patient often comes to mind when considering delirium, many episodes are more subtle. Such quiet, or hypoactive, delirium may only be suspected if one notices new cognitive slowing or inattention.

Cognitive impairment is an important risk factor for delirium. Approximately 25% of delirious patients are demented, and 40% of demented hospitalized patients are delirious. Other risk factors are male sex, severe illness, hip fracture, fever or hypothermia, hypotension, malnutrition, polypharmacy and use of psychoactive medications, sensory impairment, use of restraints, use of intravenous lines or urinary catheters, metabolic disorders, depression, and alcoholism.

Assessment

A key component of a delirium workup is review of medications, as a large number of drugs, the addition of a new agent, or the discontinuation of an agent known to cause withdrawal symptoms are all associated with the development of delirium. Laboratory evaluation of most patients should include a complete blood count, electrolytes, BUN and serum creatinine, glucose, calcium, albumin, liver function studies, urinalysis, and electrocardiography. In selected cases, serum magnesium, serum drug levels, arterial blood gas measurements, blood cultures, chest radiography, and urinary toxin screens may be helpful.

Management

Prevention is the best approach. Measures include improving cognition (frequent reorientation, activities), sleep (massage, noise reduction), mobility, vision (visual aids and adaptive equipment), hearing (portable amplifiers, cerumen disimpaction), and hydration status (volume repletion). Management of established episodes of delirium entails treatment of the underlying cause, eliminating unnecessary medications, and avoidance of restraints. For refractory cases in which the patient's or others' welfare is at risk, an antipsychotic such as risperidone, 0.25-0.5 mg, or haloperidol, 0.5-1 mg, at bedtime or twice daily may be necessary. In emergency situations, starting haloperidol at 0.5 mg by mouth or intramuscularly and repeating every 30 minutes until the agitation is controlled may be necessary, but such treatment is often followed by prolonged sedation or other complications.

Most episodes of delirium clear in a matter of days after correction of the precipitant, but some patients suffer episodes of longer duration. These individuals merit closer follow-up for the development of dementia if not already diagnosed.

IMMOBILITY

Although common in older people, reduced mobility is never normal and is often treatable if its causes are identified. It is an important cause of hospital-induced functional decline. Among hospitalized medical patients over 70, about 10% experience a decline in their ability to perform activities of daily living, much of which results from preventable reductions in mobility.

The hazards of bed rest in older adults are multiple, serious, quick to develop, and slow to reverse. Deconditioning of the cardiovascular system occurs within days and involves fluid shifts, decreased cardiac output, decreased peak oxygen uptake, and increased resting heart rate. More striking changes occur in skeletal muscle, with loss of contractile velocity and strength. Pressure sores are a third serious complication; mechanical pressure, moisture, friction, and shearing forces all predispose to their development. Thrombophlebitis and pulmonary embolism are additional serious risks. Within days after being confined to bed, the risk of postural hypotension, falls, skin breakdown, and pulmonary embolism rises rapidly in the older patient. Moreover, recovery from these changes usually takes weeks to months.

Common causes of immobility are weakness, stiffness, pain, dizziness, and comorbid illness. Weakness may result from disuse of muscles, malnutrition, electrolyte disturbances, anemia, neurologic disorders, or myopathies. The commonest cause of stiffness in older adults is osteoarthritis, but Parkinson's disease and inflammatory arthritides such as rheumatoid arthritis also are possible in this age group, and drugs such as haloperidol may also contribute. Polymyalgia rheumatica should be strongly considered in older patients with pain and stiffness, particularly of the pelvic and shoulder girdle, associated with systemic symptoms (see [Chapter 20](#)).

Pain, whether from bone (eg, osteoporosis, osteomalacia, Paget's disease, metastatic bone cancer, trauma), joints (eg, osteoarthritis, rheumatoid arthritis, hip fractures, gout), bursae, or muscle (polymyalgia rheumatica, intermittent claudication, or "pseudoclaudication"), may immobilize the patient. Painful foot problems are common as well and include plantar warts, ulcerations, bunions, corns, and ingrown and overgrown toenails. Poorly fitting shoes are a frequent cause of these disorders.

Imbalance and fear of falling are major causes of immobilization. Imbalance often results from several causes concurrently, including neurologic disorders (eg, stroke; cervical myelopathy; peripheral neuropathy due to diabetes or alcohol; and vestibulocerebellar abnormalities), orthostatic or postprandial hypotension, or drugs (eg, diuretics, antihypertensives, sedatives, neuroleptics, and antidepressants). It may also occur following prolonged bed rest.

Psychologic conditions such as severe anxiety or depression may contribute to immobilization.

Prevention & Treatment

When immobilization cannot be avoided, several measures can be employed to minimize its consequences. Adequate nutrition should be ensured, and the skin over pressure points should be inspected frequently; if the patient is unable to shift position, staff should do so every 2 hours. To minimize cardiovascular deconditioning, patients should be positioned as close to the upright position as possible, several times daily. To reduce the risks of contracture and weakness, range of motion exercises should be started immediately and isometric and isotonic exercises performed while the patient is in bed. Whenever possible, patients should assist with their own positioning, transferring, and self-care. As long as the patient remains immobilized, pharmacologic (eg, low-dose heparin) or nonpharmacologic means (eg, graduated compression stockings) should be employed to reduce the risk of thrombosis if that is consistent with the patient's goals of care.

Avoiding restraints and discontinuing invasive devices (intravenous lines, urinary catheters) may increase an elderly patient's prospects for early mobility. Once this becomes feasible, graduated ambulation should begin. Advice from a physical therapist is often helpful. Installing handrails, lowering the bed, and providing chairs of proper height with arms and rubber skid guards may make the patient safely mobile in the home. A properly fitted cane or walker may also be useful.

In treating arthritis, NSAIDs cause more serious gastrointestinal bleeding in older adults than in younger individuals. Although the newer COX-2 inhibitors may result in less serious gastrointestinal toxicity than traditional NSAIDs, it has been suggested that they are associated with higher thrombotic risks. Both classes of drugs may result in confusion, increased blood pressure, and renal toxicity. For many cases of osteoarthritis, acetaminophen or glucosamine may be effective and safer than an NSAID or COX-2 inhibitor. Exercise is effective treatment for both knee and hip osteoarthritis.

If depression is preventing a patient from participating in physical therapy, it may prove necessary to start with a short course of stimulant medication (eg, methylphenidate; see [Chapter 25](#)), at least until a more traditional antidepressant has had time to take effect.

van Baar ME et al: Effectiveness of exercise therapy in patients with osteoarthritis of the hip or knee. *Arthritis Rheum* 1999;42:1361. [\[PMID: 104032263\]](#)

FALLS & GAIT DISORDERS

Thirty percent of community-dwelling elderly persons fall each year, including half of people over age 80, and one out of four of those who fall have serious injuries. About 5% of falls result in fracture. Falls are the sixth leading cause of death for older people. Just as important, they are a contributing factor in 40% of admissions to nursing homes. Resultant hip fractures and fear of falls are major causes of loss of independence. Nonetheless, falls are not inevitable or untreatable.

Causes of Falls

Balance and ambulation require a complex interplay of cognitive, neuromuscular, and cardiovascular function. With age, balance becomes impaired and postural sway increases. This predisposes the older person to a fall when challenged by an additional insult to any of these systems.

A fall may be the clinical manifestation of an occult problem, such as pneumonia or myocardial infarction, but much more commonly falls are due to the interaction between an impaired patient and an environmental risk factor. While a warped floorboard may pose little problem for a vigorous, unmedicated, cognitively intact person, it may be sufficient to precipitate a fall and hip fracture in the patient with impaired vision, balance, muscle tone, or cognition. Thus, falls in older people are rarely due to a single cause, and effective intervention entails a comprehensive assessment of the patient's intrinsic deficits (usually diseases and medications), the activity engaged in at the time of the fall, and environmental obstacles.

Intrinsic deficits are those that impair sensory input, judgment, blood pressure regulation, reaction time, and balance and gait. Dizziness may be closely related to the deficits associated with falls and gait abnormalities. While it may be impossible to isolate a sole "cause" or a "cure" for falls, gait abnormalities, or dizziness, it is often possible to identify and ameliorate some of the underlying contributory conditions and improve the patient's overall function.

As for most geriatric conditions, medications and alcohol use are among the most common, significant, and reversible causes of falling. Benzodiazepines, sedative-hypnotics, antidepressants, neuroleptics, and the use of four or more medications simultaneously have been associated with an increased fall risk. Other often overlooked but treatable contributors include postprandial hypotension (which peaks 30-60 minutes after a meal), insomnia, urinary urgency, and peripheral edema (which can burden impaired leg strength and gait because of the additional weight).

Since most falls occur in or around the home, a visit by a visiting nurse, physical therapist, or physician reaps substantial benefits in identifying environmental obstacles and is generally reimbursed by third-party payers, including Medicare. Insufficient lighting is an underappreciated factor in many cases. In addition to the number and location of lamps, noting their wattage is also important; because of a loss of contrast sensitivity, older people often need twice the wattage to maximize visual acuity. Replacement of 60-watt bulbs with 100-watt bulbs may be cost-effective.

Complications of Falls

The most common fractures resulting from falls are of the wrist, hip, and vertebrae. There is a high mortality rate (approximately 20% in one year) in elderly women with hip fractures, particularly if they were debilitated prior to the time of the fracture.

Fear of falling again is a common, serious, but treatable factor in the elderly person's loss of confidence and independence. Referral to a physical therapist for gait training with special devices is often all that is required.

Chronic subdural hematoma is an easily overlooked complication of falls that must be considered in any elderly patient presenting with new neurologic symptoms or signs, particularly obtundation. Headache is uncommonly present. In many cases there is no history of trauma.

Patients who are unable to get up from a fall are at risk for dehydration, electrolyte imbalance, pressure sores, rhabdomyolysis, and hypothermia.

Prevention & Management

The risk of falling and consequent injury, disability, and potential institutionalization can be reduced by modifying those factors outlined in [Table 4-5](#). Emphasis is placed on treating all contributory medical conditions, minimizing environmental hazards, and reducing the number of medications—particularly those that induce parkinsonism, orthostasis (eg, alpha-blockers, calcium channel blockers, nitrates, antiparkinsonism agents, antipsychotics, tricyclic antidepressants), peripheral edema, and confusion. Also important are strength, balance, and gait training as well as steps to improve bone density (with calcium and vitamin D supplementation in most older adults and other medications as indicated).

Patients with repeated falls are often reassured by the availability of phones at floor level, a portable phone, or a lightweight radio call system. Their therapy should also include training in techniques for arising after a fall. Use of an anatomically designed external hip protector reduces hip fracture risk in frail older people but is often poorly tolerated.

URINARY INCONTINENCE

Classification (Table 4-6)

Because continence requires adequate mobility, mentation, motivation, and manual dexterity, problems outside the bladder often result in geriatric incontinence. In general, we find it useful to differentiate between "transient" or "potentially reversible" causes of incontinence and more "established" causes.

A. Transient Causes

Use of the mnemonic "DIAPPERS" may help one remember the categories of transient incontinence.

1. Delirium—A clouded sensorium impedes recognition of both the need to void and the location of the nearest toilet. Delirium is the most common cause of incontinence in hospitalized patients; once it clears, incontinence usually resolves.

2. Infection—Symptomatic urinary tract infection commonly causes or contributes to urgency and incontinence. Asymptomatic bacteriuria does not.

3. Atrophic urethritis and vaginitis—Because it usually coexists with atrophic vaginitis, atrophic urethritis can be diagnosed presumptively by the presence of vaginal mucosal telangiectasia, petechiae, erosions, erythema, or friability. Urethral inflammation may contribute to incontinence in women and can be improved by a trial of topical or oral estrogen.

4. Pharmaceuticals—Drugs are one of the most common causes of transient incontinence. Typical offending agents include potent diuretics, anticholinergics, psychotropics, opioid analgesics, alpha-blockers (in women), alpha agonists (in men), and calcium channel blockers.

5. Psychologic factors—Severe depression with psychomotor retardation may impede the ability or motivation to reach a toilet.

6. Excess urine output—Excess urine output may also overwhelm the ability of an older person to reach a toilet in time. In addition to diuretics, common causes include excess fluid intake; metabolic abnormalities (eg, hyperglycemia, hypercalcemia, diabetes insipidus); and disorders associated with peripheral edema, with its associated heavy nocturia when previously dependent legs assume a horizontal position in bed. Edema may be due to heart failure, venous insufficiency, malnutrition, cirrhosis, and use of calcium channel blockers or NSAIDs.

7. Restricted mobility—(See Immobility section, above.) If mobility cannot be improved, access to a urinal or commode (eg, at the bedside) may improve continence.

8. Stool impaction—This is a common cause of urinary incontinence in hospitalized or immobile patients. Although the mechanism is still unknown, a clinical clue to its presence is the onset of both urinary and fecal incontinence. Disimpaction restores urinary continence.

B. Established Causes

Causes of established incontinence ([Figure 4-2](#)) should be addressed after the transient causes have been uncovered and managed appropriately.

1. Detrusor overactivity (urge incontinence)—Detrusor overactivity refers to uninhibited bladder contractions that cause leakage. It is the most common cause of established geriatric incontinence, accounting for two-thirds of cases, and is usually idiopathic. Women will complain of urinary leakage after the onset of an intense urge to urinate that cannot be forestalled. In men the symptoms are similar, but detrusor overactivity commonly coexists with urethral obstruction from benign prostatic hyperplasia. Because detrusor overactivity also may be due to bladder stones or tumor, the abrupt onset of otherwise unexplained urge incontinence—especially if accompanied by perineal or suprapubic discomfort or sterile hematuria—should be investigated by cystoscopy and cytologic examination of a urine specimen.

2. Urethral incompetence (stress incontinence)—Urethral incompetence is the second most common cause of established urinary incontinence in older women. Urinary incontinence is most commonly seen in men after radical prostatectomy. Stress incontinence is characterized by instantaneous leakage of urine in response to a stress maneuver. It commonly coexists with detrusor overactivity. Typically, urinary loss occurs with laughing, coughing, or lifting heavy objects. Leakage is worse or occurs only during the day, unless another abnormality (eg, detrusor overactivity) is also present. To test for stress incontinence, have the patient relax her perineum and cough vigorously (a single cough) while standing with a full bladder. Instantaneous leakage indicates stress incontinence if urinary retention has been excluded by postvoiding residual determination using ultrasound. A delay of several seconds or persistent leakage suggests that the problem is instead caused by an uninhibited bladder contraction induced by coughing.

3. Urethral obstruction—Rarely present in women, urethral obstruction (due to prostatic enlargement, urethral stricture, bladder neck contracture, or prostatic cancer) is a common cause of established incontinence in older men. It can present as dribbling incontinence after voiding, urge incontinence due to detrusor overactivity (which coexists in two-thirds of cases), or overflow incontinence due to urinary retention. Renal ultrasound is required to exclude hydronephrosis in men whose postvoiding residual urine exceeds 150 mL. In older men for whom surgery is planned, urodynamic confirmation of obstruction is strongly advised.

4. Detrusor underactivity (overflow incontinence)—Detrusor underactivity is the least common cause of incontinence. It may be idiopathic or due to sacral lower motor nerve dysfunction ("neurogenic bladder"). When it causes incontinence, detrusor underactivity is associated with urinary frequency, nocturia, and frequent leakage of small amounts. The elevated postvoiding residual urine (generally over 450 mL) distinguishes it from detrusor overactivity and stress incontinence, but only urodynamic testing differentiates it from urethral obstruction in men. Such testing usually is not required in women, in whom obstruction is rarely present.

Treatment

A. Transient Causes

Each identified transient cause should be treated regardless of whether an established cause coexists. For patients with urinary retention induced by an anticholinergic agent, discontinuation of the drug should first be considered. If this is not feasible, substituting a less anticholinergic agent (eg, sertraline instead of desipramine for depression) may be useful.

B. Established Causes

1. Detrusor overactivity—The cornerstone of treatment is behavioral therapy. Patients are instructed to void every 1-2 hours while awake. Once daytime continence is restored, the interval is increased by 30 minutes until the interval is 4-5 hours. Most patients who become continent during the day on this regimen become continent at night as well. For patients who are unable to manage on their own, caregivers should ask whether they need to void at suitable intervals.

Pelvic floor exercises, behavioral approaches, and biofeedback can be extremely helpful in training cognitively intact, motivated patients. Results superior to those achieved with use of bladder relaxants are possible.

If behavioral approaches prove insufficient, drug therapy to relax the detrusor may be necessary. Regimens should be monitored, as they may lead to delirium, dry mouth, or urinary retention. Use of oxybutynin (2.5-5 mg three or four times daily), long-acting oxybutynin (5-15 mg daily), or tolterodine (1-2 mg twice daily) may reduce episodes of incontinence. In men with both benign prostatic hyperplasia and detrusor overactivity, urodynamic testing should be done if prescription of a bladder relaxant is planned in order to avoid precipitating urinary retention. In refractory cases, where intermittent catheterization is feasible, the physician may choose intentionally to induce urinary retention with a bladder relaxant and have the patient empty the bladder three or four times daily. Clean but not sterile technique is required.

2. Urethral incompetence (stress incontinence)—Although a last resort, surgery is the most effective treatment for stress incontinence, resulting in a cure rate of 75-85% even in older women. For women who wish to avoid surgery and who can employ them indefinitely, pelvic muscle exercises are effective for mild to moderate stress incontinence; they can be combined, if necessary, with biofeedback, electrical stimulation, or vaginal cones. Pelvic floor exercises can be taught during bimanual vaginal examination or by asking the patient to try to contract the muscle that they use to stop the flow of urine. It is often necessary to perform 30-60 exercises daily for 6 weeks before significant improvement will be noticed.

The effectiveness of topical or oral estrogens is likely to be low unless atrophic vaginitis with urethral irritation is present.

Occasionally, a pessary or even a tampon (for women with vaginal stenosis) provides some relief, especially for frail women.

3. Urethral obstruction—Surgical decompression is the most effective treatment for obstruction, especially in the setting of urinary retention. A variety of newer, less invasive techniques make decompression feasible even for frail men. For the nonoperative candidate with urinary retention, intermittent or indwelling catheterization is used. For a man with prostatic obstruction who is not in retention and who wishes to defer surgery or is not a good surgical candidate, treatment with alpha-blocking agents (eg, terazosin, 1-10 mg daily; prazosin, 1-5 mg orally twice daily; tamsulosin, 0.4-0.8 mg daily) may relieve symptoms. Finasteride or the herbal supplement saw palmetto may partially relieve symptoms in a minority of patients, but the onset of effect may take many months.

4. Detrusor underactivity—For the patient with a poorly contractile bladder, augmented voiding techniques (eg, double voiding, suprapubic pressure) often prove effective. If further emptying is needed, intermittent or indwelling catheterization is the only option. Antibiotics should be used only for symptomatic upper urinary tract infection or as prophylaxis against recurrent symptomatic infections in a patient using intermittent catheterization; they should not be used as prophylaxis with an indwelling catheter.

WEIGHT LOSS & MALNUTRITION

Undernutrition affects substantial numbers of elderly persons and often precedes hospitalization for "failure to thrive." Unintended weight loss exceeding 5% in 1 month or 10% in 6 months deserves evaluation.

[Table 4-7](#) lists causes of weight loss in older adults and may suggest points of history to explore. Useful laboratory and radiologic studies include complete blood count, serum chemistries (including glucose, TSH, creatinine, calcium), urinalysis, and chest film. These studies are intended to uncover an occult metabolic or neoplastic cause but are not exhaustive.

Treatment with nutritional supplements may lead to weight gain, but they are expensive; use of instant breakfast powder in whole milk (for those who can tolerate dairy products) is a less costly alternative. Megestrol acetate has been employed as an appetite stimulant (primarily in cancer and AIDS patients) but has not been shown to increase body mass or lengthen life in the elderly population.

For those who have lost the ability to feed themselves, assiduous hand feeding may allow maintenance of weight. Although artificial nutrition and hydration ("tube feeding") may seem a more convenient alternative, it deprives the patient of the taste and texture of food as well as the social milieu typically associated with mealtime; before this option is chosen, the patient or his or her surrogate will wish to review the benefits and burdens of the treatment in light of overall goals of care. If the patient makes repeated attempts to pull out the tube during a trial of artificial nutrition, the treatment burden becomes substantial, and the utility of tube feeding should be reconsidered. Though commonly employed, there is no evidence that tube feeding prolongs life in patients with end-stage dementia.

"Failure to thrive" is a syndrome lacking a consensus definition but generally representing a constellation of weight loss (due to some combination of causes listed in [Table 4-7](#)), weakness, and progressive functional decline. The label is typically applied when some triggering event—loss of social support, a bout of depression or pneumonia, the addition of a new medication—pulls a struggling elderly person below the threshold of successful independent living. Ideally, use of the preventive measures recommended earlier in this chapter will reduce the patient's chances of reaching this stage of frailty.

PHARMACOTHERAPY & POLYPHARMACY

There are several reasons for the greater incidence of iatrogenic drug reactions in the elderly population. Drug metabolism is often impaired in this group, due to a decrease in glomerular filtration rate, as well as reduced hepatic clearance. The latter is due to decreased activity of microsomal enzymes and reduced hepatic perfusion with aging. The volume of distribution of drugs is also affected. Since older adults have a decrease in total body water and a relative increase in body fat, water-soluble drugs become more concentrated and fat-soluble drugs have longer half-lives. Serum albumin levels decrease, especially in acutely ill patients, with reduction in protein binding of some drugs (eg, warfarin, phenytoin), leaving more free (active) drug available.

Older individuals often have varying responses to a given serum drug level. Thus, they are more sensitive to some drugs (eg, opioids) and less sensitive to others (eg, beta-blocking agents).

Finally, the older patient with multiple chronic conditions is likely to be receiving many drugs, including nonprescribed agents. Thus, adverse drug reactions and dosage errors are more likely to occur, especially if the patient has visual, hearing, or memory deficits.

Precautions in Administering Drugs

The following suggestions are designed to reduce the risk of drug toxicity.

A. Drug Selection and Administration

The symptom requiring treatment may be due to another drug, leading to a "prescribing cascade," in which adverse drug effects are attributed to new medical conditions, in time resulting in prescription of still more medications.

Nonpharmacologic means should be tried before drugs. Pharmacotherapy is not necessarily indicated in some common clinical situations. In asymptomatic bacteriuria, for example, antibiotics need not be given unless the disorder is associated with obstructive uropathy, other anatomic abnormalities, or stones. Ankle edema is often due to venous insufficiency, drugs (NSAIDs, calcium channel blockers), malnutrition, or inactivity in chair-bound patients and need not be treated with diuretics unless associated with heart failure. Leg elevation in the evening or fitted pressure-gradient stockings are often helpful.

Therapy is begun with less than the usual adult dosage and the dosage increased slowly, consistent with its pharmacokinetics in older patients. However, age-related changes in drug distribution and clearance are variable among individuals, and some require full doses. After determining acceptable measures of success and toxicity, the dose is increased until one or the other is reached.

Despite the importance of beginning new drugs in a slow, measured fashion, all too often an inadequate trial is permitted (in terms of duration of course, or ultimate dose) before they are discontinued. Angiotensin-converting enzyme inhibitors and antidepressants, in particular, are frequently stopped before therapeutic dosages are reached.

Steps are taken to improve adherence to the prescribed medical regimen. The following increase the odds of nonadherence: The patient lives alone; uses more than one pharmacy or provider; is prescribed medications with multiple daily doses; has a drug regimen that is changed frequently; is prescribed a large number of drugs; has difficulty reaching a pharmacy; and has poor cognition, vision, or dexterity. When possible, the physician should keep the dosing schedule simple, the number of pills low, and the medication changes infrequent.

A family member is asked to bring in all medications at each visit for reinforcing instructions regarding reasons for drug use, dosage, frequency of administration, and possible adverse effects.

Although serum drug levels may be useful for monitoring certain drugs with narrow therapeutic windows (eg, phenytoin, theophylline, lithium, tricyclic antidepressants), toxicity can still occur even with "normal" therapeutic levels of many drugs.

Trials of individual drug discontinuation should be considered (including antihypertensives, digoxin, antiepileptics), particularly in a controlled environment such as a nursing facility.

B. Considerations with Specific Drug Classes

1. Anticoagulants—Many elderly patients with atrial fibrillation are not anticoagulated because physicians fear injuries and secondary bleeding due to falls. Head injuries due to falls are usually of greatest concern, and occur in about 1% of falls. Given that anticoagulation can result in an annual absolute risk reduction in stroke of 3-8%, the benefits of anticoagulation outweigh the risks of falling in most instances.

2. Glaucoma medications—Not only can topical beta-blockers cause systemic side effects (eg, bradycardia)—so too can oral carbonic anhydrase inhibitors. The latter may produce malaise, anorexia, and weight loss.

3. Analgesics—Meperidine is associated with an increased risk of delirium and seizures in older adults and should be avoided in this population. Of the NSAIDs, indomethacin carries the highest risk of causing confusion. For treatment of mild osteoarthritis, use of acetaminophen on a scheduled basis is safer than use of an NSAID, with comparable effectiveness.

4. Antihypertensives—In most instances, the first choice for treating hypertension in older people is a thiazide in low dosage, eg, hydrochlorothiazide 12.5 mg by mouth daily. Thiazides increase the risk of attacks of gout flares, perhaps less so at this dosage. Concomitant use of an NSAID can exacerbate hypertension.

5. Cold remedies—Over-the-counter cold remedies frequently cause adverse effects in elderly people. The anticholinergic properties of many can create confusion (even in nondemented persons), impair bladder emptying, or cause constipation, and decongestants not infrequently cause urinary hesitancy or retention in men.

6. Antiemetics—Prochlorperazine and metoclopramide both can cause drug-induced parkinsonism.

5. Care at the End of Life - *Michael W. Rabow, MD, & Steven Z. Pantilat, MD*

■ THE END OF LIFE

DIAGNOSIS OF THE END OF LIFE

In the United States, approximately 2.3 million people die each year. Despite all the successes of medical progress, death inevitably comes, and clinicians battling to prolong life must recognize when life is ending in order to continue caring properly for their patients. Unfortunately, end-of-life practices do not always meet the standards set by professional organizations. While death itself remains a mystery and while caring for the dying traditionally has not been well researched or adequately taught as part of medical training, caring for patients at the end of life is an important responsibility and a rewarding opportunity for clinicians. End-of-life care refers to focusing care for those approaching death on the goals of relieving distressing symptoms and promoting quality of life rather than attempting to cure underlying disease. From the medical perspective, the end of life may be defined as that time when death—whether due to terminal illness, acute or chronic illness, or age itself—is expected within weeks to months and can no longer be reasonably forestalled by medical intervention.

Clinicians play an important role in helping patients understand that their lives are ending. This information influences patients' treatment decisions and may change how they spend their remaining time. While certain diseases such as cancer are amenable to prognostic estimates regarding the time course to death, the other common causes of mortality in the United States—including heart disease, stroke, chronic lung disease, and dementia—have variable and difficult to predict prognoses. Even for patients with cancer, clinician estimates of prognosis are often inaccurate and generally overly optimistic. Nonetheless, clinical experience, epidemiologic data, guidelines from professional organizations,* and formal computer-based modeling and prediction tools# may be employed to help patients identify the end period of their lives. Recognizing that patients may have different levels of comfort with prognostic information, clinicians can introduce the topic by simply saying, "I have information about the likely time course of your illness. Would you like to talk about it now?"

*For example, the National Hospice Organization.

#For example, the Acute Physiology and Chronic Health Evaluation (APACHE) system or the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment (SUPPORT) model.

EXPECTATIONS ABOUT THE END OF LIFE

Patients' experiences of the end of life are influenced by their expectations about how they will die and the meaning of death. Many people fear how they will die more than death itself. Patients report fear of dying in pain or of suffocation, of loss of control, indignity, isolation, and being a burden to their families. All of these anxieties can be alleviated with good supportive care provided by an attentive group of caretakers.

For most of human history, death has been regarded as part of the natural process of life. However, with medical advances forestalling the end of life, death has become "medicalized." No longer seen clearly as a profound personal and spiritual event basic to the human condition, death is often regarded as a failure of medical science. This can create or heighten a sense of guilt about the failure to prevent dying. Both the general public and clinicians are complicit in denying death, treating dying persons as patients and death as an enemy to be battled furiously in hospitals rather than as an inevitable outcome to be experienced as a part of life at home. Approximately 80% of people in the United States die in hospitals or long-term care facilities.

The clinician may continue to pursue cure of potentially reversible disease for some patients. For all, however, offering comfort and helping the patient prepare for death are foremost considerations. Patients at the end of life identify a number of elements as important to quality end-of-life care: adequate pain and symptom management, avoiding inappropriate prolongation of dying, achieving a sense of control, relieving the burden on others, and strengthening relationships with loved ones. Clinicians can help patients pursue their care goals in a process called advance care planning.

COMMUNICATION & THE ROLE OF THE CLINICIAN AT THE END OF LIFE

Caring for patients at the end of life requires the same skills clinicians employ in other tasks of medical care: diagnosis of treatable conditions, providing patient education, sharing in decision-making, and expressing understanding and caring. Communication skills are vitally important. In particular, clinicians must become experts at delivering bad news and then dealing with its consequences ([Table 5-1](#)). Higher-quality communication is associated with greater satisfaction and awareness of patient wishes. Three further obligations are central to the clinician's role at this time. First, he or she must work to identify, understand, and relieve suffering, which may include physical, psychologic, social, or spiritual distress. Disease, disability, and disintegration at the end of life can threaten a person's sense of integrity or "intactness" and thereby cause suffering. In assisting with redirection and growth, providing support, assessing meaning, and fostering transcendence, clinicians can help ameliorate their patients' suffering and help the patient and family live fully during this stage of life. Second, clinicians caring for patients at the end of life must serve as a facilitator or catalyst for hope. While a particular outcome may be extremely unlikely (such as cure of advanced cancer following exhaustive conventional and experimental treatments), hope may be defined as the patient's belief in what is still possible. Although expecting a "miraculous cure" may be simplistic and even harmful, hope for relief of pain, for reconciliation with loved ones, for discovery of meaning in the life remaining, and for spiritual transformation is still quite supportable at the end of life. With questions such as "What is still possible now for you?"—"What do you wish for before you die?"—"What good might come of this?" clinicians can help patients uncover hope, explore meaningful and realistic goals, and develop strategies to realize them.

Third, patients' feelings of isolation and fear engendered by the prospect of dying demand that clinicians assert that care will continue to be provided throughout the final stage of life. Perhaps the essential principle of care at the end of life is this promise of nonabandonment: a clinician's pledge to an individual patient to serve as a caring partner, a resource for creative problem-solving and relief of suffering, a guide during uncertain times, and a witness to the patient's experiences—no matter what happens. Dying patients need their clinicians to offer their presence—not necessarily the ability to solve all problems but rather a commitment to recognize and receive the patients' difficulties and experiences with respect and empathy. At its best, the patient-clinician relationship can be a covenant of compassion and a recognition of common humanity.

CARING FOR THE FAMILY

In caring for patients at the end of life, clinicians must appreciate the central role played by family, friends, and romantic partners and often must deal with strong emotions of fear, anger, shame, sadness, and guilt experienced by those individuals. While significant others may support and comfort a patient at the end of life, the threatened loss of a loved one may also create or reveal dysfunctional or painful family dynamics. Furthermore, clinicians must be attuned to the potential impact of illness on the patient's family: substantial physical caregiving responsibilities and financial burdens as well as increased rates of anxiety, depression, chronic illness, and even mortality. Family caregivers commonly provide the bulk of care for patients at the end of life, yet their work is often not acknowledged or compensated.

Clinicians can help families confront the imminent loss of a loved one ([Table 5-2](#)) and often must negotiate amid complex and changing family needs. Identifying a spokesperson for the family, conducting family meetings, allowing all to be heard, and providing time for consensus may help the clinician work effectively with the family.

THE LIMITS OF CARE AT THE END OF LIFE

Many clinicians find caring for patients at the end of life to be one of the most rewarding aspects of practice. However, working with the dying requires tolerance of great uncertainty, ambiguity, and existential challenges. Clinicians must recognize and respect their own limitations and attend to their own needs in order to avoid being overburdened, overly distressed, or emotionally depleted. Open recognition of their own feelings enables clinicians to process their emotions and take steps to care for themselves: conferring and consulting with colleagues, retreating, relaxing and recuperating, obtaining informal or professional support, or even—under extraordinary circumstances—transferring the care of a patient to another clinician when it is no longer possible for the original clinician to meet the patient's needs. Moreover, care of patients at the end of life is not solely the responsibility of physicians. Ideally, physicians, nurses, social workers, psychologists, therapists (physical, occupational, recreational), dietitians, clergy, and volunteers should coordinate their efforts to care for patients and can support one another as part of an interdisciplinary team.

Clinicians may be limited in caring for persons at the end of life not only by their emotional responses but by a sense of moral obligation as well. While the ethical, legal, and professional controversies over clinician-assisted suicide are beyond the scope of this chapter, clinicians should be aware of the "right to die" movement as an expression, at least in part, of patient dissatisfaction with how people are cared for at the end of life. In the United States, clinician-assisted suicide is illegal in every state but Oregon—and legal there only with careful restrictions. While individual clinicians must decide for themselves within the evolving legal context what their personal limits may be in caring for patients who request aid in dying (eg, clinician-assisted suicide), all clinicians can reclaim their long-privileged and universally accepted role of caring for the dying. They can do so by dedicating themselves not to abandon their patients and by providing appropriate attention to symptom management, sensitivity to psychologic and social stresses, and unconditional presence and openness to spiritual challenges at the end of life. Research has demonstrated that palliative care interventions can cause some patients who have requested clinician-assisted suicide to withdraw their request.

■ THE SETTING & STRUCTURE OF CARE

ETHICAL & LEGAL BACKGROUND

Clinicians' care of patients at the end of life is guided by the same ethical and legal principles that inform other types of medical care. Foremost are truth-telling, nonmaleficence, beneficence, autonomy, proportionality, and distributive justice. These must guide clinicians in helping patients make difficult decisions about care, including decisions about the withdrawal and withholding of support.

Three additional ethical considerations are relevant to care at the end of life. First, important ethical principles may be in conflict. For example, while a patient may desire a particular medical intervention, the clinician may decline to undertake the intervention if it is of no therapeutic benefit (ie, futile) or violates the clinician's own moral code. In practice, what constitutes futility is often a matter of controversy. However, most disagreements can be resolved through repeated discussions between clinicians and families.

Second, although clinicians and family members often feel differently about withholding versus withdrawing support, there is consensus among ethicists, supported by legal precedent, of their ethical equivalence. Patients have the same right to stop unwanted medical treatments once begun as they do to refuse those treatments in the first place, including nutrition and hydration.

Third, the ethical principle of "double effect" argues that the potential to hasten imminent death is acceptable if it comes as the unintended consequence of a primary intention to provide comfort and relieve suffering. For example, sufficient doses of morphine should be provided to control pain even if there is the potential unintended secondary effect of depressing respiration. The ethical argument for the practice of terminal sedation is based on this principle. In practice, one can almost always find an effective pain regimen without rendering a patient unconscious or hastening death.

ADVANCE DIRECTIVES

Well-informed, competent adults have a right not to accept medical intervention even if this is likely to result in death. Many are willing to sacrifice some quantity of life in exchange for protecting a certain quality of life. In order to further patient autonomy, clinicians are obligated to inform patients about the risks, benefits, alternatives, and expected outcomes of end-of-life medical interventions such as cardiopulmonary resuscitation, intubation and mechanical ventilation, vasopressor medication, hospitalization and ICU care, and nutrition and hydration. Advance directives are oral or written statements made by patients when they are competent that are intended to guide care should they become incompetent. Advance directives allow patients to project their autonomy into the future to a time when they are incompetent and are an important part of advance care planning. While oral statements about these matters are ethically binding, they are not legally binding in all states. Written advance directives give effect to the patient's wishes in these matters. State-specific advance directive forms are available from a number of sources, including the Web site www.partnershipforcaring.org.

In addition to documenting patient preferences for care, the Durable Power of Attorney for Health Care (DPOA-HC) allows the patient to designate a surrogate decision-maker. The DPOA-HC is important since it is often difficult to anticipate what decisions will need to be made. The responsibility of the surrogate is to provide "substituted judgment"—to decide as the *patient* would, not as the *surrogate* wants. In the absence of a designated surrogate, clinicians usually turn to family members or next of kin. Unfortunately, surveys demonstrate that clinicians and families often are no better than chance at predicting patient wishes, so it is imperative to have these discussions with all patients.

Clinicians should educate all patients—ideally, well before the end of life—about the opportunity to formulate an advance directive. Most patients have already thought about end-of-life issues, want to discuss them with their clinician, want the clinician to bring up the subject, and feel better for having had the discussion. Chart reminders to clinicians can increase the frequency of advance directive completions. It is especially important during discussions about end-of-life care that clinicians reassure patients about the ability to control pain and other symptoms and make an explicit pledge not to abandon the patient. Despite regulations requiring clinicians to inform patients of their rights to formulate an advance directive, only about 10% of people in the United States (including clinicians themselves) actually have executed them, and studies have shown that clinicians are often unaware of or actually ignore their patients' advance directives.

DNAR ORDERS

Clinicians can encourage patients to express their preferences for the use of CPR. Most patients and many clinicians are uninformed or misinformed about the nature and success of CPR. Only about 15% of all patients who undergo CPR in the hospital survive to hospital discharge. Moreover, among certain populations—especially those with systemic noncardiac disease—the likelihood of survival to hospital discharge following CPR ([Table 5-3](#)) is virtually nil.

Patients may ask their clinician to write an order that CPR not be attempted on them. Although this order initially was referred to as a DNR ("do not resuscitate") order, many clinicians prefer the term DNAR ("do not attempt resuscitation") to emphasize the low likelihood of success.

Patients deciding about CPR preferences should also be informed about the sequelae of surviving CPR. It may result in fractured ribs, lacerated internal organs, and neurologic disability, and there is a high likelihood of a need for other aggressive interventions, such as ICU care, if CPR is successful.

For some patients at the end of life, decisions about CPR may be not about whether they will live but about how they will die. Clinicians should correct the misconception that withholding CPR in appropriate circumstances is tantamount to "not doing everything" or "just letting someone die." Frequently, CPR will not improve the quality of a dying patient's life or alter the patient's underlying prognosis. While respecting the patient's right ultimately to make the decision—and keeping in mind their own biases and prejudices—clinicians should offer explicit recommendations about DNAR orders and protect dying patients and their families from feelings of guilt and from the sorrow associated with vain hopes. Finally, clinicians should encourage patients and their families to make proactive decisions about what is wanted in end-of-life care rather than focusing only on what is not to be done.

HOSPICE & OTHER PALLIATIVE CARE INSTITUTIONS

While most patients die in hospitals and long-term care facilities, good care of the dying may not be the central goal of most hospitals and nursing homes. Only a minority of US hospitals currently have formal palliative care programs. Hospice is an approach to care where the most urgent objective is to provide a caring environment for meeting the physical and emotional needs of the dying. Hospice care focuses on the patient and family rather than the disease and on providing comfort and pain relief rather than on treating illness or prolonging life. Hospices provide intensive caring with the goal of helping people live well until they die.

The hospice philosophy emphasizes individualized attention, human contact, and an interdisciplinary team approach involving clinicians, nurses, health aides, social workers, psychologists, therapists (physical, occupational, recreational), dietitians, chaplains, and volunteers. Hospice care can include arranging for respite for family caregivers and providing legal, financial, and other services. While some hospice care is provided in hospitals and institutional residences, about 80% of patients receiving it remain at home where they can be cared for by the family and visiting hospice staff. Primary care clinicians are strongly encouraged to continue caring for their patients during the time they are receiving hospice care.

Hospice care has been shown to increase patient satisfaction, to ease family anxiety, and even to reduce costs depending on when patients are referred to hospice care. About 25% of all patients who die receive hospice care, and 63% of these people have end-stage cancer. Hospice care tends to be utilized late in the course of the end of life. The average length of stay in hospices in the United States is just 36 days, with 15% of patients dying within 7 days after beginning hospice care.

Most hospice organizations require clinicians to estimate the patient's probability of survival to be less than 6 months, since this is a criterion for eligibility to receive Medicare coverage (a benefit available since 1982). Regrettably, the hospice benefit tends to be unavailable to people who are homeless or isolated or who have terminal prognoses that are difficult to quantify.

Many of the goals of hospice care, such as relief of suffering and attention to the patient as a person, are relevant to curative medical care. However, the emphasis on patient well-being rather than on cure, the direct acknowledgment of death and dying issues, and the effort to care for people in their homes make hospice an important alternative to acute hospital care at the end of life. While the initiation of hospice care is often described as a transition from aggressive care to comfort care, hospice care also provides "aggressive" care, though not directed at achieving a cure. It is more appropriate to consider hospice care as one among many health care resources available to patients at the end of life. For the dying, it may be appropriate to "treat" pneumonia with morphine and antipyretics rather than with antibiotics. Helping patients decide when to avail themselves of the resources of hospice or inpatient palliative care is an important function even for clinicians providing the most aggressive and intensive curative medical interventions.

CULTURAL ISSUES

The individual's experience of dying occurs in the context of a complex interaction of personal, philosophic, and cultural influences. Various religious, ethnic, gender, class, and cultural traditions inform patients' styles of communication, comfort in discussing particular topics, expectations about dying and medical interventions, and attitudes about the appropriate disposition of dead bodies. There are differences in knowledge and beliefs regarding advance directives, autopsy, organ donation, hospice care, and withdrawal of support among patients of different ethnic groups. While each patient must be considered an individual, understanding cultural assumptions and beliefs and respecting ethnic traditions are important responsibilities of the clinician caring for a patient at the end of life, especially when the cultures of origin of the clinician and patient differ.

■ MANAGEMENT OF PAIN & OTHER COMMON SYMPTOMS

For patients at the end of life, maximizing the quality of life—rather than postponing death—is the first priority of care. In this context, symptoms that cause disability and suffering must be considered medical emergencies and managed aggressively by frequent elicitation, continuous reassessment, and individualized treatment. While patients at the end of life may experience a host of bothersome symptoms, pain, dyspnea, and delirium are reported to be among the most feared and burdensome. The palliative care of pain and a selected number of other common symptoms is described below. Throughout, the principles of good end-of-life care dictate that comfort is the main focus of palliative care and that properly informed patients or their surrogates may decide to pursue aggressive symptom relief even if, as a known but unintended consequence, the treatments hasten demise.

PAIN AT THE END OF LIFE

Definition & Prevalence

Pain is a common problem for patients at the end of life—up to 75% of patients dying of cancer experience pain—and it is what many people say they fear most about dying. Pain is a common complaint among patients with noncancer diagnoses as well. Pain is undertreated at the end of life. Up to 50% of severely ill hospitalized patients spent half of their time during the last 3 days of life in moderate to severe pain. The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) has recently promulgated new pain management standards for all patient care organizations accredited by JCAHO.

The experience of pain includes the patient's emotional reaction to it and is influenced by many factors, including the patient's prior experiences with pain, the meaning of the pain, emotional stresses, and the influence of family and culture. Pain is a subjective phenomenon, and clinicians cannot reliably detect its existence or quantify its severity without asking the patient directly. A useful means of assessing pain and evaluating the effectiveness of analgesia is to ask the patient to rate the degree of pain along a numerical or visual pain scale ([Table 5-4](#)).

Barriers to Good Care

Poor management of pain at the end of life has been documented in many settings. Some clinicians refer pain management to others when they believe that a patient's pain is not due to the disease for which they are treating the patient. Even oncologists often misperceive the origin of their patients' pain and inappropriately ignore complaints of pain.

Many clinicians have limited training and clinical experience with pain management and thus are understandably reluctant to attempt to manage severe pain. Lack of knowledge about the proper selection and dosing of analgesic medications carries with it attendant and typically exaggerated fears about the side effects of pain medications, including the possibility of respiratory depression with an overdose of opioids. Most clinicians, however, can develop good pain management skills, and nearly all pain, even at the end of life, can be managed without hastening death through respiratory depression.

Fears of the physiologic effects of opioids are often coupled with concerns on the part of clinician, patient, or family that patients will become addicted to opioid pain medications. While physiologic **tolerance** (requiring increasing dosage to achieve the same analgesic effect) and **dependence** (requiring continued dosing to prevent symptoms of medication withdrawal) are expected with opioid use, at the end of life the use of opioids for relief of pain and dyspnea is not associated with a risk of psychologic **addiction** (misuse of a substance for purposes other than one for which it was prescribed and despite negative consequences in health, employment, or legal and social spheres). Even patients who demonstrate some of the behaviors sometimes associated with addiction (demand for specific medications and doses, anger and irritability, poor cooperation or disturbed interpersonal reactions) may in fact not be addicted. The term **pseudo-addiction** has been used when patients exhibit behaviors associated with addiction but only because their pain is inadequately treated. Once they achieve pain relief, these behaviors cease. In all cases, clinicians must be willing to use appropriate doses of opioids in order to relieve distressing symptoms for patients at the end of life.

Finally, some clinicians fear legal repercussions from prescribing the high doses of opioids sometimes necessary to control pain at the end of life. Some states have enacted special licensing and documentation requirements for opioid prescribing. However, governmental and professional medical groups and regulators are making it clear that appropriate treatment of pain is a fundamental responsibility of the clinician. While some clinicians nevertheless remain apprehensive about the legal implications of overtreatment, clinicians have recently been successfully sued for undertreatment of pain. Although clinicians may feel trapped between consequences of over- or underprescribing opioids, there remains a wide range of practice in which clinicians can appropriately treat pain. Referral to pain management experts is appropriate whenever pain cannot be controlled expeditiously by the primary clinician.

Principles of Pain Management

General guidelines for management of pain are recommended for the treatment of all patients with pain (see [Table 5-5](#)). Because pain is so common at the end of life, all patients should be asked about its presence. Clinicians should ask about the nature, severity, timing, location, quality, and aggravating and relieving factors of the pain. Distinguishing between somatic, visceral, and neuropathic pain is essential to proper tailoring of pain treatments. The goal of pain management is properly decided by the patient. While some patients may wish to be completely free of pain even at the cost of significant sedation, most will wish to control pain at a level that still allows maximal functioning. Hospice clinicians regularly report a success rate higher than 90% in relieving pain in terminally ill patients.

Chronic severe pain should be treated continuously. For ongoing pain, one can give a long-acting analgesic around the clock plus a short-acting drug as needed for "breakthrough" pain. At the end of life, the oral route of administration is preferred because it is easier to administer at home, is not painful, and imposes no risk from needle exposure. Rectal, transdermal, and subcutaneous administration are also frequently used, as is intravenous administration when necessary. Patient-controlled analgesia (PCA) of intravenous medications is appreciated by patients, may lead to less medication use, and has been adapted for use with oral administration.

When possible, the cause of pain should be diagnosed and treated, assuming that the burden of these efforts does not increase the patient's suffering. Removing the underlying cause of pain can preempt the need for ongoing treatment with analgesic medications along with their side effects. Regardless of decisions about seeking and treating the underlying cause of pain, however, prompt symptomatic relief of pain should be offered to every patient.

Pharmacologic Pain Management Strategies

Typically, pain can be well controlled with analgesic medications—both opioid and nonopioid. Evidence-based guidelines are available from the Agency for Healthcare Research and Quality and other organizations (<http://www.guideline.gov>). For mild to moderate pain, acetaminophen, aspirin, and nonsteroidal anti-inflammatory drugs (NSAIDs) may be sufficient. For moderate to severe pain, analgesics that include those agents combined with opioids may be helpful. Severe pain typically requires pure opioid agonists.

A. Acetaminophen and NSAIDs

Appropriate doses of acetaminophen may be just as effective as an analgesic and antipyretic as NSAIDs but without anti-inflammatory effects and without the risk of gastrointestinal bleeding or ulceration. Acetaminophen can be given at a dosage of 500-1000 mg orally every 6 hours, though it can be taken every 4 hours as long as the risk of hepatotoxicity is kept in mind. Hepatotoxicity is a concern at doses greater than 4 g/d chronically, and doses for elderly patients and those with liver disease generally should not exceed 2 g/d.

Aspirin (325-650 mg orally every 4 hours) is an effective analgesic, antipyretic, and anti-inflammatory medication. Gastrointestinal irritation and bleeding, bleeding from other sources, allergy, and an association with Reye's syndrome in children and teenagers limit its use.

Commonly used NSAIDs and their dosages are listed in [Table 5-6](#). Like aspirin, the other NSAIDs are antipyretic, analgesic, and anti-inflammatory. NSAIDs inhibit prostaglandin synthesis, inhibiting platelet aggregation and consequently increasing the risk of gastrointestinal bleeding by 1.5 times normal. The risks of bleeding and nephrotoxicity from NSAIDs are both increased in the elderly. Gastrointestinal bleeding and ulceration may be decreased with the concurrent use of proton pump inhibitors (eg, omeprazole, 20-40 mg orally daily) or with the new class of NSAIDs that inhibit only cyclooxygenase-2. COX-2 inhibitors include celecoxib (100 mg/d to 200 mg twice daily orally), rofecoxib (12.5-50 mg/d orally), and valdecoxib (10 mg/d orally). The NSAIDs, including COX-2 inhibitors, can lead to exacerbations of congestive heart failure and should be used with caution in patients with that disorder.

B. Opioid Medications

For many patients at the end of life, opioids are the mainstay of pain management. Opioids are appropriate for severe pain due to any cause. Opioid medications are listed in [Table 5-7](#). Full opioid agonists such as morphine, hydromorphone, oxycodone, methadone, fentanyl, hydrocodone, and codeine are used most commonly. Hydrocodone and codeine are typically combined with acetaminophen or an NSAID. Short-acting formulations of oral morphine sulfate (starting dosage 4 mg orally every 3-4 hours), hydromorphone (1 mg orally every 3-4 hours), or oxycodone (5 mg orally every 3-4 hours) are useful for acute pain and as rescue treatment for patients experiencing pain that breaks through long-acting medications. For chronic stable pain, one should give sustained-release morphine (two or three times a day), oxycodone (two or three times a day), methadone (three or four times a day), or transdermal fentanyl (starting dose 25 ug every 3 days, with 24-40 hours required to achieve full analgesia).

Meperidine is not useful for chronic pain because it has a short half-life and a toxic metabolite that can cause irritability and seizures. Partial agonists such as buprenorphine are limited by a dose-related ceiling effect. Mixed agonist-antagonists such as pentazocine and butorphanol tartrate also have a ceiling effect and are contraindicated in patients already receiving full agonist opioids since they may reverse the pain control achieved by the full agonist and cause a withdrawal effect.

A useful technique for opioid management of chronic pain at the end of life is **equianalgesic dosing** ([Table 5-7](#)). The dosages of any full opioid agonists used to control pain can be translated into an equivalent dose of any other opioid. In this way, 24-hour opioid requirements and dosing regimens established initially using shorter-acting opioid medications can be translated into equivalent dosages of longer-acting medications or formulations. Cross-tolerance is often incomplete, however, so less than the full calculated equianalgesic dosage is generally administered initially when switching between opioid formulations.

While some clinicians and patients inexperienced with the management of severe chronic pain may feel more comfortable with combined nonopioid-opioid agents, because of the toxicities of acetaminophen and NSAIDs at higher doses, full agonist opioids provide more flexibility in dosing and the dose may be increased as required for more effective analgesia. There is no maximal allowable or effective dose for full opioid agonists. The dose should be increased to whatever is necessary to relieve pain, remembering that certain types of pain may respond better to agents other than opioids.

While physiologic tolerance is possible with opioids, failure of a previously effective opioid dose to adequately relieve pain is usually due to an increase in the underlying pain. In this case, for moderate pain, the dosage of opioid can be increased by 25-50%. For severe pain, a dosage increase of 50-100% may be appropriate. The frequency of dosing should be adjusted so that pain control is continuous. In addition, chronic dosing may be adjusted by adding the amount of short-acting opioid necessary for breakthrough pain over the preceding 24 hours to the long-acting medication dose. In establishing or reestablishing adequate dosing, frequent reassessment of the patient's pain and medication side effects is necessary.

As dosages of opioids are increased, increasing difficulty with the side effects of opioids is to be expected. Constipation is common and should be anticipated and prevented in all patients. The prophylaxis and management of opioid-induced constipation are outlined below.

Sedation can be expected with opioids, though tolerance to this effect typically develops within 24-72 hours at a stable dose. Sedation typically appears well before significant respiratory depression. If treatment for sedation is desired, dextroamphetamine (2.5-7.5 mg orally at 8 AM and noon) or methylphenidate (2.5-10 mg orally at 8 AM and noon) may be helpful. Some patients even use caffeinated beverages to help manage minor opioid sedation.

Although sedation is more common, patients may experience euphoria when first taking opioids or when the dosage is increased. However, patients generally develop tolerance to this effect after a few days at a stable dose. At higher doses of opioids, patients may develop multifocal myoclonus. This symptom will typically resolve after lowering the dose or switching opioids. While waiting for the level of the offending medication to fall, low doses of clonazepam or dantrolene may be helpful for treating myoclonus.

Nausea due to opioids may occur with initiation of therapy and resolve after a few days. If it is severe or persistent, it can be treated with prochlorperazine, 10 mg orally or intravenously every 8 hours or 25 mg rectally every 6 hours.

Although clinicians may worry about respiratory depression with opioids, that effect is uncommon when a low dose is given initially and titrated upward slowly. Even patients with pulmonary disease can tolerate low-dose opioids, though they should be monitored carefully. Clinicians should not allow concerns about respiratory depression to prevent them from treating pain adequately.

True allergy (with urticaria) to opioids is rare. More commonly, patients will describe an intolerance due to side effects such as nausea, pruritus, or urinary retention in response to a particular opioid. If such symptoms develop, they can usually be relieved by lowering the dose or switching to another opioid.

C. Neuropathic Pain

Although many types of pain will respond to opioids, neuropathic pain—which patients typically describe as burning, shooting, "pins and needles," or electricity and which is commonly associated with numbness—may respond better to antidepressants (tricyclic antidepressants [TCAs] in particular) and anticonvulsants like gabapentin, clonazepam, and carbamazepine ([Table 5-8](#)). It is therefore essential when taking the history to listen for words that suggest neuropathic pain. The TCAs are a good first choice and usually have an effect within days and at lower doses than are needed for an antidepressant effect. Desipramine, 25-150 mg/d orally, and nortriptyline, 25-150 mg/d orally, are good first choices as they cause less orthostatic hypotension and have fewer anticholinergic effects than amitriptyline. One can start with a low dosage (25 mg orally daily) and titrate upward every 4 or 5 days. Other antidepressant medications such as sustained-release bupropion may also be effective for neuropathic pain; however, the selective serotonin reuptake inhibitors (SSRIs) are not.

The anticonvulsants can be used in the same dosages as are used to prevent seizures. Because carbamazepine can cause bone marrow suppression, a complete blood count is obtained periodically in patients taking this drug. Gabapentin can cause sedation, dizziness, ataxia, and gastrointestinal side effects and therefore should be started at low dosages of 100-300 mg orally three times a day. The dose of gabapentin can be titrated upward by 300 mg/d every 4 or 5 days to a dosage of 3600 mg/d or higher. Gabapentin is relatively safe in accidental overdosage and may be preferred over TCAs for a patient with a history of congestive heart failure or arrhythmia or if there is a risk of suicide.

Other medication classes may be effective for neuropathic pain as well. The lidocaine patch is effective in postherpetic neuralgia and may be effective in other types of neuropathic pain also. A new patch is applied to the painful region daily. Mexiletine at a starting dosage of 150 mg orally once or twice a day can also be used for treating neuropathic pain but should be avoided in patients with arrhythmias. The dosage can be increased slowly to a maximum of 300 mg orally three times daily if side effects such as nausea, vomiting, tremor, dizziness, unsteadiness, and paresthesias do not limit dosing. Baclofen can be helpful for treating lancinating or paroxysmal neuropathic pain. Side effects including dizziness, somnolence, and gastrointestinal distress can be mitigated by starting at a low dosage (5 mg orally two or three times daily) and titrating slowly upward to a dosage of 30-90 mg/d. Because abrupt withdrawal from baclofen can cause a syndrome that includes delirium and seizures, the drug should be tapered slowly before being discontinued.

D. Adjuvant Pain Medications and Treatments

If pain cannot be controlled without uncomfortable medication side effects, clinicians should consider using lower doses of multiple medications rather than larger doses of one or two medications. This may be particularly true for neuropathic pain. For bone pain, the anti-inflammatory effect of NSAIDs can be particularly helpful. Radiation therapy and bisphosphonates may also relieve bone pain. For some patients, such as those with pain from pancreatic cancer, a nerve block—in this case, block of the celiac plexus—can provide dramatic relief. Intrathecal pumps may be useful for patients with severe pain responsive to opioids but who require such large doses that systemic side effects such as sedation and constipation become limiting. Neurolysis, rhizotomy, or ablative surgery and neurosurgery may be tried in selected patients. Cannabinoids have not been proven to work as analgesics. Chemotherapeutic agents are sometimes used for symptom management with palliative intent.

Corticosteroids such as dexamethasone or prednisone can be helpful for patients with headache due to increased intracranial pressure, pain from spinal cord compression, metastatic bone pain, and neuropathic pain due to invasion or infiltration of nerves by tumor. Because of the side effects of long-term corticosteroid administration, they are most appropriate in patients with end-stage disease.

Nonpharmacologic Treatments

Nonpharmacologic therapies are also valuable in treating pain. Hot or cold packs, massage, and physical therapy can be helpful for musculoskeletal pain. Similarly, biofeedback, acupuncture, chiropractic, meditation, music therapy, cognitive behavioral therapy, guided imagery, cognitive distraction, and framing may be of help in treating pain. Because mood and psychologic issues play an important role in the patient's perception of and response to pain, psychotherapy, support groups, prayer, and pastoral counseling can also help in the management of pain. Major depression, which may be instigated by chronic pain or may alter the response to pain, should be treated aggressively.

DYSPNEA

Dyspnea is the subjective experience of difficulty in breathing and may be characterized by patients as tightness in the chest, shortness of breath, or a feeling of suffocation. Dyspnea is common among dying patients—up to one-half of severely ill patients may experience severe dyspnea.

Treatment of dyspnea is usually first directed at the cause, which may be related to pneumonia, pulmonary embolism, pleural effusion, bronchospasm, tracheal obstruction, neuromuscular disease, restriction of movement of the chest or abdominal walls, cardiac ischemia, congestive heart failure, superior vena cava syndrome, or severe anemia.

At the end of life, dyspnea is often treated nonspecifically with opioids. Immediate-release morphine, preferably via the oral or buccal route, treats dyspnea effectively and typically at doses lower than would be necessary for the relief of moderate pain. Supplemental oxygen may be useful for the dyspneic patient who is hypoxic and may provide subjective benefit to other dyspneic patients as well. However, a nasal cannula and face mask are sometimes not well tolerated, and fresh air from a window or fan may provide relief. Judicious use of nonpharmacologic relaxation techniques such as meditation and guided imagery may be beneficial for some patients. Benzodiazepines may be useful for the anxiety associated with dyspnea but do not appear to act directly to relieve dyspnea.

NAUSEA & VOMITING

Nausea and vomiting are common and distressing symptoms. As with pain, the management of nausea may be maximized by continuous dosing. An understanding of the four major inputs to the vomiting center may help direct treatment (see [Chapter 14](#)).

The chemoreceptor trigger zone may be stimulated by certain drugs (eg, morphine, NSAIDs), metabolic derangements, and chemotherapeutic agents. Vomiting associated with a particular opioid may be avoided by substitution with an equianalgesic dose of another opioid or a sustained-release formulation. In addition to the other dopamine receptor antagonist antiemetics listed in [Table 14-2](#) that block the trigger zone, haloperidol (0.5-5 mg orally every 4-6 hours) is commonly used. Vomiting associated with chemotherapy may respond to agents such as ondansetron, granisetron, and dolasetron.

Vomiting may be due to stimulation of peripheral afferent nerves from the gut. Offering patients small amounts of food only when they are hungry may prevent nausea and vomiting. Nasogastric suction may provide rapid, short-term relief for vomiting associated with constipation, gastroparesis, or gastric outlet obstruction, with the addition of laxatives, prokinetic agents (metoclopramide, 10-20 mg orally or intravenously four times a day), scopolamine (1.5-mg patch every 3 days), and high-dose corticosteroids as more definitive treatment. Treatment with high-dose corticosteroids (eg, dexamethasone, 20 mg orally or intravenously) or cyclizine (5 mg orally every 8 hours) may be useful for nausea and vomiting due to disease of intra-abdominal or pelvic organs.

Increased intracranial pressure may cause vomiting and may be relieved with high-dose corticosteroids or palliative cranial radiation. Vomiting due to disturbance of the vestibular apparatus may be treated with anticholinergic and antihistaminic agents (including diphenhydramine, 25 mg orally or intravenously every 8 hours, or scopolamine, 1.5-mg patch every 3 days).

The beneficial effects of benzodiazepines for vomiting may derive less from any primary antiemetic action than from their sedative and amnestic effects in the setting of anticipatory vomiting, and for that reason they should rarely be used alone for the relief of nausea.

Finally, many patients find dronabinol (2.5-20 mg orally every 4-6 hours) helpful in the management of nausea and vomiting.

CONSTIPATION

Given the frequent use of opioids, poor dietary intake, and physical inactivity, constipation is a common problem among the dying. Clinicians must inquire about any difficulty with hard or infrequent stools. Constipation is an easily treatable cause of discomfort and distress (see [Chapter 14](#)).

Constipation may be prevented or relieved if patients can increase their activity and their intake of dietary fiber and fluids. Simple considerations such as privacy, undisturbed toilet time, and a bedside commode rather than a bedpan may be important for some patients.

For patients taking opioids, anticipating and preventing constipation is important. A prophylactic bowel regimen of stool softeners (docusate) and stimulants (bisacodyl or senna) should be started when opioid treatment is begun. Lactulose, sorbitol, magnesium citrate, and enemas can be added as needed ([Table 14-4](#)).

DELIRIUM & AGITATION

Many terminally ill patients die in a state of delirium—a disturbance of consciousness and a change in cognition that develops over a short time and is manifested by misinterpretations, illusions, hallucinations, disturbances in the sleep-wake cycle, psychomotor disturbances (eg, lethargy, restlessness), and mood disturbance (eg, fear, anxiety). Delirium complicated by myoclonus or convulsions at the end of life has been called **terminal restlessness**.

Careful attention to patient safety and nonpharmacologic strategies to help the patient remain oriented (clocks, calendars, a familiar environment, reassurance and redirection from caregivers) may be sufficient to prevent or manage minor delirium. Some delirious patients may be "pleasantly confused," and a decision by the patient's family and the clinician not to treat delirium may be justified.

More commonly, however, delirium at the end of life is distressing to patients and family and requires treatment. Delirium may interfere with the family's ability to feel comforting to the patient and may prevent a patient from being able to recognize and report important symptoms.

While there are many reversible causes of delirium (see [Chapter 25](#)), identifying and correcting the underlying cause at the end of life is often simply a question of attention to the choice and dosing of psychoactive medications.

When the cause of delirium cannot be identified, treated, or corrected rapidly enough, delirium may be treated symptomatically with neuroleptics. Haloperidol (1-10 mg orally, subcutaneously, intramuscularly, or intravenously twice or three times a day) is used commonly, but significant extrapyramidal adverse effects may occur. Newer agents such as risperidone (1-3 mg orally twice a day) also may be helpful in delirium.

As an adjuvant to the above neuroleptics, especially in the setting of anxiety, benzodiazepines such as lorazepam (0.5-2 mg orally, sublingually, subcutaneously, or intravenously every 4-6 hours) may be useful. When delirium is refractory to treatment and remains intolerable, sedation may be required to provide relief and may be achieved rapidly with midazolam (0.5-5 mg/h subcutaneously or intravenously) or barbiturates.

■ OTHER SPECIFIC TASKS OF CARING

NUTRITION & HYDRATION

Tube feedings do not prevent aspiration pneumonia, and there is debate about whether artificial nutrition prolongs life in the terminally ill. In fact, there has been a growing awareness of the potential medical benefits of forgoing unwanted or artificial nutrition and hydration (including tube feedings, parenteral nutrition, and intravenous hydration) at the end of life.

Eating without hunger and artificial nutrition are associated with a number of potential complications. Force feeding may cause nausea and vomiting in ill patients, and eating will lead to diarrhea in the setting of malabsorption. Nutrition may increase oral and airway secretions and the risk of choking, aspiration, and dyspnea. Nasogastric and gastrostomy tube feeding and total parenteral nutrition impose risks of infection, epistaxis, pneumothorax, electrolyte imbalance, and aspiration—as well as the need to physically restrain the delirious patient to prevent dislodgment of catheters and tubes.

Withholding nutrition at the end of life causes remarkably little hunger or distress. Ill people often have no hunger with total caloric deprivation, and the associated ketonemia produces a sense of well-being, analgesia, and mild euphoria. However, carbohydrate intake even in small amounts (such as that provided by 5% intravenous dextrose solution) blocks ketone production and may blunt the positive effects of total caloric deprivation.

Withholding hydration may lead to death in a few days to a month. The quality of life for those at the end of life may be adversely affected by supplemental hydration because of its contribution to oral and airway secretions (leading to aspiration or the "death rattle"), polyuria, and the development or worsening of ascites, pleural or other effusions, and peripheral and pulmonary edema.

Although it is unclear to what extent withholding hydration at the end of life creates an uncomfortable sensation of thirst, any such sensation is usually relieved by simply moistening the dry mouth. Ice chips, hard candy, swabs, or a solution of equal parts nystatin solution, viscous lidocaine, diphenhydramine, and minted mouthwash is effective.

Individuals at the end of life have a right to refuse nutrition and hydration. However, providing or withholding oral food and water is not simply a medical decision since doing so may have profound social and cultural significance for patients, families, and clinicians themselves. Withholding supplemental enteral or parenteral nutrition and hydration challenges the assumption that offering food is an expression of compassion and love. In fact, individuals at the end of life who choose to forgo nutrition and hydration are unlikely to suffer from hunger or thirst. Family and friends can be encouraged to express their love and caring in ways other than intrusive attempts at forced feeding or hydration.

WITHDRAWAL OF CURATIVE EFFORTS

Requests from appropriately informed and competent patients or their surrogates for withdrawal of life-sustaining interventions must be respected. The clinician receiving such requests should recognize and explore the significance of this change in health care goals. Alternatively, clinicians may determine unilaterally that further intervention is medically inappropriate—eg, continuing renal dialysis in a patient dying of multi-organ failure. In such cases, the clinician's intention to withdraw a specific intervention should be communicated to the patient and family. If differences of opinion exist about the professional propriety of what is being done, the assistance of an institutional ethics committee should be sought.

Limitation of life support prior to death is an increasingly common practice in intensive care units. The withdrawal of life-sustaining interventions such as mechanical ventilation must be approached carefully to avoid needless patient suffering and distress for those in attendance. Clinicians should educate the patient and family about the expected course of events and the difficulty of determining the precise timing of death after withdrawal of support. Sedative and analgesic agents should be administered to ensure patient comfort even at the risk of respiratory depression or hypotension. Scopolamine (10 ug/h subcutaneously or intravenously, or a 15-mg patch every 3 days) or atropine (1% ophthalmic solution, 1 or 2 drops sublingually as often as every hour) can be used for controlling airway secretions and the resultant "death rattle." A guideline for withdrawal of mechanical ventilation is provided in [Table 5-9](#).

PSYCHOLOGIC, SOCIAL, & SPIRITUAL ISSUES

Dying is not exclusively or even primarily a biomedical event. It is an intimate personal experience with profound psychologic, interpersonal, and existential meanings. For many people at the end of life, the prospect of impending death stimulates a deep and urgent assessment of their identity, the quality of their relationships, and the meaning and purpose of their existence. As Ira Byock, a national leader in end-of-life care, has observed, while the relief of physical symptoms is the "first priority" in caring for patients at the end of life, the "ultimate goal" remains helping patients to die well.

Psychologic Challenges

In 1969, Elisabeth Kubler-Ross identified five psychologic stages or patterns of emotions that patients at the end of life may experience: denial and isolation, anger, bargaining, depression, and acceptance. Not every patient will experience these emotions, and not necessarily in an orderly progression. In addition to these five stages are the perpetual challenges of anxiety and fear of the unknown. Simple information, listening, assurance, and support may help patients with these psychologic challenges. In fact, patients and families rank emotional support as one of the most important aspects of good end-of-life care. Psychotherapy and group support may be beneficial as well.

Despite the significant emotional stress of facing death, clinical depression is not normal at the end of life and should be treated. Cognitive and affective signs of depression (such as hopelessness) may help distinguish depression from the low energy and other vegetative signs common with end-stage illness. Although traditional antidepressant treatments such as selective serotonin reuptake inhibitors are effective, more rapidly acting medications such as dextroamphetamine or methylphenidate may be particularly useful when the end of life is near.

Social Challenges

At the end of life, patients should be encouraged to discharge personal, professional, and business obligations. This might include completing important work or personal projects, distributing possessions, writing a will, and making funeral and burial arrangements. The prospect of death often prompts patients to examine the quality of their interpersonal relationships, including the relationship with the clinician. Dying may intensify a patient's need to feel cared for by the doctor, highlighting the clinician's obligation of nonabandonment and the need for clinician empathy and compassion. Concern about estranged relationships or "unfinished business" with significant others and interest in reconciliation may become paramount at this time. At the end of life, even healthy interpersonal relationships must reach completion ([Table 5-10](#)).

Spiritual Challenges

Spirituality is the attempt to understand or accept the underlying meaning of life, one's relationships to oneself and other people, one's place in the universe, and the possibility of a "higher power" in the universe. Spirituality is distinguished from particular religious practices or beliefs and is generally considered a universal human concern.

Perhaps because of an inappropriately exclusive attention to the biologic challenge of forestalling death or perhaps from feelings of discomfort or incompetence, clinicians frequently ignore their patients' spiritual concerns or reflexively refer these important issues to psychiatrists or other caretakers (nurses, social workers, clergy). However, the existential challenges of dying are central to the well-being of people at the end of life and are the proper concern of clinicians. Within a biologic, psychosocial, and spiritual model of medical care, clinicians may work to provide more than simple physical comfort and control of bothersome symptoms. Clinicians can help patients to die well by providing care to the whole person—by providing physical comfort and social support and by helping patients discover their own unique

meaning in the world and an acceptance of death as a part of life.

Unlike physical ailments such as infections and fractures, which usually require a clinician's intervention to be treated, the patient's spiritual concerns often require only a clinician's attention, listening, and witness. Clinicians might choose to inquire about the patient's spiritual concerns and ask whether the patient wishes to discuss them. For example, asking, "How are you within yourself?" communicates that the clinician is interested in the patient's whole experience and provides an opportunity for the patient to share perceptions about his or her inner life. Questions that might constitute an existential "review of systems" are presented in [Table 5-11](#).

Attending to the spiritual concerns of patients calls for listening to their stories. Story-telling gives patients the opportunity to verbalize what is meaningful to them and to leave something of themselves behind—the promise of being remembered. Story-telling may be facilitated by suggesting that the patient share his or her life story with family members, record it on audio or video tape, assemble a photo album, organize a scrapbook, or write an autobiography.

While dying may be a period of inevitable loss of physical functioning, the end of life also offers an opportunity for psychologic, interpersonal, and spiritual development. Individuals may grow—even achieve a heightened sense of well-being or transcendence—in the process of dying. Through listening, support, and presence, clinicians may help foster this learning and be a catalyst for this transformation. Rather than thinking of dying simply as the termination of life, clinicians and patients may be guided by a developmental model of dying that recognizes a series of lifelong developmental tasks and landmarks and allows for growth at the end of life.

■ TASKS AFTER DEATH

After the death of a patient, the clinician is called upon to perform a number of tasks, both required and recommended. The clinician must plainly and directly inform the family of the death. Providing words of sympathy and reassurance, time for questions and initial grief, and a quiet private room for the family at this time is appropriate and much appreciated.

THE PRONOUNCEMENT & DEATH CERTIFICATE

In most states of the United States, clinicians are legally required to confirm the death of a patient in a formal process called "pronouncement." The clinician must verify the absence of spontaneous respirations and cardiac activity and the presence of fixed and dilated pupils. A note describing these findings and the time of death is entered in the patient's chart.

While the pronouncement may often seem like an awkward and unnecessary formality, clinicians may use this time to reassure the patient's loved ones at the bedside that the patient died peacefully and that all appropriate care had been given. Both clinicians and families may use the ritual of the pronouncement as an opportunity to begin to process emotionally the death of the patient.

Accurately reporting the underlying cause of death on the death certificate is also legally required and important both for patients' families (for insurance purposes and the need for an accurate family medical history) and for the epidemiologic study of disease and public health. Physicians are untrained in and unskilled at correctly completing death certificates. The physician should be specific about the major cause of death (eg, "decompensated cirrhosis") and its contributory cause (eg, "hepatitis B and hepatitis C infections and chronic alcoholic hepatitis") as well as any associated conditions (eg, "acute renal failure")—and not simply put down "cardiac arrest" as the cause of death.

AUTOPSY & ORGAN DONATION

Discussing the options and obtaining consent for autopsy and organ donation with patients themselves prior to death is usually the best practice. This advances the principle of patient autonomy and lessens the responsibilities of distressed family members during the period immediately following the death. After a patient dies, however, designated organ transplant personnel are more successful than the treating clinicians at obtaining consent for organ donation from surviving family members. Federal regulations now require that a designated representative of an organ procurement organization approach the family about organ donation. Most people in the United States support the donation of organs for transplants. Currently, however, organ transplantation is severely limited by the availability of donor organs. Many potential donors and the families of actual donors experience a sense of reward in contributing, even through death, to the lives of others.

Clinicians must be sensitive to ethnic and cultural differences in attitudes about autopsy and organ donation. Patients or their families should be reminded of their right to limit autopsy or organ donation in any way they choose. Pathologists can perform autopsies without interfering with funeral plans or the appearance of the deceased.

The results of an autopsy may help surviving family members (and clinicians) understand the exact cause of a patient's death and foster a sense of closure. A clinician-family conference to review the results of the autopsy provides a good opportunity for clinicians to assess how well families are grieving and to answer questions. Despite the advantages of conducting postmortem examinations, autopsy rates have fallen drastically to less than 15% today. Families report refusing autopsies out of fear of disfigurement of the body or delay of the funeral—or say they were simply not asked. They allow autopsies in order to advance medical knowledge, to identify the exact cause of their loved one's death, and to be reassured that appropriate care was given. Routinely addressing these issues when discussing autopsy may help increase the autopsy rate; the most important mistake is the failure to ask for permission to perform it.

FOLLOW-UP & GRIEVING

Proper care of patients at the end of life includes following up with surviving family members after the patient has died. Following up enables the clinician to assess how families are grieving, to reassure them about the nature of normal grieving, and to identify complicated grief or depression. Clinicians can recommend support groups and counseling as needed. A card or telephone call from the clinician to the family days to weeks after the patient's death (and perhaps on the anniversary of the death) allows the clinician to express concern for the family and the deceased.

After a patient dies, the clinician too may need to grieve. Although clinicians may be relatively unaffected by the deaths of some patients, other deaths may cause distressing feelings of sadness, loss, and guilt. These emotions should be recognized as the first step toward processing them or preventing them in the future.

For clinicians, grieving the loss of a patient is normal. Each clinician may find personal or communal resources that help with the process of grieving. Shedding tears, the support of colleagues, time for reflection, and traditional or personal mourning rituals all may be effective. Attending the funeral of a patient who has died can be a satisfying personal experience that is almost universally appreciated by families and that may be the final element in caring well for people at the end of life.

Table 5-5. Recommended clinical approach to pain management.¹

Ask about pain regularly. Assess pain systematically (quality, description, location, intensity or severity, aggravating and ameliorating factors, cognitive responses). Ask about goals for pain control, management preferences.

Believe the patient and family in their reports of pain and what relieves it.

Choose pain control options appropriate for the patient, family, and setting. Consider drug type, dosage, route, contraindications, side effects. Consider nonpharmacologic adjunctive measures.

Deliver interventions in a timely, logical, coordinated manner.

Empower patients and their families. Enable patients to control their course to the greatest extent possible.

Follow up to reassess persistence of pain, changes in pain pattern, development of new pain.

Table 5-6. Useful nonsteroidal anti-inflammatory drugs.¹

Drug	Usual Dose for Adults = 50 kg	Usual Dose for Adults < 50 kg ²	Cost per Unit	Cost for 30 Days ³	Comments ⁴
Acetaminophen ⁵ (Tylenol, Datril, etc)	650 mg q4h or 975 mg q6h	10-15 mg/kg q4h (oral); 15-20 mg/kg q4h (rectal)	\$0.04/325 mg (oral) OTC \$0.50/325 mg (rectal) OTC	\$14.40 (oral) \$180.00 (rectal)	Not an NSAID because it lacks peripheral anti-inflammatory effects. Equivalent to aspirin as analgesic and antipyretic agent.
Aspirin ⁶	650 mg q4h or 975 mg q6h	10-15 mg/kg q4h (oral); 15-20 mg/kg q4h (rectal)	\$0.03/325 mg OTC \$0.24/300 mg (rectal) OTC	\$10.80 (oral) \$86.40 (rectal)	Available also in enteric-coated form that is more expensive and more slowly absorbed but better tolerated.
Celecoxib ⁵ (Celebrex)	200 mg qd (osteoarthritis), 100-200 mg bid (rheumatoid arthritis)	100 mg qd-bid	\$1.58/100 mg \$2.76/200 mg	\$82.80 OA; \$165.60 RA	Cyclooxygenase 2 inhibitors. No antiplatelet effects. Lower doses for elderly who weigh < 50 kg. Lower incidence of endoscopic gastrointestinal ulceration. Not known if true lower incidence of gastrointestinal bleeding. Celecoxib contraindicated in sulfonamide allergy.
Valdecoxib (Bextra)	10 mg qd for OA or RA	10 mg qd	\$2.92/10 mg or 20 mg	\$87.60	
Rofecoxib ⁵ (Vioxx)	12.5-25 mg qd for OA	12.5 mg qd	\$2.76/12.5 mg \$2.76/25 mg	\$82.80 OA	
Choline magnesium salicylate ⁷ (Trilasate)	1000-1500 mg tid	25 mg/kg tid	\$0.68/500 mg	\$183.60	Salicylates cause less gastrointestinal distress and renal impairment than NSAIDs but are probably less effective in pain management than NSAIDs.
Choline salicylate ⁷ (Arthropan)	870 mg q3-4h		\$48.93/480 mL; 174 mg/mL OTC	\$98.00	Minimal antiplatelet effects.
Diclofenac (Voltaren, Cataflam, others)	50-75 mg bid-tid		\$0.91/50 mg, \$1.06/75 mg	\$81.90 \$95.40	May impose higher risk of hepatotoxicity. Low incidence of gastrointestinal side effects. Enteric-coated product, slow onset.
Diclofenac Sustained Release (Voltaren-XR)	100-200 mg qd		\$4.20/100 mg	\$252.00	
Diflunisal ⁸ (Dolobid)	500 mg q12h		\$1.29/500 mg	\$77.40	Fluorinated acetylsalicylic acid derivative.
Etodolac (Lodine)	200-400 mg q6-8h		\$1.42/300 mg	\$170.40	Perhaps less gastrointestinal toxicity.
Fenoprofen calcium (Nalfon)	300-600 mg q6h		\$0.47/300 mg or 600 mg	\$56.40	Perhaps more side effects than others, including tubulointerstitial nephritis.
Flurbiprofen (Ansaid)	50-100 mg tid-qid		\$0.79/50 mg, \$1.19/100 mg	\$94.80 \$142.80	Adverse gastrointestinal effects may be more common among elderly.
Ibuprofen (Motrin, Advil, Rufen, others)	400-800 mg q6h	10 mg/kg q6-8h	\$0.20/400 mg Rx \$0.28/600 mg Rx \$0.05/200 mg OTC	\$48.00 \$33.60 \$9.00	Relatively well tolerated. Less gastrointestinal toxicity.
Indomethacin (Indocin, Indometh, others)	25-50 mg bid-qid		\$0.37/25 mg; \$0.63/50 mg	\$44.40 \$75.60	Higher incidence of dose-related toxic effects, especially gastrointestinal and bone marrow effects.
Ketoprofen (Orudis, Oruvail, others)	25-50 mg q6-8h (max 300 mg/d)		\$0.96/50 mg Rx \$1.07/75 mg Rx \$0.10/12.5 mg OTC	\$172.80 \$128.40 \$18.00	Lower doses for elderly.
Ketorolac tromethamine (Toradol)	10 mg q4-6h to a maximum of 40 mg/d PO		\$0.93/10 mg	Not recommended	Short-term use (< 5 days) only; otherwise, increased risk of gastrointestinal side effects.
Ketorolac tromethamine ⁹ (Toradol)	60 mg initially, then 30 mg q6h IM		\$7.40/30 mg	Not recommended	Intramuscular NSAID as alternative to opioid. Lower doses for elderly. Short-term use (< 5 days) only.
Magnesium salicylate (various)	650 mg q4h		\$0.17/325 mg OTC	\$40.80	
Meclofenamate sodium ¹⁰ (Meclomen)	50-100 mg q6h		\$3.40/100 mg	\$408.00	Diarrhea more common.
Mefenamic acid (Ponstel)	250 mg q6h		\$1.39/250 mg	\$166.80	
Nabumetone (Relafen)	500-1000 mg once daily (max dose 2000 mg/d)		\$1.30/500 mg \$1.53/750 mg	\$137.70	May be less ulcerogenic than ibuprofen, but overall side effects may not be less.
Naproxen (Naprosyn, Anaprox, Aleve [OTC], others)	200-500 mg q6-8h	5 mg/kg q8h	\$1.16/500 mg Rx \$0.10/220 mg OTC	\$104.40 \$9.00 OTC	Generally well tolerated. Lower doses for elderly.
Oxaprozin (Daypro)	600-1200 mg once daily		\$1.51/600 mg	\$90.60	Similar to ibuprofen. May cause rash, pruritus, photosensitivity.
Piroxicam (Feldene)	20 mg daily		\$2.64/20 mg	\$79.20	Single daily dose convenient. Long half-life. May cause higher rate of gastrointestinal bleeding and dermatologic side effects.
Sodium salicylate	325-650 q3-4h		\$0.06/650 mg OTC	\$14.40	
Sulindac (Clinoril)	150-200 mg bid		\$0.98/150 mg; \$1.21/200 mg	\$58.80 \$72.60	May cause higher rate of gastrointestinal bleeding. May have less nephrotoxic potential.
Tolmetin (Tolectin)	200-600 mg qid		\$0.65/200 mg; \$1.30/600 mg	\$78.00 \$156.00	Perhaps more side effects than others, including anaphylactic reactions.

OTC = over-the-counter; Rx = prescription; OA = osteoarthritis; RA = rheumatoid arthritis.

¹Modified from Jacox AK et al: Management of Cancer Pain: Quick Reference Guide for Clinicians No. 9. AHCPR Publication No. 94-0593. Rockville, MD: Agency for Health Care Policy and Research, Public Health Service, U.S. Department of Health and Human Services. March 1994.

²Acetaminophen and NSAID dosages for adults weighing less than 50 kg should be adjusted for weight.

³Cost to pharmacist (average wholesale price, generic when possible) for quantity listed. Source: *Drug Topics Red Book*, May 2003; Vol. 22, No. 5.

⁴The adverse effects of headache, tinnitus, dizziness, confusion, rashes, anorexia, nausea, vomiting, gastrointestinal bleeding, diarrhea, nephrotoxicity, visual disturbances, etc, can occur with any of these drugs. Tolerance and efficacy are subject to great individual variations among patients. Note: All NSAIDs can increase serum lithium levels.

⁵Acetaminophen, celecoxib, rofecoxib, and valdecoxib lack the antiplatelet activities of other NSAIDs.

⁶May inhibit platelet aggregation for 1 week or more and may cause bleeding.

⁷May have minimal antiplatelet activity.

⁸Administration with antacids may decrease absorption.

⁹Has the same gastrointestinal toxicities as oral NSAIDs.

¹⁰Coombs-positive autoimmune hemolytic anemia has been associated with prolonged use.

¹Modified from Jacox AK et al: Management of Cancer Pain: Quick Reference Guide for Clinicians No. 9. AHCPR Publication No. 94-0593. Rockville, MD. Agency for Health Care Policy and Research, U.S. Department of Health and Human Services. March 1994. Reproduced in part from Hosp Formul 1994;29(8 Part 2):586. (Erstad BL: A rational approach to the management of acute pain. J Clin Pharm Ther 1994;19:1-10. Blackwell Science, Ltd, Oxford, UK. 1994. Communications, Inc.

²Published tables vary in the suggested doses that are equianalgesic to morphine. Clinical response is the criterion that must be applied for each patient; titration to clinical efficacy is required. Because of cross-tolerance among these drugs, it is usually necessary to use a lower than equianalgesic dose initially when changing drugs and to retitrate to response.

³**Caution:** Recommended doses do not apply for adult patients with renal or hepatic insufficiency or other conditions affecting drug metabolism.

⁴**Caution:** For morphine, hydromorphone, and oxymorphone, rectal administration is an alternative route for patients unable to take oral medications. Equianalgesic doses may differ from oral doses. Opioid should normally be used for initial therapy.

⁵Not recommended for chronic pain. Doses listed are for brief therapy of acute pain only. Switch to another opioid for long-term therapy.

⁶**Caution:** Doses of aspirin and acetaminophen in combination products must also be adjusted to the patient's body weight (Table 5-6).

⁷**Caution:** Doses of codeine above 60 mg often are not appropriate because of diminishing incremental analgesia with increasing doses but continually increasing nausea, constipation, and sedation.

⁸**Caution:** Monitor total acetaminophen dose carefully, including any OTC use. Total acetaminophen dose maximum 4 g/d. If liver impairment or heavy alcohol use, maximum is 2 g/d.

Table 5-9. Guidelines for withdrawal of mechanical ventilation.¹

1. Stop neuromuscular blocking agents.

2. Administer opioids or sedatives to eliminate distress.

If not already sedated, begin with fentanyl 100 µg (or morphine sulfate 10 mg) by intravenous bolus and infusion of fentanyl 100 µg per hour intravenously (or morphine sulfate 10 mg per hour intravenously).

Distress is indicated by RR > 24, nasal flaring, use of accessory muscles of respiration, HR increase > 20%, MAP increase > 20%, grimacing, clutching.

3. Discontinue vasoactive agents and other agents unrelated to patient comfort, such as antibiotics, intravenous fluids, and diagnostic procedures.

4. Decrease FiO₂ to room air and PEEP to 0 cm H₂O.

5. Observe patient for distress.

If patient is distressed, increase opioids by repeating bolus dose and increasing hourly infusion rate by 50 µg fentanyl (or 5 mg morphine sulfate),² then return to observation.

If patient is not distressed, place on T piece and observe.

If patient continues without distress, extubate patient and continue to observe for distress.

¹Adapted, with permission, from San Francisco General Hospital Guidelines for Withdrawal of Mechanical Ventilation/Life Support.

²Ventilatory support may be increased until additional opioids have effect.

DIAGNOSIS OF SKIN DISORDERS

Morphology

Every skin disease produces a characteristic primary skin lesion. This chapter will group diseases according to the types of lesions they cause and guide the reader through the history, physical findings, and laboratory tests that discriminate among the differential diagnoses.

History

A detailed history is important, though in the case of skin cancer or moles (nevi) the physical examination takes precedence. Important components of a history include systemic disorders; prescription, OTC and alternative systemic and topical medications; and exposure to physical and chemical agents in the home and work environments.

Physical Examination

It is best to examine the entire skin surface, including the nails, scalp, palms, soles, and mucous membranes, in bright (preferably natural) light. Total skin examination allows recognition of typical disease patterns and ensures that no potentially important lesions are overlooked. In examining the face for nonmelanoma skin cancer, special attention should be paid to the lid margins, nose, ears, and lips—areas of sun exposure.

PRINCIPLES OF DERMATOLOGIC THERAPY

Planning Topical Treatment

In general, it is better to be familiar with a few dermatologic drugs and treatment methods than to attempt to use a great many. Inappropriate chronic use of a topical corticosteroids may cause irreversible side effects.

Frequently Employed Treatment Measures

A. Bathing

Soap should be used only in the axillae and groin and on the feet by persons with dry or irritated skin. Soaking in water for 10-15 minutes before applying topical corticosteroids enhances their efficacy.

B. Topical Therapy

In general, topical agents used by prescription are supplied in only one strength, and thus, with the exception of [Table 6-1](#), concentrations will not be listed in this chapter. Exceptions include hydrocortisone (1% and 2.5%); triamcinolone acetonide cream and ointment (0.025% and 0.1%) or solution (0.1%); and fluocinolone cream, ointment, or solution (0.01%), or cream and ointment (0.025%). There is little evidence that one concentration has clinical effects that are significantly different from another. Nondermatologists should become familiar with a few agents and use them properly rather than try to master the universe of topical agents. All useful antifungals come in only one strength.

1. Corticosteroids—Representative topical corticosteroid creams, lotions, ointments, gels, and sprays are presented in [Table 6-1](#). Specific indications for topical steroid therapy will be discussed in the context of specific dermatologic entities. However, a few basic principles of topical steroid therapy should be mentioned here. Topical steroids are divided into classes based on their potency. There is little (except price) to recommend one agent over another within the same class. For a given agent, an ointment is more potent than a cream; however, ointments are generally more greasy. The potency of a topical steroid may be dramatically increased by applying an occlusive dressing over the steroid. Such dressings may include gloves, plastic wrap, or plastic occlusive suits for patients with generalized erythroderma or atopy. Caution should be used in applying topical steroids to areas of thin skin (face, scrotum, vulva, skin folds). Topical steroid use on the eyelids may result in glaucoma or cataracts. One may estimate the amount of topical steroid needed by using the "rule of nines" (as in burn evaluation; see [Figure 38-3](#)). In general, it takes an average of 20-30 g to cover the body surface of an adult once. Systemic absorption does occur, but adrenal suppression, diabetes, hypertension, osteoporosis, and other complications of systemic steroids are very rare with topical steroid therapy.

2. Emollients for dry skin ("moisturizers")—Dry skin is not related to water intake but to abnormal function of the epidermis. Many types of emollients are available. Petrolatum, mineral oil, Aquaphor, and Eucerin cream are the heaviest and best. Emollients are most effective when applied to wet skin immediately after a bath. They should be applied with the "grain" of the hairs rather than by rubbing up and down to avoid folliculitis. If the skin is too greasy after application, pat dry with a damp towel.

In some cases, lotions may be useful and are not as greasy as creams and ointments. The appearance of dry skin and ichthyosis may be improved by lactic acid products (Lac-Hydrin, U-Lactin) or glycolic acid-containing lotions (Aqua Glycolic) provided no inflammation (erythema or pruritus) is present. Moisturizers that mimic the skin's normal lipids and thus feel less greasy than ointments include SBR Lipocream and Triceram Cream.

3. Drying agents for weepy dermatoses—If the skin is weepy from infection or inflammation, drying agents may afford relief. The best drying agent is water, and repeated compresses, with or without such agents as aluminum salts (Burow's solution, Domeboro tablets) or colloidal oatmeal (Aveeno) are a good first step. Shake lotions (eg, starch or calamine lotions) and powders (especially if the process is acute) may result in messy crusts and are seldom used by dermatologists.

4. Topical antipruritics—Lotions that contain 0.5% each of camphor and menthol (Sarna) are effective for mild pruritic dermatoses. Pramoxine hydrochloride, 1% cream or lotion, or pramoxine hydrochloride, 1%, with 0.5% menthol, as a surface anesthetic may be an effective antipruritic agent (Prax, PrameGel, Aveeno Anti-Itch lotion). Hydrocortisone, 1% or 2.5%, may be incorporated for its anti-inflammatory effect (Pramosone cream, lotion, or ointment). Doxepin cream 5% may reduce pruritus due to eczematous dermatoses. It appears most effective when applied together with a topical steroid of the appropriate class for the condition or site being treated. Like pramoxine, it is a steroid enhancer, improving response to a given strength of topical steroid. Drowsiness and dry mouth may occur. Monoamine oxidase inhibitors should be discontinued at least 2 weeks before treatment.

5. Systemic antipruritic drugs—

a. Antihistamines—H₁ blockers are the agents of choice for pruritus when due to histamine, such as in urticaria. Otherwise, they appear to relieve pruritus only by their sedating and not their antihistamine effects. Except in the case of urticaria, nonsedating antihistamines are of little or no value in inflammatory skin diseases such as atopic dermatitis and are rarely indicated.

Traditional H₁ antihistamines are usually grouped into six classes ([Table 19-1](#)). Alkylamines (chlorpheniramine and dexchlorpheniramine) are the least sedating. Ethanolamines (diphenhydramine) are very sedating, as are phenothiazines (promethazine). Piperidines (cyproheptadine), piperazines (hydroxyzine), and ethylenediamines (tripelennamine) cause less sedation. The least sedating antihistamines are loratadine and famotidine. Cetirizine is also relatively nonsedating. Some tricyclic antidepressants, such as doxepin, have potent antihistaminic activity and are useful in urticaria and other forms of pruritus.

b. Systemic corticosteroids—(See [Chapter 26](#).)

Burr S: Emollients for managing dry skin conditions. Prof Nurse 1999;15:43. [\[PMID: 10595180\]](#)

Weissnar E et al: Systemic drugs with antipruritic potency. Skin Therapy Lett 2000;5:1. [\[PMID: 10854341\]](#)

Yosipovitch G et al: The diagnostic and therapeutic approach to idiopathic generalized pruritus. Int J Dermatol 1999;38: 881. [\[PMID: 10632764\]](#)

Sunscreens

Protection from ultraviolet light should begin at birth but will reduce the incidence of actinic keratoses and some nonmelanoma skin cancers when initiated at any age. The best protection is shelter, but protective clothing, avoidance of direct sun exposure during the peak hours of the day, and the assiduous use of chemical sunscreens are important. Estimates are that if fair children were to use such sunscreens regularly, their lifetime risk of skin cancer might be reduced by 75%.

A number of highly effective sunscreens are available in cream, lotion, and nongreasy gel and liquid formulations. Fair-complexioned persons should use a sunscreen with an SPF (sun protective factor) of at least 15 and preferably 30-40 every day. For those who are sensitive to PABA (*p*-aminobenzoic acid), PABA-free formulations are available. Sunscreens with high SPF values (> 30) afford some protection against UVA as well as UVB light exposure and may be helpful in managing photosensitivity disorders.

Physical blockers (titanium dioxide and zinc oxide [Blue Lizard]) are available in vanishing formulations.

Gasparro FP: Sunscreens, skin photobiology, and skin cancer: the need for UVA protection and evaluation of efficacy. *Environ Health Perspect* 2000;108(Suppl 1):71. [\[PMID: 10698724\]](#)

Green AA et al: Daily sunscreen application and betacarotene supplementation in prevention of basal-cell and squamous-cell carcinoma of the skin: a randomised controlled trial. *Lancet* 1999;354:723. [\[PMID: 10475183\]](#)

Complications of Topical Dermatologic Therapy

Complications of topical therapy can be largely avoided. They fall into several categories.

A. Allergy

Of the topical antibiotics, neomycin has the greatest potential for sensitization. Diphenhydramine, benzocaine, and ethylenediamine are potential sensitizers in topical medications. Preservatives and even the topical steroids themselves can cause allergic contact dermatitis.

B. Irritation

Preparations of retinoic acid, benzoyl peroxide, and other acne medications should be applied sparingly to the skin when it is dry. Sunscreens may cause irritation or an acne-like eruption.

C. Absorption

Drugs may be absorbed through the skin, especially through broken or inflamed skin, or from under occlusive dressings. The possibility of systemic absorption has special implications for pregnant women or women who may become pregnant while using the topical medication. A few notable examples of topical drugs that may be harmful to a fetus include podophyllum resin, lindane, and tretinoin (Retin-A). In most cases, substitutes are available (eg, permethrin or precipitated sulfur may be substituted for lindane). In general it is always prudent to consult a pharmacology textbook or pharmacist when prescribing medications for pregnant or nursing women.

D. Overuse

Fluorinated topical corticosteroids may induce acne-like lesions on the face (steroid rosacea) and atrophic striae in body folds.

Journe F et al: Sunscreen sensitization: a 5-year study. *Acta Derm Venereol* 1999;79:211. [\[PMID: 10384919\]](#)

 - DIAGNOSIS OF SKIN DISORDERS
 -
-

I. COMMON DERMATOSES

Dermatologic diseases will be discussed according to the types of lesions they cause. Therefore, in order to make a diagnosis, it is best to (1) focus on the type of individual lesion the patient exhibits; (2) choose the morphologic category the lesions seem to fit; and then (3) identify the specific features of the history, physical examination, and laboratory tests that will establish the working diagnosis.

The major morphologic types of skin lesion are listed in [Table 6-2](#) along with the disorders with which they are most prominently associated. Miscellaneous skin, hair, and nail disorders and drug eruptions are discussed at the end of the chapter.

PIGMENTED LESIONS

Deaths from **malignant melanoma** are prevented by early diagnosis followed by excision. The nondermatologist clinician must be able to evaluate pigmented lesions and appropriately refer for evaluation all potential malignant melanomas. In order to avoid missing some malignant melanomas, it is understood that many patients will be referred for what ultimately prove to be benign lesions.

In general, a **benign mole** is a small (< 6 mm), well-circumscribed lesion with a well-defined border and a single shade of pigment from beige or pink to dark brown. The physical examination must take precedence over the history, though a reliable history that a lesion has been present without change for decades is obviously a comfort.

Suspicious moles have an irregular notched border where the pigment appears to be leaking into the normal surrounding skin; the topography may be irregular, ie, partly raised and partly flat. Color variegation is present, and colors such as pink, blue, gray, white, and black are indications for referral. The American Cancer Society has proposed the mnemonic "ABCD = Asymmetry, Border irregularity, Color variegation, and Diameter greater than 6 mm." Bleeding and ulceration are ominous signs. A mole that stands out from the patient's other moles deserves special scrutiny. A patient with a large number of moles is statistically at increased risk for melanoma and deserves careful and periodic examination, particularly if the lesions are atypical.

The history of a changing mole (evolution) is the single most important historical reason for close evaluation and possible referral. Referral of suspicious pigmented lesions is always appropriate.

Moles have their own natural history. In the patient's first decade of life, moles often appear as flat, small, brown lesions. They are called **junctional nevi** because the nevus cells are at the junction of the epidermis and dermis. Over the next 2 decades, these moles grow in size and often become raised, reflecting the appearance of a dermal component, giving rise to **compound nevi**. Moles may darken and grow during pregnancy. As Caucasian patients enter their seventh and eighth decades, most moles have lost their junctional component and dark pigmentation and undergo fibrosis or other degenerative changes. Still, at every stage of life, normal moles should be well demarcated, symmetric, and uniform in contour and color.

CONGENITAL NEVI

The management of small congenital nevi—less than a few centimeters in diameter—is controversial. The vast majority will never become malignant, but some experts feel that the risk of melanoma in these lesions may be somewhat increased. Since 1% of whites are born with these lesions, management should be conservative and excision advised only for lesions in cosmetically nonsensitive areas where the patient cannot easily see the lesion and note any suspicious changes. Excision should be considered for congenital nevi whose contour (bumpiness, nodularity) or color (different shades) makes it difficult for examiners to note early signs of malignant change. Giant congenital melanocytic nevi (> 5% BSA) are at greater risk for development of melanoma, and surgical removal in stages is often recommended.

Egan CL et al: Cutaneous melanoma risk and phenotypic changes in large congenital nevi. J Am Acad Dermatol 1998;39:923. [\[PMID: 9843003\]](#)

ATYPICAL (DYSPLASTIC) NEVI

The term "atypical nevus" or "atypical mole" has supplanted "dysplastic nevus." The diagnosis of atypical moles is made clinically and not histologically, and moles should be removed only if they are suspected to be melanomas. Clinically, these moles are large (> 5 mm in diameter), with an ill-defined, irregular border and irregularly distributed pigmentation. It is estimated that 5-10% of the United States population have one or more atypical nevi. Studies have defined an increased risk of melanoma in the following populations: patients with 50 or more nevi with one or more atypical moles and one mole at least 8 mm or larger, and patients with a few to many definitely atypical moles. These patients deserve education and regular (usually every 6-12 months) follow-up. Kindreds with familial melanoma (numerous atypical nevi and a strong family history) deserve even closer attention, as the risk of developing single or even multiple melanomas in these individuals approaches 50% by age 50.

BLUE NEVI

Blue nevi are small, slightly elevated, and blue-black lesions. They are common in persons of Asian descent, and an individual patient may have several of them. If present without change for many years, they may be considered benign, since malignant blue nevi are rare. However, blue-black papules and nodules that are new or growing must be evaluated to rule out nodular melanoma.

Knoell KA et al: Familial multiple blue nevi. J Am Acad Dermatol 1998;39(2 Part 2):322. [\[PMID: 9703144\]](#)

FRECKLES & LENTIGINES

Freckles (ephelides) and lentigines are flat brown spots. Freckles first appear in young children, darken with ultraviolet exposure, and fade with cessation of sun exposure. In adults, depending on the fairness of the complexion, flat brown spots (lentigines), often with sharp borders, gradually appear in sun-exposed areas, particularly the dorsa of the hands. They do not fade with cessation of sun exposure. They should be evaluated like all pigmented lesions: If the pigmentation is homogeneous and they are symmetric and flat, they are most likely benign. Solar lentigines, so-called liver spots, improve in over 80% of individuals treated with topical 0.1% tretinoin once nightly for 6-10 months.

SEBORRHEIC KERATOSES

Seborrheic keratoses are benign plaques, beige to brown or even black, 3-20 mm in diameter, with a velvety or warty surface. They appear to be stuck or pasted onto the skin. They are common—especially in the elderly—and may be mistaken for melanomas or other types of cutaneous neoplasms. Although they may be frozen with liquid nitrogen or curetted if they itch or are inflamed, no treatment is needed.

Gill D et al: The prevalence of seborrheic keratoses in persons aged 15 to 30 years. Arch Dermatol 2000;136:759. [\[PMID: 10871940\]](#)

MALIGNANT MELANOMA

- May be flat or raised.
- Should be suspected in any pigmented skin lesion with recent change in appearance.
- Examination with good light may show varying colors, including red, white, black, and bluish.
- Borders typically irregular.

General Considerations

Malignant melanoma is the leading cause of death due to skin disease. There were 51,400 cases of melanoma in the United States in 2001, with 7800 deaths. One in four cases of melanoma occur before the age of 40. Melanoma is the most common cancer of women between the ages of 25 and 29 and the second most common cause in women ages 30-34. Overall survival for melanomas in Caucasians rose from 60% in 1960-1963 to 85% in 1983-1990, due primarily to earlier detection of lesions.

Tumor thickness is the single most important prognostic factor. Ten-year survival rates—related to thickness in millimeters—are as follows: < 0.76 mm, 96%; 0.76-1.69 mm, 81%; 1.7-3.6 mm, 57%; and > 3.6 mm, 31%. With lymph node involvement, the 5-year survival rate is 30%, and with distant metastases, it is less than 10%. More accurate prognoses can be made on the basis of thickness, site, histologic features, and sex of the patient.

Clinical Findings

Primary malignant melanomas may be classified into various clinicohistologic types, including lentigo maligna melanoma (arising on sun-exposed skin of older individuals), superficial spreading malignant melanoma (the most common type, occurring in two-thirds of individuals developing melanoma), nodular malignant melanoma, acral-lentiginous melanomas (arising on palms, soles, and nail beds), malignant melanomas on mucous membranes, and miscellaneous forms such as amelanotic (nonpigmented) melanoma and melanomas arising from blue nevi (rare) and congenital nevi.

While superficial spreading melanoma is largely a disease of Caucasians, persons of other races are at risk for other types of melanoma, particularly acral lentiginous melanoma. These occur as dark, sometimes irregularly shaped lesions on the palms and soles and as new, often broad and solitary, darkly pigmented longitudinal streaks in the nails. Acral lentiginous melanoma may be a difficult diagnosis because benign pigmented lesions of the hands, feet, and nails occur commonly in more darkly pigmented persons and clinicians may hesitate to biopsy the palms and especially the soles and nail beds. As a result, the diagnosis is often delayed until the tumor has become clinically obvious and histologically thick. Clinicians should give special attention to new or changing lesions in these areas.

Melanomas vary from macules to nodules. Variegation of color from flesh tints to pitch black and a frequent admixture of white, blue, purple, and red may occur. The border tends to be irregular, and growth may be rapid or indolent. Melanomas are often larger than 6 mm. Again, one should refer lesions based on a suspicion of melanoma rather than delay until the diagnosis is certain. Dermoscopy—use of a special magnifying device to evaluate pigmented lesions—helps select suspicious lesions that require biopsy. In experienced hands, the specificity is 85% and the sensitivity 95%.

Treatment

Treatment of melanoma consists of excision. After histologic diagnosis, the area is usually reexcised with margins dictated by the thickness of the tumor. Large margins (radius = 5 cm) are no longer indicated. Thin low-risk and intermediate-risk tumors require only conservative margins of 1-3 cm. More specifically, surgical margins of 0.5 cm for melanoma in situ and 1 cm for lesions less than 1 mm in thickness are most often recommended.

Sentinel lymph node biopsy (selective lymphadenectomy) using preoperative lymphoscintigraphy and intraoperative lymphatic mapping is effective for staging melanoma patients with intermediate risk without clinical adenopathy and is recommended for all patients with lesions over 1 mm in thickness or with high-risk histologic features. Alpha interferon and vaccine therapy may reduce recurrences in patients with high-risk melanomas. Referral of intermediate-risk and high-risk patients to centers with expertise in melanoma is strongly recommended.

SCALING DISORDERS

ATOPIC DERMATITIS (ECZEMA)

Essentials of Diagnosis

- Pruritic, exudative, or lichenified eruption on face, neck, upper trunk, wrists, and hands and in the antecubital and popliteal folds.
- Personal or family history of allergic manifestations (eg, asthma, allergic rhinitis, atopic dermatitis).
- Tendency to recur.

General Considerations

Atopic dermatitis looks different at different ages and in people of different races. Because most patients have scaly dry skin at some point, this disease is being discussed under scaly dermatoses. However, acute flares may present with red patches that are weepy, shiny, or lichenified (ie, thickened, with more prominent skin markings) and plaques and papules. Diagnostic criteria for atopic dermatitis must include pruritus, typical morphology and distribution (flexural lichenification in adults), and a tendency toward chronic or chronically relapsing dermatitis. Also helpful are (1) a personal or family history of atopic disease (asthma, allergic rhinitis, atopic dermatitis), (2) xerosis-ichthyosis, (3) facial pallor with infraorbital darkening, (4) elevated serum IgE, (5) fissures under the ear lobes, (6) a tendency toward nonspecific hand dermatitis, (7) a tendency toward repeated skin infections, and (8) nipple eczema.

Clinical Findings

A. Symptoms and Signs

Itching may be severe and prolonged. The epidermal inflammation of acute dermatitis results in rough, red patches without the thickening and discrete demarcation of a proliferative epidermal disorder such as psoriasis. The distribution of the lesions is characteristic, with involvement of the face, neck, and upper trunk ("monk's cowl"). The bends of the elbows and knees are involved. The skin is dry, leathery, and lichenified. Pigmented persons tend to present with a papular eruption, and poorly demarcated hypopigmented patches (pityriasis alba) are commonly seen on the cheeks and extremities. In black patients with severe disease, pigmentation may be lost in lichenified areas.

B. Laboratory Findings

Food allergy is an uncommon cause of flares of atopic dermatitis in adults. Blinded food challenges are the most reliable method of diagnosing suspected food allergy. RASTs or skin tests may suggest dust mite allergy. Eosinophilia and increased serum IgE levels may be present but are nonspecific.

Differential Diagnosis

Atopic dermatitis must be distinguished from seborrheic dermatitis (frequent scalp and face involvement, greasy and scaly lesions, and quick response to therapy). Contact dermatitis and impetigo may be in the differential, especially for hyperacute, weepy flares of atopic dermatitis (although typically these diseases do not have a chronic course and characteristic distribution). Patients with active lesions are almost always colonized with *Staphylococcus aureus*, and impetiginization of atopic skin should be considered and treated when the patient presents with an acute flare.

Treatment

Treatment is most effective if the patient is instructed about the general principles of skin care and exactly how to use medications.

A. General Measures

Atopic patients have hyperirritable skin. Anything that dries or irritates the skin will potentially trigger dermatitis. Atopic individuals are sensitive to low humidity and often get worse in the winter, when the air is dry. Adults with atopic disorders should not bathe more than once daily. Soap should be confined to the armpits, groin, and feet. Washcloths and brushes should not be used. Soaps should not be drying, and Dove, Eucerin, Aveeno, Basis, Alpha Keri, Purpose, and other soaps or cleansers, such as Cetaphil or Aquanil, may be recommended. After rinsing, the skin should be patted dry (not rubbed) and then immediately—within three minutes—covered with a thin film of an emollient such as Aquaphor, Eucerin, Vaseline, or a corticosteroid as needed. Triceram cream, a therapeutic moisturizer, will reduce inflammation as well as moisturize without a greasy or occlusive feel. It is much more expensive than traditional moisturizers. Atopic patients may be irritated by scratchy fabrics, including wools and acrylics. Cottons are preferable, but synthetic blends also are tolerated. Other triggers of eczema in some patients include sweating, ointments, hot bathing, and animal danders.

To determine the potential effect of foods, the patient may eliminate one food at a time for several months and monitor the severity of the disease. Dairy products and wheat are the most common offenders. Foods that are a problem typically cause itching within minutes to a few hours after ingestion.

B. Local Treatment

Corticosteroids should be applied sparingly to the dermatitis twice to four times daily and rubbed in well. Their potency should be appropriate to the severity of the dermatitis. In general, one should begin with hydrocortisone or another slightly stronger mild steroid (Aclovate, Desonide) and use triamcinolone 0.1% for short periods of time. It is vital that patients taper corticosteroids and substitute emollients when the dermatitis clears to avoid the side effects of corticosteroids. Tapering is also important to avoid rebound flares of the dermatitis that may follow their abrupt cessation. Doxepin cream 5% may be used up to four times daily and is best applied simultaneously with the topical steroid. Stinging and drowsiness occur in 25%. Tacrolimus ointment (Protopic 0.03%) and pimecrolimus ointment (Elidel 1%) are effective in managing atopic dermatitis as first-line steroid-sparing agents applied twice daily. Burning on application occurs in about half of patients using Protopic and in 10-25% of Elidel users, but it may resolve with continued treatment. These medications do not appear to cause skin atrophy, striae, or other topical steroid-associated side effects and are safe for application on the face and even the eyelids. Treatment is dictated by the stage of the dermatitis.

1. Acute weeping lesions—Use saline or aluminum subacetate solution (Domeboro tablets, one in a pint of cool water) or colloidal oatmeal (Aveeno; dispense one box, and use as directed on box) as soothing or astringent soaks, baths, or wet dressings for 10-30 minutes two to four times daily. Lesions on extremities particularly may be bandaged for protection at night. Steroid lotions or creams are preferred to ointments for this stage. Use high-potency corticosteroids after bathing but spare the face and body folds. Tacrolimus may not be tolerated at this stage. Systemic corticosteroids may be required (see below).

2. Subacute or scaly lesions—At this stage, the lesions are dry but still red and pruritic. Mid- to high-potency steroids in ointment form should be continued until scaling and elevated skin lesions are cleared and itching is decreased substantially. At that point, patients should begin a 2- to 4-week taper from twice-daily to daily to alternate-day dosing with topical steroids to reliance on emollients, with occasional use of steroids on specific itchy areas. Instead of tapering the frequency of usage of a more potent steroid, it may be preferable to switch to a low-potency steroid such as hydrocortisone or alclometasone. Tacrolimus and pimecrolimus are more expensive alternatives and may be added if steroids cannot be stopped to avoid the complications of chronic topical steroid use.

3. Chronic, dry, lichenified lesions—Thickened and usually well-demarcated, they are best treated with high-potency to ultra-high-potency steroid ointments. Nightly occlusion for 2-6 weeks may enhance the initial response. Occasionally, adding tar preparations such as LCD (liquor carbonis detergens) 10% in Aquaphor or 2% crude coal tar may be beneficial.

C. Systemic and Adjuvant Therapy

Systemic corticosteroids are indicated only for severe acute exacerbations. Oral prednisone dosages should be high enough to suppress the dermatitis quickly, usually starting with 40-60 mg daily for adults. The dosage is then tapered to nil over a period of 2-4 weeks. Owing to the chronic nature of atopic dermatitis and the side effects of chronic systemic corticosteroids, long-term use of these agents is not recommended for maintenance therapy. Classic antihistamines may relieve severe pruritus. Hydroxyzine, diphenhydramine, or doxepin may be useful—the dosage increased gradually to avoid drowsiness. Fissures, crusts, erosions, or pustules indicate staphylococcal infection clinically. Therefore, antistaphylococcal antibiotics given systemically—such as dicloxacillin or first-generation cephalosporins—may be helpful in management and are often used during flares. Phototherapy can be an important adjunct for severely affected patients, and the properly selected patient with recalcitrant disease may benefit greatly from therapy with UVB with or without coal tar, UVA, or PUVA. Oral cyclosporine may be used for the most severe and recalcitrant cases.

Complications of Treatment

The clinician should monitor for skin atrophy. **Eczema herpeticum**, a generalized herpes simplex infection manifested by monomorphic vesicles, crusts, or erosions superimposed on atopic dermatitis or other extensive eczematous processes, is treated successfully with oral acyclovir, 200 mg five times daily, or intravenous acyclovir in a dose of 10 mg/kg intravenously every 8 hours (500 mg/m² every 8 hours).

Smallpox vaccination is absolutely contraindicated in patients with atopic dermatitis or a history thereof because of the risk of eczema vaccinatum. Atopic dermatitis patients may develop generalized vaccinia by contact with recent vaccine recipients who still have pustular or crusted vaccination sites. Eczema vaccinatum and generalized vaccinia are indications for vaccinia immune globulin.

Prognosis

Atopic dermatitis runs a chronic or intermittent course. Affected adults may have only hand dermatitis. Poor prognostic factors for persistence into adulthood in atopic dermatitis include onset early in childhood, early generalized disease, and asthma. Only 40-60% of these patients have lasting remissions.

LICHEN SIMPLEX CHRONICUS (CIRCUMSCRIBED NEURODERMATITIS)

Essentials of Diagnosis

- Chronic itching.
- Lichenified lesions with exaggerated skin lines overlying a thickened, well-circumscribed scaly plaque.
- Predilection for nape of neck, wrists, external surfaces of forearms, lower legs, scrotum, and vulva.

General Considerations

Lichen simplex chronicus represents a self-perpetuating scratch-itch cycle.

Clinical Findings

Intermittent itching incites the patient to scratch the lesions. Itching may be so intense as to interfere with sleep. Dry, leathery, hypertrophic, lichenified plaques appear on the neck, ankles, perineum, or almost anywhere. The patches are rectangular, thickened, and hyperpigmented. The skin lines are exaggerated.

Differential Diagnosis

This disorder can be differentiated from plaque-like lesions such as psoriasis (redder lesions having whiter scales on the elbows, knees, and scalp and nail findings), lichen planus (violaceous, usually smaller polygonal papules), and nummular (coin-shaped) dermatitis. Lichen simplex chronicus may complicate chronic atopic dermatitis.

Treatment

Clobetasol, halobetasol, diflorasone, and betamethasone dipropionate in an augmented vehicle are effective without occlusion and are used twice daily for several weeks. In some patients, flurandrenolide (Cordran) tape may be more effective, since it prevents scratching and rubbing of the lesion. These superpotent steroids are probably the treatment of choice but must be used with careful follow-up to avoid local side effects. The injection of triamcinolone acetonide suspension (5-10 mg/mL) into the lesions may occasionally be curative. Use of tars, such as 10% LCD (liquor carbonis detergens) with topical steroids, or continuous occlusion with DuoDerm (occlusive flexible hydrocolloid dressing) for 7 days at a time for 1-2 months, may also be helpful. The area should be protected and the patient encouraged to become

aware of when he or she is scratching.

Prognosis

The disease tends to remit during treatment but may recur or develop at another site.

PSORIASIS

Essentials of Diagnosis

- Silvery scales on bright red, well-demarcated plaques, usually on the knees, elbows, and scalp.
- Nail findings including pitting and onycholysis (separation of the nail plate from the bed).
- Mild itching (usually).
- May be associated with psoriatic arthritis.
- Histopathology is not often useful and can be confusing.

General Considerations

Psoriasis is a common benign, chronic inflammatory skin disease that probably has a genetic basis. Injury or irritation of normal skin tends to induce lesions of psoriasis at the site (Koebner's phenomenon). Psoriasis has several variants—the most common is the plaque type. Eruptive (guttate) psoriasis consisting of myriad lesions 3-10 mm in diameter occurs occasionally after streptococcal pharyngitis. Grave, occasionally life-threatening forms (generalized pustular and erythrodermic psoriasis) may rarely occur. Plaque-type or extensive erythrodermic psoriasis with abrupt onset may accompany HIV infection.

Clinical Findings

There are often no symptoms, but itching may occur. Although psoriasis may occur anywhere, one should examine the scalp, elbows, knees, palms and soles, and nails. The lesions are red, sharply defined plaques covered with silvery scales. The glans penis and vulva may be affected. Occasionally, only the flexures (axillae, inguinal areas) are involved. Fine stippling ("pitting") in the nails is highly suggestive of psoriasis. Psoriatics often have a pink or red intergluteal fold. Not all patients have findings in all locations, but the occurrence of a few may help make the diagnosis when other lesions are not typical. Some patients present mainly with hand or foot dermatitis and only minimal findings elsewhere, posing a difficult diagnostic problem. There may be associated arthritis that can resemble the rheumatoid variety but with a negative rheumatoid factor; distal interphalangeal joints are frequently involved, especially if there are nail changes.

Differential Diagnosis

The combination of red plaques with silvery scales on elbows and knees, with scaliness in the scalp or nail findings, is diagnostic. Psoriasis lesions are well demarcated and affect extensor surfaces—in contrast to atopic dermatitis, with poorly demarcated plaques in flexural distribution. In body folds, scraping and culture for candida and examination of scalp and nails will distinguish psoriasis from intertrigo and candidiasis. Dystrophic changes in nails may simulate onychomycosis, but again, the general examination combined with a potassium hydroxide (KOH) or fungal culture will be valuable in diagnosis. The cutaneous features of Reiter's syndrome mimic psoriasis.

Treatment

There are many therapeutic options in psoriasis, to be chosen according to the extent and severity of disease and with a clear understanding of the risks and benefits of therapy.

A. Limited Disease

For many patients, the easiest regimen is to use a high-potency to highest-potency topical steroid cream or ointment. It is best to restrict the ultra-high-potency steroids to 2-3 weeks of twice-daily use and then use them in a pulse fashion three or four times on weekends or switch to a midpotency corticosteroid. Topical corticosteroids rarely induce a lasting remission. They may induce tachyphylaxis or cause psoriasis to become unstable. Additional measures are therefore commonly added to topical steroid therapy. Tar preparations such as Fototar cream, LCD (liquor carbonis detergens) 10% in Nutraderm lotion, alone or mixed directly with triamcinolone 0.1%, are useful adjuncts when applied twice daily. Occlusion alone has been shown to clear isolated plaques in 30-40% of patients. Occlusive dressings such as thin DuoDerm are placed on the lesions and left undisturbed for as long as possible (a minimum of 5 days, up to 7 days) and then replaced. Responses may be seen within several weeks. Calcipotriene ointment 0.005%, a vitamin D analog, is used twice daily for treatment of moderate-plaque psoriasis. It has become the second most commonly used topical treatment for psoriasis (after topical steroids). Initially, patients are treated with twice-daily steroids plus calcipotriene twice daily. This rapidly clears the lesions. Calcipotriene is then used alone once daily and with the steroid once daily for several weeks. Eventually, the topical steroids are stopped, and once- or twice-daily calcipotriene is continued chronically. Calcipotriene usually cannot be applied to the groin or on the face because of irritation. Treatment of extensive psoriasis with calcipotriene may result in hypercalcemia. Calcipotriene is incompatible with many topical steroids (but not halobetasol), so if used concurrently it must be applied at a different time.

Tazarotene gel, a topical retinoid, is useful for the treatment of mild to moderate plaque psoriasis. About 50% of patients obtained at least 75% improvement of their skin lesions with twice-daily application, though fewer than 10% of plaques completely clear with 8 weeks of treatment. Tazarotene gel is available in 0.05% and 0.1% formulations. There is no difference between once-daily and twice-daily applications of the 0.1% formulation, but the 0.05% formulation is less effective when used once daily. This agent appears to be similar to calcipotriene in that it may be used to augment the benefits of other forms of treatment. It is more expensive than calcipotriene and more irritating. Tazarotene gel is compatible with topical steroids and may be applied simultaneously.

For the scalp, start with a tar shampoo, used daily if possible. For thick scales, use 6% salicylic acid gel (eg, Keralyt), P & S solution (phenol, mineral oil, and glycerin), or fluocinolone acetonide 0.01% in oil (Derma-Smoother/FS) under a shower cap at night, and shampoo in the morning. In order of increasing potency, triamcinolone 0.1%, or fluocinolone, betamethasone dipropionate, fluocinonide or amcinonide, and clobetasol are available in solution form for use on the scalp twice daily. For psoriasis in the body folds, treatment is much more difficult, since potent steroids cannot be used. When mild corticosteroids are not effective and involvement or itch is severe, some of the modalities described immediately below may be required.

B. Generalized Disease

If psoriasis involves more than 30% of the body surface, it is difficult to treat with topical agents. The treatment of choice is outpatient UVB light exposure three times weekly. Clearing occurs in an average of 7 weeks, and maintenance may be needed since relapses are frequent. Severe psoriasis unresponsive to outpatient ultraviolet light may be treated in a psoriasis day care center with the Goeckerman regimen, which involves use of crude coal tar for many hours and exposure to UVB light. Such treatment may offer the best chance for prolonged remissions.

PUVA (psoralen plus ultraviolet A, ie, ultraviolet light in the 320- to 400-nm wavelength range) may be effective even in patients who have failed standard UVB treatment. Long-term use of PUVA is associated with an increased risk of skin cancer (especially squamous cell carcinoma and perhaps melanoma), particularly in persons with fair complexions or those who have received ionizing radiation. Thus, periodic examination of the skin is imperative. Atypical lentigines are a common complication termed "PUVA lentigines." There can be rapid aging of the skin in fair individuals. Cataracts have not been reported with proper use of protective glasses. PUVA may be used in combination with other therapy, such as acitretin or methotrexate.

Parenteral corticosteroids should not be used because of the possibility of induction of pustular lesions. Methotrexate is very effective for severe psoriasis in doses up to 25 mg once weekly. It should be used according to published protocols. Liver biopsy is performed initially after methotrexate has been used long enough by the patient to demonstrate that it is effective and well tolerated, and then at intervals depending on the cumulative dose, usually 1.5-2 g. Administration of folic acid, 1-2 mg daily, will eliminate nausea caused by methotrexate without compromising efficacy.

Acitretin, a synthetic retinoid, is most effective for pustular psoriasis in dosages of 0.5-0.75 mg/kg/d, but it also improves erythrodermic and plaque types and psoriatic arthritis. Liver enzymes and serum lipids must be checked periodically. Because acitretin is a teratogen and persists for long periods in fat, women of childbearing age must wait at least 3 years after completing acitretin treatment before considering pregnancy. When used as single agents, retinoids will flatten psoriatic plaques, but high doses may be required for complete clearing. Retinoids find their greatest use when combined with phototherapy—either UVB or PUVA, with which they are synergistic.

Cyclosporine dramatically improves psoriasis and may be used to control severe cases. Rapid relapse (rebound) is the rule after cessation of therapy, so another agent must be added if cyclosporine is stopped. Systemic immunomodulators can be effective in treating psoriasis, though the exact indications for these agents are still unclear. The TNF inhibitors etanercept (Enbrel) and infliximab (Remicade) have both shown substantial antipsoriatic activity comparable to that of the most potent immunosuppressives. Cost and potential toxicity are current limitations in use. Alefacept (Amevive), a human fusion protein, inhibits activation of T cells by binding to

CD2, selectively targeting memory-effector T cells. It does not seem to increase infections, and responses are rapid (within 2 weeks) and durable. Efalizumab, an anti-CD11a monoclonal antibody, is well tolerated and has moderate efficacy, and no systemic toxicity has been reported to date.

Prognosis

The course tends to be chronic and unpredictable, and the disease may be refractory to treatment.

PITYRIASIS ROSEA

Essentials of Diagnosis

- Oval, fawn-colored, scaly eruption following cleavage lines of trunk.
- Herald patch precedes eruption by 1-2 weeks.
- Occasional pruritus.

General Considerations

This is a common mild, acute inflammatory disease which is 50% more common in females. Young adults are principally affected, mostly in the spring or fall. Concurrent household cases have been reported.

Clinical Findings

Itching is common but is usually mild. The diagnosis is made by finding one or more classic lesions. The lesions consist of oval, fawn-colored plaques up to 2 cm in diameter. The centers of the lesions have a crinkled or "cigarette paper" appearance and a collarette scale, ie, a thin bit of scale that is bound at the periphery and free in the center. Only a few lesions in the eruption may have this characteristic appearance, however. Lesions follow cleavage lines on the trunk (so-called Christmas tree pattern), and the proximal portions of the extremities are often involved. A variant that affects the flexures (axillae and groin), so called inverse pityriasis rosea, and a papular variant, especially in black patients, also occur. An initial lesion ("herald patch") that is often larger than the later lesions often precedes the general eruption by 1-2 weeks. The eruption usually lasts 6-8 weeks and heals without scarring.

Differential Diagnosis

A serologic test for syphilis should be performed if at least a few perfectly typical lesions are not present and especially if there are palmar and plantar or mucous membrane lesions or adenopathy, features that are suggestive of secondary syphilis. For the nonexpert, an RPR test in all cases is not unreasonable. Tinea corporis may present with red, slightly scaly plaques, but rarely are there more than a few lesions of tinea corporis compared to the many lesions of pityriasis rosea. A scraping of scale for a KOH test will rapidly make the diagnosis. Seborrheic dermatitis on occasion presents on the body with poorly demarcated patches over the sternum, in the pubic area, and in the axillae. The classic lesions of pityriasis rosea are not present. Tinea versicolor, viral exanthems, and drug eruptions may simulate pityriasis rosea.

Treatment

Pityriasis rosea often requires no treatment. In Asians, Hispanics, or blacks, in whom lesions may remain hyperpigmented for some time, more aggressive management may be indicated. The most effective management consists of daily UVB treatments, or prednisone as used for contact dermatitis. Topical steroids of medium strength (triamcinolone 0.1%) may also be used if pruritus is bothersome. Oral erythromycin for 14 days was reported to clear 73% of patients within 2 weeks (compared with none of the patients on placebo).

Prognosis

Pityriasis rosea is usually an acute self-limiting illness that disappears in about 6 weeks.

Sharma PK et al: Erythromycin in pityriasis rosea: a double-blind, placebo-controlled clinical trial. J Am Acad Dermatol 2000;42(2 Part 1):241. [\[PMID: 10642679\]](#)

SEBORRHEIC DERMATITIS & DANDRUFF

Essentials of Diagnosis

- Dry scales and underlying erythema.
- Scalp, central face, presternal, interscapular areas, umbilicus, and body folds.

General Considerations

Seborrheic dermatitis is an acute or chronic papulosquamous dermatitis. Seborrheic dermatitis may represent an inflammatory reaction to *Malassezia furfur* yeasts.

Clinical Findings

Pruritus is an inconstant finding. The scalp, face, chest, back, umbilicus, eyelid margins, and body folds have dry scales or oily yellowish scurf. Fissuring and secondary infection are occasionally present. Patients with Parkinson's disease, patients who become acutely ill and are hospitalized, and patients with HIV infection often have seborrheic dermatitis.

Differential Diagnosis

There is a spectrum from seborrheic dermatitis to scalp psoriasis. Extensive seborrheic dermatitis may simulate intertrigo in flexural areas, but scalp, face, and sternal involvement suggest seborrheic dermatitis. Scaling of the scalp due to tinea capitis may simulate dandruff or seborrheic dermatitis, but alopecia is usually present in tinea capitis.

Treatment

A. Seborrhea of the Scalp

Shampoos that contain zinc pyrithione or selenium are used daily if possible. These may be alternated with ketoconazole shampoo (1% or 2%) used twice weekly. A combination of shampoos is used in refractory cases. Tar shampoos are also effective for milder cases and for scalp psoriasis. Topical corticosteroid solutions or lotions are then added if necessary and are used twice daily. (See treatment for scalp psoriasis, above.)

B. Facial Seborrheic Dermatitis

The mainstay of therapy is a mild corticosteroid (hydrocortisone 1%, alclometasone, desonide) used intermittently and not near the eyes. Potent fluorinated corticosteroids used on the face may produce steroid rosacea or atrophy and telangiectasia. These are rarely indicated for seborrheic dermatitis. If the disorder cannot be controlled with intermittent use of a topical steroid alone, ketoconazole (Nizoral) 2% cream is added twice daily. Topical tacrolimus (Protopic) and pimecrolimus (Elidel) are steroid-sparing alternatives.

C. Seborrheic Dermatitis of Nonhairy Areas

Low-potency steroid creams—ie, 1% or 2.5% hydrocortisone, desonide, or alclometasone dipropionate—are highly effective.

D. Seborrhea of Intertriginous Areas

Avoid greasy ointments. Apply low-potency steroid lotions or creams twice daily for 5-7 days and then once or twice weekly for maintenance as necessary. Ketoconazole cream may be a useful adjunct. Tacrolimus or pimecrolimus topically may avoid steroid atrophy in chronic cases.

E. Involvement of Eyelid Margins

"Marginal blepharitis" usually responds to gentle cleaning of the lid margins nightly as needed, with undiluted Johnson and Johnson Baby Shampoo using a cotton swab.

Prognosis

The tendency is to lifelong recurrences. Individual outbreaks may last weeks, months, or years.

Johnson BA et al: Treatment of seborrheic dermatitis. Am Fam Physician 2000;61:2703. [PMID: 10821151]

FUNGAL INFECTIONS OF THE SKIN

Mycotic infections are traditionally divided into two principal groups—superficial and deep. In this chapter, we will discuss only the superficial infections: tinea corporis and tinea cruris, dermatophytosis of the feet and dermatophytid of the hands, tinea unguium (onychomycosis), and tinea versicolor. See [Chapter 36](#) for discussion of deep mycoses.

The diagnosis of fungal infections of the skin is usually based on the location and characteristics of the lesions and on the following laboratory examinations: (1) direct demonstration of fungi in 10% KOH of scrapings from suspected lesions—"If it's scaly, scrape it" is a time-honored maxim; (2) cultures of organisms from skin scrapings; and (3) histologic sections of nails stained with periodic acid-Schiff (Hotchkiss-McManus) technique, which may be diagnostic if scrapings and cultures are negative.

Principles of Treatment

In general, treatment follows a diagnosis confirmed by KOH preparation or culture, especially if systemic antifungal therapy is to be used. Many other diseases cause scaling, and use of an antifungal agent without a firm diagnosis makes subsequent diagnosis more difficult. In general, fungal infections are treated topically except for those involving the nails or those deep in hair follicles on the face or body.

Griseofulvin is safe and effective for treating dermatophyte infections of the skin (except for the scalp and nails). It is more economical than the newer agents. Itraconazole, an azole antifungal, rapidly accumulates in the nail plate from the matrix and nail bed and persists for 6 months after oral administration is discontinued.

Terbinafine is an allylamine oral antifungal. It has excellent activity against dermatophytes. In vitro activity against yeast forms is variable, but the drug is active against hyphal forms. It is well delivered to the nail plate and persists in the nail for 6-9 months after treatment has ended.

Fluconazole has excellent activity against yeasts and may be the treatment of choice for many forms of mucocutaneous candidiasis. It is not known whether fluconazole is selectively delivered to the keratin compartment, and there have not been sufficient studies to determine effective doses in treating dermatophytosis. Fluconazole appears to require longer treatment courses and so is more expensive than either itraconazole or terbinafine for the treatment of dermatophytosis.

Itraconazole, fluconazole, and terbinafine can all cause elevation of liver function tests and—though rarely in the dosing regimens used for the treatment of dermatophytosis—clinical hepatitis. Ketoconazole is no longer recommended for the treatment of dermatophytosis (except for tinea versicolor) because of the higher rate of hepatitis when it is used for more than a month.

General Measures & Prevention

Since moist skin favors the growth of fungi, dry the skin carefully after bathing or after perspiring heavily. Talc or other drying powders may be useful. The use of topical corticosteroids for other diseases may be complicated by intercurrent tinea or candidal infection, and topical antifungals are often used in intertriginous areas with steroids to prevent this.

Rupke SJ: Fungal skin disorders. Prim Care 2000;27:407. [PMID: 10815051]

1. Tinea Corporis or Tinea Circinata (Body Ringworm)

Essentials of Diagnosis

- Ring-shaped lesions with an advancing scaly border and central clearing or scaly patches with a distinct border.
- On exposed skin surfaces or the trunk.
- Microscopic examination of scrapings or culture confirms the diagnosis.

General Considerations

The lesions are often on exposed areas of the body such as the face and arms. A history of exposure to an infected cat may occasionally be obtained, usually indicating microsporum infection. All species of dermatophytes may cause this disease, but *Trichophyton rubrum* is the most common pathogen, usually representing extension onto the trunk or extremities of tinea cruris, pedis, or manuum.

Clinical Findings

A. Symptoms and Signs

Itching may be present. In classic lesions, rings of erythema have an advancing scaly border and central clearing, occasionally with hyperpigmentation.

B. Laboratory Findings

Hyphae can be demonstrated by removing peripheral scale and examining it microscopically using KOH. The diagnosis may be confirmed by culture.

Differential Diagnosis

Positive fungal studies distinguish tinea corporis from other skin lesions with annular configuration, such as the annular lesions of psoriasis, lupus erythematosus, syphilis, granuloma annulare, and pityriasis rosea. Psoriasis has typical lesions on elbows, knees, scalp, and nails. Secondary syphilis is often manifested by characteristic palmar, plantar, and mucous membrane lesions. Tinea corporis rarely has the large number of lesions seen in pityriasis rosea. Granuloma annulare lacks scales.

Complications

Complications include extension of the disease down the hair follicles (in which case it becomes much more difficult to cure), pyoderma, and dermatophytid.

Prevention

Treat infected household pets (microsporum infections).

Treatment

A. Local Measures

The following applied topically are effective against dermatophyte infections other than those of the nails: miconazole, 2% cream; clotrimazole, 1% solution, cream, or lotion; ketoconazole, 2% cream; econazole, 1% cream or lotion; sulconazole, 1% cream; oxiconazole, 1% cream; ciclopirox, 1% cream; naftifine, 1% cream or gel; butenafine cream; and terbinafine, 1% cream. Miconazole, clotrimazole, butenafine, and terbinafine are available OTC. Allylamines (especially terbinafine and butenafine) require shorter courses and lead to the most rapid response and prolonged remissions. Treatment should be continued for 1-2 weeks after clinical clearing. Betamethasone dipropionate with clotrimazole (Lotrisone) is overused by nondermatologists. In general, short-term use of betamethasone-clotrimazole does not justify the expense, and chronic improper use may result in side effects from the high-potency steroid component, especially in body folds. Cases of tinea that are clinically resistant to this combination have been reported.

B. Systemic Measures

Griseofulvin (ultramicrosize), 250-500 mg twice daily, is used. Typically, only 2-4 weeks of therapy are required. Itraconazole as a single week-long pulse of 200 mg once daily is also effective in tinea corporis. Terbinafine, 250 mg daily for 1 month, is an alternative.

Prognosis

Body ringworm usually responds promptly to conservative topical therapy or to griseofulvin by mouth within 4 weeks.

2. Tinea Cruris (Jock Itch)

Essentials of Diagnosis

- Marked itching in intertriginous areas, usually sparing the scrotum.
- Peripherally spreading, sharply demarcated, centrally clearing erythematous lesions.
- May have associated tinea infection of feet or toenails.
- Laboratory examination with microscope or culture confirms diagnosis.

General Considerations

Tinea cruris lesions are confined to the groin and gluteal cleft. Intractable pruritus ani may occasionally be caused by a tinea infection.

Clinical Findings

A. Symptoms and Signs

Itching may be severe, or the rash may be asymptomatic. The lesions have sharp margins, cleared centers, and active, spreading scaly peripheries. Follicular pustules are sometimes encountered. The area may be hyperpigmented on resolution.

B. Laboratory Findings

Hyphae can be demonstrated microscopically in potassium hydroxide preparations. The organism may be cultured readily.

Differential Diagnosis

Tinea cruris must be distinguished from other lesions involving the intertriginous areas, such as candidiasis, seborrheic dermatitis, intertrigo, psoriasis of body folds ("inverse psoriasis"), erythrasma, and rarely tinea versicolor. Candidiasis is generally bright red and marked by satellite papules and pustules outside of the main border of the lesion. *Candida* typically involves the scrotum. Tinea versicolor can be diagnosed by the KOH preparation. Seborrheic dermatitis also often involves the face, sternum, and axillae. Intertrigo tends to be more red, less scaly, and present in obese individuals in moist body folds with less extension onto the thigh. Inverse psoriasis is characterized by distinct plaques. Other areas of typical psoriatic involvement should be checked, and the KOH examination will be negative. Erythrasma is best diagnosed with Wood's light—a brilliant coral-red fluorescence is seen.

Treatment

A. General Measures

Drying powder (eg, miconazole nitrate [Zeasorb-AF]) should be dusted into the involved area in patients with excessive perspiration or occlusion of skin due to obesity. Underwear should be loose-fitting.

B. Local Measures

Any of the preparations listed in the section on tinea corporis may be used. There is great variation in expense, with miconazole, clotrimazole, butenafine, and terbinafine available OTC and usually at a lower price. Terbinafine cream is curative in over 80% of cases after once-daily use for 7 days.

C. Systemic Measures

Griseofulvin ultramicrosize is reserved for severe cases. Give 250-500 mg orally twice daily for 1-2 weeks. One week of either itraconazole, 200 mg daily, or terbinafine, 250 mg daily, is also effective.

Prognosis

Tinea cruris usually responds promptly to topical or systemic treatment. It may leave behind postinflammatory hyperpigmentation.

Crawford F et al: Topical treatments for fungal infections of the skin and nails of the foot. Cochrane Database Syst Rev 2000(2):CD001434. [PMID: 10796792]

3. Tinea Manuum & Tinea Pedis (Dermatophytosis, Tinea of Palms & Soles, "Athlete's Foot")

Essentials of Diagnosis

- Most often presenting with asymptomatic scaling.
- May progress to fissuring or maceration in toe web spaces.
- Itching, burning, and stinging of interdigital webs, palms, and soles seen occasionally; deep vesicles in inflammatory cases.
- The fungus is shown in skin scrapings examined microscopically or by culture of scrapings.

General Considerations

Tinea of the feet is an extremely common acute or chronic dermatosis. Certain individuals appear to be more susceptible than others. Most infections are caused by trichophyton species.

Clinical Findings

A. Symptoms and Signs

The presenting symptom may be itching, burning, or stinging. Pain may indicate secondary infection with complicating cellulitis. Interdigital tinea pedis is the most common cause of leg cellulitis in healthy individuals. Tinea pedis has several presentations that vary with the location. On the sole and heel, tinea may appear as chronic noninflammatory scaling, occasionally with thickening and cracking of the epidermis. This may extend over the sides of the feet in a "moccasin" distribution. The KOH preparation is usually positive. Tinea pedis often appears as a scaling or fissuring of the toe webs, perhaps with sodden maceration. As the web spaces become more macerated, the KOH preparation and fungal culture are less often positive because bacterial species begin to dominate. Finally, there may also be grouped vesicles distributed anywhere on the soles or palms, generalized exfoliation of the skin of the soles, or nail involvement in the form of discoloration and thickening and crumbling of the nail plate.

B. Laboratory Findings

Hyphae can be demonstrated microscopically in skin scales treated with 10% potassium hydroxide. Culture does not always demonstrate pathogenic fungi from macerated areas.

Differential Diagnosis

Differentiate from other skin conditions involving the same areas, such as interdigital erythrasma (use Wood's light). Psoriasis may be a cause of chronic scaling on the palms or soles and may cause nail changes. Repeated fungal cultures should be negative, and the condition will not respond to antifungal therapy. Contact dermatitis (from shoes) will often involve the dorsal surfaces and will respond to topical or systemic corticosteroids. Vesicular lesions should be differentiated from pompholyx (dyshidrosis) and scabies by proper scraping of the roofs of individual vesicles. Rarely, gram-negative organisms may cause toe web infections in the setting of prior tinea or in its absence. Culture is not very specific, because gram-negative organisms can be cultured from normal toe webs. This entity is treated with aluminum salts (see below) and imidazole antifungal agents or ciclopirox.

Prevention

The essential factor in prevention is personal hygiene. Wear open-toed sandals if possible. Use of rubber or wooden sandals in community showers and bathing places is often recommended, though the effectiveness of this practice has not been studied. Careful drying between the toes after showering is essential. A hair dryer used on low setting may be used. Socks should be changed frequently, and absorbent nonsynthetic socks are preferred. Apply dusting and drying powders as necessary. The use of powders containing antifungal agents (eg, Zeasorb-AF) or chronic use of antifungal creams may prevent recurrences of tinea pedis.

Treatment

A. Local Measures

1. Macerated stage—Treat with aluminum subacetate solution soaks for 20 minutes twice daily. Broad-spectrum antifungal creams and solutions (containing imidazoles or ciclopirox instead of tolnaftate and haloprogin) will help combat diphtheroids and other gram-positive organisms present at this stage and alone may be adequate therapy. If topical imidazoles fail, often 1 week of once-daily allylamine treatment (terbinafine or butenafine) will result in clearing.

2. Dry and scaly stage—Use any of the agents listed in the section on tinea corporis. The addition of urea 10% lotion or cream (Carmol) under an occlusive dressing may increase the efficacy of topical treatments in thick ("moccasin") tinea of the soles.

B. Systemic Measures

Griseofulvin should be used only for severe cases or those recalcitrant to topical therapy. If the infection is cleared by systemic therapy, the patient should be encouraged to begin maintenance with topical therapy, since recurrence is common.

Itraconazole, 200 mg daily for 2 weeks or 400 mg daily for 1 week, or terbinafine, 250 mg daily for 2-4 weeks, may be used in refractory cases.

Prognosis

For many individuals, tinea pedis is a chronic affliction, temporarily cleared by therapy only to recur.

Roldan YB et al: Erysipelas and tinea pedis. Mycoses 2000; 43:181. [\[PMID: 10948816\]](#)

Tanner TL: Rhus (Toxicodendron) dermatitis. Prim Care 2000; 27:493. [\[PMID: 10815057\]](#)

4. Tinea Versicolor (Pityriasis Versicolor)

Essentials of Diagnosis

- Pale macules with fine scales that will not tan, or hyperpigmented macules.
- Velvety, tan, pink, whitish, or brown macules that scale with scraping.
- Central upper trunk the most frequent site.
- Yeast and short hyphae observed on microscopic examination of scales.

General Considerations

Tinea versicolor is a mild, superficial *Malassezia furfur* infection of the skin (usually of the trunk). This yeast is a colonizer of all humans, which accounts for the high recurrence rate after treatment. It is not understood why some patients manifest the spore and hyphal form of the organism and the clinical disease. The eruption is often called to patients' attention by the fact that the involved areas will not tan, and the resulting hypopigmentation may be mistaken for vitiligo. A hyperpigmented form is not uncommon.

Clinical Findings

A. Symptoms and Signs

Lesions are asymptomatic, but a few patients note itching. The lesions are velvety, tan, pink, white, or brown macules that vary from 4-5 mm in diameter to large confluent areas. The lesions initially do not look scaly, but scales may be readily obtained by scraping the area. Lesions may appear on the trunk, upper arms, neck, face, and groin.

B. Laboratory Findings

Large, blunt hyphae and thick-walled budding spores ("spaghetti and meatballs") may be seen under the 10× objective when skin scales have been cleared in 10% KOH. Fungal culture is not useful.

Differential Diagnosis

Vitiligo usually presents with periorificial or periungual lesions. Vitiligo (and not tinea versicolor) is characterized by total depigmentation, not just a lessening of pigmentation. Vitiligo does not scale. Pink and red-brown lesions on the chest are differentiated from seborrheic dermatitis of the same areas by the KOH preparation.

Treatment & Prognosis

Topical treatments include selenium sulfide lotion, which may be applied from neck to waist daily and left on for 5-15 minutes for 7 days; this treatment is repeated weekly for a month and then monthly for maintenance. Ketoconazole shampoo lathered on the chest and back and left on for 5 minutes may also be used weekly for maintenance. One must stress to the patient that the raised and scaly aspects of the rash are being treated; the alterations in pigmentation may take months to fade or fill in. Tinver lotion (contains sodium thiosulfate) is effective. Irritation and odor are common complaints from patients. Relapses are common.

Sulfur-salicylic acid soap or shampoo (Sebulex) or zinc pyrithione-containing shampoos used on a continuing basis may be effective prophylaxis.

Ketoconazole, 200 mg daily orally for 1 week or 400 mg as a single oral dose, results in short-term cure of 90% of cases. Patients should be instructed not to shower for 12-18 hours after taking ketoconazole, because it is delivered in sweat to the skin. The single dose may not work in more hot and humid areas, and more protracted therapy carries a small but finite risk of drug-induced hepatitis for a completely benign disease. Without maintenance therapy, recurrences will occur in over 80% of "cured" cases over the subsequent 2 years.

Newer imidazole creams, solutions, and lotions are quite effective for localized areas but are too expensive for use over large areas such as the chest and back.

Rogers CJ et al: Diagnosing tinea versicolor: don't scrape, just tape. Pediatr Dermatol 2000;17:68. [\[PMID: 10720993\]](#)

DISCOID LUPUS ERYTHEMATOSUS (CHRONIC CUTANEOUS LUPUS ERYTHEMATOSUS)

Essentials of Diagnosis

- Localized red plaques, usually on the face.
- Scaling, follicular plugging, atrophy, dyspigmentation, and telangiectasia of involved areas.
- Histology distinctive.
- Photosensitive.

General Considerations

This type of lupus erythematosus is a localized inflammation of the skin occurring most frequently in areas exposed to solar irradiation. Permanent hair loss and loss of pigmentation are common sequelae. Systemic lupus erythematosus is discussed in [Chapter 20](#).

Clinical Findings

A. Symptoms and Signs

Symptoms are usually mild. The lesions consist of dusky red, well-localized, single or multiple plaques, 5-20 mm in diameter, usually on the face. The scalp, external ears, and oral mucous membranes may be involved. There is atrophy, telangiectasia, depigmentation, and follicular plugging. The lesion may be covered by dry, horny, adherent scales. On the scalp, significant hair loss may occur.

B. Laboratory Findings

If ANA is positive in high titer or when the clinical picture suggests systemic involvement, the findings of antibody to double-stranded DNA and hypocomplementemia suggest the diagnosis of systemic lupus erythematosus. Rare patients with marked photosensitivity and a picture otherwise suggestive of lupus have negative ANA tests but are positive for antibodies against Ro/SSA. A direct immunofluorescence test reveals basement membrane antibody but may be falsely positive in sun-exposed skin.

Differential Diagnosis

The diagnosis is based on the clinical appearance confirmed by skin biopsy in all cases. The scales are dry and "thumbtack-like" and can thus be distinguished from those of seborrheic dermatitis and psoriasis. Older lesions that have left depigmented scarring (classically in the concha of the ear) or areas of hair loss will also differentiate lupus from these diseases. Ten percent of patients with systemic lupus erythematosus have discoid skin lesions, and 5% of patients with discoid lesions have SLE. Medications (hydrochlorothiazide, calcium channel blockers) may induce chronic cutaneous lupus erythematosus with a positive Ro.

Treatment

A. General Measures

Protect from sunlight. Use high SPF (> 30) sunblock with UVB and UVA coverage daily. **Caution:** Do not use any form of radiation therapy. Avoid using drugs that are potentially photosensitizing (eg, thiazides, piroxicam) where possible.

B. Local Treatment

The following should be tried before systemic therapy: high-potency corticosteroid creams applied each night and covered with airtight, thin, pliable plastic film (eg, Saran Wrap); Cordran tape; or ultra-high-potency corticosteroid cream or ointment applied twice daily without occlusion.

C. Local Infiltration

Triamcinolone acetonide suspension, 2.5-10 mg/mL, may be injected into the lesions once a month. This should be tried before systemic therapy.

D. Systemic Treatment

1. Antimalarials—Caution: These drugs should be used only when the diagnosis is secure, because they have been associated with flares of psoriasis, which may be in the differential diagnosis. They may also cause ocular changes, and ophthalmologic evaluation is required every 6 months.

a. Hydroxychloroquine sulfate—0.2-0.4 g orally daily for several months may be effective and is often used prior to chloroquine. A 3-month trial is recommended.

b. Chloroquine sulfate—250 mg daily may be effective in some cases where hydroxychloroquine is not.

c. Quinacrine (Atabrine)—100 mg daily may be the safest of the antimalarials, since eye damage has not been reported. It colors the skin yellow and is therefore not acceptable to some patients. It may be added to the above antimalarials for incomplete responses.

2. Isotretinoin—Isotretinoin, 1 mg/kg/d, is effective in chronic or subacute cutaneous lupus erythematosus. Recurrences are prompt and predictable on discontinuation of therapy. Because of teratogenicity, the drug is used with caution in women of childbearing age using effective contraception with negative pregnancy tests before and during therapy.

3. Thalidomide—Thalidomide is a potent teratogen but very effective in refractory cases in doses of 50-100 mg daily. Monitor for neuropathy.

Prognosis

The disease is persistent but not life-endangering unless systemic lupus intervenes, which is uncommon. Treatment with antimalarials is effective in perhaps 60% of cases. Although the only morbidity may be cosmetic, this can be of overwhelming significance in more darkly pigmented patients with widespread disease. Scarring alopecia can be prevented or lessened with close attention and aggressive therapy.

Patel P et al: Cutaneous lupus erythematosus: a review. Dermatol Clin 2002;20:373. [\[PMID: 12170873\]](#)

CUTANEOUS T CELL LYMPHOMA (MYCOSIS FUNGOIDES)

Essentials of Diagnosis

- Localized or generalized erythematous scaling plaques.
- Pruritus.
- Lymphadenopathy.
- Distinctive histology.

General Considerations

Mycosis fungoides is a cutaneous T cell lymphoma that begins on the skin and may involve only the skin for years or decades. Certain medications (including SSRIs) may produce eruptions clinically and histologically identical to those of mycosis fungoides, so this possibility must always be considered.

Clinical Findings

A. Symptoms and Signs

Patients present with localized or generalized erythematous patches or plaques, usually on the trunk. Plaques are almost always over 5 cm in diameter. Pruritus is a frequent complaint. The lesions often begin as nondescript or nondiagnostic patches, and it is not unusual for the patient to have skin lesions for more than a decade before the diagnosis can be confirmed. In more advanced cases, tumors appear. Lymphadenopathy may occur locally or widely. Lymph node enlargement may be due to benign expansion of the node (dermatopathic lymphadenopathy) or by specific involvement with mycosis fungoides.

B. Laboratory Findings

The skin biopsy remains the basis of diagnosis, though at times numerous biopsies are required before the diagnosis can be confirmed. In addition, circulating atypical cells (Sézary cells) can be detected in the blood by sensitive methods. Eosinophilia may be present.

Differential Diagnosis

Mycosis fungoides may be confused with psoriasis, a drug eruption, an eczematous dermatitis, Hansen's disease (leprosy), or tinea corporis. Histologic examination can distinguish these conditions.

Treatment

The treatment of mycosis fungoides is complex. Early and aggressive treatment has not been proved to cure or prevent progression of the disease. Topical mechlorethamine ointment or solution, topical steroids, and PUVA are all used for early patches and plaques. Radiation therapy for local lesions and systemic agents such as retinoids, antitumor chemotherapeutic drugs, and alpha interferon are used alone or in various combinations for more advanced disease or in patients who fail topical therapy.

Prognosis

Mycosis fungoides is usually slowly progressive (over decades). Prognosis is better in patients with patch or plaque stage disease and worse in patients with erythroderma, tumors, and lymphadenopathy. Survival is not reduced in patients with limited patch disease. Elderly patients with patch and plaque stage disease commonly die of other causes. Overly aggressive treatment may lead to complications and premature demise.

EXFOLIATIVE DERMATITIS (EXFOLIATIVE ERYTHRODERMA)

Essentials of Diagnosis

- Scaling and erythema over most of the body.
- Itching, malaise, fever, chills, weight loss.

General Considerations

A preexisting dermatosis is the cause of exfoliative dermatitis in up to 63% of cases, including psoriasis, atopic dermatitis, contact dermatitis, pityriasis rubra pilaris, and seborrheic dermatitis. Reactions to topical or systemic drugs (eg, sulfonamides) account for perhaps 20-40% of cases and cancer (cutaneous T cell lymphoma, Sezary syndrome) for 10-20%. Causation of the remainder is indeterminable. At the time of acute presentation, without a clear-cut prior history of skin disease or drug exposure, it may be impossible to make a specific diagnosis of the underlying condition, and diagnosis may require observation.

Clinical Findings

A. Symptoms and Signs

Symptoms may include itching, weakness, malaise, fever, and weight loss. Chills are prominent. Redness and scaling may be generalized and sometimes include loss of hair and nails. Generalized lymphadenopathy may be due to lymphoma or leukemia or may be part of the clinical picture of the skin disease (dermatopathic lymphadenitis). The mucosa is spared.

B. Laboratory Findings

A skin biopsy is required and may show changes of a specific inflammatory dermatitis or cutaneous T cell lymphoma or leukemia. Peripheral leukocytes may show clonal rearrangements of the T cell receptor in Sezary syndrome.

Differential Diagnosis

It may be impossible to identify the cause of exfoliative dermatitis early in the course of the disease, so careful follow-up is necessary. Psoriasis, severe seborrheic dermatitis, and drug eruptions may have an erythrodermic phase.

Complications

Debility (protein loss) and dehydration may develop in patients with generalized inflammatory exfoliative erythroderma, or sepsis may occur.

Treatment

A. Topical Therapy

Home treatment is with cool to tepid baths and application of mid-potency steroids under wet dressings or with the use of an occlusive plastic suit. If the exfoliative erythroderma becomes chronic and is not manageable in an outpatient setting, hospitalize the patient. Keep the room at a constant warm temperature and provide the same topical treatment as for an outpatient.

B. Specific Measures

Stop all drugs, if possible. Systemic corticosteroids may provide spectacular improvement in severe or fulminant exfoliative dermatitis, but long-term therapy should be avoided (see [Chapter 26](#)). In addition, systemic corticosteroids must be used with caution because some patients with erythroderma have psoriasis and could develop pustular psoriasis. For cases of psoriatic erythroderma and pityriasis rubra pilaris, either acitretin or methotrexate may be indicated. Erythroderma secondary to lymphoma or leukemia requires specific topical or systemic chemotherapy. Suitable antibiotic drugs with coverage for staphylococcus should be given when there is evidence of bacterial infection.

Prognosis

Most patients recover completely or improve greatly over time but may require chronic therapy. Deaths are rare in the absence of cutaneous T cell lymphoma. A minority of patients will suffer from undiminished erythroderma for indefinite periods.

Levine N: Exfoliative erythroderma. Skin biopsy is required to determine the cause of this pruritic eruption. Geriatrics 2000;55:25. [\[PMID: 10953683\]](#)

MISCELLANEOUS SCALING DERMATOSES

Isolated scaly patches may represent actinic (solar) keratoses, nonpigmented seborrheic keratoses, or Bowen's or Paget's disease.

Actinic Keratoses

Actinic keratoses are small (0.2-1 cm) patches—flesh-colored, pink, or slightly hyperpigmented—that feel like sandpaper and are tender when the finger is drawn over them. They occur on sun-exposed parts of the body in persons of fair complexion. Actinic keratoses are considered premalignant, but only 1:1000 lesions per year progress to become squamous cell carcinomas.

Application of liquid nitrogen is a rapid and effective method of eradication. The lesions crust and disappear in 10-14 days. An alternative treatment is the use of 1-5% fluorouracil cream. This agent may be rubbed into the lesions morning and night until they become first red and sore and then crusted and eroded (usually 2-3 weeks), and then stopped. Carac (0.5% fluorouracil) may be used once daily for a longer period (6 weeks to several months). Keratoses may clear with less irritation. Any lesions that persist should be evaluated for possible biopsy.

Weiss J et al: Effective treatment of actinic keratosis with 0.5% fluorouracil cream for 1, 2, or 4 weeks. Cutis 2002;70(2 Suppl):22. [\[PMID: 12353677\]](#)

Dinehart SM: The treatment of actinic keratoses. J Am Acad Dermatol 2000;42(1 Part 2):25. [\[PMID: 10607354\]](#)

Bowen's Disease & Paget's Disease

Bowen's disease (intraepidermal squamous cell carcinoma) occurs either on sun-exposed or sun-protected cutaneous surfaces. The lesion is usually a small (1-3 cm), well-demarcated, slightly raised, pink to red, scaly plaque and may resemble psoriasis or a large actinic keratosis. While it may take some time, these lesions may progress to invasive squamous cell carcinoma. Excision or other definitive treatment is indicated.

Extramammary Paget's disease, considered by some to be a manifestation of apocrine sweat gland carcinoma, resembles chronic eczema and may involve apocrine areas such as the genitalia. There seems to be less likelihood of an underlying sweat gland carcinoma if the lesions are on the vulva than if they are on the perianal area. Mammary Paget's disease of the nipple, a unilateral or rarely bilateral red scaling plaque that may ooze, is associated with an underlying intraductal mammary carcinoma.

Zollo JD et al: The Roswell Park Cancer Institute experience with extramammary Paget's disease. Br J Dermatol 2000;142:59. [\[PMID: 10651695\]](#)

INTERTRIGO

Intertrigo is caused by the macerating effect of heat, moisture, and friction. It is especially likely to occur in obese persons and in humid climates. The symptoms are itching, stinging, and burning. The body folds develop fissures, erythema, and sodden epidermis, with superficial denudation. Candidiasis may complicate intertrigo. "Inverse psoriasis," tinea cruris, erythrasma, and candidiasis must be ruled out.

Maintain hygiene in the area, and keep it dry. Compresses may be useful acutely. Hydrocortisone 1% and an imidazole cream or nystatin cream are effective. Recurrences are common.

VESICULAR DERMATOSES

HERPES SIMPLEX (COLD OR FEVER SORE; GENITAL HERPES)

Essentials of Diagnosis

- Recurrent small grouped vesicles on an erythematous base, especially in the orolabial and genital areas.
- May follow minor infections, trauma, stress, or sun exposure; regional lymph nodes may be swollen and tender.
- Tzanck smear is positive for multinucleated epithelial giant cells; viral cultures and direct fluorescent antibody tests are positive.

General Considerations

Over 85% of adults have serologic evidence of herpes simplex type 1 (HSV-1) infections, most often acquired asymptomatically in childhood. Occasionally, primary infections may be manifested as severe gingivostomatitis. Thereafter, the subject may have recurrent self-limited attacks, provoked by sun exposure, orofacial surgery, fever, or a viral infection.

About 25% of the United States population has serologic evidence of infection with herpes simplex type 2 (HSV-2). HSV-2 causes lesions whose morphology and natural history are similar to those caused by HSV-1 on the genitalia of both sexes. The infection is acquired by sexual contact. In monogamous heterosexual couples where one partner has HSV-2 infection, seroconversion of the noninfected partner occurs in 10% over a 1-year period. Up to 70% of such infections appeared to be transmitted during periods of asymptomatic shedding. Owing to changes in sexual behavior, up to 40% of newly acquired cases of genital herpes are due to HSV-1.

Clinical Findings

A. Symptoms and Signs

The principal symptoms are burning and stinging. Neuralgia may precede or accompany attacks. The lesions consist of small, grouped vesicles that can occur anywhere but which most often occur on the vermilion border of the lips, the penile shaft, the labia, the perianal skin, and the buttocks. Regional lymph nodes may be swollen and tender. The lesions usually crust and heal in 1 week. Patients can be educated to recognize attacks that they previously did not identify as recurrences of herpes simplex. Herpes simplex is the most common cause of painful genital ulcerations in patients with HIV infection.

B. Laboratory Findings

Lesions of herpes simplex must be distinguished from chancroid, syphilis, pyoderma, or trauma. Direct immunofluorescent antibody slide tests offer rapid, sensitive diagnosis. Viral culture may also be helpful. The Tzanck smear, which demonstrates multinucleated cells, is the least sensitive test. Herpes simplex and varicella-zoster viruses cannot be distinguished on the Tzanck smear. Herpes serology is not used in the diagnosis of an acute genital ulcer. However, specific HSV 2 serology by Western blot or new ELISA assays can determine who is HSV-infected and potentially infectious. Likewise, a negative serology documents lack of infection, ie, risk for infection. Such testing is very useful in couples in which only one partner reports a history of genital herpes.

Complications

Complications include pyoderma, eczema herpeticum, herpetic whitlow, herpes gladiatorum (epidemic herpes in wrestlers transmitted by contact), esophagitis, neonatal infection, keratitis, and encephalitis.

Prevention

Sunscreens are very useful adjuncts in preventing sun-induced recurrences. Prophylactic use of oral acyclovir may prevent recurrences. Acyclovir should be started at a dosage of 200 mg five times daily beginning 24 hours prior to ultraviolet light exposure, dental surgery, or orolabial cosmetic surgery. Comparable doses are 500 mg twice daily for valacyclovir and 250 mg twice daily for famciclovir.

Treatment

A. Systemic Therapy

Three systemic agents are available for the treatment of herpes infections: acyclovir, its valine analog valacyclovir, and famciclovir. All three agents are very effective and, when used properly, virtually nontoxic. Only acyclovir is available for intravenous administration. In the nonimmunocompromised, with the exception of severe orolabial herpes, only genital disease is treated. For first clinical episodes (including primary) herpes simplex, the dosage of acyclovir is 200 mg orally five times daily (or 800 mg three times daily); of valacyclovir, 1000 mg twice daily; and of famciclovir, 250 mg three times daily. The duration of treatment is from 7 to 10 days depending on the severity of the outbreak. Most cases of recurrent herpes are mild and do not require therapy. In addition, pharmacotherapy is of limited benefit, with studies finding a reduction in the average outbreak by only 12-24 hours. If treatment is desired, recurrent genital herpes outbreaks may be treated with 3 days of valacyclovir, 500 mg twice daily, or with 5 days of acyclovir, 200 mg five times a day, or with famciclovir, 125 mg twice daily. Valacyclovir, 2 g twice daily for 1 day, is approved for recurrences of orolabial herpes. The addition of a potent topical steroid three times daily reduces the duration, size, and pain of orolabial herpes treated with an oral antiviral agent.

In patients with frequent or severe recurrences, suppressive therapy is most effective in controlling disease. Suppressive treatment will reduce outbreaks by 85% and reduces viral shedding by more than 90%. The recommended suppressive doses, taken continuously, are acyclovir, 400 mg twice daily; valacyclovir, 500 mg once daily; or famciclovir, 125-250 mg twice daily. Long-term suppression appears very safe, and after 5-7 years a substantial proportion of patients can discontinue treatment. It is unknown if the suppression of outbreaks and asymptomatic shedding will reduce transmission, but given the reduction of viral titers such therapy provides this might be considered as part of patient education. Barrier protection is not completely effective, since shedding occurs from widespread areas of the perineum not covered by condoms.

B. Local Measures

In general, topical therapy is not effective. It is strongly urged that 5% acyclovir ointment, if used at all, be limited to the restricted indications for which it has been approved, ie, initial herpes genitalis and mucocutaneous herpes simplex infections in immunocompromised patients. Penciclovir cream, to be applied at the first

symptom every 2 hours while awake for 4 days for recurrent orolabial herpes, reduces the average attack duration from 5 days to 4.5 days.

Prognosis

Aside from the complications described above, recurrent attacks last several days, and patients recover without sequelae.

HERPES ZOSTER (SHINGLES)

Essentials of Diagnosis

- Pain along the course of a nerve followed by painful grouped vesicular lesions.
- Involvement is unilateral; some lesions (< 20) may occur outside the affected dermatome.
- Lesions are usually on face or trunk.
- Tzanck smear positive, especially in vesicular lesions.

General Considerations

Herpes zoster is an acute vesicular eruption due to the varicella-zoster virus. It usually occurs in adults. With rare exceptions, patients suffer only one attack. Dermatomal herpes zoster does not imply the presence of a visceral malignancy. Generalized disease, however, raises the suspicion of an associated immunosuppressive disorder such as Hodgkin's disease or HIV infection. HIV-infected patients are 20 times more likely to develop zoster, often before other clinical findings of HIV disease are present. A history of HIV risk factors and HIV testing when appropriate should be considered, especially in zoster patients under 55 years of age.

Clinical Findings

Pain usually precedes the eruption by 48 hours or more and may persist and actually increase in intensity after the lesions have disappeared. The lesions consist of grouped, tense, deep-seated vesicles distributed unilaterally along a dermatome. The commonest distributions are on the trunk or face. Up to 20 lesions may be found outside the affected dermatomes. Regional lymph glands may be tender and swollen.

Differential Diagnosis

Since poison oak and poison ivy dermatitis can occur unilaterally, they must be differentiated at times from herpes zoster. Allergic contact dermatitis is pruritic; zoster is painful. One must differentiate herpes zoster from lesions of herpes simplex, which occasionally occurs in a dermatomal distribution. One should use doses of antivirals appropriate for zoster in the absence of a clear diagnosis. Facial zoster may simulate erysipelas initially, but zoster is unilateral and shows vesicles after 24-48 hours. The pain of preeruptive herpes zoster may lead the clinician to diagnose migraine, myocardial infarction, acute abdomen, herniated nucleus pulposus, etc, depending on the dermatome involved.

Complications

Sacral zoster may be associated with bladder and bowel dysfunction. Persistent neuralgia, anesthesia or scarring of the affected area following healing, facial or other nerve paralysis, and encephalitis may occur. Postherpetic neuralgia is most common after involvement of the trigeminal region, and in patients over the age of 55. Early (within 72 hours after onset) and aggressive antiviral treatment of herpes zoster reduces the severity and duration of postherpetic neuralgia. Zoster ophthalmicus (V₁) can result in visual impairment.

Treatment

A. General Measures

1. Immunocompetent host—Since early treatment of zoster reduces postherpetic neuralgia, those with a risk of developing this complication should be treated, ie, those over age 55. In addition, younger patients with acute moderate to severe pain may be benefited by effective antiviral therapy. Treatment can be given with oral acyclovir, 800 mg five times daily; famciclovir, 500 mg three times daily; or valacyclovir, 1 g three times daily—all for 7 days. For reasons of increased bioavailability and ease of dosing schedule, the preferred agents are those given three times daily. Patients should maintain good hydration, and elderly patients with reduced renal function should be followed closely. The dose of antiviral should be adjusted for renal function as recommended. Nerve blocks may be important in the management of initial severe pain. Ophthalmologic consultation is vital for involvement of the first branch of the trigeminal nerve. Systemic corticosteroids are effective in reducing acute pain, improving quality of life, and returning patients to normal activities much more quickly. They do not increase the risk of dissemination in immunocompetent hosts. If not contraindicated, a tapering 3-week course of prednisone, starting at 60 mg/d, should be considered for its adjunctive benefit in immunocompetent patients. Oral corticosteroids do not reduce the prevalence, severity, or duration of postherpetic neuralgia beyond that achieved by effective antiviral therapy.

2. Immunocompromised host—Given the safety and efficacy of currently available antivirals, most immunocompromised patients with herpes zoster are candidates for antiviral therapy. The dosage schedule is as listed above, but treatment should be continued until the lesions have completely crusted and are healed or almost healed (up to 2 weeks). Corticosteroids should not be given adjunctively in immunosuppressed hosts since they increase the risk of dissemination. Progression of disease may necessitate intravenous therapy with acyclovir, 10 mg/kg intravenously, three times daily. After 3-4 days, oral therapy may be substituted if there has been a good response to intravenous therapy. Adverse effects include decreased renal function from crystallization, nausea and vomiting, and abdominal pain.

Foscarnet, administered in a dosage of 40 mg/kg two or three times daily intravenously, is indicated for treatment of acyclovir-resistant varicella-zoster virus infections.

B. Local Measures

Calamine or starch shake lotions may be of some help.

C. Postherpetic Neuralgia

The most effective treatment is prevention with early and aggressive antiviral therapy. Once established, postherpetic neuralgia may be treated with capsaicin ointment, 0.025-0.075%, or lidocaine (Lidoderm) topical patches. Chronic postherpetic neuralgia may be relieved by regional blocks (stellate ganglion, epidural, local infiltration, or peripheral nerve), with or without corticosteroids added to the injections. Amitriptyline, 25-75 mg as a single nightly dose, is the first-line oral therapy beyond simple analgesics. Gabapentin, up to 3600 mg daily (starting at 300 mg three times daily), may be added for additional pain relief.

Prognosis

The eruption persists 2-3 weeks and usually does not recur. Motor involvement in 2-3% may lead to temporary palsy.

VARIOLA (SMALLPOX) & VACCINIA

Essentials of Diagnosis

- Prodromal high fever.
- Eruption progressing from papules to vesicles to pustules, then crusts.
- All lesions in the same stage.
- Face and distal extremities (including palms and soles) favored.

General Considerations

Concern for the use of smallpox virus as a bioterrorist weapon has led to the reintroduction of vaccination in some segments of the population (first responders and the military). (See [Chapter 1](#))

Clinical Findings

The incubation period for variola averages 12 days (7-17 days). The prodrome begins with abrupt onset of high fever, severe headaches, and backaches. At this stage, the infected person appears quite ill. The infectious phase begins with the appearance of an enanthem, followed in 1-2 days by a skin eruption. The lesions begin as macules, progressing to papules, then pustules, and finally crusts over 14-18 days. The face and distal extremities are favored. The face is affected first, followed by the upper extremities, then the lower extremities and trunk, completely evolving over 1 week. Lesions are relatively monomorphous, especially in each anatomic region.

Inoculation with vaccinia produces a papular lesion on day 2-3 that progresses to an umbilicated papule by day 4 and a pustular lesion by the end of the first week. The lesion then collapses centrally, and crusts. The crust eventually detaches up to a month after the inoculation. Persons with eczema should not be immunized as they may suffer widespread vaccinia (eczema vaccinatum) whose lesions might resemble those of smallpox. Vaccinia is moderately contagious, and patients with certain skin diseases may acquire severe generalized disease by exposure to a recently vaccinated person. Generalized vaccinia may be fatal. Prior vaccination does not prevent generalized vaccinia, but previously vaccinated individuals have milder disease. Progressive vaccinia (vaccinia gangrenosum)—progression of the primary inoculation site to a large ulceration—occurs in persons with systemic immune deficiency. It can have a fatal outcome.

Differential Diagnosis

Smallpox and vaccinia are to be distinguished from generalized varicella zoster virus infection or generalized herpes simplex. The latter two viral infections are not associated with a severe febrile prodrome. Lesions are at various stages at each anatomic site. Varicella usually appears in waves or crops. Multiple palm and sole lesions are common in variola and uncommon in generalized varicella-zoster and herpes simplex infection.

Direct fluorescent antibody testing for HSV and VZV are the first-line diagnostic tests to differentiate VZV, HSV, vaccinia, and variola. Until the diagnosis is confirmed, strict isolation of the patient is indicated. Similar fluorescent testing for variola can be performed in special laboratories.

Treatment

There is no specific and proven antiviral therapy for vaccinia or variola. Vaccinia immune globulin is used to treat eczema vaccinatum and progressive vaccinia. Cidofovir may have some activity against these poxviruses.

POMPHOLYX; VESICULOBULLOUS HAND ECZEMA (DYSHIDROSIS, DYSHIDROTIC ECZEMA)

Essentials of Diagnosis

- "Tapioca" vesicles of 1-2 mm on the palms, soles, and sides of fingers, associated with pruritus.
- Vesicles may coalesce to form multiloculated blisters.
- Scaling and fissuring may follow drying of the blisters.
- Appearance in the third decade, with lifelong recurrences.

General Considerations

"Dyshidrotic eczema" is a misnomer, suggesting that the vesicles of this condition are related to eccrine sweat ducts and sweating, which they are not. This is an extremely common form of hand dermatitis, preferably called pompholyx (Gr "bubble") or vesiculobullous dermatitis of the palms and soles. Patients often have an atopic background and report flares with stress. Clues to a possible cause of pompholyx are suggested by the following observations. In Scandinavia, women with contact allergy to nickel and pompholyx appear to flare when given oral challenges with nickel. Nickel-free diets have given variable results. The chelator disulfiram has been reported to cause a 25% improvement in one controlled study in nickel-sensitive patients, and oral cromolyn sodium has also been shown to be of benefit. Patients with widespread dermatitis due to any cause may develop pompholyx-like eruptions as a part of an autoeczematization response.

Clinical Findings

Small clear vesicles stud the skin at the sides of the fingers and on the palms or soles. They look like the grains in tapioca. They may be associated with intense itching. Later, the vesicles dry and the area becomes scaly and fissured.

Differential Diagnosis

Unroofing the vesicles and scraping the blister roof for a KOH examination will reveal hyphae in cases of bullous tinea. Blisters extending onto the dorsum of the hands may represent allergic contact dermatitis, and the culprit must be sought by history or by patch testing. Patients with inflammatory tinea pedis may have a vesicular dermatophytid of the palms. NSAIDs may produce an eruption very similar to that of dyshidrosis.

Prevention

There is no known way to prevent attacks.

Treatment

Topical and systemic corticosteroids help some patients dramatically. Since this is a chronic problem, systemic steroids are generally not appropriate therapy. A high-potency topical steroid used early in the attack may help abort the flare and ameliorate pruritus. Topical steroids are also important in treating the scaling and fissuring that are seen after the vesicular phase. It is essential that patients avoid anything that irritates the skin; they should wear cotton gloves inside vinyl gloves when doing dishes or other wet chores, use long-handled brushes instead of sponges, and use a hand cream after washing the hands. If a history of nickel allergy (rashes with costume jewelry or from watchbands) is obtained, nickel-free diets may be considered. Patients respond to PUVA therapy using topical psoralen and UVA light.

Prognosis

For most patients, the disease is an inconvenience. For some, vesiculobullous hand eczema can be incapacitating.

Swartling C et al: Treatment of dyshidrotic hand dermatitis with intradermal botulinum toxin. J Am Acad Dermatol 2002; 47:667. [\[PMID: 12399757\]](#)

DERMATOPHYTID (ALLERGY OR SENSITIVITY TO FUNGI)

Essentials of Diagnosis

- Pruritic, grouped vesicular lesions involving the sides and flexor aspects of the fingers and the palms.
- Fungal infection elsewhere on the body, usually the feet.
- No fungus demonstrable in lesions.

General Considerations

Dermatophytid must be considered in the differential diagnosis of vesicles on the hands and feet. It is a hypersensitivity reaction to an active focus of inflammatory dermatophytosis elsewhere on the body, usually the feet. Fungi are present in the primary lesions but are not present in the lesions of dermatophytid. The hands are most often affected, but dermatophytid may occur on other areas also.

Clinical Findings

A. Symptoms and Signs

Itching is the only symptom.

B. Laboratory Findings

This entity is best diagnosed morphologically and by response to treatment.

Differential Diagnosis

Dermatophytid must be distinguished from all diseases causing vesicular eruptions of the hands—especially contact dermatitis, pompholyx, and photosensitive drug eruptions and "id" reactions due to inflammatory rashes.

Treatment

The primary focus of tinea should be treated with an oral antifungal or by local measures as described for dermatophytosis (see above). Topical steroids with occlusion may benefit.

Prognosis

Dermatophytid clears with adequate treatment of the primary infection elsewhere on the body. An initial flare can occur when oral therapy is started. Recurrences are not uncommon.

Busch RF: Dermatophytid reaction and chronic otitis externa. Otolaryngol Head Neck Surg 1998;118(3 Part 1):420. [\[PMID: 9727132\]](#)

PORPHYRIA CUTANEA TARDA

Essentials of Diagnosis

- Noninflammatory blisters on sun-exposed sites, especially the dorsal surfaces of the hands.
- Hypertrichosis, skin fragility.
- Associated liver disease.
- Elevated urine porphyrins.

General Considerations

Porphyria cutanea tarda is the most common type of porphyria. Cases are sporadic or hereditary. The disease is associated with ingestion of certain medications (eg, estrogens), and liver disease from alcoholism or hepatitis C. In patients with liver disease, hemosiderosis is often present.

Clinical Findings

A. Symptoms and Signs

Patients complain of painless blistering and fragility of the skin of the dorsal surfaces of the hands. Facial hypertrichosis and hyperpigmentation are common.

B. Laboratory Findings

Urinary uroporphyrins are elevated two- to fivefold above coproporphyrins. Patients may also have abnormal liver function tests, evidence of hepatitis C infection, increased liver iron stores, and hemochromatosis gene mutations. Multiple triggering factors are often discovered.

Differential Diagnosis

Skin lesions identical to those of porphyria cutanea tarda may be seen in patients being maintained on dialysis and with the ingestion of certain medications (tetracyclines and NSAIDs, especially naproxen). In this so-called pseudoporphyria, the biopsy results are identical to those associated with porphyria cutanea tarda, but urine porphyrins are normal.

Prevention

Although the lesions are triggered by sun exposure, the wavelength of light triggering the lesions is beyond that absorbed by sunscreens, which for that reason are ineffective. Barrier sun protection with clothing is required.

Treatment

Stopping all triggering medications and substantially reducing or stopping alcohol consumption may alone lead to improvement. Phlebotomy without oral iron supplementation at a rate of one unit every 2-4 weeks will gradually lead to improvement. Very low dose antimalarials (as low as 200 mg of hydroxychloroquine twice weekly) will increase the excretion of porphyrins, improving the skin disease. Treatment is continued until the patient is asymptomatic. Urine porphyrins may be monitored.

Prognosis

Most patients improve with treatment. Sclerodermoid skin lesions may develop on the trunk, scalp, and face.

Rich MW: Porphyria cutanea tarda. Don't forget to look at the urine. Postgrad Med 1999;105:208. [\[PMID: 10223097\]](#)

DERMATITIS HERPETIFORMIS

Dermatitis herpetiformis is an uncommon disease manifested by pruritic papules, vesicles, and papulovesicles mainly on the elbows, knees, buttocks, posterior neck, and scalp. It appears to have its highest prevalence in Scandinavia and is associated with HLA antigens -B8, -DR3, and -DQ2. The diagnosis is made by light microscopy, which demonstrates neutrophils at the dermal papillary tips. Direct immunofluorescence studies show granular deposits of IgA along the dermal papillae. Circulating antiendomysium antibodies and antibodies to tissue transglutaminase are present in 70% of cases. Patients have gluten-sensitive enteropathy, but for the great majority it is subclinical. However, ingestion of gluten plays a role in the exacerbation of skin lesions, and strict long-term avoidance of dietary gluten has been shown to decrease the dose of dapsone (usually 100-200 mg/d) required to control the disease and may even eliminate the need for drug treatment. Although adherence to a gluten-free diet is difficult, the availability of many gluten-free foods makes this easier to accomplish. Patients with dermatitis herpetiformis are at

increased risk for development of gastrointestinal lymphoma, and this risk is reduced by a gluten-free diet.

WEEPING OR ENCRUSTED LESIONS

IMPETIGO

Impetigo is a contagious and autoinoculable infection of the skin caused by staphylococci or streptococci (or both). Classically, two forms have been recognized: (1) a vesiculopustular type, with thick golden-crusts lesions caused by *Staphylococcus aureus* or group A β -hemolytic streptococcus; and (2) a bullous type, associated with phage group II *S aureus*. However, most cases of impetigo of either presentation now appear to be due to staphylococci.

Clinical Findings

A. Symptoms and Signs

Itching is the only symptom. The lesions consist of macules, vesicles, bullae, pustules, and honey-colored gummy crusts that when removed leave denuded red areas. The face and other exposed parts are most often involved. **Ecthyma** is a deeper form of impetigo caused by staphylococci or streptococci, with ulceration and scarring. It occurs frequently on the legs and other covered areas.

B. Laboratory Findings

Gram stain and culture confirm the diagnosis.

Differential Diagnosis

The main differential diagnosis is between impetigo and acute allergic contact dermatitis or herpes simplex. Contact dermatitis may be suggested by the history or by linear distribution of the lesions, and culture should be negative for staphylococci and streptococci. Herpes simplex infection usually presents with grouped vesicles or discrete erosions and may be associated with a history of recurrences. Viral cultures of the lesions are positive.

Treatment

Topical antibiotics are not as effective as systemic antibiotics. Two percent mupirocin ointment (Bactroban), dispensed as 15 g and used three times daily for 10 days, may be effective for limited disease. If the affected area is large or if there is fever or toxicity—or if there is any concern that a nephritogenic strain of streptococcus may be causative—systemic antibiotics should be given. Dicloxacillin or cephalexin, 250 mg four times daily, is usually effective. Doxycycline, 100 mg twice daily, is a reasonable alternative. Methicillin-resistant *S aureus* (MRSA) may cause impetigo, and initial coverage for MRSA could include doxycycline, a quinolone, or trimethoprim-sulfamethoxazole. Recurrent impetigo is associated with nasal carriage of *S aureus*, treated with rifampin, 600 mg daily, or intranasal mupirocin 2% ointment twice daily for 5 days.

Crusts and weepy areas may be treated with compresses, and washcloths and towels must be segregated and washed separately.

Levine N: Eruption on the face. Bulla formation and crusting on the forehead and nose can be easily treated. Geriatrics 2002;57:17. [\[PMID: 12271824\]](#)

ALLERGIC CONTACT DERMATITIS

Essentials of Diagnosis

- Erythema and edema, with pruritus, often followed by vesicles and bullae in an area of contact with a suspected agent.
- Later, weeping, crusting, or secondary infection.
- A history of previous reaction to suspected contactant.
- Patch test with agent positive.

General Considerations

Contact dermatitis is an acute or chronic dermatitis that results from direct skin contact with chemicals or allergens. Eighty percent of cases are due to excessive exposure to or additive effects of primary or universal irritants (eg, soaps, detergents, organic solvents) and are called irritant contact dermatitis. The minority are due to actual contact allergy such as poison ivy or poison oak. The most common topicals causing allergic rashes include antimicrobials (especially neomycin), antihistamines, anesthetics (benzocaine), hair dyes, preservatives (eg, parabens), jewelry (nickel), latex, and adhesive tape. Occupational exposure is an important cause of allergic contact dermatitis. Weeping and crusting are typically due to allergic and not irritant dermatitis, which often appears red and scaly. Contact dermatitis due to latex rubber in gloves is of special concern in health care workers.

Clinical Findings

A. Symptoms and Signs

In allergic contact dermatitis, the acute phase is characterized by tiny vesicles and weepy and crusted lesions, whereas resolving or chronic contact dermatitis presents with scaling, erythema, and possibly thickened skin. Itching, burning, and stinging may be severe. The lesions, distributed on exposed parts or in bizarre asymmetric patterns, consist of erythematous macules, papules, and vesicles. The affected area is often hot and swollen, with exudation and crusting, simulating and at times complicated by infection. The pattern of the eruption may be diagnostic (eg, typical linear streaked vesicles on the extremities in poison oak or ivy dermatitis). The location will often suggest the cause: Scalp involvement suggests hair tints, sprays, or tonics; face involvement, creams, cosmetics, soaps, shaving materials, nail polish; and neck involvement, jewelry, hair dyes, etc.

B. Laboratory Findings

Gram stain and culture will rule out impetigo or secondary infection (impetiginization). If itching is generalized and impetiginized scabies is considered, a scraping for mites should be done. After the episode has cleared, the patch test may be useful if the triggering allergen is not known. In suspected photocontact dermatitis—involvement of face, "V" (suprasternal notch) of the upper chest, and hands, sparing the skin under the nose, chin, and inner upper eyelid—photopatch tests may be done by exposing the traditional patch test site to ultraviolet light after 24 hours.

Differential Diagnosis

Asymmetric distribution, blotchy erythema around the face, linear lesions, and a history of exposure help distinguish acute contact dermatitis from other skin lesions. The most commonly mistaken diagnosis is impetigo. Chronic allergic contact dermatitis must be differentiated from scabies, dermatophytid, atopic dermatitis, pompholyx, and other eczemas.

Prevention

Prompt and thorough removal of allergens by washing with water or solvents or other chemical agents may be effective if done very shortly after exposure to poison oak or ivy. Several barrier creams (eg, Stokogard, Ivy Shield) offer some protection to patients at high risk for poison oak and ivy dermatitis if applied before exposure. Iodoquinol cream (Vioform) may benefit nickel allergic patients in a similar manner. Ingestion of rhus antigen is of limited clinical value for the induction of tolerance.

The mainstay of prevention is identification of agents causing the dermatitis and avoidance of exposure or use of protective clothing and gloves. In industry-related cases, prevention may be accomplished by moving the worker to another part of the workplace with different responsibilities.

Treatment

A. Overview

While local measures are important, severe or widespread involvement is difficult to manage without systemic corticosteroids because even the highest-potency topical steroids seem not to work well on vesicular and weepy lesions. Localized involvement (except on the face) can often be managed solely with topical agents. Irritant contact dermatitis is treated by protection from the irritant and use of topical steroids as for atopic dermatitis (described above). The treatment of allergic contact dermatitis is detailed below.

B. Local Measures

1. Acute weeping dermatitis—Compresses are most often used. It is unwise to scrub lesions with soap and water. Calamine or starch shake lotions may sometimes be used in intervals between wet dressings, especially for involvement of intertriginous areas or when oozing is not marked. Lesions on the extremities may be bandaged with wet dressings for 30-60 minutes several times a day. Potent topical corticosteroids in gel or cream form may help suppress acute contact dermatitis and relieve itching. In cases where weeping is marked or in intertriginous areas, ointments will make the skin even more macerated and should be avoided. Suggested preparations are fluocinonide gel, 0.05%, used two or three times daily with compresses, or clobetasol or halobetasol cream, used twice daily for a maximum of 2 weeks—not in body folds or on the face. This should be followed by tapering of the number of applications per day or use of a mid-potency steroid such as triamcinolone 0.1% cream to prevent rebound of the dermatitis. A soothing formulation is 0.1% triamcinolone acetone in Sarna lotion (0.5% camphor, 0.5% menthol, 0.5% phenol).

2. Subacute dermatitis (subsiding)—Mid-potency (triamcinolone 0.1%) to high-potency steroids (amcinonide, fluocinonide, desoximetasone) are the mainstays of therapy.

3. Chronic dermatitis (dry and lichenified)—High- to highest-potency steroids are used in ointment form.

C. Systemic Therapy

For acute severe cases, one may give prednisone orally for 12-21 days. Prednisone, 60 mg for 4-7 days, 40 mg for 4-7 days, and 20 mg for 4-7 days without a further taper is one useful regimen. Another is to dispense seventy-eight 5-mg pills to be taken 12 the first day, 11 the second day, and so on. The key is to use enough corticosteroid (and as early as possible) to achieve a clinical effect and to taper slowly enough to avoid rebound. A Medrol Dosepak (methylprednisolone) with 5 days of medication is inappropriate on both counts. (See [Chapter 26](#).)

Prognosis

Allergic contact dermatitis is self-limited if reexposure is prevented but often takes 2-3 weeks for full resolution.

PUSTULAR DISORDERS

ACNE VULGARIS

Essentials of Diagnosis

- Occurs at puberty, though onset may be delayed into the third or fourth decade.
- Open and closed comedones are the hallmark of acne vulgaris.
- The most common of all skin conditions.
- Severity varies from purely comedonal to papular or pustular inflammatory acne to cysts or nodules.
- Face and trunk may be affected.
- Scarring may be a sequela of the disease or picking and manipulating by the patient.

General Considerations

Acne vulgaris is polymorphic. Open and closed comedones, papules, pustules, and cysts are found. The disease is activated by androgens in those who are genetically predisposed.

Acne vulgaris is more common and more severe in males. It does not always clear spontaneously when maturity is reached. Twelve percent of women and 3% of men over age 25 have acne vulgaris. This rate does not decrease until after age 44. The skin lesions parallel sebaceous activity. Pathogenic events include plugging of the infundibulum of the follicles, retention of sebum, overgrowth of the acne bacillus (*Propionibacterium acnes*) with resultant release of and irritation by accumulated fatty acids, and foreign body reaction to extrafollicular sebum. The mechanism of antibiotics in controlling acne is not clearly understood, but they may work because of their antibacterial or anti-inflammatory properties. Relapse or resistance may occur after emergence of tetracycline- or erythromycin-resistant strains of *P acnes*. These strains are usually sensitive to minocycline, however.

When a resistant case of acne is encountered in a woman, hyperandrogenism may be suspected. This may or may not be accompanied by hirsutism, irregular menses, or other signs of virilism.

Clinical Findings

There may be mild soreness, pain, or itching. The lesions occur mainly over the face, neck, upper chest, back, and shoulders. Comedones are the hallmark of acne vulgaris. Closed comedones are tiny, flesh-colored, noninflamed bumps that give the skin a rough texture or appearance. Open comedones typically are a bit larger and have black material in them. Inflammatory papules, pustules, ectatic pores, acne cysts, and scarring are also seen.

Acne may have different presentations at different ages. Preteens often present with comedones as their first lesions. Inflammatory lesions in young teenagers are often found in the middle of the face, extending outward as the patient becomes older. Women in their third and fourth decades (often with no prior history of acne) commonly present with papular lesions on the chin and around the mouth—so-called perioral dermatitis.

Differential Diagnosis

In adults, acne rosacea presents with papules and pustules in the middle third of the face, but telangiectasia, flushing, and the absence of comedones distinguish this disease from acne vulgaris. A pustular eruption on the face in patients receiving antibiotics or with otitis externa should be investigated with culture to rule out an uncommon gram-negative folliculitis. Patients who use systemic steroids or topical fluorinated steroids on the face may develop acne. Acne may be exacerbated or caused by irritating creams or oils. Pustules on the face can also be caused by tinea infections. Lesions on the back are more problematic. When they occur alone, one should suspect staphylococcal folliculitis, miliaria ("heat rash"), or, uncommonly, malassezia folliculitis. Bacterial culture, trial of an antistaphylococcal antibiotic, and observing the response to therapy will help in the differential diagnosis. In patients with HIV infection, folliculitis is common and often severe and may be either staphylococcal folliculitis or eosinophilic folliculitis.

Complications

Cyst formation, pigmentary changes in pigmented patients, severe scarring, and psychologic problems may result.

Treatment

A. General Measures

1. Education of the patient—When scarring seems out of proportion to the severity of the lesions, one must suspect that the patient is manipulating the lesions. It is essential that the patient be educated in a supportive way about this complication. Although there are exceptions, it is wise to let the patient know that at least 4-6 weeks will be required to see improvement and that old lesions may take months to fade. Therefore, improvement will be judged according to the number of new lesions forming after 6-8 weeks of therapy. Additional time will be required to see improvement on the back and chest, as these areas are slowest to respond. If hair pomades are used, they should contain glycerin and not oil. Avoid topical exposure to oils, cocoa butter (theobroma oil), and greases.

2. Diet—Foods do not cause or exacerbate acne.

B. Comedonal Acne

Treatment of acne is based on the type and severity of lesions. Comedones require treatment different from that of pustules and cystic lesions. In assessing severity, one must also take the sequelae of the lesions into account. Therefore, one must treat an individual who gets only two new lesions per month that scar or leave postinflammatory hyperpigmentation much more aggressively than a comparable patient whose lesions clear without sequelae. Soaps play little role in acne treatment, and unless the patient's skin is exceptionally oily, a mild soap should be used to avoid irritation that will limit the usefulness of other topicals, all of which are themselves somewhat irritating.

1. Topical retinoids—Tretinoin is very effective for comedonal acne or for treatment of the comedonal component of more severe acne, but its usefulness is limited by irritation. Start with 0.025% cream (not gel) and have the patient use it at first twice weekly at night, then build up to as often as nightly. A few patients cannot use even this low-strength preparation more than three times weekly, but even that may cause improvement. A pea-sized amount is sufficient to cover half the entire face. To avoid irritation, have the patient wait 20 minutes after washing to apply. Adapalene gel 0.1% and reformulated tretinoin (Renova, Retin A Micro, Avita) are other options for patients irritated by standard tretinoin preparations. Some patients—especially teenagers—do best on 0.01% gel. Although the absorption of tretinoin is minimal, its use during pregnancy is contraindicated. Some patients report photosensitivity with tretinoin. Patients should be warned that they may flare in the first 4 weeks of treatment. Tazarotene gel (0.05% or 0.1%) (Tazorac), a topical retinoid approved for treatment of psoriasis and acne, may also be effective.

2. Benzoyl peroxide—Benzoyl peroxide products are available in concentrations of 2.5%, 4%, 5%, 8%, and 10%, but it appears that 2.5% is as effective as 10% and less irritating. In general, water-based and not alcohol-based gels should be used to decrease irritation.

3. Antibiotics—Use of topical antibiotics (see below) has been demonstrated to decrease comedonal lesions.

4. Comedo extraction—Open and closed comedones may be removed with a comedo extractor but will recur if not prevented by treatment.

C. Papular Inflammatory Acne

Antibiotics are the mainstay for treatment of inflammatory acne. They may be used topically or orally. The oral antibiotics of choice are tetracycline and erythromycin. Minocycline is often effective in acne unresponsive or resistant to treatment with these antibiotics but it is expensive. Doxycycline is effective, economical, and easy to take. Rarely, other antibiotics such as trimethoprim-sulfamethoxazole (one double-strength tablet twice daily), clindamycin (150 mg twice daily), or a cephalosporin (cefadroxil or cephalexin) may be tried. Topical clindamycin phosphate and erythromycin are also used (see below). Topicals are probably the equivalent of about 500 mg/d of tetracycline given orally, which is half the usual starting dose. Topical antibiotics are used in three situations: for mild papular acne that can be controlled by topicals alone, for patients who refuse or cannot tolerate oral antibiotics, or to wean patients under good control from oral to topical preparations. It has been recommended that switching or rotating antibiotics be avoided to decrease resistance and that courses of benzoyl peroxide be used on occasion.

1. Mild acne—The first choice of topical antibiotics in terms of efficacy and relative lack of induction of resistant *P. acnes* is the combination of erythromycin or clindamycin with benzoyl peroxide topical gel. Clindamycin (Cleocin T) lotion (least irritating), gel, or solution, or one of the many brands of topical erythromycin gel or solution, may be used twice daily and the benzoyl peroxide in the morning. (A combination of erythromycin or clindamycin with benzoyl peroxide is available as a prescription item.) The addition of tretinoin 0.025% cream or 0.01% gel at night may be effective, since it works via a different mechanism.

2. Moderate acne—Tetracycline, 500 mg twice daily, erythromycin, 500 mg twice daily, doxycycline, 100 mg twice daily, and minocycline, 50-100 mg twice daily, are all effective though minocycline is more expensive. When initiating minocycline therapy, start at 100 mg in the evening for 4-7 days, then 100 mg twice daily, to decrease the incidence of vertigo. Plan a return visit in 6 weeks and at 3-4 months after that. If the patient's skin is quite clear, instructions should be given for tapering the dose by 250 mg for tetracycline and erythromycin, by 100 mg for doxycycline, or by 50 mg for minocycline every 6-8 weeks—while treating with topicals—to arrive at the lowest systemic dose needed to maintain clearing. In general, lowering the dose to zero without other therapy results in prompt recurrence of acne. Tetracycline, minocycline, and doxycycline are contraindicated in pregnancy.

It is important to discuss the issue of contraceptive failure when prescribing antibiotics for women taking oral contraceptives. Women may need to consider using barrier methods as well, and should report breakthrough bleeding. Oral contraceptives or spironolactone (50-200 mg daily) may be added as an antiandrogen in women with antibiotic-resistant acne or in women in whom relapse occurs after isotretinoin therapy.

3. Severe acne

a. Isotretinoin (Accutane)—A vitamin A analog, isotretinoin is used for the treatment of severe cystic acne that has not responded to conventional therapy. Informed consent must be obtained before its use. A dosage of 0.5-1 mg/kg/d for 20 weeks for a cumulative dose of at least 120 mg/kg is usually adequate for severe cystic acne. Patients should be offered isotretinoin therapy before they experience significant scarring if they are not promptly and adequately controlled by antibiotics. The drug is *absolutely contraindicated during pregnancy* because of its teratogenicity; two serum pregnancy tests should be obtained before starting the drug in a female and every month thereafter. Sufficient medication for only 1 month should be dispensed. Two forms of effective contraception must be used. Side effects occur in most patients, usually related to dry skin and mucous membranes (dry lips, nosebleed, and dry eyes). If headache occurs, pseudotumor cerebri must be considered. Depression has been reported. About 25% of patients will develop hypertriglyceridemia, 15% hypercholesterolemia, and 5% a lowering of high-density lipoproteins. Some patients develop minor elevations of liver function tests. Fasting blood sugar may be elevated. Miscellaneous adverse reactions include decreased night vision, musculoskeletal or bowel symptoms, rash, thinning of hair, exuberant granulation tissue in lesions, and bony hyperostoses (seen only with very high doses or with long duration of therapy). Moderate to severe myalgias necessitate decreasing the dosage or stopping the drug. Laboratory tests to be performed in all patients before treatment and after 4 weeks on therapy include cholesterol, triglycerides, and liver function studies.

Elevations of liver enzymes and triglycerides return to normal upon conclusion of therapy. The drug may induce long-term remissions in 30-40%, or acne may recur that is more easily controlled with conventional therapy in 40-50%. Occasionally, acne does not respond or promptly recurs after therapy, but it may clear after a second course.

b. Intralesional injection—In otherwise moderate acne, intralesional injection of dilute suspensions of triamcinolone acetonide (2.5 mg/mL, 0.05 mL per lesion) will often hasten the resolution of deeper papules and occasional cysts.

c. Laser, dermabrasion—Cosmetic improvement may be achieved by excision and punch-grafting of deep scars and by abrasion of inactive acne lesions, particularly flat, superficial scars. The technique is not without untoward effects, since hyperpigmentation, hypopigmentation, grooving, and scarring have been known to occur. Dark-skinned individuals do poorly. Corrective surgery within 12 months after isotretinoin therapy may not be advisable.

Prognosis

Acne vulgaris eventually remits spontaneously, but when this will occur cannot be predicted. The condition may persist throughout adulthood and may lead to severe scarring if left untreated. Patients treated with antibiotics continue to improve for the first 3-6 months of therapy. Relapse during treatment may suggest the emergence of resistant *P. acnes*. The disease is chronic and tends to flare intermittently in spite of treatment. Remissions following systemic treatment with isotretinoin may be lasting in up to 60% of cases. Relapses after isotretinoin usually occur within 3 years and require a second course in up to 20% of patients.

ROSACEA

Essentials of Diagnosis

- A chronic facial disorder of middle-aged and older people.
- A vascular component (erythema and telangiectasis) and a tendency to flush easily.
- An acneiform component (papules and pustules) may also be present.
- A glandular component accompanied by hyperplasia of the soft tissue of the nose (rhinophyma).

General Considerations

No single factor adequately explains the pathogenesis of this disorder. A statistically significant incidence of migraine headaches accompanying rosacea has been reported.

Topical steroids can change trivial dermatoses of the face into **perioral dermatitis** and **steroid rosacea**. These occur predominantly in young women and may be confused with acne rosacea.

Clinical Findings

The cheeks, nose, and chin—at times the entire face—may have a rosy hue. One sees no comedones. Inflammatory papules are prominent, and there may be pustules. Associated seborrhea may be found. The patient often complains of burning or stinging with episodes of flushing. It is not uncommon for patients to have associated ophthalmic disease, including blepharitis and keratitis. This often requires systemic antibiotic therapy.

Differential Diagnosis

Rosacea is distinguished from acne by age, the presence of the vascular component, and the absence of comedones. The rosy hue of rosacea is due to inflammation and telangiectases and generally will pinpoint the diagnosis.

Treatment

Medical management is aimed only at the inflammatory papules and pustules and the erythema that surrounds them. The only satisfactory treatment for the telangiectasias is laser surgery. Rhinophyma (soft tissue and sebaceous hyperplasia of the nose) responds only to surgical debulking. Rosacea is usually a lifelong affliction, so maintenance therapy is required.

A. Local Therapy

Metronidazole, 0.75% gel applied twice daily or 1% cream once daily, is the topical treatment of choice. If metronidazole is not tolerated, topical clindamycin (solution, gel, or lotion) used twice daily is effective. Erythromycin as described above may be helpful (see Acne Vulgaris). Five to 8 weeks of treatment are needed for significant response.

B. Systemic Therapy

Tetracycline or erythromycin, 250 or 500 mg orally twice daily on an empty stomach, should be used when topical therapy is inadequate. Minocycline or doxycycline, 50-100 mg daily to twice daily, may work in refractory cases.

Isotretinoin may succeed where other measures fail. A dosage of 0.5-1 mg/kg/d orally for 12-28 weeks is recommended. See precautions above.

Metronidazole, 250 mg twice daily for 3 weeks, may be worth trying but is seldom required. Side effects are few, though metronidazole may produce a disulfiram-like effect when the patient ingests alcohol.

Prognosis

Rosacea tends to be a stubborn and persistent process. With the regimens described above, it can usually be controlled adequately.

Thiboutot DM: Acne and rosacea. New and emerging therapies. Dermatol Clin 2000;18:63. [\[PMID: 10626112\]](#)

Zuber TJ: Rosacea. Prim Care 2000;27:309. [\[PMID: 10815045\]](#)

FOLLICULITIS (INCLUDING SYCOSIS)

Essentials of Diagnosis

- Itching and burning in hairy areas.
- Pustules in the hair follicles.

General Considerations

Folliculitis has multiple causes. It may be caused by staphylococcal infection and may be more common in the diabetic. When the lesion is deep-seated, chronic, and recalcitrant on the head and neck, it is called sycosis. Sycosis is usually propagated by the autoinoculation and trauma of shaving. The upper lip is particularly susceptible to involvement in men.

Gram-negative folliculitis, which may develop during antibiotic treatment of acne, may present as a flare of acne pustules or nodules. Klebsiella, enterobacter, *E coli*, and proteus have been isolated from these lesions.

"Hot tub folliculitis," caused by *Pseudomonas aeruginosa*, is characterized by pruritic or tender follicular or pustular lesions occurring within 1-4 days after bathing in a hot tub, whirlpool, or public swimming pool. Rarely, systemic infections may result.

Nonbacterial folliculitis may also be caused by oils that are irritating to the follicle, and these may be encountered in the workplace (machinists) or at home (various cosmetics and cocoa butter or coconut oils).

Folliculitis may also be caused by occlusion, perspiration, and rubbing, such as that resulting from tight jeans and other heavy fabrics on the upper legs.

Folliculitis on the back that looks like acne but does not respond to acne therapy may be caused by the yeast *Malassezia furfur*. This infection may require biopsy for diagnosis.

Folliculitis—so called "steroid acne"—may be seen during topical or systemic corticosteroid therapy.

A form of sterile folliculitis called eosinophilic folliculitis consisting of urticarial papules with prominent eosinophilic infiltration is common in patients with AIDS.

Pseudofolliculitis is caused by ingrowing hairs in the beard area. In this entity, the papules and pustules are located at the side of and not in follicles. It may be treated by growing a beard, by using chemical depilatories, or by shaving with a foil-guard razor. Laser hair removal is dramatically beneficial in patients with pseudofolliculitis, requires limited maintenance, and can be done on patients of any skin color. Pseudofolliculitis is a true medical indication for such a procedure and should not be considered cosmetic.

Clinical Findings

The symptoms range from slight burning and tenderness to intense itching. The lesions consist of pustules of hair follicles.

Differential Diagnosis

It is important to differentiate bacterial from nonbacterial folliculitis. The history is important for pinpointing the causes of nonbacterial folliculitis, and a Gram stain and culture are indispensable. One must differentiate folliculitis from acne vulgaris or pustular miliaria (heat rash) and from infections of the skin such as impetigo or fungal infections. Pseudomonas folliculitis is often suggested by the history of hot tub use. Eosinophilic folliculitis in AIDS often requires biopsy for diagnosis.

Complications

Abscess formation is the major complication of bacterial folliculitis.

Prevention

Correct any predisposing local causes (eg, irritations of a mechanical or chemical nature). Control of blood glucose in diabetes may reduce the number of these

infections. Be sure that the water in hot tubs and spas is treated properly with chlorine. If staphylococcal folliculitis is persistent, treatment of nasal or perineal carriage with rifampin, 600 mg daily for 5 days, or with topical mupirocin ointment 2% twice daily for 5 days, may help. Chronic oral clindamycin, 150-300 mg/d, is also effective in preventing recurrent staphylococcal folliculitis and furunculosis.

Treatment

A. Local Measures

Anhydrous ethyl alcohol containing 6.25% aluminum chloride (Xerac AC), applied to lesions and environs, may be helpful, especially for chronic folliculitis of the buttocks.

B. Specific Measures

Systemic antibiotics may be tried if the skin infection is resistant to local treatment, if it is extensive or severe and accompanied by a febrile reaction, if it is complicated, or if it involves the nose or upper lip. Extended periods of treatment (4-8 weeks or more) with antistaphylococcal antibiotics are required in some cases.

Hot tub pseudomonas folliculitis virtually always resolves without treatment but may be treated in adults with ciprofloxacin, 500 mg twice daily for 5 days.

Gram-negative folliculitis in acne patients may be treated with isotretinoin in compliance with all precautions discussed above (see Acne Vulgaris).

Folliculitis due to *M furfur* is treated with topical 2.5% selenium sulfide, 15 minutes daily for 3 weeks, or with oral ketoconazole, 200 mg daily for 7-14 days.

Eosinophilic folliculitis may be treated initially by the combination of potent topical steroids and oral antihistamines. In more severe cases, treatment is with one of the following: topical permethrin (application for 12 hours every other night for 6 weeks); itraconazole, 200-400 mg daily; UVB or PUVA phototherapy; or isotretinoin, 0.5 mg/kg/d for up to 5 months. A remission may be induced by some of these therapies, but chronic treatment may be required.

Prognosis

Bacterial folliculitis is occasionally stubborn and persistent, requiring prolonged or intermittent courses of antibiotics. Steroid folliculitis is treatable by acne therapy and resolves as steroids are discontinued.

Stulberg DL et al: Common bacterial skin infections. Am Fam Physician 2002;66:119. [\[PMID: 12126026\]](#)

MILIARIA (HEAT RASH)

Essentials of Diagnosis

- Burning, itching, superficial aggregated small vesicles, papules, or pustules on covered areas of the skin, usually the trunk.
- More common in hot, moist climates.
- Rare forms associated with fever and even heat prostration.

General Considerations

Miliaria is an acute dermatitis that occurs most commonly on the trunk and intertriginous areas. A hot, moist environment is the most frequent cause. Bedridden febrile patients are susceptible. Plugging of the ostia of sweat ducts occurs, with consequent ballooning and ultimate rupture of the sweat duct, producing an irritating, stinging reaction. Increase in numbers of resident aerobes, notably cocci, apparently plays a role.

Clinical Findings

The usual symptoms are burning and itching. In severe cases, fever, heat prostration, and even death may result. The lesions consist of small, superficial, red, thin-walled, discrete but closely aggregated vesicles (miliaria crystallina), papules (miliaria rubra), or vesicopustules or pustules (miliaria pustulosa). The reaction occurs most commonly on covered areas of the skin.

Differential Diagnosis

Miliaria is to be distinguished from drug rash and folliculitis.

Prevention

Use of an antibacterial preparation such as chlorhexidine prior to exposure to heat and humidity may help prevent the condition. Susceptible persons should avoid exposure to hot, humid environments.

Treatment

Triamcinolone acetone, 0.1% in Sarna lotion, or a mid-potency corticosteroid in a lotion or cream—but not ointment—base, should be applied two to four times daily. Secondary infections (superficial pyoderma) are treated with dicloxacillin, 250 mg four times daily by mouth. Anticholinergic drugs given by mouth may be helpful in severe cases, eg, glycopyrrolate, 1 mg twice daily.

Prognosis

Miliaria is usually a mild disorder, but severe forms (tropical anhidrosis and asthenia) result from interference with the heat-regulating mechanism.

Wenzel FG et al: Nonneoplastic disorders of the eccrine glands. J Am Acad Dermatol 1998;38:1. [\[PMID: 9448199\]](#)

MUCOCUTANEOUS CANDIDIASIS

Essentials of Diagnosis

- Severe pruritus of vulva, anus, or body folds.
- Superficial denuded, beefy-red areas with or without satellite vesicopustules.
- Whitish curd-like concretions on the oral and vaginal mucous membranes.
- Yeast on microscopic examination of scales or curd.

General Considerations

Mucocutaneous candidiasis is a superficial fungal infection that may involve almost any cutaneous or mucous surface of the body. It is particularly likely to occur in diabetics, during pregnancy, and in obese persons who perspire freely. Antibiotics and oral contraceptive agents may be contributory. Oral candidiasis may be the first sign of HIV infection (see [Chapter 31](#)).

Clinical Findings

A. Symptoms and Signs

Itching may be intense. Burning is reported, particularly around the vulva and anus. The lesions consist of superficially denuded, beefy-red areas in the depths of the body folds such as in the groin and the intergluteal cleft, beneath the breasts, at the angles of the mouth, and in the umbilicus. The peripheries of these denuded lesions are superficially undermined, and there may be satellite vesicopustules. Whitish, curd-like concretions may be present on the surface of the mucosal lesions. Paronychia and interdigital erosions may occur.

B. Laboratory Findings

Clusters of budding cells and pseudohyphae can be seen under high power when skin scales or curd-like lesions have been cleared in 10% KOH. The organism may be isolated on Sabouraud's medium.

Differential Diagnosis

Intertrigo, seborrheic dermatitis, tinea cruris, "inverse psoriasis," and erythrasma involving the same areas may mimic mucocutaneous candidiasis.

Complications

Systemic invasive candidiasis with candidemia may be seen with immunosuppression and in patients receiving broad-spectrum antibiotic and hypertonic glucose solutions, as in hyperalimentation. There may or may not be clinically evident mucocutaneous candidiasis.

Treatment

A. General Measures

Affected parts should be kept dry and exposed to air as much as possible. If possible, discontinue systemic antibiotics. For treatment of systemic invasive candidiasis, see [Chapter 36](#).

B. Local Measures

1. Nails and skin—Apply clotrimazole solution 1% three or four times daily. Gentian violet, 1%, or carbolfuchsin paint (Castellani's tincture) may be applied once or twice weekly as an alternative, but these preparations are messy.

2. Vulvar and anal mucous membranes—For vaginal candidiasis, single-dose fluconazole (150 mg) is effective. Intravaginal clotrimazole, miconazole, terconazole, or nystatin may also be used. Chronic suppressive therapy may be required for recurrent or "intractable" cases. Non-*albicans* candidal species may be identified by culture in some refractory cases and may respond to oral itraconazole, 200 mg twice daily for 2-4 weeks.

3. Balanitis—This is most frequent in uncircumcised men, and candida usually plays a role. Topical nystatin ointment is the initial treatment if the lesions are mildly erythematous or superficially erosive. Soaking with dilute aluminum acetate for 15 minutes twice daily may quickly relieve burning or itching. Chronicity and relapses, especially after sexual contact, suggest reinfection from a sexual partner who should be treated. Severe purulent balanitis is usually due to bacteria. If it is so severe that phimosis occurs, oral antibiotics—some with activity against anaerobes—are required; if rapid improvement does not occur, urologic consultation is indicated.

Prognosis

Cases of cutaneous candidiasis range from the easily cured to the intractable and prolonged.

FIGURATE ERYTHEMAS

URTICARIA & ANGIOEDEMA

Essentials of Diagnosis

- Eruptions of evanescent wheals or hives.
- Itching is usually intense but may on rare occasions be absent.
- Special forms of urticaria have special features (dermographism, cholinergic urticaria, solar urticaria, or cold urticaria).
- Most incidents are acute and self-limited over a period of 1-2 weeks.
- Chronic urticaria (episodes lasting > 6 weeks) may have an autoimmune basis.

General Considerations

Urticaria can result from many different stimuli on an immunologic or nonimmunologic basis. The most common immunologic mechanism is hypersensitivity mediated by IgE, seen for most patients with acute urticaria; another involves activation of the complement cascade. Some patients with chronic urticaria demonstrate autoantibodies directed against mast cell IgE receptors, with histamine-releasing activity. ACE inhibitor and angiotensin II receptor antagonist therapy may be complicated by urticaria or angioedema. In general, extensive costly workups are not indicated in patients who present with urticaria. A careful history and physical examination are more helpful.

Clinical Findings

A. Symptoms and Signs

Lesions are itchy red swellings of a few millimeters to many centimeters. The morphology of the lesions may vary over a period of minutes to hours, resulting in geographic or bizarre patterns. Individual lesions in true urticaria last less than 24 hours, and often only 2-4 hours. Angioedema is involvement of deeper vessels, with swelling of the lips, eyelids, palms, soles, and genitalia. Angioedema is no more likely than urticaria to be associated with systemic complications such as laryngeal edema or hypotension. In cholinergic urticaria, triggered by a rise in core body temperature (hot showers, exercise), wheals are 2-3 mm in diameter with a large surrounding red flare.

B. Laboratory Findings

Laboratory studies are not likely to be helpful in the evaluation of acute or chronic urticaria. The most common causes of acute urticaria are foods, viral infections, and medications. The cause of chronic urticaria is often not found. In patients with individual slightly purpuric lesions that persist past 24 hours, skin biopsy may confirm urticarial vasculitis. An autologous serum test is available to detect patients with an autoimmune basis for their chronic urticaria.

Differential Diagnosis

Papular urticaria resulting from insect bites persists for days. A central punctum can usually be seen. Streaked urticarial lesions may be seen in acute allergic plant dermatitis, eg, poison ivy, oak, or sumac. Contact urticaria may be caused by a host of substances, including chemicals, foods, and medications, and may be one type of reaction to latex. Urticarial response to heat, sun, water, and pressure are quite rare. Urticarial vasculitis may be seen as part of serum sickness, associated with fever and arthralgia.

In hereditary angioedema, there is generally a positive family history and gastrointestinal or respiratory symptoms. Urticaria is not part of the syndrome, and lesions are not pruritic.

Treatment

A. General Measures

A detailed search by history for a cause of acute urticaria should be undertaken, and treatment may then be tailored to include the provocative condition. The chief causes are drugs—eg, aspirin, NSAIDs, morphine, and codeine; arthropod bites—eg, insect bites and bee stings (though the latter may cause anaphylaxis as well as angioedema); physical factors such as heat, cold, sunlight, and pressure; and, presumably, neurogenic factors, as in cholinergic urticaria induced by exercise, excitement, hot showers, etc.

Other causes may include penicillins and other medications; inhalants such as feathers and animal danders; ingestion of shellfish, tomatoes, or strawberries; injections of sera and vaccines; external contactants, including various chemicals and cosmetics; and infections such as viral hepatitis.

B. Systemic Treatment

The mainstay of treatment initially includes H₁ antihistamines (see above). Hydroxyzine, 10 mg twice daily to 25 mg three times daily, may be very useful if tolerated.

Giving hydroxyzine as one dose of 50-75 mg at night may reduce sedation and other side effects. Cyproheptadine, 4 mg four times daily, may be especially useful for cold urticaria. "Nonsedating" or less sedating antihistamines are added if the generic sedating antihistamines are not effective. Fexofenadine is given in a dosage of 60

mg twice a day. Loratadine in a dosage of 10 mg/d is similar to the other H₁ antihistamines in effectiveness. Cetirizine, a metabolite of hydroxyzine, is less sedating (13% of patients) and is given in a dosage of 10 mg/d.

Doxepin (a tricyclic antidepressant), 25 mg three times daily, or, more commonly, 25-75 mg at bedtime, can be very effective in chronic urticaria. It has anticholinergic side effects.

H₂ antihistamines in combination with H₁ blockers may be helpful in patients with symptomatic dermatographism.

A few patients with chronic urticaria may respond to elimination of salicylates and tartrazine (coloring agent). Asymptomatic foci of infection—sinusitis, vaginal candidiasis, cholecystitis, and intestinal parasites—may rarely cause chronic urticaria. Systemic steroids in a dose of about 40 mg daily will usually suppress acute and chronic urticaria. However, the use of corticosteroids is rarely indicated, since properly selected combinations of antihistamines with less toxicity are usually effective. Once steroids are withdrawn, the urticaria virtually always returns if it had been chronic. Rather than using systemic steroids in difficult cases, consultation should be sought from a dermatologist or allergist with experience in managing severe urticaria. Cyclosporine (3-5 mg/kg/d) may be effective in severe cases of autoimmune chronic urticaria.

C. Local Treatment

Local treatment is rarely rewarding.

Prognosis

Acute urticaria usually lasts only a few days to 6 weeks. Half of patients whose urticaria persists for more than 6 weeks will have it for years.

ERYTHEMA MULTIFORME

Essentials of Diagnosis

- Sudden onset of symmetric erythematous skin lesions with history of recurrence.
- May be macular, papular, urticarial, bullous, or purpuric.
- "Target" lesions with clear centers and concentric erythematous rings or "iris" lesions may be noted in erythema multiforme minor. These are rare in drug-associated erythema multiforme major (Stevens-Johnson syndrome).
- Erythema multiforme minor on extensor surfaces, palms, soles, or mucous membranes. Erythema multiforme major favors the trunk.
- Herpes simplex, systemic infection or disease, and drug reactions are often associated.

General Considerations

Erythema multiforme is an acute inflammatory skin disease. Erythema multiforme is divided clinically into minor and major types based on the clinical findings. Approximately 90% of cases of erythema multiforme minor follow outbreaks of herpes simplex. Erythema multiforme major (Stevens-Johnson syndrome) is marked by toxicity and involvement of two or more mucosal surfaces (often oral and conjunctival) and is most often caused by drugs, especially sulfonamides, nonsteroidal anti-inflammatory drugs, and anticonvulsants such as phenytoin. *Mycoplasma pneumoniae* may trigger erythema multiforme major. Erythema multiforme may also present as recurring oral ulceration, with skin lesions present in only half of the cases, and is diagnosed by oral biopsy. Since erythema multiforme may have its own prodrome, many medications taken for such symptoms have been implicated in its pathogenesis without definitive proof. As in all drug eruptions, the exposure to drugs associated with erythema multiforme may be systemic or topical; any agent should be considered a potential offender.

Clinical Findings

A. Symptoms and Signs

A classic target lesion, found most commonly in herpes-associated erythema multiforme, consists of three concentric zones of color change, most often found acral on the hands and feet. Not all lesions will have this appearance. Drug-associated erythema multiforme is manifested by raised target-like lesions, with only two zones of color change and a central blister, or nondescript reddish or purpuric macules. In erythema multiforme major, mucous membrane ulcerations are present at two or more sites, causing pain on eating, swallowing, and urination.

B. Laboratory Findings

Blood tests are not useful for diagnosis. Skin biopsy is diagnostic. Direct immunofluorescence studies are negative.

Differential Diagnosis

Urticaria and drug eruptions are the chief entities that must be differentiated from erythema multiforme minor. Individual lesions of true urticaria itch should come and go within 24 hours, are usually responsive to antihistamines, and do not affect the mucosa. In erythema multiforme major, the main differential diagnosis is toxic epidermal necrolysis, and some investigators regard these entities as variants of the same disease. The presence of blisters is always worrisome and dictates the need for consultation. The differential diagnosis of blisters includes pemphigus, pemphigoid, and bullous drug eruptions. Skin biopsy is the mainstay of diagnosis.

Complications

The tracheobronchial mucosa and conjunctiva may be involved in severe cases with resultant scarring (Stevens-Johnson syndrome). Ophthalmologic consultation is recommended if ocular involvement is present.

Treatment

A. General Measures

Erythema multiforme major (Stevens-Johnson syndrome) with extensive denudation of skin is best treated in a burn unit. Otherwise, patients need not be admitted unless mucosal involvement interferes with hydration and nutrition. Patients who begin to blister should be seen daily. Immediate discontinuation of the inciting medication (before blistering occurs) improves prognosis and reduces the risk of death in erythema multiforme major.

B. Specific Measures

Although there are no good data to support the use of corticosteroids in erythema multiforme major, they are still often prescribed. If corticosteroids are to be tried in more severe cases, they should be used early, before blistering occurs, in moderate to high doses (prednisone, 100-250 mg), and stopped within days if there is no dramatic response. IGIV (0.75 g/kg/d for 4 days) has yielded dramatic benefit in severe cases. Oral and topical corticosteroids are useful in the oral variant of erythema multiforme. Oral acyclovir prophylaxis of herpes simplex infections may be effective in preventing recurrent herpes-associated erythema multiforme minor. Antistaphylococcal antibiotics are used for secondary infection, which is uncommon.

C. Local Measures

Topical therapy is not very effective in this disease. For oral lesions, 1% diphenhydramine elixir mixed with Kaopectate or with 1% dyclonine may be used as a mouth rinse several times daily.

Prognosis

Erythema multiforme minor usually lasts 2-6 weeks and may recur. Erythema multiforme major may be serious or even fatal in the most severe cases.

ERYTHEMA MIGRANS (SEE ALSO CHAPTER 34.)

Erythema migrans is a unique cutaneous eruption that characterizes the localized or generalized early stage of Lyme disease. Three to 32 days (median: 7 days) after a tick bite, there is gradual expansion of redness around the papule representing the bite site. The advancing border is usually slightly raised, warm, red to bluish-red, and free of any scale. Centrally, the site of the bite may clear, leaving only a rim of peripheral erythema, or it may become indurated, vesicular, or necrotic. The annular erythema usually grows to a median diameter of 15 cm (range: 3-68 cm, but virtually always > 5 cm). It is accompanied by a burning sensation in half of patients; rarely, it is pruritic or painful. Twenty percent of patients will develop multiple secondary annular lesions similar in appearance to the primary lesion but without indurated centers and generally of smaller size. In the southeastern United States, similar lesions are seen in patients without evidence of Lyme borreliosis. The etiology of these cases is unclear, but they are not due to borrelia.

Without treatment, erythema migrans and the secondary lesions fade in a median of 28 days, though some may persist for months. Ten percent of untreated patients experience recurrences over the ensuing months. Treatment with systemic antibiotics (see Table 34-4) is necessary to prevent systemic involvement. However, only 60-70% of those with systemic involvement experience erythema migrans.

Ledbetter LS et al: Large, patchy skin eruptions after a hiking trip. Erythema chronicum migrans hallmarks Lyme disease. Postgrad Med 2000;107:51. [PMID: 10844941]

ERYSIPELAS

Essentials of Diagnosis

- Edematous, spreading, circumscribed, hot, erythematous area, with or without vesicles or bullae.
- Central face frequently involved.
- Pain, chills, fever, and systemic toxicity may be striking.

General Considerations

Erysipelas is a superficial form of cellulitis that occurs classically on the cheek, caused by β -hemolytic streptococci.

Clinical Findings

A. Symptoms and Signs

The symptoms are pain, malaise, chills, and moderate fever. A bright red spot appears first, very often near a fissure at the angle of the nose. This spreads to form a tense, sharply demarcated, glistening, smooth, hot area. The margin characteristically makes noticeable advances in days or even hours. The lesion is somewhat edematous and can be pitted slightly with the finger. Vesicles or bullae occasionally develop on the surface. The lesion does not usually become pustular or gangrenous and heals without scar formation. The disease may complicate any break in the skin that provides a portal of entry for the organism.

B. Laboratory Findings

Leukocytosis is almost invariably present; blood cultures may be positive.

Differential Diagnosis

Erysipeloid is a benign bacillary infection producing redness of the skin of the fingers or the backs of the hands in fishermen and meat handlers.

Complications

Unless erysipelas is promptly treated, death may result from extension of the process and systemic toxicity, particularly in the very young and in the aged.

Treatment

Place the patient at bed rest with the head of the bed elevated. Intravenous antibiotics effective against group A beta-hemolytic streptococci and staphylococci are indicated for the first 48 hours in all but the mildest cases. A 7-day course is completed with penicillin VK, 250 mg, dicloxacillin, 250 mg, or a first-generation cephalosporin, 250 mg, orally four times a day. Alternatives in penicillin-allergic patients include clindamycin or trimethoprim-sulfamethoxazole.

Prognosis

Erysipelas was at one time a life-threatening infection. It can now usually be quickly controlled with systemic penicillin or erythromycin therapy (see the references under Cellulitis).

CELLULITIS

Cellulitis, a diffuse spreading infection of the skin, usually on the lower leg, may be due to one of several organisms, usually gram-positive cocci, though gram-negative rods such as *Escherichia coli* may also be responsible. The lesion is hot and red. The major portal of entry for lower leg cellulitis is toe web tinea pedis with fissuring of the skin at this site. The toe webs should be carefully examined in all cases and any associated web space tinea pedis treated aggressively. Attempts to isolate the responsible organism by injecting and then aspirating saline are successful in 20% of cases. In cases of venous stasis, the only clue to cellulitis may be a new localized area of tenderness. Recurrent attacks may sometimes affect lymphatic vessels, producing a permanent swelling called "solid edema."

Two potentially life-threatening entities that can mimic cellulitis (ie, present with a painful, red, swollen lower extremity) include deep venous thrombosis and necrotizing fasciitis. The diagnosis of necrotizing fasciitis should be suspected in a patient who has a very toxic appearance, bullae, crepitus or anesthesia of the involved skin, overlying skin necrosis, and laboratory evidence of rhabdomyolysis or DIC. While these findings may be present with severe cellulitis and bacteremia, it is essential to rule out necrotizing fasciitis because rapid surgical debridement is essential. Other skin lesions that may resemble cellulitis include sclerosing panniculitis, an acute, exquisitely tender red plaque on the medial lower legs above the malleolus in patients with venous stasis or varicosities, and acute severe contact dermatitis on a limb, which produces erythema, vesiculation, and edema as seen in cellulitis, but with itching instead of pain. The erythema and edema are also more superficial than in cellulitis.

Intravenous or parenteral antibiotics may be required for the first 24-72 hours. In mild cases or following the initial parenteral therapy, dicloxacillin or cephalexin, 250-500 mg four times daily for 7-10 days, is usually adequate. In patients in whom intravenous treatment is not instituted, the first dose of oral antibiotic can be increased to 750-1000 mg to achieve rapid high blood levels.

ANTHRAX

Bacillus anthracis infection must be distinguished from routine bacterial cellulitis. Infection is usually acquired by direct exposure to infected livestock or meat but may also be a consequence of bioterrorism. A painless papule appears at the site of inoculation 1-7 days after exposure. Inflammation is intense, forming marked nonpitting edema or a blister containing clear or serosanguineous fluid 1-2 cm around the primary lesion. There is neither pain nor tenderness. The blistered skin undergoes necrosis centrally and forms an eschar. Edema may become massive, and regional adenopathy may be present. Twenty percent of untreated cases are fatal. The

eschar dries and falls off in 1-2 weeks. The diagnosis is made by Gram stain or culture of the blister fluid or material beneath or adjacent to the eschar. Incision and drainage are to be avoided. For mild cases, treatment is ciprofloxacin 500 mg or doxycycline 100 mg twice daily. For severe cases, ciprofloxacin 400 mg intravenously every 12 hours is recommended. Treatment is for 7-10 days in naturally acquired cases or for 60 days in the event of infection resulting from bioterrorist activity.

BLISTERING DISEASES

PEMPHIGUS

Essentials of Diagnosis

- Relapsing crops of bullae.
- Often preceded by mucous membrane bullae, erosions, and ulcerations.
- Superficial detachment of the skin after pressure or trauma variably present (Nikolsky's sign).
- Acantholysis on biopsy.
- Immunofluorescence studies are confirmatory.

General Considerations

Pemphigus is an uncommon intraepidermal blistering disease occurring on skin and mucous membranes. It is caused by autoantibodies to adhesion molecules expressed in the skin and mucous membranes (desmoglein 3, sometimes desmoglein I and plakoglobin in pemphigus vulgaris), and to a complex containing desmosomal proteins, including desmoglein I (in pemphigus foliaceus). These autoantibodies cause acantholysis, the separation of epidermal cells from each other. The cause is unknown, and in the preantibiotic, presteroid era the condition, if untreated, was usually fatal within 5 years. The bullae appear spontaneously and are tender and painful when they rupture. If the lesions become extensive, the complications of the disease lead to great toxicity and debility. Drug-induced autoimmune pemphigus from drugs including penicillamine and captopril has been reported. There are several forms of pemphigus: **pemphigus vulgaris** and its variant, **pemphigus vegetans**, and the more superficially blistering **pemphigus foliaceus** and its variant, **pemphigus erythematosus**. All forms may occur at any age but most commonly in middle age. The vulgaris form begins in the mouth in over 50% of cases. The foliaceus form is especially apt to be associated with other autoimmune diseases, or it may be drug-induced, eg, by exposure to penicillamine. Paraneoplastic pemphigus, a unique form of the disorder, is associated with numerous types of benign and malignant neoplasms.

Clinical Findings

A. Symptoms and Signs

Pemphigus is characterized by an insidious onset of flaccid bullae in crops or waves. In pemphigus vulgaris, lesions often appear first on the oral mucous membranes, and these rapidly become erosive. In some cases, erosions and crusts predominate over blisters. The scalp is another site of early involvement. Rubbing a cotton swab or finger laterally on the surface of uninvolved skin may cause easy separation of the epidermis (**Nikolsky's sign**).

B. Laboratory Findings

The diagnosis is made by light microscopy and by direct and indirect immunofluorescence microscopy. Microscopically, acantholysis is the hallmark of pemphigus, but in some patients there may be eosinophilic spongiosis initially. Immunofluorescence microscopy shows intercellular deposits of IgG and C3 in the epidermis. Indirect immunofluorescence microscopy detects circulating pemphigus antibodies that correspond with disease activity and help in management.

Differential Diagnosis

Blistering diseases include erythema multiforme, drug eruptions, bullous impetigo, contact dermatitis, dermatitis herpetiformis, and bullous pemphigoid, but flaccid blisters are not typical of these diseases, and acantholysis is not seen. All of these diseases have clinical characteristics and different immunofluorescence test results that distinguish them from pemphigus.

Paraneoplastic pemphigus is clinically, histologically, and immunologically distinct from other forms of the disease. Oral erosions and erythematous plaques resembling erythema multiforme are seen. Survival rates are low because of the underlying malignancy.

Complications

Secondary infection commonly occurs; this is a major cause of morbidity and mortality. Disturbances of fluid, electrolyte, and nutritional intake can occur as a result of painful oral ulcers.

Treatment

A. General Measures

When the disease is severe, hospitalize the patient at bed rest and provide antibiotics and intravenous feedings as indicated. Anesthetic troches used before eating ease painful oral lesions.

B. Systemic Measures

Pemphigus requires systemic therapy as early in its course as possible. However, the main morbidity in this disease is due to the side effects of such therapy. Initial therapy is with systemic steroids: prednisone, 60-80 mg daily. In all but the most mild cases, a steroid-sparing agent is added from the beginning, since the course of the disease is long and the steroid-sparing agents take several weeks to exert their activity. Azathioprine (100-200 mg daily) or mycophenolate mofetil (1 g twice daily) is used most frequently, the latter seeming to be the most reliable and recommended for most cases. In refractory cases, monthly IGIV at 2 g/kg intravenously over 3 days is useful and has replaced high-dose steroids plus cyclophosphamide and pulse intravenous steroids as rescue therapy. In pemphigus foliaceus and mild cases of pemphigus vulgaris, tetracycline, 500 mg, and nicotinamide, 500 mg, three times daily, may be tried. Dapsone may also be tried as a steroid-sparing agent, especially in pemphigus foliaceus.

C. Local Measures

In patients with limited disease, skin and mucous membrane lesions should be treated with topical corticosteroids. Complicating infection requires appropriate systemic and local antibiotic therapy.

Prognosis

The course tends to be chronic in most patients, though some appear to experience remission. Infection is the most frequent cause of death, usually from *Staphylococcus aureus* septicemia.

OTHER BLISTERING DISEASES

Many other skin disorders are characterized by formation of bullae, or blisters. These include bullous pemphigoid, cicatricial pemphigoid, dermatitis herpetiformis, and pemphigoid gestationis.

Bullous Pemphigoid

Bullous pemphigoid is a relatively benign pruritic disease characterized by tense blisters in flexural areas, usually remitting in 5 or 6 years, with a course characterized by exacerbations and remissions. Most affected persons are over the age of 60 (often in their 70s or 80s), and men are affected twice as frequently as women. The appearance of blisters may be preceded by urticarial or edematous lesions for months. Oral lesions are present in about one-third of affected persons. The disease may occur in various forms, including localized, vesicular, vegetating, erythematous, erythrodermic, and nodular. There is no statistical association with internal malignant disease.

The diagnosis is made by biopsy and direct immunofluorescence examination. Light microscopy shows a subepidermal blister. With direct immunofluorescence, IgG and C3 are found at the dermal-epidermal junction. If the patient has only a few blisters, ultrapotent steroids may be adequate. Prednisone at dosages of 60-80 mg/d is often used to achieve rapid control of more widespread disease. Although slower in onset of action, tetracycline or erythromycin, 500 mg three times daily, alone or combined with nicotinamide—*not nicotinic acid or niacin!*—(up to 1.5 g/d), if tolerated, may control the disease in patients who cannot use corticosteroids or may allow decreasing or eliminating steroids after control is achieved. Dapsone is particularly effective in mucous membrane pemphigoid. If these drugs are not effective, methotrexate, 5-25 mg weekly, or azathioprine, 50 mg one to three times daily, may be used as steroid-sparing agents. Mycophenolate mofetil (1 g twice daily) or IGIV as used for pemphigus vulgaris may be used in refractory cases.

Nousari HC et al: Pemphigus and bullous pemphigoid. Lancet 1999;354:667. [PMID: 10466686]

Herpes (Pemphigoid) Gestationis

Herpes gestationis occurs in about one in 50,000-60,000 pregnancies. The vesicles and bullae often appear first in periumbilical distribution, and there may be erythematous papules and plaques. It usually begins in the fifth or sixth month of pregnancy, or the onset may be delayed to the postpartum period. The disease is self-limited, but it may recur in subsequent pregnancies. Use of estrogens or progesterone or the onset of menses may trigger flare-ups. The risks to mother and fetus appear to be limited but include an increase in prematurity and small-for-gestational-age infants. Blisters are subepidermal, with eosinophils present. Direct immunofluorescence shows C3 at the basement membrane zone in most cases. IgG is found less often.

Corticosteroids are the treatment of choice and are sometimes effective when used topically only.

Engineer L et al: Pemphigoid gestationis: a review. Am J Obstet Gynecol 2000;183:483. [PMID: 10942491]

PAPULES

WARTS

Essentials of Diagnosis

- Verrucous papules anywhere on the skin or mucous membranes, usually no larger than 1 cm in diameter.
- Prolonged incubation period (average 2-18 months). Spontaneous "cures" are frequent (50%).
- "Recurrences" (new lesions) are frequent.

General Considerations

Warts are caused by human papillomaviruses. The type of mucocutaneous surface infected and the morphology of the wart are closely related to the HPV type causing the infection. Especially in genital warts, simultaneous infection with numerous wart types is common. Genital HPVs are divided into low-risk and high-risk types depending on the likelihood of their association with cervical and anal cancer.

Clinical Findings

There are usually no symptoms. Tenderness on pressure occurs with plantar warts; itching occurs with anogenital warts. Occasionally a wart will produce mechanical obstruction (eg, nostril, ear canal, urethra).

Warts vary widely in shape, size, and appearance. Flat warts are most evident under oblique illumination. Subungual warts may be dry, fissured, and hyperkeratotic and may resemble hangnails or other nonspecific changes. Plantar warts resemble plantar corns or calluses.

Differential Diagnosis

Some warty-looking lesions are actually hypertrophic actinic keratoses or squamous cell carcinomas. Some genital warty lesions may be due to secondary syphilis (condylomata lata). The lesions of molluscum contagiosum may be mistaken for warts, especially when they are very large in immunocompromised persons. Seborrheic keratosis may also be confused with warts. In AIDS, wart-like lesions may be caused by varicella-zoster virus.

Prevention

The use of condoms may reduce transmission of genital warts. A person with flat warts should be educated about the infectivity of warts and advised not to scratch or traumatize the areas. Using an electric shaver may prevent autoinoculation.

Treatment

Treatment is aimed at inducing "wart-free" intervals for as long as possible without scarring, since no treatment can guarantee a remission or prevent recurrences. In immunocompromised patients, the goal is even more modest, ie, to control the size and number of lesions present.

A. Removal

For common warts of the hands, patients are usually offered liquid nitrogen or keratolytic agents. The former may work in fewer treatments but requires office visits and is painful. Keratolytic agents are irritating but effective and usually painless if used correctly. They can be used at home but must be applied almost daily for 8-12 weeks for maximum effect.

1. Liquid nitrogen—Liquid nitrogen is applied to achieve a thaw time of 20-45 seconds. Two freeze-thaw cycles are given every 2-4 weeks for several visits. Scarring will occur if it is used incorrectly or too aggressively. For example, the face, dorsal hands, and legs are more sensitive than the palms. Improper use along the sides of the fingers has been reported to cause nerve damage and paresthesias. Liquid nitrogen may cause permanent depigmentation in darkly pigmented individuals. It is useful on dry penile warts and on filiform warts involving the face and body. Liquid nitrogen may be used for condylomas, but snipping of lesions followed by light electrodesiccation is more effective.

2. Keratolytic agents and occlusion—Any of the following salicylic acid products may be used against common warts or plantar warts: Occlusal, Trans-Ver-Sal, and Duofilm. Plantar warts may be treated by applying a 40% salicylic acid plaster (Medioplast) after paring. The plaster may be left on for 5-6 days, then removed, the lesion pared down, and another plaster applied. Although it may take weeks or months to eradicate the wart, the method is safe and effective with almost no side effects. Chronic occlusion alone with water-impermeable tape (duct tape, adhesive tape) for months may be effective.

3. Podophyllum resin—Anogenital warts are often initially treated by painting each wart carefully (protecting normal skin) every 2-3 weeks with 25% podophyllum resin (podophyllin) in compound tincture of benzoin. Pregnant patients should not be so treated. The purified active component of the resin, podofilox, is available for use at home twice daily three consecutive days a week for cycles of 4-6 weeks. It is less irritating and more effective than podophyllum resin. After a single 4-week cycle, 45% of patients were wart-free; but of these, 60% relapsed at 6 weeks. Thus, multiple cycles of treatment are often necessary.

4. Imiquimod—A 5% cream of this local interferon inducer has moderate activity in clearing external genital warts. Seventy-seven percent of women and 40% of men with external genital warts had complete clearing of their lesions, and 90% and 74%, respectively, had greater than 50% reduction in their warts. The superior response in women may relate to enhanced penetration of the moist skin of the vulva as compared with the penile shaft. Treatment is once daily on 3 alternate days per week. Response may be slow, with patients who eventually cleared having responses at 8 weeks (44%) or 12 weeks (69%). Once cleared, about 13% had recurrences in the short term.

There is less pregnancy risk than with podophyllum resin (category B versus category X with podophyllin). It is more expensive than podophyllotoxin, but given the high rate of response in women and its safety and low relapse rate, it appears to be the "patient-administered" treatment of choice in women. In men, the more rapid response, lower cost, and similar efficacy make podophyllotoxin the initial treatment of choice, with imiquimod used for recurrences or refractory cases. Anecdotally, this agent may also have efficacy in superficial flat warts.

5. Operative removal—Plantar warts may be removed by blunt dissection. Local anesthetic is injected into the base, and the wart is then removed with a curette or scissors or by shaving off at the base of the wart with a scalpel. Trichloroacetic acid or Monsel's solution on a tightly wound cotton-tipped applicator may be painted on the wound, or light electrocautery may be used. Excision of warts, however, may result in a permanent painful scar on the foot and is not recommended. For genital warts, snip biopsy (scissors) removal followed by light electrocautery is more effective than cryotherapy but does scar. It is often preferred by patients with pedunculated or large lesions that require multiple cryotherapy or podophyllin treatments for removal.

6. Laser therapy—The CO₂ laser is effective for treating recurrent warts, periungual warts, plantar warts, and condylomata acuminata. It leaves open wounds which must fill in with granulation tissue over 4-6 weeks and is best reserved for warts resistant to other modalities. Lasers with emissions of 585, 595, or 532 nm may also be used every 3-4 weeks to gradually ablate the wart. This is no more effective than cryotherapy in controlled trials. For genital warts, it has not been shown that laser therapy is more effective than electrosurgical removal.

7. Other agents—Bleomycin diluted to 1 unit/mL may be injected into warts. It has been shown to have a high cure rate for plantar and common warts. It should not be used on digital warts because of the potential complications of Raynaud's phenomenon, nail loss, and terminal digital necrosis.

B. Immunotherapy

Cimetidine in doses of 35-50 mg/kg daily may benefit younger patients with common warts. Squaric acid dibutylester may be effective. It is applied in a concentration of 0.2-2% directly to the warts from once weekly to five times weekly to induce a mild contact dermatitis. Between 60% and 80% of warts clear over 10-20 weeks. Injection of candida antigen may be used in the same way.

C. Retinoids

Tretinoin (Retin-A) cream or gel applied topically twice daily may be effective (anecdotally) for facial or beard flat warts. Extensive warts have been reported to disappear when oral retinoids are administered for 4- 8 weeks.

D. Physical Modalities

Soaking warts in hot (42.2 °C) water for 10-30 minutes daily for 6 weeks has resulted in dramatic involution in some cases.

Prognosis

There is a striking tendency to the development of new lesions. Warts may disappear spontaneously or may be unresponsive to treatment.

CALLOSITIES & CORNS OF FEET OR TOES

Callosities and corns are caused by pressure and friction due to faulty weight-bearing, orthopedic deformities, improperly fitting shoes, or neuropathies.

Tenderness on pressure and "after-pain" are the only symptoms. The hyperkeratotic well-localized overgrowths always occur at pressure points. Fingerprint lines are preserved over the surface (not so in warts). On paring, a glassy core is found (which differentiates these disorders from plantar warts, which have multiple capillary bleeding points or black dots when pared). A soft corn often occurs laterally on the proximal portion of the fourth toe as a result of pressure against the bony structure of the interphalangeal joint of the fifth toe.

Treatment consists of correcting mechanical abnormalities that cause friction and pressure. Shoes must be properly fitted and orthopedic deformities corrected. Callosities may be removed by careful paring of the callus after a warm water soak or with keratolytic agents as found in various brands of corn pads.

Plantar hyperkeratosis of the heels can be treated successfully by using 20% urea (Ureacin 20) or 12% lactic acid (Lac-Hydrin) or combinations nightly and a pumice stone after soaking in water.

Women who tend to form calluses and corns should not wear confining footgear and high-heeled shoes.

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum, caused by a poxvirus, presents as single or multiple rounded, dome-shaped, waxy papules 2-5 mm in diameter that are umbilicated. Lesions at first are firm, solid, and flesh-colored but upon reaching maturity become softened, whitish, or pearly gray and may suppurate. The principal sites of involvement are the face, lower abdomen, and genitals.

The lesions are autoinoculable and spread by wet skin-to-skin contact. In sexually active individuals, they may be confined to the penis, pubis, and inner thighs and are considered a sexually transmitted disease.

Molluscum contagiosum is common in patients with AIDS, usually with a helper T cell count < 100/uL. AIDS patients tend to develop extensive lesions over the face and neck as well as in the genital area.

The diagnosis is easily established in most instances because of the distinctive central umbilication of the dome-shaped lesion. The best treatment is by curettage or applications of liquid nitrogen as for warts—but more briefly, since molluscum contagiosum is more responsive to therapy than warts. When lesions are frozen, the central umbilication often becomes more apparent. Light electrosurgery with a fine needle is also effective. It has been estimated that individual lesions persist for about 2 months. They are difficult to eradicate in patients with AIDS unless immunity improves, in which case spontaneous clearing may occur.

BASAL CELL CARCINOMA

Basal cell carcinomas are the most common form of cancer. They occur on sun-exposed skin in otherwise normal fair-skinned individuals. The most common presentation is a papule or nodule that may have a central scab or erosion. Occasionally the nodules have stippled pigment (pigmented basal cell carcinoma). Intradermal nevi without pigment on the face of older white individuals may resemble basal cell carcinomas. Basal cell carcinomas grow slowly, attaining a size of 1-2 cm or more in diameter, often after years of growth. There is a waxy, "pearly" appearance, with telangiectatic vessels easily visible. It is the pearly or translucent quality of these lesions that is most diagnostic, a feature best appreciated if the skin is stretched. Less common types include morpheaform or scar-like lesions. These are hypopigmented, somewhat thickened plaques. On the back and chest, basal cell carcinomas appear as reddish, somewhat shiny, scaly plaques.

Clinicians should examine the skin routinely, looking for bumps, patches, and scabbed lesions. When examining the face, look at the eyelid margins and medial canthi, the nose and alar folds, the lips, and then around and behind the ears. While metastases almost never occur, therapy of basal cell carcinomas may cause significant cosmetic deformity in these areas, particularly for inadequately treated or recurrent lesions. Neglected lesions may ulcerate and produce great destruction. Basal cell carcinomas of the medial canthi are particularly dangerous. Recurrent lesions around the nose and ears may track along cartilage underneath the skin, requiring treatment of much more extensive areas than are apparent from inspection.

Lesions suspected to be basal cell carcinomas should be biopsied, by shave or punch biopsy. Therapy is then aimed at eradication with minimal cosmetic deformity, often by excision and suturing with recurrence rates of 5% or less. The technique of three cycles of curettage and electrodesiccation depends on the skill of the operator and is not recommended for head and neck lesions. After 4-6 weeks of healing, it leaves a broad, hypopigmented, at times hypertrophic scar. Radiotherapy is effective and sometimes appropriate for older individuals (over 65), but recurrent tumors after radiation therapy are more difficult to treat and may be more aggressive. Mohs surgery—removal of the tumor followed by immediate frozen section histopathologic examination of margins with subsequent reexcision of tumor-positive areas and final closure of the defect—gives the highest cure rates (98%) and results in least tissue loss. It is appropriate therapy for tumors of the eyelids or for recurrent lesions, or where tissue sparing is needed for cosmesis. Sun avoidance, particularly in children, is essential to lower the incidence of new basal cell cancers. Patients with basal cell carcinomas must be followed for 5 years to detect new or recurrent lesions.

Garner KL et al: Basal and squamous cell carcinoma. Prim Care 2000;27:447. [\[PMID: 10815054\]](#)

Jerant AF et al: Early detection and treatment of skin cancer. Am Fam Physician 2000;62:357. [\[PMID: 10929700\]](#)

SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma usually occurs subsequent to prolonged sun exposure on exposed parts in fair-skinned individuals who sunburn easily and tan poorly. It may arise from an actinic keratosis. The lesions appear as small red, conical, hard nodules that occasionally ulcerate. The frequency of metastasis is not precisely known, though metastatic spread is said to be less likely with squamous cell carcinoma arising out of actinic keratoses than with those that arise de novo. In actinically induced squamous cell cancers, rates of metastasis are estimated from retrospective studies to be 3-7%. Squamous cell carcinomas of the lip, oral cavity, tongue, and genitalia have much higher rates of metastasis and require special management.

Keratoacanthomas most often act in benign fashion but resemble squamous cell carcinomas histologically and for all practical purposes should be treated as though they were skin cancers.

Examination of the skin and therapy are essentially the same as for basal cell carcinoma. The preferred treatment of squamous cell carcinoma is excision. Electrodesiccation and curettage and x-ray radiation may be used for some lesions, and fresh tissue microscopically controlled excision (Mohs) is recommended for high-risk lesions (lips, temples, ears, nose) and for recurrent tumors. Some keratoacanthomas respond to intralesional injection of fluorouracil or methotrexate, but they must be excised if they do not. Follow-up for squamous cell carcinoma must be more frequent and thorough than for basal cell carcinoma, starting at every 3 months, with careful examination of lymph nodes. In addition, palpation of the lips is essential to detect hard or indurated areas that represent early squamous cell carcinoma. All such cases must be biopsied. Multiple squamous cell carcinomas are very common on the sun-exposed skin of organ transplant patients because of the host's immunosuppressed state. The tumors begin to appear after 5 years of immunosuppression. Biologic behavior may be aggressive, and careful management is required.

VIOLACEOUS TO PURPLE PAPULES & NODULES

LICHEN PLANUS

Essentials of Diagnosis

BR> • Pruritic, violaceous, flat-topped papules with fine white streaks and symmetric distribution.

- Lacy lesions of the buccal mucosa.
- Commonly seen along linear scratch marks (Koebner phenomenon) on anterior wrists, penis, legs.
- Histopathologic examination is diagnostic.

General Considerations

Lichen planus is an inflammatory pruritic disease of the skin and mucous membranes characterized by distinctive papules with a predilection for the flexor surfaces and trunk. The three cardinal findings are typical skin lesions, mucosal lesions, and histopathologic features of band-like infiltration of lymphocytes and melanophages in the dermis. Drugs causing lichen planus-like reactions include gold, streptomycin, tetracycline, iodides, chloroquine, quinacrine, quinidine, NSAIDs, phenothiazines, and hydrochlorothiazide. Hepatitis C infection is found with greater frequency in lichen planus patients than in controls. Lichen planus has been seen after exposure to color film developing solutions.

Clinical Findings

Itching is mild to severe. The lesions are violaceous, flat-topped, angulated papules, 1-4 mm in diameter, discrete or in clusters, with very fine white streaks on the surface (Wickham's striae) on the flexor surfaces of the wrists and on the penis, lips, tongue, and buccal and vaginal mucous membranes. Mucosal lichen planus has been reported in the genital and anorectal areas, the gastrointestinal tract, the bladder, the larynx, and the conjunctiva. The papules may become bullous or ulcerated. The disease may be generalized. Mucous membrane lesions have a lacy white network overlying them that may be confused with leukoplakia. The Koebner phenomenon (appearance of lesions in areas of trauma) may be seen.

A special form of lichen planus is the erosive or ulcerative variety. On palms and soles, it can be disabling. It is a major problem in the mouth or genitalia, and squamous cell carcinoma may develop.

Differential Diagnosis

Lichen planus must be distinguished from similar lesions produced by medications (see above) and other papular lesions such as psoriasis, lichen simplex chronicus, and syphilis. Lichen planus on the mucous membranes must be differentiated from leukoplakia. Erosive oral lesions require biopsy and often direct immunofluorescence for diagnosis since lichen planus may simulate other erosive diseases. Histologic examination may make the distinction from graft-versus-host disease and in some cases from lichen planus-like drug eruptions.

Treatment

A. Topical Therapy

Superpotent topical corticosteroids applied twice daily are most helpful for localized disease in nonflexural areas. Alternatively, high-potency corticosteroid cream or ointment may be used nightly under thin pliable plastic film.

Topical tacrolimus appears effective in oral and vaginal erosive lichen planus, but chronic therapy is required to prevent relapse. Concern regarding absorption suggests monitoring blood counts when treating mucosal lesions.

B. Systemic Therapy

Corticosteroids (see [Chapter 26](#)) may be required in severe cases or in circumstances where the most rapid response to treatment is desired. Unfortunately, relapse almost always occurs as the steroids are tapered, making systemic corticosteroid therapy an impractical option for the management of chronic lichen planus.

Isotretinoin and acitretin by mouth appear to be effective in some cases of oral and cutaneous lichen planus.

Psoralens plus long-wave ultraviolet light (PUVA) may be effective treatment for lichen planus.

Prognosis

Lichen planus is a benign disease, but it may persist for months or years and may be recurrent. Hypertrophic lichen planus and oral lesions tend to be especially

persistent, and neoplastic degeneration has been described in chronically eroded lesions.

KAPOSI'S SARCOMA

Before 1980 in the USA, this rare malignant skin lesion was seen mostly in elderly white men, had a chronic clinical course, and was rarely fatal. Kaposi's sarcoma occurs endemically in an often aggressive form in young black men of equatorial Africa, but it is rare in American blacks. Epidemic clusters of Kaposi's sarcoma, predominantly in homosexual men with AIDS, have been found in large cities of the United States. Human herpes virus 8 (HHV-8), or Kaposi's sarcoma-associated herpes virus (KSHV), is universally present in all forms of Kaposi's sarcoma. The epidemiology of infection with this virus parallels the incidence of Kaposi's sarcoma in various risk groups and geographic regions. The virus is present in the skin lesions and circulating B lymphocytes of persons with Kaposi's sarcoma but uncommonly in their normal skin. A serologic test is available to detect infection with this virus, but its sensitivity is insufficient for commercial use at this time.

Red or purple plaques or nodules on cutaneous or mucosal surfaces are characteristic. Kaposi's sarcoma commonly involves the gastrointestinal tract, but in asymptomatic patients these lesions are not sought or treated. Pulmonary Kaposi's sarcoma may be life-threatening and is managed aggressively. The incidence of AIDS-associated Kaposi's sarcoma is diminishing.

For Kaposi's sarcoma in the elderly, palliative local therapy with intralesional chemotherapy or radiation is usually all that is required. In the setting of iatrogenic immunosuppression, the treatment of Kaposi's sarcoma is primarily reduction of doses of immunosuppressive medications. In AIDS-associated Kaposi's sarcoma, the patient should first be given effective anti-HIV antiretrovirals (including a protease inhibitor), because in most cases this treatment alone is associated with improvement. Other therapeutic options include cryotherapy or intralesional vinblastine (0.1-0.5 mg/mL) for cosmetically objectionable lesions, radiation therapy for accessible and space-occupying lesions, and laser surgery for certain intraoral and pharyngeal lesions. Systemic chemotherapy is indicated in patients with rapidly progressive skin disease (more than 10 new lesions per month), with edema or pain, and with symptomatic visceral disease or pulmonary disease. Liposomal doxorubicin is highly effective in controlling these cases and has considerably less toxicity—and greater efficacy—than anthracycline monotherapy or combination chemotherapeutic regimens.

PRURITUS (ITCHING)

Pruritus is a disagreeable sensation that provokes a desire to scratch. It is modulated by central factors, including cortical ones. Not all cases of pruritus are mediated by histamine.

Although many cases of generalized pruritus can be attributed to dry skin—whether naturally occurring and precipitated or aggravated by climatic conditions or arising from disease states—there are many other causes: scabies, dermatitis herpetiformis, atopic dermatitis, pruritus vulvae et ani, miliaria, insect bites, pediculosis, contact dermatitis, drug reactions, urticaria, urticarial eruptions of pregnancy, psoriasis, lichen planus, lichen simplex chronicus, exfoliative dermatitis, folliculitis, bullous pemphigoid, and fiberglass dermatitis.

Persistent pruritus not explained by cutaneous disease should prompt a staged workup for systemic causes. Perhaps the commonest cause of pruritus associated with systemic disease is uremia in conjunction with hemodialysis. Both this condition and the pruritus of obstructive biliary disease may be helped by phototherapy with ultraviolet B or PUVA. Naltrexone and nalmefene have been shown to relieve the pruritus of liver disease. Bilirubin may be normal in patients with hepatic pruritus, and the severity of the liver disease may not correlate with the degree of itching. Naltrexone is not effective in pruritus associated with renal failure. Endocrine disorders such as hypo- or hyperthyroidism, psychiatric disturbances, lymphoma, leukemia, and other internal malignant disorders, iron deficiency anemia, and certain neurologic disorders may also cause pruritus. Danazol, 400-800 mg daily, may be tried for pruritus associated with myeloproliferative disorders and other systemic illnesses.

Burning or itching involving the face, scalp, and genitalia may be manifestations of primary depression and treatable with drugs such as tricyclics (amitriptyline, imipramine, doxepin), SSRIs, and other antidepressants.

Prognosis

Elimination of external factors and irritating agents may give complete relief from pruritus. Pruritus accompanying specific skin disease will subside when the disease is controlled. Idiopathic pruritus and that accompanying serious internal disease may not respond to any type of therapy.

Bergasa NV et al: Oral nalmefene therapy reduces scratching activity due to the pruritus of cholestasis: a controlled study. J Am Acad Dermatol 1999;41(3 Part 1):431. [\[PMID: 10459118\]](#)

Twycross R et al: Itch: scratching more than the surface. QJM 2003;96:7. [\[PMID: 12509645\]](#)

ANOGENITAL PRURITUS

Essentials of Diagnosis

- Itching, chiefly nocturnal, of the anogenital area.
- Examination is highly variable, ranging from no skin findings to excoriations and inflammation of any degree, including lichenification.

General Considerations

Most cases have no obvious cause, but multiple specific causes have been identified. Anogenital pruritus may be due to intertrigo, psoriasis, lichen simplex chronicus, or seborrheic or contact dermatitis (from soaps, colognes, douches, contraceptives, and perhaps scented toilet tissue), or it may be due to irritating secretions, as in diarrhea, leukorrhea, or trichomoniasis, or to local disease (candidiasis, dermatophytosis, erythrasma). Oxyuriasis (pinworm) is a rare cause in adults. Lichen sclerosus may at times be the cause. Erythrasma is easily diagnosed by demonstration of coral-red fluorescence with Wood's light; it is easily cured with erythromycin orally and topically.

Uncleanliness may be at fault. In pruritus ani, hemorrhoids are often found, and leakage of mucus and bacteria from the distal rectum onto the perianal skin may be important in cases in which no other skin abnormality is found.

Many women experience pruritus vulvae. In women, pruritus ani by itself is rare, and pruritus vulvae does not usually involve the anal area, though anal itching will usually spread to the vulva. In men, pruritus of the scrotum is most commonly seen in the absence of pruritus ani. When all possible known causes have been ruled out, the condition is diagnosed as idiopathic or essential pruritus—by no means rare.

Clinical Findings

A. Symptoms and Signs

The only symptom is itching, which is chiefly nocturnal. Physical findings are usually not present, but there may be erythema, fissuring, maceration, lichenification, excoriations, or changes suggestive of candidiasis or tinea.

B. Laboratory Findings

Urinalysis and blood glucose testing may lead to a diagnosis of diabetes mellitus. Microscopic examination or culture of tissue scrapings may reveal yeasts or fungi. Stool examination may show pinworms.

Differential Diagnosis

The etiologic differential diagnosis consists of candida infection, parasitosis, local irritation from contact with drugs and irritants, and other primary skin disorders of the genital area such as psoriasis, seborrhea, intertrigo, or lichen sclerosus et atrophicus.

Prevention

Instruct the patient in proper anogenital hygiene after treating systemic or local conditions.

Treatment

A. General Measures

Treating constipation, preferably with high-fiber management (psyllium), may help. Instruct the patient to use very soft or moistened tissue or cotton after bowel movements and to clean the perianal area thoroughly with cool water if possible. Women should use similar precautions after urinating. Instruct the patient regarding the harmful and pruritus-inducing effects of scratching.

B. Local Measures

Pramoxine cream or lotion or hydrocortisone-pramoxine (Pramosone), 1% or 2.5% cream, lotion, or ointment, is helpful in managing pruritus in the anogenital area. The ointment or cream should be applied after a bowel movement. Potent fluorinated topical corticosteroids may lead to atrophy and striae if used for more than a few days and should in general be avoided. This includes combinations with antifungals. The use of strong steroids on the scrotum may lead to persistent severe burning upon withdrawal of the drug. Soaks with aluminum subacetate solution, 1:20, are of value if the area is acutely inflamed and oozing. Underclothing should be changed daily. Affected areas may be painted with Castellani's solution. Balneol Perianal Cleansing Lotion or Tucks premoistened pads, ointment, or cream (all Tucks preparations contain witch hazel) may be very useful for pruritus ani.

Prognosis

Although benign, anogenital pruritus may be persistent and recurrent.

Vincent C: Anorectal pain and irritation: anal fissure, levator syndrome, proctalgia fugax, and pruritus ani. Prim Care 1999;26:53. [\[PMID: 9922294\]](#)

SCABIES

Essentials of Diagnosis

- Generalized very severe itching.
- Pruritic vesicles and pustules in "runs" or "galleries," especially on finger webs and the heels of the palms and in wrist creases.
- Mites, ova, and brown dots of feces visible microscopically.
- Red papules or nodules on the scrotum and on the penile glans and shaft are pathognomonic.

General Considerations

Scabies is caused by infestation with *Sarcoptes scabiei*. The infestation usually spares the head and neck (though even these areas may be involved in infants, in the elderly, and in patients with AIDS). Scabies is usually acquired by sleeping with or in the bedding of an infested individual or by other close contact. The entire household may be affected.

Clinical Findings

A. Symptoms and Signs

Itching is almost always present and can be quite severe. The lesions consist of more or less generalized excoriations with small pruritic vesicles, pustules, and "runs" or "burrows" in the web spaces and on the heels of the palms, wrists, elbows, and around the axillae. Often, burrows are found only on the feet, as they have been scratched off in other locations. The burrow appears as a short irregular mark, 2-3 mm long and the width of a hair. Characteristic lesions may occur on the nipples in females and as pruritic papules on the scrotum or penis in males. Pruritic papules may be seen over the buttocks.

B. Laboratory Findings

The diagnosis should be confirmed by microscopic demonstration of the organism, ova, or feces in a mounted specimen. The success of this procedure depends on choosing the best unexcoriated lesions from interdigital webs, wrists, elbows, or feet. A No. 15 blade is used to scrape the lesion until it is flat. Pinpoint bleeding may result from the scraping. The mite, ova, and feces can be seen under the light microscope.

Differential Diagnosis

Scabies must be distinguished from the various forms of pediculosis and from other causes of pruritus.

Treatment & Prognosis

Treatment is aimed at killing scabies mites and controlling the dermatitis, which can persist for months after effective eradication of the mites. Bedding and clothing should be laundered or cleaned or set aside for 14 days in plastic bags. If secondary pyoderma is present, it is treated with systemic antibiotics. Unless treatment is aimed at all infected persons in a family or institutionalized group, reinfestations will probably occur. Resistance to 5% permethrin cream is very rare.

Permethrin 5% cream is highly effective and safe in the management of scabies. Treatment consists of a single application for 8-12 hours. It may be repeated in 1 week. The drug has been used safely in infants aged 2 months to 5 years and is the treatment of choice in children. An alternative drug is crotamiton cream or lotion, which may be applied in the same way as lindane but is used nightly for 4 nights. It is far less effective if used for only 48 hours.

Pregnant patients should be treated only if they have documented scabies themselves. Permethrin 5% cream once for 12 hours—or 5% or 6% sulfur in petrolatum applied nightly for 3 nights from the collarbones down—may be used.

Patients will continue to itch for several weeks after treatment. Use of triamcinolone 0.1% cream will help resolve the dermatitis. Scabies in nursing home patients, institutionalized or mentally impaired (especially Down's syndrome) patients, and AIDS patients may be much more difficult to treat.

Most failures in normal hosts are related to incorrect use or incomplete treatment of the housing unit. In these cases, repeat treatment with permethrin once weekly for 2 weeks, with reeducation regarding the method and extent of application, is suggested. In immunocompetent individuals, ivermectin in a dose of 200 ug/kg is effective in about 75% of cases with a single dose and 95% of cases with two doses 2 weeks apart. In immunosuppressed hosts and those with crusted (hyperkeratotic) scabies, multiple doses of ivermectin (every 2 weeks for two or three doses) plus topical therapy with permethrin once or twice weekly may be effective when topical treatment and oral therapy alone fail.

Persistent pruritic postscabietic papules may be treated with mid- to high-potency steroids or with intralesional triamcinolone acetonide (2.5-5 mg/mL).

PEDICULOSIS

Essentials of Diagnosis

- Pruritus with excoriation.
- Nits on hair shafts; lice on skin or clothes.
- Occasionally, sky-blue macules (maculae ceruleae) on the inner thighs or lower abdomen in pubic louse infestation.

General Considerations

Pediculosis is a parasitic infestation of the skin of the scalp, trunk, or pubic areas. Body lice usually occur among people who live in overcrowded dwellings with inadequate hygiene facilities. Pubic lice may be acquired by sexual transmission. Head lice may be transmitted by shared use of hats or combs and are epidemic among children of all socioeconomic classes in elementary schools. Head lice are very uncommon among black children. Adults contacting children with head lice frequently acquire the infestation.

There are three different varieties: (1) pediculosis pubis, caused by *Pthirus pubis* (pubic louse, "crabs"); (2) pediculosis corporis, by *Pediculus humanus* var *corporis* (body louse); and (3) pediculosis capitis, caused by *Pediculus humanus* var *capitis* (head louse).

Head and body lice are similar in appearance and are 3-4 mm long. The body louse can seldom be found on the body, because the insect comes onto the skin only to feed and must be looked for in the seams of the clothing. Trench fever, relapsing fever, and typhus are transmitted by the body louse in countries where those diseases are endemic.

Clinical Findings

Itching may be very intense in body louse infestations, and scratching may result in deep excoriations, especially over the upper shoulders, posterior flanks, and neck. In some cases, only itching is present, with few excoriations seen. Pyoderma may be the presenting sign in any of these infestations. Head lice can be found on the scalp or may be manifested as small nits resembling pussy willow buds on the scalp hairs close to the skin. They are easiest to see above the ears and at the nape of the neck. Pubic louse infestations are occasionally generalized, particularly in hairy individuals; the lice may even be found on the eyelashes and in the scalp.

Differential Diagnosis

Head louse infestation must be distinguished from seborrheic dermatitis, body louse infestation from scabies, and pubic louse infestation from anogenital pruritus and eczema.

Treatment

Body lice are treated by disposing of the infested clothing. For pubic lice, lindane lotion or cream (Kwell, Scabene) is used. A thin layer is applied to the infested and adjacent hairy areas. It is removed after 8 hours by thorough washing. Permethrin rinse 1% for 10 minutes and permethrin cream 5% applied for 8 hours are effective alternatives. Sexual contacts should be treated. Clothes and bedclothes should be washed and dried at high temperature if possible.

Permethrin 1% cream rinse (Nix) is a topical OTC pediculicide and ovicide and is the treatment of choice for head lice. It is applied to the scalp and hair and left on for 30 minutes to 8 hours before being rinsed off. Treatment should be repeated in 1 week. Five percent permethrin lotion may be used in refractory cases. Permethrin resistance of head lice is common. Malathion lotion 1% (Ovide) is very effective, but it is highly volatile and flammable, so application must be done in a well-ventilated room or out of doors. Nits are removed meticulously with a fine-toothed comb under bright illumination. For involvement of eyelashes, petrolatum is applied thickly twice daily for 8 days, and remaining nits are then plucked off. Adults with head lice virtually always acquire their infestation from elementary school-aged children, so a source of infection must always be sought. Head lice are extremely difficult to eradicate in the epidemic setting, probably because the currently available pediculicides are not uniformly ovicidal when applied as directed.

SKIN LESIONS DUE TO OTHER ARTHROPODS

Essentials of Diagnosis

- Localized rash with pruritus.
- Furuncle-like lesions containing live arthropods.
- Tender erythematous patches that migrate ("larva migrans").
- Generalized urticaria or erythema multiforme in some patients.

General Considerations

Some arthropods (eg, mosquitoes and biting flies) are readily detected as they bite. Many others are not, eg, because they are too small, because there is no immediate reaction, or because they bite during sleep. Reactions may be delayed for hours; many are allergic. Patients are most apt to consult a clinician when the lesions are multiple and pruritus is intense.

Many persons will react severely only to their earliest contacts with an arthropod, thus presenting pruritic lesions when traveling, moving into new quarters, etc. Body lice, fleas, bedbugs, and mosquitoes should be considered. Spiders are often incorrectly believed to be the source of bites; they rarely attack humans, though the brown spider (*Loxosceles laeta*, *Loxosceles reclusa*) may cause severe necrotic reactions and death due to intravascular hemolysis, and the black widow spider (*Latrodectus mactans*) may cause severe systemic symptoms and death. (See also [Chapter 39](#).)

In addition to arthropod bites, the most common lesions are venomous stings (wasps, hornets, bees, ants, scorpions) or bites (centipedes), furuncle-like lesions due to fly maggots or sand fleas in the skin, and a linear creeping eruption due to a migrating larva.

Clinical Findings

The diagnosis may be difficult when the patient has not noticed the initial attack but suffers a delayed reaction. Individual bites are often in clusters and tend to occur either on exposed parts (eg, midges and gnats) or under clothing, especially around the waist or at flexures (eg, small mites or insects in bedding or clothing). The reaction is often delayed for 1-24 hours or more. Pruritus is almost always present and may be all but intolerable once the patient starts to scratch. Secondary infection may follow scratching. Urticarial wheals are common. Papules may become vesicular. The diagnosis is aided by searching for exposure to arthropods and by considering the patient's occupation and recent activities.

The principal arthropods are as follows:

- 1. Fleas:** Fleas are bloodsucking ectoparasites that feed on dogs, cats, humans, and other species. Flea saliva produces papular urticaria in sensitized individuals. To break the life cycle of the flea, one must treat the home and pets, using quick-kill insecticides, residual insecticides, and a growth regulator. Obviously, this is a repetitive job.
- 2. Bedbugs:** In crevices of beds or furniture; bites tend to occur in lines or clusters. Papular urticaria is a characteristic lesion of bedbug (*Cimex lectularius*) bites. The closely related kissing bug has a painful bite.
- 3. Ticks:** Usually picked up by brushing against low vegetation. Ticks may transmit Rocky Mountain spotted fever, Lyme disease, relapsing fever, and ehrlichiosis.
- 4. Chiggers or red bugs:** These are larvae of trombiculid mites. A few species confined to particular regions and locally recognized habitats (eg, berry patches, woodland edges, lawns, brush turkey mounds in Australia, poultry farms) attack humans, often around the waist, on the ankles, or in flexures, raising intensely itching erythematous papules after a delay of many hours. The red chiggers may sometimes be seen in the center of papules that have not yet been scratched.
- 5. Bird and rodent mites:** Larger than chiggers, bird mites infest pigeon lofts or nests of birds in eaves. Bites are multiple anywhere on the body. Room air conditioning units may suck in bird mites and infest the inhabitants of the room. Rodent mites from mice or rats may cause similar effects. Pet gerbils may be infested with bird mites. The diagnosis of bird mites or rodent mites may easily be overlooked.
- 6. Mites in stored products:** These are white and almost invisible and infest products such as copra, vanilla pods, sugar, straw, cottonseeds, and cereals. Persons who handle these products may be attacked, especially on the hands and forearms and sometimes on the feet. Infested bedding may occasionally lead to generalized dermatitis.
- 7. Caterpillars of moths with urticating hairs:** The hairs are blown from cocoons or carried by emergent moths, causing severe and often seasonally recurrent

outbreaks after mass emergence. The gypsy moth is a cause in the eastern United States.

8. Tungiasis: Tungiasis is due to the burrowing flea known as *Tunga penetrans* and is found in Africa, the West Indies, and South and Central America. The female burrows under the skin, sucks blood, swells to 0.5 cm, and then ejects her eggs onto the ground. Ulceration, lymphangitis, gangrene, and septicemia may result, in some cases with lethal effect. Ethyl chloride spray will kill the insect when applied to the lesion, and disinfestation may be accomplished with insecticide applied to the terrain. Simple surgical excision is usually performed.

Differential Diagnosis

Arthropods should be considered in the differential diagnosis of skin lesions showing any of the above symptoms.

Prevention

Arthropod infestations are best prevented by avoidance of contaminated areas, personal cleanliness, and disinfection of clothing, bedclothes, and furniture as indicated. Chiggers, bedbugs, and mites can be killed by permethrin applied to the head and clothing. (It is not necessary to remove clothing.)

Treatment

Living arthropods should be removed carefully with tweezers after application of alcohol and preserved in alcohol for identification. In endemic Rocky Mountain spotted fever areas, ticks should not be removed with the bare fingers.

Corticosteroid lotions or creams are helpful. Topical antibiotics may be applied if secondary infection is suspected. Localized persistent lesions may be treated with intralesional corticosteroids.

Stings produced by many arthropods may be alleviated by applying papain powder (Adolph's Meat Tenderizer) mixed with water, or aluminum chloride hexahydrate (Xerac AC).

Extracts from venom sacs of bees, wasps, yellow jackets, and hornets are available for immunotherapy of patients at risk for anaphylaxis.

Elston DM et al: What's eating you? Bedbugs. *Cutis* 2000;65:262. [PMID: 10826083]

INFLAMMATORY NODULES

ERYTHEMA NODOSUM

Essentials of Diagnosis

- Painful red nodules without ulceration on anterior aspects of legs.
- Slow regression over several weeks to resemble contusions.
- Women are predominantly affected by a ratio of 4-8:1 over men.
- Some cases associated with infection or drug sensitivity.

General Considerations

Erythema nodosum is a symptom complex characterized by tender, erythematous nodules that appear most commonly on the extensor surfaces of the lower legs. It usually lasts about 6 weeks and may recur. The disease may be associated with various infections—streptococcosis, primary coccidioidomycosis, other deep fungal infections, tuberculosis, *Yersinia pseudotuberculosis* and *Yersinia enterocolitica* infection, or syphilis. It may accompany sarcoidosis and inflammatory bowel disease. Erythema nodosum may be associated with pregnancy or with use of oral contraceptives or other medication.

Clinical Findings

A. Symptoms and Signs

The swellings are exquisitely tender and may be preceded by fever, malaise, and arthralgia. They are most often located on the anterior surfaces of the legs below the knees but may occur (rarely) on the arms, trunk, and face. The lesions, 1-10 cm in diameter, are at first pink to red; with regression, all the various hues seen in a contusion can be observed.

B. Laboratory Findings

The histologic finding of septal panniculitis is characteristic of erythema nodosum. Evaluation of patients presenting with acute erythema nodosum should include a careful history and physical examination for prior upper respiratory infection or diarrheal illness, symptoms of any deep fungal infection endemic to the area, a chest x-ray, a PPD, and two consecutive DNaseB titers at 2- to 4-week intervals. If no underlying cause is found, only a small percentage of patients will go on to develop a significant underlying illness (usually sarcoidosis) over the next year.

Differential Diagnosis

Erythema induratum from tuberculosis is seen on the posterior surfaces of the legs and may ulcerate. Lupus panniculitis presents as tender nodules on the buttocks and posterior arms that heal with depressed scars. Polyarteritis nodosa is less inflammatory, and the subcutaneous nodules are often associated with a fixed livedo. In the late stages, erythema nodosum must be distinguished from simple bruises and contusions.

Treatment

One must first identify and treat the underlying cause. Primary therapy is with nonsteroidal anti-inflammatory agents in usual doses. Saturated solution of potassium iodide, 5-15 drops three times daily, results in prompt involution in many cases. Side effects of potassium iodide include salivation, swelling of salivary glands, and headache. Complete bed rest may be advisable if the lesions are painful. Systemic therapy directed against the lesions themselves may include corticosteroid therapy (see [Chapter 26](#)) unless contraindicated by associated infection.

Prognosis

The lesions usually disappear after about 6 weeks, but they may recur.

Garcia-Porrúa C et al: Erythema nodosum: etiologic and predictive factors in a defined population. *Arthritis Rheum* 2000;43:584. [PMID: 10728752]

FURUNCULOSIS (BOILS) & CARBUNCLES

Essentials of Diagnosis

- Extremely painful inflammatory swelling based on a hair follicle that forms an abscess.
- Predisposing condition (diabetes mellitus, HIV disease, injection drug use) sometimes present.
- Coagulase-positive *Staphylococcus aureus* is the causative organism.

General Considerations

A furuncle (boil) is a deep-seated infection (abscess) involving the entire hair follicle and adjacent subcutaneous tissue. The most common sites of occurrence are the hairy parts exposed to irritation and friction, pressure, or moisture. Because the lesions are autoinoculable, they are often multiple. Thorough investigation usually fails to uncover a predisposing cause; however, diabetes mellitus (especially if using insulin injections), injection drug use, allergy injections, and HIV disease all increase the risk of staphylococcal infections by increasing the rate of nasal carriage.

A carbuncle consists of several furuncles developing in adjoining hair follicles and coalescing to form a conglomerate, deeply situated mass with multiple drainage points.

Clinical Findings

A. Symptoms and Signs

Pain and tenderness may be prominent. The abscess is either rounded or conical. It gradually enlarges, becomes fluctuant, and then softens and opens spontaneously after a few days to 1-2 weeks to discharge a core of necrotic tissue and pus. The inflammation occasionally subsides before necrosis occurs. Infection of the soft tissue around the nails (paronychia) may be due to staphylococci when it is acute or candida when chronic.

B. Laboratory Findings

There may be slight leukocytosis, but a white blood cell count is rarely required. Although *S aureus* is almost always the cause, pus should be cultured to rule out methicillin-resistant *S aureus* or other bacteria. Culture of the anterior nares may identify chronic staphylococcal carriage in cases of recurrent cutaneous infection.

Differential Diagnosis

The most common entity in the differential is an inflamed epidermal inclusion cyst that suddenly becomes red and tender, and expands greatly in size over 1 to a few days. The history of a prior cyst in the same location, the presence of a clearly visible cyst orifice, and the extrusion of malodorous cheesy rather than purulent material helps in the diagnosis. Tinea profunda (deep dermatophyte infection of the hair follicle) may simulate recurrent furunculosis. Furuncle is also to be distinguished from deep mycotic infections such as sporotrichosis (often in gardeners) and blastomycosis, from other bacterial infections such as anthrax and tularemia (rare), and from acne cysts. Hidradenitis suppurativa presents with recurrent tender sterile abscesses in the axillae and groin, on the buttocks, or below the breasts. The presence of old scars or sinus tracts plus negative cultures suggests this diagnosis.

Complications

Serious and sometimes fatal cavernous sinus thrombosis may occur as a complication of a manipulated furuncle on the central portion of the upper lip or near the nasolabial folds. Perinephric abscess, osteomyelitis, and even endocarditis may rarely occur.

Treatment

A. Specific Measures

Incision and drainage is recommended for all loculated suppurations and is the mainstay of therapy. Systemic antibiotics are indicated (chosen on the basis of cultures and sensitivity tests if possible). Sodium dicloxacillin or cephalexin, 1 g daily in divided doses by mouth for 10 days, is usually effective. Doxycycline 100 mg twice daily, trimethoprim-sulfamethoxazole one tablet twice daily, clindamycin 150-300 mg twice daily, and ciprofloxacin 500 mg twice daily are effective against strains of staphylococci resistant to other antibiotics.

Recurrent furunculosis may be effectively treated with a combination of dicloxacillin, 250-500 mg four times daily for 2-4 weeks, and rifampin, 300 mg twice daily for 5 days during this period. Chronic clindamycin, 150-300 mg daily for 1-2 months, may also cure recurrent furunculosis. Family members and intimate contacts may need evaluation for staphylococcal carrier state and perhaps concomitant treatment. Applications of topical 2% mupirocin to the nares, axillae, and anogenital areas twice daily for 5 days eliminates the staphylococcal carrier state.

B. Local Measures

Immobilize the part and avoid overmanipulation of inflamed areas. Use moist heat to help larger lesions "localize." Use surgical incision and debridement *after* the lesions are "mature." It is not necessary to incise and drain an acute staphylococcal paronychia. Inserting a flat metal spatula or sharpened hardwood stick into the nail fold where it adjoins the nail will release pus from a mature lesion. Inflamed epidermal cysts may be treated in the initial stages with intralesional injections of triamcinolone acetonide into the borders of the lesions, attempting not to puncture the cyst itself. Drainage of fluctuant lesions results in rapid resolution and reduction of pain.

Prognosis

Recurrent crops may harass the patient for months or years.

PHOTODERMATITIS

Essentials of Diagnosis

- Painful or pruritic erythema, edema, or vesiculation on sun-exposed surfaces: the face, neck, hands, and "V" of the chest.
- Inner upper eyelids spared, as is the area under the chin.

General Considerations

Photodermatitis is an acute or chronic skin reaction due to hypersensitivity to sunlight or other sources of radiation, photosensitization of the skin by certain drugs, or idiosyncrasy to actinic light as seen in some constitutional disorders including the porphyrias and many hereditary disorders (phenylketonuria, xeroderma pigmentosum, and others). Contact photosensitivity may occur with perfumes, antiseptics, and other chemicals.

Photodermatitis is manifested most commonly as phototoxicity—a tendency for the individual to sunburn more easily than expected—or, as photoallergy, a true immunologic reaction that often presents with dermatitis.

Clinical Findings

A. Symptoms and Signs

The acute inflammatory skin reaction, if severe enough, is accompanied by pain, fever, gastrointestinal symptoms, malaise, and even prostration, but this is very rare. Signs include erythema, edema, and possibly vesiculation and oozing on exposed surfaces. Peeling of the epidermis and pigmentary changes often result. The key to diagnosis is localization of the rash to photoexposed areas, though these eruptions may become generalized with time to involve even photoprotected areas. The lower lip is commonly involved in hereditary polymorphous light eruption, a disorder seen in persons of Native American descent.

B. Laboratory Findings

Blood and urine tests are not helpful in diagnosis unless porphyria cutanea tarda is suggested by the presence of blistering, scarring, milia (white cysts 1-2 mm in diameter) and skin fragility of the dorsal hands, and facial hypertrichosis. Testing for photosensitivity may define the wavelengths of light triggering the reaction. This is critical in determining the form of photoprotection recommended.

Differential Diagnosis

The differential diagnosis is long. If a clear history of the use of a topical or systemic photosensitizer is not available and if the eruption is persistent, then a workup including biopsy and light testing may be required. Photodermatitis must be differentiated from contact dermatitis that may develop from one of the many substances in suntan lotions and oils, as these may often have a similar distribution. Sensitivity to actinic rays may also be part of a more serious condition such as porphyria cutanea tarda or lupus erythematosus. These disorders are diagnosed by appropriate blood or urine tests. Phenothiazines, quinine or quinidine, griseofulvin, sulfonyleureas, nonsteroidal anti-inflammatory agents, and antibiotics (eg, some tetracyclines) may photosensitize the skin. Polymorphous light eruption is a very common idiopathic photodermatitis that affects both sexes equally and often has its onset in the third to fourth decades except in Native Americans and Latinos, in whom it commonly presents in childhood. Polymorphous light eruption is chronic in nature. Transitory periods of spontaneous remission do occur. The action spectrum usually lies in the short (below 320 nm) ultraviolet wavelengths but may also extend into the long ultraviolet wavelengths (320-400 nm).

Complications

Some individuals continue to be chronic light reactors even when they apparently are no longer exposed to photosensitizing drugs.

Prevention

While sunscreens are useful agents in general and should be used by persons with photosensitivity, patients may react to such low amounts of energy that sunscreens alone may not be sufficient. Sunscreens with an SPF of 30-50, usually containing avobenzone (Parasol 1789), titanium dioxide, and micronized zinc oxide, are especially useful in patients with photoallergic dermatitis.

Treatment

A. Specific Measures

Drugs should be suspected in cases of photoallergy even if the particular medication (such as hydrochlorothiazide) has been used for months.

B. Local Measures

When the eruption is vesicular or weepy, treatment is similar to that of any acute dermatitis, using cooling and soothing wet dressing.

Sunscreens should be used as described above. Mid-potency to high-potency topical steroids are of limited benefit in phototoxic reactions but may help in polymorphous light eruption and photoallergic reactions. Since the face is often involved, close monitoring is necessary to avoid side effects of potent steroids.

C. Systemic Measures

Aspirin may have some value for fever and pain of acute sunburn, as prostaglandins appear to play a pathogenetic role in the early erythema. Systemic corticosteroids in doses as described for acute contact dermatitis may be required for severe photosensitivity reactions. Otherwise, different photodermatoses may be treated in specific ways.

Patients with severe photodermatitis may require immunosuppressives, such as azathioprine, in the range of 50-150 mg/d, or cyclosporine, 3-5 mg/kg/d.

Prognosis

The most common phototoxic sunburn reactions are usually benign and self-limiting except when the burn is severe or when it occurs as an associated finding in a more serious disorder. Polymorphous light eruption and some cases of photoallergy can persist for years.

Vassileva SG et al: Antimicrobial photosensitive reactions. Arch Intern Med 1998;158:871. [\[PMID: 9778198\]](#)

ULCERS

DECUBITUS ULCERS (BEDSORES, PRESSURE SORES)

Bedsore (pressure sore) is a special type of ulcer caused by impaired blood supply and tissue nutrition resulting from prolonged pressure over bony or cartilaginous prominences. The skin overlying the sacrum and hips is most commonly involved, but bedsore may also be seen over the occiput, ears, elbows, heels, and ankles. They occur most readily in aged, paralyzed, debilitated, and unconscious patients. Low-grade infection may occur as a complication.

Differential Diagnosis

Herpes simplex virus should be suspected in ulcers in immunocompromised patients, particularly if there is a scalloped border, representing the erosions of herpetic vesicles. Rarely, ulcerated lesions in the perianal area represent actual skin cancers. Rapidly expanding ulcers may also represent pyoderma gangrenosum associated with inflammatory bowel disease. Ecthyma gangrenosum is an ulcerating lesion, commonly due to *Pseudomonas*, and observed in neutropenic patients. All ulcerative lesions should be biopsied and cultured if suspicious or if they do not heal properly.

Prevention

Good nursing care, good nutrition, and maintenance of skin hygiene are important preventive measures. The skin and the bed linens should be kept clean and dry. Bedfast, paralyzed, moribund, listless, or incontinent patients who are candidates for the development of decubiti must be turned *frequently* (at least every hour) and must be examined at pressure points for the appearance of small areas of redness and tenderness. Written schedules can be very helpful. Water-filled mattresses, rubber pillows, alternating-pressure mattresses, and thick papillated foam pads are useful in prevention and in the treatment of lesions. "Donut" devices should not be used.

Treatment

A large number of treatments and protocols exist for management of decubiti. Early lesions should be treated with topical antibiotic powders and adhesive absorbent bandage (Gelfoam). Once clean, they may be treated with hydrocolloid dressings such as DuoDerm. Established lesions require surgery for debridement, cleansing, and dressing. A spongy foam pad placed under the patient may work best in some cases. It must be laundered often. In general, topical antiseptics are not recommended. Systemic antibiotics are required for deep infections.

Theaker C et al: Risk factors for pressure sores in the critically ill. Anaesthesia 2000;55:221. [\[PMID: 10671839\]](#)

LEG ULCERS SECONDARY TO VENOUS INSUFFICIENCY

Essentials of Diagnosis

- Past history of varicosities, thrombophlebitis, or postphlebotic syndrome.
- Irregular ulceration, often on the medial aspect of the lower legs above the malleolus.
- Edema of the legs, varicosities, hyperpigmentation, and red and scaly areas (stasis dermatitis) and scars from old ulcers support the diagnosis.

General Considerations

Patients at risk may have a history of venous insufficiency, either with obvious varicosities or with a past history of thrombophlebitis, or with immobility of the calf muscle group (paraplegics, etc). Red, pruritic patches of stasis dermatitis often precede ulceration. Because venous insufficiency is the most common cause of lower leg ulceration, testing of venous competence is still a required part of the evaluation even when no changes of venous insufficiency are present.

Clinical Findings

A. Symptoms and Signs

Classically, chronic edema is followed by a dermatitis, which is often pruritic. These changes are followed by hyperpigmentation, skin breakdown, and eventually sclerosis of the skin of the lower leg. The ulcer base may be clean, but it often has a yellow fibrin eschar that often requires surgical treatment. Ulcers that appear on the feet, toes, or above the knees should be approached with other diagnoses in mind.

B. Laboratory Findings

Thorough evaluation of the patient's vascular system (including measurement of the ankle/brachial index) is essential. Doppler and light rheography examinations as office procedures are usually sufficient (except in the diabetic) to elucidate the cause of most vascular cases of lower leg ulceration.

Differential Diagnosis

The differential includes vasculitis, pyoderma gangrenosum, arterial ulcerations, infection, trauma, skin cancer, arachnid bites, and sickle cell anemia. When the diagnosis is in doubt, a punch biopsy from the border (not base) of the lesion may be helpful.

Prevention

Compression stockings to reduce edema are the most important means of prevention. Compression should achieve a pressure of 30 mm Hg below the knee and 40 mm Hg at the ankle. The stockings should not be used in patients with arterial insufficiency with an ankle-brachial pressure index less than 0.7. Pneumatic sequential compression devices may be of great benefit when edema is refractory to standard compression dressings.

Treatment

A. Local Measures

Institution of compression therapy is begun after cleaning of the ulcer with saline or cleansers such as Saf-Cleans. A curette or small scissors can be used to remove the yellow fibrin eschar, under local anesthesia if the areas are very tender.

The ulcer is treated with metronidazole gel to reduce bacterial growth and odor. Any red dermatitic skin is treated with a medium- to high-potency steroid ointment. The ulcer is then covered with an occlusive hydroactive dressing (DuoDerm or Cutinova) or a polyurethane foam (Allevyn) followed by an Unna zinc paste boot. This is changed weekly. The ulcer should begin to heal within weeks, and healing should be complete within 2-3 months. If the patient is diabetic, becaplermin (Regranex) may be applied to the ulcer along with good local treatment in those ulcers which are not becoming smaller or developing a granulating base. Some ulcerations require grafting. Full- or split-thickness grafts often do not take, and pinch grafts (small shaves of skin laid onto the bed) may be more effective. Cultured epidermal cell grafts—or Apligraf, a bilayered skin construct—may accelerate wound healing, but they are very expensive. They should be considered in refractory ulcers, especially those which have not healed after a year or more of conservative therapy.

B. Systemic Therapy

Pentoxifylline, 400 mg three times daily administered with compression, is beneficial in accelerating healing of leg ulcers. Zinc supplementation is occasionally beneficial in patients with low serum zinc levels. If cellulitis accompanies the ulcer, systemic antibiotics are recommended: dicloxacillin, 250 mg orally four times a day; ciprofloxacin, 500 mg orally twice a day; or levofloxacin, 500 mg once daily.

Prognosis

The combination of compression stockings and newer dressings enables venous stasis ulcers to heal within weeks or months. Topical growth factors, antibiotics, debriding agents, and xenografts and autografts have been shown to be effective in recalcitrant cases. Ongoing control of edema is essential to prevent recurrent ulceration.

PIGMENTARY DISORDERS

*Hirutism is discussed in [Chapter 26](#).

Although the color of skin may be altered by many diseases and agents, the vast majority of patients have either an increase or decrease in pigment secondary to some inflammatory disease such as acne or atopic dermatitis.

Other pigmentary disorders include those resulting from exposure to exogenous pigments such as carotenemia, argyria, deposition of other metals (such as gold when given chronically for rheumatoid arthritis), and tattooing. Other endogenous pigmentary disorders are attributable to metabolic substances—including hemosiderin (iron)—in purpuric processes, or to homogentisic acid in ochronosis, bile pigments, and carotenes.

Classification

One should first determine whether the disorder is hyper- or hypopigmentation, ie, an increase or decrease in normal skin colors. Each may be considered to be primary or to be secondary to other disorders.

A. Primary Pigmentary Disorders

1. Hyperpigmentation—The disorders in this category are nevoid and congenital or acquired, and include pigmented nevi, ephelides (juvenile freckles), and lentigines (senile freckles). Hyperpigmentation occurs also in arsenical melanosis or in association with Addison's disease (due to lack of the inhibitory influence of cortisol on the production of melanocyte-stimulating hormone by the pituitary gland). Axillary freckling and cafe au lait spots may be seen in neurofibromatosis. **Melasma (chloasma)** occurs as patterned hyperpigmentation of the face, usually as a direct effect of estrogens. It occurs not only during pregnancy but also in 30-50% of women taking oral contraceptives, and rarely in men. One report suggests that such men have low testosterone and elevated LH levels.

2. Hypopigmentation and depigmentation—The disorders in this category are vitiligo, albinism, and piebaldism. In vitiligo, pigment cells (melanocytes) are destroyed. Vitiligo, present in approximately 1% of the population, may be associated with hyperthyroidism and hypothyroidism, pernicious anemia, diabetes mellitus, and Addison's disease. Albinism represents a number of different genetically determined traits, with different phenotypes. These often affect the eye and vision. Piebaldism, a localized hypomelanosis manifested by a white forelock, is an autosomal dominant trait that in some cases may be associated with neurologic abnormalities. Hypopigmented ash leaf spots may be seen in tuberous sclerosis. Hypopigmented halos are common around nevi and may occur around melanomas.

B. Secondary Pigmentary Disorders

Any damage to the skin (irritation, allergy, infection, excoriation, burns, or dermatologic therapy such as chemical peels and freezing with liquid nitrogen) may result in hyper- or hypopigmentation. Several disorders of clinical importance are as described below:

1. Hyperpigmentation—The most common type of secondary hyperpigmentation occurs after another dermatologic condition, such as acne, and is most commonly seen in dark-skinned persons. It is called postinflammatory hyperpigmentation.

Berloque hyperpigmentation is the pigmentation due to phototoxicity from chemicals in the rinds of limes and other citrus fruits and to celery. Pigmentation may be produced by certain drugs, eg, chloroquine, chlorpromazine, minocycline, and amiodarone. Irritation from benzoyl peroxide and tretinoin can result in hyperpigmentation, as may topical fluorouracil. Fixed drug eruptions to phenolphthalein in laxatives, to trimethoprim-sulfamethoxazole, to NSAIDs, and to tetracyclines, for example, are further causes.

2. Hypopigmentation—Leukoderma is a disorder that may complicate atopic dermatitis, lichen planus, psoriasis, discoid lupus erythematosus, and lichen simplex chronicus. Practitioners must exercise special care in using liquid nitrogen on any patient with olive or darker complexions, since doing so may result in hypopigmentation or depigmentation, at times permanent. Intralesional or intra-articular injections of high concentrations of corticosteroids may also cause localized temporary hypopigmentation.

Differential Diagnosis

One must distinguish true lack of pigment from pseudoachromia, such as occurs in tinea versicolor, pityriasis simplex, and seborrheic dermatitis. The evaluation of pigmentary disorders in Caucasians is helped by Wood's light, which accentuates epidermal pigmentation and highlights hypopigmentation.

Complications

Actinic keratoses and skin cancers are more likely to develop in persons with vitiligo and albinism. There may be severe emotional trauma in extensive vitiligo and other types of hypo- and hyperpigmentation, particularly when they occur in naturally dark-skinned persons.

Treatment & Prognosis

A. Hyperpigmentation

Therapeutic bleaching preparations generally contain hydroquinone. Hydroquinone has occasionally caused unexpected hypopigmentation, hyperpigmentation, or even secondary ochronosis and pigmented milia, particularly with prolonged use.

The role of exposure to ultraviolet light cannot be overstressed as a factor promoting or contributing to most disorders of hyperpigmentation, and such exposure should be minimized. Melasma, ephelides, and postinflammatory hyperpigmentation may be treated with varying success with 3-4% hydroquinone cream, gel, or solution and a sunscreen containing UVA photoprotectants (Avobenzone, zinc oxide, titanium dioxide). Tretinoin cream, 0.025-0.05%, may be added. Superficial melasma responds well, but if there is predominantly dermal deposition of pigment (does *not* enhance with Wood's light), the prognosis is poor. Response to therapy takes months and requires avoidance of sunlight. Hyperpigmentation often recurs after treatment if the skin is exposed to ultraviolet light. Solar lentigines respond to liquid nitrogen application. Tretinoin, 0.1% cream used over 10 months, will fade solar lentigines (liver spots), hyperpigmented facial macules in Asians, and postinflammatory hyperpigmentation in blacks. New laser systems for the removal of epidermal and dermal pigments are available, and referral should be considered for patients whose responses to medical treatment are inadequate.

B. Hypopigmentation

The pigment dilution is stable in various forms of albinism, spontaneous return of pigment is rare in vitiligo, and in secondary hypopigmentation, repigmentation may occur spontaneously. Cosmetics such as Covermark and Dermablend are highly effective for concealing disfiguring patches. Therapy of vitiligo is long and tedious, and the patient must be strongly motivated. If less than 20% of the skin is involved (most cases), topical methoxsalen, 0.1% in ethanol and propylene glycol or in Acid Mantle cream or Unibase, is used, with cautious exposure to long-wavelength ultraviolet light (UVA), followed by thorough washing and sun avoidance. With 20-25% involvement, oral PUVA is best. Severe phototoxic response (sunburn) may occur with topical or oral psoralens plus UVA. The face and upper chest respond best, and the fingertips and the genital areas do not respond to this treatment. Years of treatment are often required. Newer techniques of using epidermal autografts and cultured epidermis combined with PUVA therapy give hope for surgical correction of vitiligo. Potent topical corticosteroids have been advocated for treatment of vitiligo, with daily use for 10 days followed by 10 days of rest, then repetition.

BALDNESS (ALOPECIA)

Baldness Due to Scarring

Cicatricial baldness may occur following chemical or physical trauma, lichen planopilaris, severe bacterial or fungal infections, severe herpes zoster, chronic discoid lupus erythematosus, scleroderma, and excessive ionizing radiation. The specific cause is often suggested by the history, the distribution of hair loss, and the appearance of the skin, as in lupus erythematosus. Biopsy is useful in the diagnosis of scarring alopecia, but specimens must be taken from the active border and not from the scarred central zone.

Scarring alopecias are irreversible and permanent. It is important to diagnose and treat the scarring process as early in its course as possible.

Baldness Not Due to Scarring

Nonscarring alopecia may occur in association with various systemic diseases such as systemic lupus erythematosus, secondary syphilis, hyper- or hypothyroidism, iron deficiency anemia, and pituitary insufficiency. The only treatment necessary is prompt and adequate control of the underlying disorder, in which case hair loss may be reversible.

Androgenetic (pattern) baldness, the most common form of alopecia, is of genetic predetermination. The earliest changes occur at the anterior portions of the calvarium on either side of the "widow's peak" and on the crown (vertex) of the skull. The extent of hair loss is variable and unpredictable. Rogaine Extra Strength, a solution containing 50 mg/mL of minoxidil, is available over the counter. The best results are achieved in persons with recent onset (< 5 years) and smaller areas of alopecia. Approximately 40% of patients treated twice daily for a year will have moderate to dense growth. Finasteride (Propecia), 1 mg orally daily, has similar efficacy and may be additive to minoxidil. As opposed to minoxidil, finasteride is used only in males.

Hair loss or thinning of the hair in women results from the same cause as common baldness in men (androgenetic alopecia) and may be treated with minoxidil (Rogaine). A workup consisting of determination of serum testosterone, DHEAS, iron, total iron binding capacity, thyroid function tests and a complete blood count will identify most other causes of hair thinning in premenopausal women. Women who complain of thin hair but show little evidence of alopecia need follow-up, because more than 50% of the scalp hair can be lost before the clinician can perceive it.

Telogen effluvium is a transitory increase in the number of hairs in the telogen (resting) phase of the hair growth cycle. This may occur spontaneously, may appear at the termination of pregnancy, may be precipitated by "crash dieting," high fever, stress from surgery or shock, or malnutrition, or may be provoked by hormonal contraceptives. Whatever the cause, telogen effluvium usually has a latent period of 2-4 months. The prognosis is generally good. The condition is diagnosed by the presence of large numbers of hairs with white bulbs coming out upon gentle tugging of the hair. Counts of hairs lost by the patient on combing or shampooing often exceed 150 per day, compared to an average of 70-100. In one study, a major cause of telogen effluvium was found to be iron deficiency, and the hair counts bore a clear relationship to serum iron levels.

Alopecia areata is of unknown cause but is believed to be an immunologic process. Typically, there are patches that are perfectly smooth and without scarring. Tiny hairs 2-3 mm in length, called "exclamation hairs," may be seen. Telogen hairs are easily dislodged from the periphery of active lesions. The beard, brows, and lashes may be involved. Involvement may extend to all of the scalp hair (alopecia totalis) or to all scalp and body hair (alopecia universalis). Severe forms may be treated by systemic corticosteroid therapy, although recurrences follow discontinuation of therapy. Alopecia areata is occasionally associated with Hashimoto's thyroiditis, pernicious anemia, Addison's disease, and vitiligo.

Intralesional corticosteroids are frequently effective for alopecia areata. Triamcinolone acetonide in a concentration of 2.5-10 mg/mL is injected in aliquots of 0.1 mL at approximately 1- to 2-cm intervals, not exceeding a total dose of 30 mg per month for adults. Alternatively, anthralin 0.5% ointment used daily may help some patients. Alopecia areata is usually self-limiting, with complete regrowth of hair in 80% of patients, but some mild cases are resistant, as are the extensive totalis and universalis types. Both topical diphencyprone and squaric acid dibutylester have been used to treat persistent alopecia areata. The principle is to sensitize the skin, and then intermittently apply weaker concentrations to produce and maintain a slight dermatitis. Hair regrowth in 3-6 months in some patients has been reported to be remarkable. Long-term safety and efficacy have not been established. Support groups for patients with extensive alopecia areata are very beneficial. In **trichotillomania** (the pulling out of one's own hair), the patches of hair loss are irregular and growing hairs are always present, since they cannot be pulled out until they are long enough. The patches are often unilateral, occurring on the same side as the patient's dominant hand. The patient may be unaware of the habit.

Drug-induced alopecia is becoming increasingly important. Incriminated drugs include thallium, excessive and prolonged use of vitamin A, retinoids, antimitotic agents, anticoagulants, antithyroid drugs, oral contraceptives, trimethadione, allopurinol, propranolol, indomethacin, amphetamines, salicylates, gentamicin, and levodopa. While chemotherapy-induced alopecia is very distressing, it must be emphasized to the patient before treatment that it is invariably reversible.

NAIL DISORDERS

1. Morphologic Abnormalities of the Nails

Classification

Nail disorders may be classified as (1) local, (2) congenital or genetic, and (3) those associated with systemic or generalized skin diseases.

A. Local Nail Disorders

1. Onycholysis (distal separation of the nail plate from the nail bed, usually of the fingers) is caused by excessive exposure to water, soaps, detergents, alkalies, and industrial cleaning agents. Candidal infection of the nail folds and subungual area, nail hardeners, and drug-induced photosensitivity may cause onycholysis, as may hyper- and hypothyroidism and psoriasis.

2. Distortion of the nail occurs as a result of chronic inflammation of the nail matrix underlying the eponychial fold. Such changes may also be caused by warts, tumors, nevi, synovial and mucous cysts, etc, impinging on the nail matrix.

3. Discoloration and crumbly thickened nails are noted in dermatophyte infection and psoriasis.

4. Allergic reactions (to formaldehyde and resins in undercoats and polishes or to nail glues) are characterized by onycholysis or by grossly distorted, hypertrophic, and misshapen nails.

B. Congenital and Genetic Nail Disorders

1. A longitudinal single nail groove may occur as a result of a genetic or traumatic defect in the nail matrix.

2. Nail atrophy may be congenital.

3. Clubbed fingers may be congenital.

C. Nail Changes Associated with Systemic or Generalized Skin Diseases

1. Beau's lines (transverse furrows) may follow any serious systemic illness.

2. Atrophy of the nails may be related to trauma or to vascular or neurologic disease.

3. Clubbed fingers may be due to the prolonged hypoxemia associated with cardiopulmonary disorders. (See [Chapter 9](#).)

4. Spoon nails may be seen in anemic patients.

5. Stippling or pitting of the nails is seen in psoriasis, alopecia areata, and hand eczema.

6. Nail hyperpigmentation may be caused by zidovudine, doxorubicin, cyclophosphamide, bleomycin, daunorubicin, fluorouracil, hydroxyurea, melphalan, mechlorethamine, and nitrosoureas.

Differential Diagnosis

It is important to distinguish congenital and genetic disorders from those caused by trauma and environmental disorders. Onychomycosis may cause nail changes identical to those seen in psoriasis. Careful examination for more characteristic lesions elsewhere on the body is essential to the diagnosis of the nail disorders. Cancer should be suspected (eg, Bowen's disease or squamous cell carcinoma) as the cause of any persistent solitary subungual or periungual lesion.

Complications

Secondary bacterial infection occasionally occurs in onychodystrophies and leads to considerable pain and disability and more serious consequences if circulation or innervation is impaired. Toenail changes may lead to an ingrown nail—in turn often complicated by bacterial infection and occasionally by exuberant granulation tissue. Poor pedicuring and poorly fitting shoes may contribute to this complication. Cellulitis may result.

Treatment & Prognosis

Treatment consists usually of careful debridement and pedicuring and, above all, reduction of exposure to irritants (soaps, detergents, alkali, bleaches, solvents, etc). Congenital or genetic nail disorders are usually uncorrectable. Longitudinal grooving due to temporary lesions of the matrix, such as warts, synovial cysts, and other impingements, may be cured by removal of the offending lesion. Intradermal triamcinolone acetonide suspension, 2.5 mg/mL, may be injected in the area of the nail matrix at intervals of 2-4 weeks for the successful management of various types of inflammatory nail dystrophies (psoriasis, lichen planus) but is painful.

If it is necessary to remove dystrophic nails for any reason (eg, fungal nails or severe psoriasis), a nonsurgical method is to apply urea 40%, anhydrous lanolin 20%, white wax 5%, white petrolatum 25%, and silica gel type H. The nail folds are painted with compound tincture of benzoin and covered with cloth adhesive tape. The urea ointment is applied generously to the nail surface and covered with plastic film, and then adhesive tape. The ointment is left on for 5-10 days; then the nail plate may be curetted off. Medication can then be applied that is appropriate for the condition being treated.

2. Tinea Unguium (Onychomycosis)

Tinea unguium is a trichophyton infection of one or more (but rarely all) fingernails or toenails. The species most commonly found is *Trichophyton rubrum*. "Saprophytic" fungi may rarely (< 5%) cause onychomycosis.

The nails are lusterless, brittle, and hypertrophic, and the substance of the nail is friable. Laboratory diagnosis is mandatory since only 50% of dystrophic nails are due to dermatophytosis. Portions of the nail should be cleared with 10% potassium hydroxide and examined under the microscope for hyphae. Fungi may also be cultured. Periodic acid-Schiff stain of a histologic section of the nail plate will also demonstrate the fungus readily.

Onychomycosis is difficult to treat because of the long duration of therapy required and the frequency of recurrences. Fingernails respond more readily than toenails. For toenails, it is in some situations best to discourage therapy and to control discomfort by paring the thickened nail plate.

Topical treatment has relatively low efficacy (10% or less), but in well-motivated patients with minimally thickened nails it can be useful. Naftifine gel 1% or ciclopirox nail lacquer (Penlac) 8% applied twice daily may clear fingernails in 4-6 months and toenails in 12-18 months.

In general, systemic therapy is required for the treatment of nail onychomycosis. Fingernails can virtually always be cleared, whereas toenails respond in about 60% of cases. For fingernails, ultramicrosize griseofulvin, 750 mg or more daily for 6 months, is often effective. Treatment alternatives are itraconazole, 200 mg daily for 2 months; itraconazole, 400 mg the first 7 days of each month for 2 months; and terbinafine, 250 mg daily for 6 weeks. Once clear, fingernails often remain free of disease for years. The efficacy of griseofulvin for toenails is too low to be considered a therapeutic option in most cases. Ketoconazole, with its risk of hepatotoxicity with long-term use, is also not recommended. Terbinafine, 250 mg daily for 3 months, or itraconazole, 200 mg daily for 3 months or 400 mg for the first 7 days of each month for 3 months, may be effective for toenail onychomycosis, but these agents are not FDA-approved for that purpose. About 60% of patients will have substantial improvement, and 25-35% will be mycologically and clinically cured at 1 year. Itraconazole interacts with numerous other medications and requires gastric acid to be absorbed.

In comparative trials, terbinafine, 250 mg daily for 3 months, has efficacy equal to or superior to that of itraconazole. About 75% of patients have significant clinical improvement, and 35-50% are cured at 1 year. The combination of a topical antifungal nail lacquer for 1 year and oral terbinafine for 3 months was superior to the oral agent alone, doubling the cure rate. Terbinafine is associated with fewer drug interactions than itraconazole (but may result in prolonged prothrombin times in patients taking warfarin). Also unlike itraconazole, terbinafine is absorbed in patients with low gastric acid (those receiving H₂ blockers). The rate of long-term recurrences following these forms of treatment is unknown. No matter which therapy is used, constant topical treatment for any coexistent tinea pedis is mandatory and should probably be continued for life to attempt to prevent recurrence.

DERMATITIS MEDICAMENTOSA (DRUG ERUPTION)

Essentials of Diagnosis

- Usually, abrupt onset of widespread, symmetric erythematous eruption.
- May mimic any inflammatory skin condition.
- Constitutional symptoms (malaise, arthralgia, headache, and fever) may be present.

General Considerations

As is well recognized, only a minority of cutaneous drug reactions result from allergy. True allergic drug reactions involve prior exposure, an "incubation" period, reactions to doses far below the therapeutic range, manifestations different from the usual pharmacologic effects of the drug, involvement of only a small portion of the population at risk, restriction to a limited number of syndromes (anaphylactic and anaphylactoid, urticarial, vasculitic, etc), and reproducibility.

Rashes are among the most common adverse reactions to drugs and occur in 2-3% of hospitalized patients. Amoxicillin, trimethoprim-sulfamethoxazole, and ampicillin or penicillin are the commonest causes of urticarial and maculopapular reactions. Toxic epidermal necrolysis and Stevens-Johnson syndrome are most commonly produced by sulfonamides and anticonvulsants. Phenolphthalein, pyrazolone derivatives, tetracyclines, NSAIDs, trimethoprim-sulfamethoxazole, and barbiturates are the major causes of fixed drug eruptions.

Clinical Findings

A. Symptoms and Signs

The onset is usually abrupt, with bright erythema and often severe itching, but may be delayed. Fever and other constitutional symptoms may be present. The skin reaction usually occurs in symmetric distribution.

[Table 6-3](#) summarizes the types of skin reactions, their appearance and distribution, and the common offenders in each case.

B. Laboratory Findings

Routinely ordered blood work is of no value in the diagnosis of drug eruptions. However, skin biopsies may be helpful in making the diagnosis.

Differential Diagnosis

Observation after discontinuation, which may be a slow process, helps establish the diagnosis. Rechallenge, though of theoretical value, may pose a danger to the patient and is best avoided.

Complications

Some cutaneous drug reactions may be associated with a clinical complex involving other organs (complex drug reactions). The organ systems involved depend on the individual medication or drug class. Most common is an infectious mononucleosis-like illness and hepatitis associated with administration of anticonvulsants.

Treatment

A. General Measures

Systemic manifestations are treated as they arise (eg, anemia, icterus, purpura). Antihistamines may be of value in urticarial and angioneurotic reactions. Epinephrine 1:1000, 0.5-1 mL intravenously or subcutaneously, should be used as an emergency measure. In severe cases, corticosteroids may be used at doses similar to those used for acute contact dermatitis.

B. Local Measures

Extensive blistering eruptions resulting in erosions and superficial ulcerations demand hospitalization and nursing care as for burn patients.

Prognosis

Drug rash usually disappears upon withdrawal of the drug and proper treatment.

Table 6-1. Useful topical dermatologic therapeutic agents.

Agent	Formulations, Strengths, and Prices ¹	Apply	Potency Class	Common Indications	Comments
Corticosteroids					
Hydrocortisone acetate	Cream 1%: \$3.42/30 g Ointment 1%: \$3.54/30 g Lotion 1%: \$20.20/120 mL	bid	Low	Seborrheic dermatitis. Pruritus ani. Intertrigo.	Not the same as hydrocortisone butyrate or valerate! Not for poison oak! OTC lotion (Aquinil HC). OTC solution (Scalpicin, T Scalp).
	Cream 2.5%: \$8.84/30 g Ointment 2.5%: \$8.84/30 g Lotion 2.5%: \$52.03/60 mL	bid	Low	As for 1% hydrocortisone.	Perhaps better for pruritus ani. Not clearly better than 1%. More expensive. Not OTC.
Alclometasone dipropionate (Aclovate)	Cream 0.05%: \$19.71/15 g Ointment 0.05%: \$41.09/45 g	bid	Low	As for hydrocortisone.	More efficacious than hydrocortisone. Perhaps causes less atrophy.
Desonide	Cream 0.05%: \$18.17/15 g Ointment 0.05%: \$45.92/60 g Lotion 0.05%: \$36.69/60 mL	bid	Low	As for hydrocortisone. For lesions on face or body folds resistant to hydrocortisone.	More efficacious than hydrocortisone. Can cause rosacea or atrophy. Not fluorinated.
Prednicarbate (Dermatop)	Emollient cream 0.1%: \$16.81/15 g Ointment 0.1%: \$16.81/15g	bid	Medium	As for triamcinolone.	May cause less atrophy. No generic formulations. Preservative-free.
Triamcinolone acetonide	Cream 0.1%: \$2.70/15 g Ointment 0.1%: \$2.70/15 g Lotion 0.1%: \$13.64/60 mL	bid	Medium	Eczema on extensor areas. Used for psoriasis with tar. Seborrheic dermatitis and psoriasis on scalp.	Caution in body folds, face. Economical in 0.5 lb and 1 lb sizes for treatment of large body surfaces. Economical as solution for scalp.
	Cream 0.025%: \$1.82/15 g Ointment 0.025%: \$4.26/80 g	bid	Medium	As for 0.1% strength.	Possibly less efficacy and few advantages over 0.1% formulation.
Fluocinolone acetonide	Cream 0.025%: \$3.05/15 g Ointment 0.025%: \$4.20/15 g	bid	Medium	As for triamcinolone.	
	Solution 0.01%: \$11.00/60 mL	bid	Medium	As for triamcinolone solution.	
Mometasone furoate (Elocon)	Cream 0.1%: \$25.08/15 g Ointment 0.1%: \$25.08/15 g Lotion 0.1%: \$51.92/60 mL	qd	Medium	As for triamcinolone.	Often used inappropriately on the face or in children. Not fluorinated.
Diflorasone diacetate	Cream 0.05%: \$35.52/15 g Ointment 0.05%: \$50.91/30 g	bid	High	Nummular dermatitis. Allergic contact dermatitis. Lichen simplex chronicus.	
Amcinonide (Cyclocort)	Cream 0.1%: \$18.52/15 g Ointment 0.1%: \$20.58/15 g	bid	High	As for betamethasone.	
Fluocinonide (Lidex)	Cream 0.05%: \$9.00/15 g Gel 0.05%: \$21.01/15 g Ointment 0.05%: \$20.85/15 g Solution 0.05%: \$26.08/60 mL	bid	High	As for betamethasone. Gel useful for poison oak.	Economical generics. Lidex cream can cause stinging on eczema. Lidex emollient cream preferred.
Betamethasone dipropionate (Diprolene)	Cream 0.05%: \$7.80/15 g Ointment 0.05%: \$9.40/15 g Lotion 0.05%: \$18.01/60 mL	bid	Ultra-high	For lesions resistant to high-potency steroids. Lichen planus. Insect bites.	Economical generics available.
Clobetasol propionate (Temovate)	Cream 0.05%: \$23.99/15 g Ointment 0.05%: \$23.99/15 g Lotion 0.05%: \$53.10/50 mL	bid	Ultra-high	As for betamethasone dipropionate.	Somewhat more potent than diflorasone. Limited to 2 continuous weeks of use. Limited to 50 g or less per week. Cream may cause stinging; use "emollient cream" formulation. Generic available.
Halobetasol propionate (Ultravate)	Cream 0.05%: \$32.16/15 g Ointment 0.05%: \$32.16/15 g	bid	Ultra-high	As for clobetasol.	Same restrictions as clobetasol. Cream does not cause stinging. Compatible with calcipotriene (Dovonex).
Flurandrenolide (Cordran)	Tape: \$18.84/80" × 30" roll	q12h	Ultra-high	Lichen simplex chronicus.	Protects the skin and prevents scratching.
Nonsteroidal anti-inflammatory agents		bid	N/A	Atopic dermatitis.	Steroid substitute not causing atrophy or striae. Burns in 40% (+) of patients with eczema.
Tacrolimus (Protopic)	Ointment 0.1%: \$64.09/30 g Ointment 0.03%: \$59.95/30 g				
Pimecrolimus	Cream 1%: \$47.52/30 g	bid	N/A	Steroid substitute not causing atrophy or striae. Does not burn.	
Antibiotics (for acne)					
Clindamycin phosphate	Solution 1%: \$11.52/30 mL Gel 1%: \$32.12/30 mL Lotion 1%: \$44.68/60 mL Pledge 1%: \$46.40/60	bid	N/A	Mild papular acne.	Lotion is less drying for patients with sensitive skin.
Erythromycin	Solution 2%: \$7.53/60 mL Gel 2%: \$24.73/30 g Pledge 2%: \$25.34/60	bid	N/A	As for clindamycin.	Many different manufacturers. Economical.
Erythromycin/ Benzoyl peroxide (Benzamycin)	Gel \$58.94/23.3 g Gel \$124.05/46.6 g	bid	N/A	As for clindamycin. Can help treat comedonal acne.	No generics. More expensive. More effective than other topical antibiotics. Main jar requires refrigeration.
Clindamycin/ Benzoyl peroxide (Benzeclin)	Gel: \$57.75/25 g Gel: \$109.73/50 g	bid		As for benzamycin.	No generic. More effective than either agent alone.
Antibiotics (for impetigo)		tid	N/A	Impetigo, folliculitis.	Because of cost use limited to tiny areas of impetigo. Used in the nose twice daily for 5 days to reduce staphylococcal carriage.
Mupirocin (Bactroban)	Ointment 2%: \$43.85/22 g Cream 2%: \$30.22/15 g				
Antifungals					
Clotrimazole	Cream 1%: \$4.50/15 g OTC Solution 1%: \$15.52/30 mL	bid	N/A	Dermatophyte and candida infections.	Available OTC. Inexpensive generic cream available.
Miconazole	Cream 2%: \$3.20/30 g OTC	bid	N/A	As for clotrimazole.	As for clotrimazole.
Other imidazoles Econazole (Spectazole)	Cream 1%: \$18.78/15 g	qd	N/A	As for clotrimazole.	No generic. Somewhat more effective than clotrimazole and miconazole.
Ketoconazole	Cream 2%: \$16.46/15 g	qd	N/A	As for clotrimazole.	No generic. Somewhat more effective than clotrimazole and miconazole.
Oxiconazole (Oxistat)	Cream 1%: \$22.82/15 g Lotion 1%: \$38.41/30 mL	bid	N/A		
Sulconazole (Exelderm)	Cream 1%: \$12.56/15 g Solution 1%: \$27.05/30 mL	bid	N/A	As for clotrimazole.	No generic. Somewhat more effective than clotrimazole and miconazole.
Other antifungals		qd	N/A	Dermatophytes.	Fast response; high cure rate; expensive.
Butenafine (Mentax) (Lotrimin Ultra, OTC)	Cream 1%: \$35.18/15 g Cream 1%: 8.28/12 g				

Ciclopirox (Loprox) (Penlac)	Cream 0.77%: \$40.71/30 g Lotion 0.77%: \$82.80/60 mL Solution 8%: \$126.26/6.6 mL	bid	N/A	As for clotrimazole.	No generic. Somewhat more effective than clotrimazole and miconazole.
Naftifine (Naftin)	Cream 1%: \$41.62/30 g Gel 1%: \$66.93/60 mL	qd	N/A	Dermatophytes.	No generic. Somewhat more effective than clotrimazole and miconazole.
Terbinafine (Lamisil)	Cream 1%: \$6.79/12 g OTC	qd	N/A	For dermatophytes.	Fast clinical response. OTC. Less expensive than butenafine or naftifine.
Antipruritics Camphor/ menthol	Compounded lotion (0.5% of each)	bid-tid	N/A	For mild eczema, xerosis, mild contact dermatitis.	
Pramoxine hydrochloride (PRAX)	Lotion 1%: \$12.40/120 mL	qid	N/A	Dry skin, varicella, mild eczema, pruritus ani.	OTC formulations (Prax, Aveeno Anti-Itch Cream or Lotion; Itch-X Gel). By prescription mixed with 1% or 2% hydrocortisone.
Doxepin (Zonalon)	Cream 5%: \$35.98/30 g	qid	N/A	Topical antipruritic, best used in combination with appropriate topical steroid to enhance efficacy.	Can cause sedation.
Emollients Aveeno	Cream, lotion, others	qd-tid	N/A	Xerosis, eczema.	Choice is most often based on personal preference by patient.
Aqua glycolic	Cream, lotion, shampoo, others	qd-tid	N/A	Xerosis. Ichthyosis, keratosis pilaris. Mild facial wrinkles. Mild acne or seborrheic dermatitis.	Contains 8% glycolic acid. Available from other makers, eg, Alpha Hydrox, or generic 8% glycolic acid lotion. May cause stinging on eczematous skin.
Aquaphor	Ointment: \$3.68/52.5 g	qd-tid	N/A	Xerosis. Eczema. For protection of area in pruritus ani.	Not as greasy as petrolatum.
Carmol	Lotion 10%: \$8.25/180 mL Cream 20%: \$7.59/90 g	bid	N/A	Contains urea as humectant.	Nongreasy hydrating agent (10%); debrides keratin (20%).
Complex 15	Lotion: \$6.48/240 mL Cream: \$4.82/75 g	qd-tid	N/A	Xerosis. Lotion or cream recommended for split or dry nails.	Active ingredient is a phospholipid.
DML	Cream, lotion, facial moisturizer	qd-tid	N/A	As for Complex 15.	Face cream has sunscreen.
Dermasil	Lotion, cream	qd-tid	N/A	Xerosis, eczema.	
Eucerin	Cream: \$5.10/120 g Lotion: \$5.10/240 mL	qd-tid	N/A	Xerosis, eczema.	Many formulations made. Eucerin Plus contains alphahydroxy acid and may cause stinging on eczematous skin. Facial moisturizer has SPF 25 sunscreen.
Lac-Hydrin-Five	Lotion: \$10.12/240 mL	bid	N/A	Xerosis, ichthyosis, keratosis pilaris.	Expensive, not OTC.
Lubriderm	Lotion: \$5.03/300 mL	qd-tid	N/A	Xerosis, eczema.	Unscented usually preferred.
Neutrogena	Cream, lotion, facial moisturizer: \$7.39/240 mL	qd-tid	N/A	Xerosis, eczema.	Face cream has titanium-based sunscreen.
SBR Lipocream	Cream: \$6.78/30 g	qd-tid	N/A	Xerosis, eczema.	Less greasy but effective moisturizer.
Triceram Cream	Cream: \$30.00-\$31.50/3.4 oz tube	bid	N/A	Xerosis, eczema.	Contains ceramide; anti-inflammatory and non-greasy moisturizer.
U-Lactin	Lotion: \$7.13/240 mL	qd	N/A	Hyperkeratotic heels.	Moisturizes and removes keratin.

TABLES

Table 6-1. Useful topical dermatologic therapeutic agents.

Table 6-2. Morphologic categorization of skin lesions and diseases.

Pigmented	Freckle, lentigo, seborrheic keratosis, nevus, blue nevus, halo nevus, dysplastic nevus, melanoma
Scaly	Psoriasis, dermatitis (atopic, stasis, seborrheic, chronic allergic contact or irritant contact), xerosis (dry skin), lichen simplex chronicus, tinea, tinea versicolor, secondary syphilis, pityriasis rosea, discoid lupus erythematosus, exfoliative dermatitis, actinic keratoses, Bowen's disease, Paget's disease, intertrigo
Vesicular	Herpes simplex, varicella, herpes zoster, dyshidrosis (vesicular dermatitis of palms and soles), vesicular tinea, dermatophytid, dermatitis herpetiformis, miliaria, scabies, photosensitivity
Weepy or encrusted	Impetigo, acute contact allergic dermatitis, any vesicular dermatitis
Pustular	Acne vulgaris, acne rosacea, folliculitis, candidiasis, miliaria, any vesicular dermatitis
Figurate ("shaped") erythema	Urticaria, erythema multiforme, erythema migrans, cellulitis, erysipelas, erysipeloid, arthropod bites
Bullous	Impetigo, blistering dactylitis, pemphigus, pemphigoid, porphyria cutanea tarda, drug eruptions, erythema multiforme, toxic epidermal necrolysis
Papular	Hyperkeratotic: warts, corns, seborrheic keratoses Purple-violet: lichen planus, drug eruptions, Kaposi's sarcoma Flesh-colored, umbilicated: molluscum contagiosum Pearly: basal cell carcinoma, intradermal nevi Small, red, inflammatory: acne, miliaria, candidiasis, scabies, folliculitis
Pruritus ¹	Xerosis, scabies, pediculosis, bites, systemic causes, anogenital pruritus
Nodular, cystic	Erythema nodosum, furuncle, cystic acne, follicular (epidermal) inclusion cyst
Photodermatitis (photodistributed rashes)	Drug, polymorphic light eruption, lupus erythematosus
Morbilliform	Drug, viral infection, secondary syphilis
Erosive	Any vesicular dermatitis, impetigo, aphthae, lichen planus, erythema multiforme
Ulcerated	Decubiti, herpes simplex, skin cancers, parasitic infections, syphilis (chancre), chancroid, vasculitis, stasis, arterial disease

¹Not a morphologic class but included because it is one of the most common dermatologic presentations.

-

Table 6-3. Skin reactions due to systemic drugs.

Reaction	Appearance	Distribution and Comments	Common Offenders
Toxic erythema	Morbilliform, maculopapular, exanthematous reactions.	The commonest skin reaction to drugs. Often more pronounced on the trunk than on the extremities. In previously exposed patients, the rash may start in 2-3 days. In the first course of treatment, the eruption often appears about the seventh to ninth days. Fever may be present.	Antibiotics (especially ampicillin and trimethoprim-sulfamethoxazole), sulfonamides and related compounds (including thiazide diuretics, furosemide, and sulfonylurea hypoglycemic agents), and barbiturates.
Erythema multiforme major	Target-like lesions. Bullae may occur. Mucosal involvement.	Mainly on the extensor aspects of the limbs.	Sulfonamides, penicillamine, barbiturates, and NSAIDs.
Erythema nodosum	Inflammatory cutaneous nodules.	Usually limited to the extensor aspects of the legs. May be accompanied by fever, arthralgias, and pain.	Oral contraceptives.
Allergic vasculitis	Inflammatory changes may present as urticaria that lasts over 24 hours, hemorrhagic papules ("palpable purpura"), vesicles, bullae, or necrotic ulcers.	Most severe on the legs.	Sulfonamides, indomethacin, phenytoin, allopurinol, and ibuprofen.
Purpura	Itchy, petechial macular rash.	Dependent areas. Results most typically from thrombocytopenia.	Thiazides, sulfonamides, sulfonylureas, barbiturates, quinine, and sulindac.
Eczema	Similar to contact dermatitis.	A rare epidermal reaction in patients previously sensitized by external exposure who are given the same or a related substance systemically.	Penicillin, neomycin, phenothiazines, and local anesthetics.
Exfoliative dermatitis and erythroderma	Red and scaly.	Entire skin surface.	Allopurinol, sulfonamides, isoniazid, gold, or carbamazepine.
Photosensitivity: Increased sensitivity to light, often of ultraviolet A wavelengths, but may be due to UVB or visible light as well	Sunburn, vesicles, papules in photodistributed pattern.	Exposed skin of the face, the neck, and the backs of the hands and, in women, the lower legs. Exaggerated response to ultraviolet light. On occasion, ultraviolet emission from fluorescent lighting may be sufficient.	Sulfonamides and sulfonamide-related compounds (thiazide diuretics, furosemide, sulfonylureas), tetracyclines (especially demeclocycline), phenothiazines, sulindac, amiodarone, and NSAIDs.
Drug-related lupus erythematosus	May present with a photosensitive rash accompanied by fever, polyarthritis, myalgia, and serositis.	Less severe than systemic lupus erythematosus, sparing the kidneys and central nervous system. Recovery often follows drug withdrawal.	Most commonly hydralazine and procainamide; less often, isoniazid and phenytoin.
Lichenoid and lichen planus-like eruptions	Pruritic, erythematous to violaceous polygonal papules that coalesce or expand to form plaques.	May be in photo- or nonphoto-distributed pattern.	Bismuth, carbamazepine, chlordiazepoxide, chloroquine, chlorpropamide, dapsone, ethambutol, furosemide, gold salts, hydroxychloroquine, levamisole, meprobamate, methyl dopa, paraphenylenediamine salts, penicillamine, phenothiazines, pindolol, propranolol, quinidine, quinine, quinacrine, streptomycin, sulfonylureas, tetracyclines, thiazides, and triprolidine.
Fixed drug eruptions	Single or multiple demarcated, round, erythematous plaques that often become hyperpigmented.	Recur at the same site when the drug is repeated. Hyperpigmentation, if present, remains after healing.	Numerous drugs, including antimicrobials, analgesics, barbiturates, cardiovascular drugs, heavy metals, antiparasitic agents, antihistamines, phenolphthalein, ibuprofen, and naproxen.
Toxic epidermal necrolysis	Large sheets of erythema, followed by separation, which looks like scalded skin.	Rare.	In adults, the eruption has occurred after administration of many classes of drugs, particularly barbiturates, phenytoin, sulfonamides, and NSAIDs.
Urticaria	Red, itchy wheals that vary in size from < 1 cm to many centimeters. May be accompanied by angioedema.	Chronic urticaria is rarely caused by drugs.	Acute urticaria: penicillins, NSAIDs, sulfonamides, opiates, and salicylates. Angioedema is common in patients receiving ACE inhibitors.
Pruritus	Itchy skin without rash.		Pruritus ani may be due to overgrowth of candida after systemic antibiotic treatment. NSAIDs may cause pruritus without a rash.
Hair loss		Hair loss most often involves the scalp, but other sites may be affected.	A predictable side effect of cytotoxic agents and oral contraceptives. Diffuse hair loss also occurs unpredictably with a wide variety of other drugs, including anticoagulants, antithyroid drugs, newer antimicrobials, cholesterol-lowering agents, heavy metals, corticosteroids, androgens, NSAIDs, retinoids (isotretinoin, etretinate), and beta-blockers.
Pigmentary changes	Flat hyperpigmented areas.	Forehead and cheeks (chloasma, melasma). The most common pigmentary disorder associated with drug ingestion. Improvement is slow despite stopping the drug.	Oral contraceptives are the usual cause.
	Blue-gray discoloration.	Light-exposed areas.	Chlorpromazine and related phenothiazines.
	Brown or blue-gray pigmentation.	Generalized.	Heavy metals (silver, gold, bismuth, and arsenic). Arsenic, silver, and bismuth are not used therapeutically, but patients who receive gold for rheumatoid arthritis may show this reaction.
	Yellow color.	Generalized.	Usually quinacrine.
	Blue-black patches on the shins. Blue-black pigmentation of the nails and palate and depigmentation of the hair.		Minocycline, chloroquine.
	Slate-gray color.	Primarily in photoexposed areas.	Chloroquine.
			Amiodarone.

	Brown discoloration of the nails.	Especially in more darkly pigmented patients.	Zidovudine (azidothymidine; AZT), hydroxyurea.
Psoriasiform eruptions	Scaly red plaques.	May be located on trunk and extremities. Palms and soles may be hyperkeratotic. May cause psoriasiform eruption or worsen psoriasis.	Chloroquine, lithium, beta-blockers, and quinacrine.
Pityriasis rosea-like eruptions	Oval, red, slightly raised patches with central scale.	Mainly on the trunk.	Barbiturates, bismuth, captopril, clonidine, gold salts, methopromazine, metoprolol, metronidazole, and tripeleminamine.
Seborrheic dermatitis-like eruptions	Diffuse redness and loose scale.	On scalp, face, mid chest, axillae, groin.	Cimetidine, gold salts, and methyldopa.
Bullous eruptions	Tense blisters > 1 cm.	Hands, feet, genital areas common; other sites possible.	Aspirin, barbiturates, bromides, chlorpromazine, warfarin, phenytoin, sulfonamides and related compounds, and promethazine.

SYMPTOMS OF OCULAR DISEASE

Redness

Redness is the most frequently encountered symptom of ocular disorders. It is due to hyperemia of the conjunctival, episcleral, or ciliary vessels; erythema of the eyelids; or subconjunctival hemorrhage. The major differential diagnoses are conjunctivitis, corneal disorders, acute glaucoma, and acute uveitis ([Table 7-1](#)).

Vafidis G: When is red eye not just conjunctivitis? Practitioner 2002;246:469, 474, 478. [\[PMID: 12132264\]](#)

Ocular Discomfort

Ocular pain may be caused by trauma (chemical, mechanical, or physical), infection, inflammation, or sudden increase in intraocular pressure.

Foreign body sensation is most commonly due to corneal or conjunctival foreign bodies. Other causes are disturbances of the corneal epithelium and rubbing of eyelashes against the cornea (trichiasis).

Photophobia is commonly due to corneal inflammation, aphakia, iritis, or albinism. A less common cause is fever associated with various systemic infections.

Itching is characteristically associated with allergic eye disease.

Scratching and burning due to dryness of the eyes are common complaints of older people but may occur at any age. Deficiency of tear film components may be due to dry environment, local ocular disease, systemic disorders (eg, Sjogren's disease), or drugs (eg, atropine-like agents).

Watering is usually due to inadequate tear drainage through obstruction of the lacrimal drainage system or malposition of the lower lid. Reflex tearing occurs with any disturbance of the corneal epithelium.

"Eyestrain" & Headache

Eyestrain is discomfort associated with prolonged reading or close work. Refractive error, presbyopia, inadequate illumination, and latent ocular deviation are causes, as are corneal inflammation, iritis, and acute glaucoma. Headache is rarely due to ocular disorders but is a major symptom of giant cell arteritis, a cause of visual loss.

Conjunctival Discharge

Purulent discharge usually indicates bacterial infection of the conjunctiva, cornea, or lacrimal sac. Viral conjunctivitis or keratitis produces watery discharge; allergic conjunctivitis results in tearing, ropy discharge, and itching.

Visual Loss

The most important causes of blurred vision are refractive error, cataract, macular degeneration, diabetic retinopathy, vitreous hemorrhage, retinal detachment involving the macula, central retinal vein occlusion, central retinal artery occlusion, corneal opacities, and optic nerve disorders.

Monocular field loss indicates disease of the retina or optic nerve. Important causes are retinal detachment, chronic glaucoma, branch retinal artery or vein occlusion, optic neuritis, and anterior ischemic optic neuropathy, which also produce bilateral visual loss. Lesions of the optic chiasm due to pituitary tumors result in bitemporal field loss. Retrochiasmal lesions cause contralateral homonymous field defects. The more posterior the lesion in the visual pathway, the more congruous are the defects in the two eyes. Cerebrovascular disease and tumors are responsible for most lesions of the retrochiasmal visual pathways.

Visual Impairment & Blindness

An individual is visually impaired if the best corrected distant visual acuity in the better eye is 20/80 or less or if visual fields are significantly restricted. Legal blindness is defined as visual acuity for distant vision of 20/200 or less in the better eye with best correction or widest diameter of the visual field subtending an angle of less than 20 degrees. There are 500,000 legally blind people in the United States; half are over 65. The leading causes of blindness are glaucoma, diabetic retinopathy, and macular degeneration. Most states require best corrected visual acuity with both eyes of 20/40 for an unrestricted driving license.

WHO estimates that 30 million of the world's population have vision of 10/200 or less. The most frequent causes of blindness worldwide are cataract, trachoma, leprosy, onchocerciasis, and xerophthalmia. In the developed world, cataract, age-related macular degeneration, diabetic retinopathy, and glaucoma are the leading causes.

Buch H et al: Prevalence and causes of visual impairment according to World Health Organization and United States criteria in an aged, urban Scandinavian population: the Copenhagen City Eye Study. Ophthalmology 2001;108:2347. [\[PMID: 11733284\]](#)

Diplopia

Double vision typically results from extraocular muscle imbalance. This may be caused by head injury, vascular disturbance, intracranial tumors, or intraorbital lesions; myasthenia gravis; Wernicke's syndrome; Graves' ophthalmopathy; or muscle entrapment as a result of orbital blowout fracture. Monocular diplopia, which persists when the fellow eye is covered, is usually due to refractive error or lens opacities.

"Spots Before the Eyes" & "Flashing Lights"

Spots before the eyes (floaters) are often caused by benign vitreous opacities. However, they may also be caused by posterior vitreous detachment, vitreous hemorrhage, or posterior uveitis. Sudden onset of floaters, particularly when associated with flashing lights (photopsia), necessitates dilated fundal examination to exclude a retinal tear or detachment.

Murphy C et al: Casebook: flashes and floaters. Practitioner 2002;246:483. [\[PMID: 12132265\]](#)

OCULAR EXAMINATION

Abbreviations and symbols commonly used in ophthalmology are listed in the accompanying box.

ABBREVIATIONS & SYMBOLS USED IN OPHTHALMOLOGY	
A or Acc	Accommodation
Acc or x	Axis of cylindrical lens
BI or BO	Base-in or base-out (prism)
CF	Counting fingers
Cyl	Cylindrical lens or cylinder
D	Diopter (lens strength)
E	Emphoria
EOG	Electrooculography
EMG	Extraocular muscles or movements
ERG	Electroretinography
H	Hypertropia
HMT	Hand movements
HT	Hypertropia
IOP	Intraocular pressure
J1, J2, J3, etc	Test types (Jaeger) for testing reading vision
KP	Keratic precipitates
LP	Light perception
Lproj	Light projection
NLP	No light perception
RPC	Rear point of convergence
OD (R, or RE)	Oculus dexter (right eye)
OS (L, or LE)	Oculus sinister (left eye)
OU	Oculus uterque (both eyes)
PD	Interpupillary distance
PH	Pinhole
PRSG	Pupils round, regular, and equal
S or sph	Spherical lens
ET	Esotropia (with L or R)
VA	Visual acuity
VDR	Visual evoked response
X	Exophoria
XT	Exotropia
+	Plus or convex lens
-	Minus or concave lens
cu	Combined with
∞	Infinity (5 meters [20 feet] or more distance)
°	Degree (measurement of strabismus angle)
Δ	Prism diopter

Visual Acuity (VA)

Corrected distant visual acuity should be tested for each eye in turn, using a Snellen chart, annotated according to the distance at which each line can be read by a normal individual. Visual acuity is expressed as a fraction—the test distance over the figure assigned to the lowest line the patient can read. If the patient is unable to read the top line of the chart, acuity is recorded as counting fingers (CF), hand movements (HM), perception of light (LP), or no light perception (NLP). Distant acuity is usually measured at 20 feet. A corrected acuity of less than 20/30 is abnormal.

If assessment of distant visual acuity is not possible, near acuity can be tested with a reduced Snellen chart or standardized reading test types. The patient must be wearing an appropriate reading correction.

Visual Fields

Confrontation testing, preferably using a 5-mm red target, is valuable for rapid assessment of field defects. Amsler charts are the easiest method of detecting central field abnormalities due to macular disease.

Pupils

The pupils are examined for absolute and relative size and reactions to both light and accommodation. A large, poorly reacting pupil may be due to third nerve palsy, iris damage caused by acute glaucoma, or pharmacologic mydriasis. A small, poorly reacting pupil is observed in Horner's syndrome, inflammatory adhesions between iris and lens (posterior synechiae), or neurosyphilis (Argyll Robertson pupils). Physiologic anisocoria is a common cause of unequal pupils that react normally.

A relative afferent pupillary defect, in which the pupillary light reaction is reduced when light is shined into the affected eye compared with the normal eye, indicates optic nerve disease. It is detected with the "swinging light test," in which the pupillary light reactions are compared as a bright light is moved from one eye to the other.

Extraocular Movements

Examination of extraocular movements begins with an assessment of whether the two eyes are correctly aligned. A misalignment of the visual axes under binocular viewing conditions is known as a manifest deviation, or **tropia**. A deviation when binocular function is disrupted is known as a latent deviation, or **phoria**. A manifest deviation may be apparent by comparing the relative positions of the corneal light reflexes. A more reliable test is the **cover test**, in which the deviated eye moves to take up fixation when the other eye is occluded. The correctional movement is in the opposite direction to that of the original manifest deviation. If no manifest deviation is present, occlusion of one eye will elicit any latent deviation because binocular function will have been disrupted. As the occluder is removed (**uncover test**), latent deviation is then detected by any correctional movement that occurs to reestablish the normal alignment of the eyes. Latent deviation is common among normal individuals.

Horizontal diplopia indicates dysfunction of the medial and lateral rectus muscles; vertical diplopia results from dysfunction of the superior and inferior recti and the obliques. The false outer image arises from the affected eye. If muscle contraction is impaired, the image separation will be greatest in its normal direction of action; if a muscle cannot relax, image separation will be greatest in the direction opposite to its normal action. For example, a paretic lateral rectus or a tethered medial rectus of the right eye will cause maximal image separation on looking to the right.

Nystagmus in the primary position is always abnormal. Minor degrees of nystagmus at the extremes of gaze are normal. Other forms of physiologic nystagmus include optokinetic nystagmus and that induced by rotation or caloric stimulation. Exaggerated gaze-evoked nystagmus may be due to drugs or posterior fossa disease.

Proptosis (Exophthalmos)

Proptosis is suspected when there is widening of the palpebral aperture, with exposure of sclera both superiorly and inferiorly. (Eyelid retraction causes more exposure superiorly than inferiorly.) By viewing from above while the patient is asked to look down and the upper lids are lifted by the examiner, a further estimate of the degree of proptosis can be made. Exophthalmometry provides objective assessment. In nonaxial proptosis, there is also horizontal or vertical displacement of the globe, indicating the presence of a mass lesion outside the extraocular muscle cone.

The most frequent cause of proptosis in adults is dysthyroid eye disease. Other causes include cellulitis, tumors, and orbital pseudotumor.

Ptosisis

Neurologic causes of ptosis include Horner's syndrome, in which the pupil is constricted, and third nerve palsy, in which there are abnormalities of eye movements and the pupil may be dilated. Myasthenia gravis is always considered; pupils are normal.

Anterior Segment Examination

Although slit-lamp examination is more sensitive, examination with a flashlight and loupe usually provides sufficient information for initial anterior chamber assessment. Patterns of redness indicate the site of the problem. In conjunctivitis, it extends diffusely across the globe and the inner surface of the lids. Keratitis, intraocular inflammation, and acute glaucoma lead to predominantly circumcorneal injection. Episcleritis and scleritis cause localized or diffuse deep injection, which in the case of scleritis is associated with blue discoloration.

Focal lesions of the cornea due to infection or trauma can be differentiated from the diffuse corneal haze of acute glaucoma and from the cloudiness of the anterior chamber and perhaps hypopyon (white cells within the anterior chamber) of iritis. Instillation of fluorescein and examination with a blue light aids in detection of corneal epithelial defects.

Direct Ophthalmoscopy

Ideally, direct ophthalmoscopy with dilation provided by tropicamide 0.5-1% is used for examining the retina. It only rarely induces angle-closure glaucoma (see below). Assessment of the red reflex and clarity of fundal details indicates the degree of media opacity. Abnormalities may then be localized to the cornea, lens, or vitreous by variations of focus of the ophthalmoscope and use of parallax.

The optic disk is examined for swelling, pallor, and glaucomatous cupping. Macular lesions causing poor central vision are usually apparent. The retinal vessels are scrutinized for caliber and wall changes. Retinal hemorrhages, exudates, and cotton-wool spots are noted. In hospital patients, dilation should be noted in the record to avoid confusion on neurologic examination.

OPHTHALMOLOGIC REFERRALS

Sudden loss of vision requires emergency ophthalmologic consultation. Important causes in an uninflamed eye are vitreous hemorrhage, retinal detachment, exudative age-related macular degeneration, retinal artery or vein occlusions, anterior ischemic optic neuropathy, giant cell arteritis, and optic neuritis. In an inflamed eye, acute anterior uveitis, acute glaucoma, and corneal ulcer are possibilities. Other emergencies include orbital cellulitis, gonococcal keratoconjunctivitis, and ocular trauma.

Patients developing gradual loss of vision should also be referred. The principal causes are cataract, atrophic age-related macular degeneration, chronic glaucoma, chronic uveitis, and intraorbital and intracranial tumors.

Patients with diabetes must undergo annual examination through dilated pupils. Any myopic patient should be warned of the increased risk of retinal detachment and made aware of the importance of reporting relevant symptoms. First-degree adult relatives of patients with glaucoma are screened annually.

REFRACTIVE ERRORS

Refractive errors are the most common cause of blurred vision. In **emmetropia** (the normal state), objects at infinity are seen clearly with the unaccommodated eye. Objects nearer than infinity are seen with the aid of accommodation, which increases the refractive power of the lens. In **hyperopia**, objects at infinity are not seen clearly unless accommodation is used, and near objects may not be seen because accommodative capacity is finite. Hyperopia is corrected with plus (convex) lenses. In **myopia**, the unaccommodated eye brings to a focus images of objects closer than infinity, the distance of such objects from the patient becoming progressively shorter with increasing myopia. Thus, the high myope is able to focus on very near objects without glasses. Objects beyond this distance cannot be seen without the aid of corrective (minus, concave) lenses. In **astigmatism**, the refractive errors in the horizontal and vertical axes differ.

Various surgical techniques are available for the correction of refractive errors, particularly myopia, including photorefractive keratectomy (PRK), in which the excimer laser is used to reshape the anterior cornea; laser in situ keratomileusis (LASIK), in which a portion of the corneal stroma undergoes laser remodeling and is then replaced under an anterior corneal flap; and extraction of the clear crystalline lens.

Presbyopia is the natural loss of accommodative capacity with age. Emmetropes usually notice inability to focus on objects at a normal reading distance at about age 45. Hyperopes experience symptoms at an earlier age. Presbyopia is corrected with plus lenses for near work. Insertion of a multifocal intraocular lens is a potential alternative.

Use of a pinhole will overcome most refractive errors and thus allows their exclusion as a cause of visual loss. Transient refractive errors occur in diabetes—typically when diabetic control is erratic—and may be the presenting feature. Autoinoculation of scopolamine from seasickness patches or atropine from vials for parenteral use leads to inadvertent pupillary dilation and loss of accommodation.

Mannis MJ et al: Making sense of refractive surgery in 2001: why, when, for whom, and by whom? Mayo Clinic Proc 2001;76: 823. [\[PMID: 11499822\]](#)

McLeod SD: The challenge of presbyopia. Arch Ophthalmol 2002;120:1572. [\[PMID: 12427074\]](#)

Contact Lenses

Contact lenses are used mostly for correction of refractive errors but also in the management of diseases of the cornea, conjunctiva, or lids. The various types are hard lenses, rigid gas-permeable lenses, and soft lenses. Hard lenses are much more durable and easier to care for than soft lenses but are more difficult to tolerate. Rigid gas-permeable lenses are an effective compromise.

Contact lens care includes cleaning and sterilization whenever the lenses are removed and removal of protein deposits as required. Sterilization is accomplished by thermal or chemical methods. For individuals developing reactions to preservatives in contact lens solutions, preservative-free systems are available. All contact lenses can be inserted in the morning and removed at night. Soft lenses are also available for extended wear. Disposable soft lenses to avoid the necessity for lens cleaning and sterilization are available for daily wear or extended wear.

The major risk from contact lens wear is corneal ulceration, potentially a blinding condition. Soft lenses present the major hazard, particularly with extended wear, for which there is an approximately eightfold increase in risk of corneal ulceration compared with daily wear. The increased risk from extended wear begins with the first night of overnight wear and increases progressively thereafter. Disposable lenses are also associated with corneal ulceration.

Contact lens wearers should be made aware of the risks they face and ways to minimize them, such as avoiding extended-wear soft lenses and maintaining meticulous lens hygiene. Whenever there is ocular discomfort or redness, contact lenses should be removed. Ophthalmologic care is sought if symptoms persist.

Sucheki JK et al: A comparison of contact lens-related complications in various daily wear modalities. CLAO J 2000; 26:204. [\[PMID: 11071345\]](#)

DISORDERS OF THE LIDS & LACRIMAL APPARATUS

Hordeolum

Hordeolum is a common staphylococcal abscess that is characterized by a localized red, swollen, acutely tender area on the upper or lower lid. Internal hordeolum is a meibomian gland abscess that points onto the conjunctival surface of the lid; external hordeolum or sty is smaller and on the margin. The chief symptom is pain of an intensity directly related to the amount of swelling.

Warm compresses are helpful. Incision may be indicated if resolution does not begin within 48 hours. An antibiotic ointment (bacitracin or erythromycin) applied to the eyelid every 3 hours may be beneficial during the acute stage. Internal hordeolum may lead to generalized cellulitis of the lid.

Chalazion

Chalazion is a common granulomatous inflammation of a meibomian gland that may follow an internal hordeolum. It is characterized by a hard, nontender swelling on the upper or lower lid. The conjunctiva in the region of the chalazion is red and elevated. If the chalazion is large enough to impress the cornea, vision will be distorted.

Tumors

Verrucae and papillomas of the skin of the lids can often be excised by the general physician if they do not involve the lid margin; otherwise, surgery should be performed by an ophthalmologist so as to avoid permanent notching of the lid. Basal cell epithelioma, squamous cell carcinoma, meibomian gland carcinoma, and malignant melanoma should be excluded by microscopic examination of the excised material since 2% of lesions thought to be benign clinically are found to be malignant. Basal cell epithelioma is the most common of these lesions. Mohs' technique of intraoperative examination of excised tissue is particularly valuable in ensuring complete excision of eyelid tumors.

Blepharitis

Blepharitis is a common chronic bilateral inflammatory condition of the lid margins. Anterior blepharitis involves the eyelid skin, eyelashes, and associated glands. It may be ulcerative, because of infection by staphylococci, or seborrheic, and associated with seborrhea of the scalp, brows, and ears. Both types may be present. Posterior blepharitis involves eyelids secondary to dysfunction of the meibomian glands. There may be bacterial infection, particularly with staphylococci, or primary glandular dysfunction, in which there is a strong association with acne rosacea.

Symptoms are irritation, burning, and itching. In anterior blepharitis, the eyes are "red-rimmed," and scales or granulations can be seen clinging to the lashes. In posterior blepharitis, the lid margins are hyperemic with telangiectasias; the meibomian glands and their orifices are inflamed, with dilation of the glands, plugging of the orifices, and abnormal secretions. The lid margin is frequently rolled inward to produce a mild entropion, and the tears may be frothy or abnormally greasy.

Both anterior and, more particularly, posterior blepharitis may be complicated by hordeola or chalazions; abnormal lid or lash positions, producing trichiasis; recurrent conjunctivitis; epithelial keratitis of the lower third of the cornea; marginal corneal infiltrates; and inferior corneal vascularization and thinning.

In anterior blepharitis, cleanliness of the scalp, eyebrows, and lid margins is effective local therapy. Scales must be removed from the lids daily with a damp cotton applicator and baby shampoo. An antistaphylococcal antibiotic eye ointment such as bacitracin or erythromycin is applied daily to the lid margins with a cotton-tipped applicator. Antibiotic sensitivity studies may be required in severe staphylococcal blepharitis.

In mild posterior blepharitis, regular meibomian gland expression may be sufficient to control symptoms. Inflammation of the conjunctiva and cornea indicates a need for more active treatment, including long-term low-dose systemic antibiotic therapy, usually with tetracycline (250 mg twice daily), doxycycline (100 mg daily), or erythromycin (250 mg three times daily), and short-term topical steroids, eg, prednisolone, 0.125% twice daily. Topical therapy with antibiotics such as ciprofloxacin 0.3% ophthalmic solution twice daily may be helpful but should be restricted to short courses.

Entropion & Ectropion

Entropion (inward turning of usually the lower lid) occurs occasionally in older people as a result of degeneration of the lid fascia, or may follow extensive scarring of the conjunctiva and tarsus. Surgery is indicated if the lashes rub on the cornea. Botulinum toxin injections may also be used for temporary correction of the involutional lower eyelid entropion of older people.

Ectropion (outward turning of the lower lid) is common with advanced age. Surgery is indicated if there is excessive tearing, exposure keratitis, or a cosmetic problem.

Davies RP: Surgical options for eyelid problems. Aust Fam Physician 2002;31:239. [PMID: 11926155]

Dacryocystitis

Dacryocystitis is infection of the lacrimal sac due to obstruction of the nasolacrimal system. It may be acute or chronic and occurs most often in infants and in persons over 40. It is usually unilateral.

In acute dacryocystitis, the usual infectious organisms are *S aureus* and β -hemolytic streptococci; in chronic dacryocystitis, *S epidermidis*, anaerobic streptococci, or *Candida albicans*.

Acute dacryocystitis is characterized by pain, swelling, tenderness, and redness in the tear sac area; purulent material may be expressed. In chronic dacryocystitis, tearing and discharge are the principal signs, and mucus or pus may also be expressed.

Acute dacryocystitis responds well to systemic antibiotic therapy, but recurrences are common if the obstruction is not removed. The chronic form may be kept latent with antibiotics, but relief of the obstruction is the only cure. In adults, the standard procedure for obstruction of the lacrimal drainage system is dacryocystorhinostomy, which involves surgical exploration of the lacrimal sac and formation of a fistula into the nasal cavity. Laser-assisted endoscopic dacryocystorhinostomy and balloon dilation or probing of the nasolacrimal system are alternatives. Congenital nasolacrimal duct obstruction often resolves spontaneously but if necessary can be treated by probing of the nasolacrimal system.

Dolman PJ: Comparison of external dacryocystorhinostomy with nonlaser endonasal dacryocystorhinostomy. Ophthalmology 2003;110:78. [PMID: 12511350]

CONJUNCTIVITIS

Conjunctivitis is the most common eye disease. It may be acute or chronic. Most cases are due to bacterial (including gonococcal and chlamydial) or viral infection. Other causes include keratoconjunctivitis sicca, allergy, and chemical irritants. The mode of transmission of infectious conjunctivitis is usually direct contact via fingers, towels, handkerchiefs, etc, to the fellow eye or to other persons.

Conjunctivitis must be differentiated from acute uveitis, acute glaucoma, and corneal disorders (Table 7-1).

Bacterial Conjunctivitis

The organisms isolated most commonly in bacterial conjunctivitis are staphylococci, streptococci (particularly *S pneumoniae*), *haemophilus* species, *pseudomonas*, and *moraxella*. All may produce a copious purulent discharge. There is no blurring of vision and only mild discomfort. In severe cases, examination of stained conjunctival scrapings and cultures is recommended.

The disease is usually self-limited, lasting about 10-14 days if untreated. A sulfonamide (eg, sulfacetamide, 10% ophthalmic solution or ointment) instilled locally three times daily will usually clear the infection in 2-3 days. Povidone-iodine may also be effective.

A. Gonococcal Conjunctivitis

Gonococcal conjunctivitis, usually acquired through contact with infected genital secretions, is manifested by a copious purulent discharge. It is an ophthalmologic emergency because corneal involvement may rapidly lead to perforation. The diagnosis should be confirmed by stained smear and culture of the discharge. In this disorder, a 5-day course of parenteral ceftriaxone, 1-2 g daily, is required. Topical antibiotics such as erythromycin and bacitracin may be added. In such patients, other sexually transmitted diseases, including chlamydiosis, syphilis, and HIV infection, should be tested for.

B. Chlamydial Keratoconjunctivitis

1. Trachoma—(*Chlamydia trachomatis* serotypes A-C.) Trachoma is a major cause of blindness worldwide. Recurrent episodes of infection in childhood are manifest as bilateral follicular conjunctivitis, epithelial keratitis, and corneal vascularization (pannus). Cicatrization of the tarsal conjunctiva leads to entropion and trichiasis in adulthood, with secondary central corneal scarring.

The diagnosis is made in Giemsa-stained conjunctival scrapings. Treatment should be started on the basis of clinical findings without waiting for laboratory confirmation. Oral tetracycline or erythromycin, 250 mg six times a day, or doxycycline, 100 mg twice a day, is given for 3-5 weeks. Single-dose therapy with azithromycin, 20 mg/kg, may also be effective. Local treatment is not necessary. Surgical treatment includes correction of eyelid deformities and corneal transplantation.

2. Inclusion conjunctivitis—(*C trachomatis* serotypes D-K.) The agent of inclusion conjunctivitis is a common cause of genital tract disease in adults. The eye is usually involved following accidental contact with genital secretions. Adult inclusion conjunctivitis thus occurs most frequently in sexually active young adults. The disease starts with acute redness, discharge, and irritation. The eye findings consist of follicular conjunctivitis with mild keratitis. A nontender preauricular lymph node can often be palpated. Healing usually leaves no sequelae. Cytologic examination of conjunctival scrapings shows a picture similar to that of trachoma. Treatment is with oral tetracycline or erythromycin, 250-500 mg four times a day, or doxycycline, 300 mg initially followed by 100 mg once a day, for 2 weeks. Before treatment, all cases should be assessed for genital tract infection so that management can be adjusted accordingly, and other venereal diseases sought for.

Viral Conjunctivitis

One of the most common causes of viral conjunctivitis is adenovirus type 3. Conjunctivitis due to this agent is usually associated with pharyngitis, fever, malaise, and preauricular adenopathy (pharyngoconjunctival fever). Locally, the palpebral conjunctiva is red, and there is a copious watery discharge and scanty exudate. Children are more often affected than adults, and contaminated swimming pools are sometimes the source of infection. Epidemic keratoconjunctivitis is caused by adenovirus types 8 and 19. It is more likely to be complicated by visual loss due to corneal subepithelial infiltrates. The disease lasts at least 2 weeks. Local sulfonamide therapy may prevent secondary bacterial infection, hot compresses reduce the discomfort of the associated lid edema, and weak topical steroids (eg, prednisolone, 0.125% four times daily) treat the corneal infiltrates.

Keratoconjunctivitis Sicca (Dry Eyes)

This is a common disorder, particularly in elderly women. A wide range of conditions predispose to or are characterized by dry eyes. Hypofunction of the lacrimal glands, causing loss of the aqueous component of tears, may be due to aging, hereditary disorders, systemic disease (eg, Sjogren's syndrome), or systemic and

topical drugs. Excessive evaporation of tears may be due to environmental factors (eg, a hot, dry, or windy climate) or abnormalities of the lipid component of the tear film, as in blepharitis. Mucin deficiency may be due to malnutrition, infection, burns, or drugs. Hormone replacement therapy may increase the risk of dry eyes.

The patient complains of dryness, redness, or a scratchy feeling of the eyes. In severe cases there is persistent marked discomfort, with photophobia, difficulty in moving the eyelids, and often excessive mucus secretion. In many cases, inspection reveals no abnormality, but on slit-lamp examination there are subtle abnormalities of tear film stability and reduced volume of the tear film meniscus along the lower lid. In more severe cases, damaged corneal and conjunctival cells stain with 1% rose bengal, which is to be avoided in serious cases because of the intense pain. In the most severe cases there is marked conjunctival injection, loss of the normal conjunctival and corneal luster, epithelial keratitis that may progress to frank ulceration, and mucous strands. Schirmer's test, which measures the rate of production of the aqueous component of tears, may be helpful, but false-positive and false-negative results are frequent.

Treatment depends upon cause. In most early cases, the corneal and conjunctival epithelial changes are reversible. Aqueous deficiency can be treated by replacement of the aqueous component of tears with various types of artificial tears. The simplest preparations are physiologic (0.9%) or hypo-osmotic (0.45%) solutions of sodium chloride. Balanced salt solution is more physiologic but also more expensive. All of these drop preparations can be used every half-hour but in most cases are needed only three or four times a day. More prolonged duration of action can be achieved with drop preparations containing methylcellulose (eg, Isopto Plain) or polyvinyl alcohol (eg, Liquifilm Tears or HypoTears), or by using petrolatum ointment (Lacri-Lube). Such mucomimetics are particularly indicated when there is mucin deficiency. Artificial tear preparations are generally very safe and without side effects. However, the preservatives necessary to maintain their sterility are potentially toxic and allergenic and may cause keratitis and cicatrizing conjunctivitis in frequent users. Furthermore, the development of such reactions may be misinterpreted by both the patient and the doctor as a worsening of the dry eye state requiring more frequent use of the artificial tears and leading in turn to further deterioration, rather than being recognized as a need to change to a preservative-free preparation. If the mucus is tenacious, mucolytic agents (eg, acetylcysteine, 20% six times a day) may provide some relief. Lacrimal punctal occlusion by canalicular plugs or surgery is useful in severe cases. Blepharitis is treated as described above. Associated blepharospasm responds to botulinum toxin injections.

Allergic Eye Disease

Allergic eye disease takes a number of different forms but all are atopic, manifested as atopic asthma, atopic dermatitis, or allergic rhinitis. Symptoms include itching, tearing, redness, stringy discharge, and, occasionally, photophobia and visual loss.

Allergic conjunctivitis is a benign disease, occurring usually in late childhood and early adulthood. It may be seasonal, developing usually during the spring or summer, or perennial. Clinical signs are limited to conjunctival hyperemia and edema (chemosis), the latter at times being marked and sudden in onset. Vernal keratoconjunctivitis also tends to occur in late childhood and early adulthood. It is usually seasonal, with a predilection for the spring. Large "cobblestone" papillae are noted on the upper tarsal conjunctiva. There may be lymphoid follicles at the limbus. Atopic keratoconjunctivitis is a more chronic disorder of adulthood. Both the upper and the lower tarsal conjunctivas exhibit a fine papillary conjunctivitis with fibrosis, resulting in forniceal shortening and entropion with trichiasis. Staphylococcal blepharitis is a complicating factor. Corneal involvement, including refractory ulceration, is frequent during exacerbations of both vernal and atopic keratoconjunctivitis. They may also be complicated by herpes simplex keratitis.

For mild and moderately severe allergic eye disease, topical levocabastine, a histamine H₁-receptor antagonist, or ketorolac tromethamine, a nonsteroidal anti-inflammatory agent, is applied topically four times daily. Ketotifen 0.025%, which has histamine H₁-receptor antagonist, mast cell stabilizer, and eosinophil inhibitor activity, is applied two to four times daily; olopatadine 0.1%, applied twice daily, reduces symptoms by a similar mechanism. Topical lodoxamine tromethamine 0.1%, a mast cell stabilizer, applied four times daily, produces longer-term prophylaxis but the therapeutic response is delayed. Topical vasoconstrictors and antihistamines are advocated in hay fever conjunctivitis but are of limited efficacy and may produce rebound hyperemia and follicular conjunctivitis. Systemic antihistamines may be useful in prolonged atopic keratoconjunctivitis. Topical corticosteroids are essential to the control of acute exacerbations of both vernal and atopic keratoconjunctivitis. Steroid-induced side effects, including cataracts, glaucoma, and exacerbation of herpes simplex keratitis, are major problems. Systemic steroid therapy and even plasmapheresis may be required in severe atopic keratoconjunctivitis. In allergic conjunctivitis, specific allergens may be identifiable and thus avoidable. In vernal keratoconjunctivitis, a cooler climate often provides significant benefit.

PINGUECULA & PTERYGIUM

Pinguecula is a yellow elevated nodule on either side of the cornea, more commonly the nasal side, in the area of the palpebral fissure. It is common in persons over age 35. Pterygium is a fleshy, triangular encroachment of the conjunctiva onto the nasal side of the cornea and is usually associated with constant exposure to wind, sun, sand, and dust. Pterygium may be either unilateral or bilateral. There may be a genetic predisposition, but no hereditary pattern has been described. Of the two, pinguecula is more common. Both show elastoid degeneration of the conjunctival substantia propria.

Pingueculae rarely grow, but inflammation (pingueculitis) may occur. No treatment is usually required for pingueculitis or for inflammation of pterygium, but artificial tears are often beneficial, and short courses of topical nonsteroidal anti-inflammatory agents or weak steroids (prednisolone, 0.125% three times a day) may be necessary.

The indications for excision of pterygium are growth threatening vision by approaching the visual axis, marked induced astigmatism, or severe ocular irritation. Recurrence is common and often more aggressive than the primary lesion.

CORNEAL ULCER

Corneal ulcers are most commonly due to infection by bacteria, viruses, fungi, or amebas. Noninfectious causes—all of which may be complicated by infection—include neurotrophic keratitis (resulting from loss of corneal sensation), exposure keratitis (due to inadequate eyelid closure), severe dry eyes, severe allergic eye disease, and various inflammatory disorders that may be purely ocular or part of a systemic vasculitis. Delayed or ineffective treatment of corneal infection may lead to devastating consequences with intraocular infection or corneal scarring. Prompt referral is essential.

Patients present with pain, photophobia, tearing, and reduced vision. The eye is red, with predominantly circumcorneal injection, and there may be purulent or watery discharge. The corneal appearance varies according to the organisms involved.

Ladas JG et al: Systemic disorders associated with peripheral corneal ulceration. *Curr Opin Ophthalmol* 2000;11:468. [\[PMID: 11141643\]](#)

Lekskul M et al: Nontraumatic corneal perforation. *Cornea* 2000;19:313. [\[PMID: 10832690\]](#)

Bacterial Keratitis

Bacterial keratitis pursues an aggressive course. Precipitating factors include contact lens wear—especially soft contact lenses worn overnight—and corneal trauma, including laser surgery. The pathogens most commonly isolated are *Pseudomonas aeruginosa*, pneumococci, moraxella species, and staphylococci. The cornea is hazy, with a central ulcer and adjacent stromal abscess. Hypopyon is often present. The ulcer is scraped to recover material for Gram stain and culture prior to starting treatment with high-concentration topical antibiotics applied hourly for the first day. Gram-positive cocci are treated with a cephalosporin such as cefazolin, 100 mg/mL, and gram-negative bacilli are treated with an aminoglycoside such as tobramycin, 15 mg/mL. If no organisms are seen, these two agents are used together. Fluoroquinolones such as ciprofloxacin, 3 mg/mL, or ofloxacin, 3 mg/mL, are alternatives.

Schaefer F et al: Bacterial keratitis: a prospective clinical and microbiological study. *Br J Ophthalmol* 2001;85:842. [\[PMID: 11423460\]](#)

Herpes Simplex Keratitis

Herpes simplex keratitis is an important cause of ocular morbidity in adults. The ability of the virus to colonize the trigeminal ganglion leads to recurrences precipitated by fever, excessive exposure to sunlight, or immunodeficiency.

The dendritic (branching) ulcer is the most characteristic manifestation of this epithelial keratitis. More extensive ("geographic") ulcers also occur, particularly if topical corticosteroids have been used. These ulcers are most easily seen after instillation of fluorescein and examination with a blue light. Epithelial disease in itself does not lead to corneal scarring. It responds well to simple debridement and patching. More rapid healing can be achieved by the addition of topical antivirals such as trifluridine

drops, vidarabine ointment, acyclovir ointment, or ganciclovir gel. Long-term oral acyclovir reduces the rate of recurrent epithelial disease, for which topical corticosteroids must not be used.

Stromal herpes simplex keratitis produces increasingly severe corneal opacity with each recurrence. Topical antivirals alone are insufficient to control stromal disease. Thus, topical corticosteroids are used in combination, but steroid dependence is a common consequence. Corticosteroids may also enhance viral replication, exacerbating epithelial disease. Oral acyclovir, 200-400 mg five times a day, may be helpful in the treatment of severe herpetic keratitis and for prophylaxis against recurrences, particularly in atopic or HIV-infected individuals. Corneal grafting is necessitated by severe stromal scarring, but the overall outcome is relatively poor. **Caution:** For patients with known or possible herpetic disease, topical corticosteroids should be prescribed only with ophthalmologic supervision.

Halberstadt M et al: The outcome of corneal grafting in patients with stromal keratitis of herpetic and non-herpetic origin. Br J Ophthalmol 2002;86:646. [PMID: 12034687]

Wilhelmus KR: Interventions for herpes simplex virus epithelial keratitis. Cochrane Database Syst Rev 2001;1:CD002898. [PMID: 11279774]

Fungal Keratitis

Fungal keratitis tends to occur after corneal injury involving plant material or in an agricultural setting, in eyes with chronic ocular surface disease, and in contact lens wearers. It is an indolent process, with the cornea characteristically having multiple stromal abscesses and relatively little epithelial loss. Intraocular infection is common. Corneal scrapings are cultured on media suitable for fungi whenever the history or corneal appearance is suggestive of fungal disease.

Acanthamoeba Keratitis

Acanthamoeba is an important cause of suppurative keratitis in contact lens wearers. Although severe pain with perineural and ring infiltrates in the corneal stroma are characteristic, earlier forms with changes confined to the corneal epithelium are identifiable. Culture requires specialized media. Treatment is hampered by the organism's ability to encyst within the corneal stroma. Various agents have been used, including neomycin-polymyxin-gramicidin, chlorhexidine, the investigational agents propamidine isethionate and polyhexamethyl biguanide, and oral and topical imidazoles such as ketoconazole, miconazole, and itraconazole. Epithelial debridement may be useful in early infections. Corneal grafting may be required in the acute stage to arrest the progression of infection or after resolution to restore vision. Systemic immunosuppression may be needed if there is scleral involvement.

Herpes Zoster Ophthalmicus

Herpes zoster frequently involves the ophthalmic division of the trigeminal nerve. It presents with malaise, fever, headache, and periorbital burning and itching. These symptoms may precede the eruption by a day or more. The rash is initially vesicular, quickly becoming pustular and then crusting. Involvement of the tip of the nose or the lid margins indicates involvement of the eye. Ocular signs include conjunctivitis, keratitis, episcleritis, and anterior uveitis, often with elevated intraocular pressure. Recurrent anterior segment inflammation, neurotrophic keratitis, and posterior subcapsular cataract are long-term complications. Optic neuropathy, cranial nerve palsies, acute retinal necrosis, and cerebral angitis are infrequent problems in the acute stage. HIV infection is an important risk factor for herpes zoster ophthalmicus and increases the likelihood of complications.

High-dose oral acyclovir (800 mg five times a day), valacyclovir (1 g three times a day), or famciclovir (250-500 mg three times a day) started within 72 hours after appearance of the rash reduces the incidence of ocular complications but not of postherpetic neuralgia. Anterior uveitis requires treatment with topical corticosteroids and cycloplegics.

ACUTE (ANGLE-CLOSURE) GLAUCOMA

- Rapid onset in older age groups, particularly hyperopes and Asians.
- Severe pain and profound visual loss.
- Red eye, steamy cornea, dilated pupil.
- Hard eye to palpation.

General Considerations

Primary acute angle-closure glaucoma occurs only with closure of a preexisting narrow anterior chamber angle, found in elderly persons (owing to physiologic enlargement of the lens), hyperopes, and Asians. In the United States, about 1% of people over age 35 have narrow anterior chamber angles, but many never develop acute glaucoma. Angle closure may be precipitated by pupillary dilation and thus can occur from sitting in a darkened theater, at times of stress, or, rarely, from pharmacologic mydriasis. Anticholinergic or sympathomimetic agents (eg, atropine for preoperative medication, antidepressants, nebulized bronchodilators, or nasal decongestants) are also causes. Secondary acute angle-closure glaucoma may be observed with anterior uveitis, dislocation of the lens, or topiramate therapy. Symptoms are the same as in primary acute angle-closure glaucoma, but differentiation is important because of differences in management. Chronic angle-closure glaucoma is particularly common in eastern Asia. It presents in the same way as open-angle glaucoma (see below).

Clinical Findings

Patients with acute glaucoma usually seek treatment immediately because of extreme pain and blurred vision, though there are subacute cases. The blurred vision is associated with halos around lights. Nausea and abdominal pain may occur, and acute glaucoma must be remembered in the differential diagnosis of the acute abdomen. The eye is red, the cornea steamy, and the pupil moderately dilated and nonreactive to light. Tonometry reveals elevated intraocular pressure.

Differential Diagnosis

Acute glaucoma must be differentiated from conjunctivitis, acute uveitis, and corneal disorders (Table 7-1).

Treatment

A. Primary

Initial treatment in primary angle-closure glaucoma is control of intraocular pressure. A single 500-mg intravenous dose of acetazolamide, followed by 250 mg orally four times a day, is usually sufficient. Osmotic diuretics such as oral glycerol and intravenous urea or mannitol—the dosage of all three being 1-2 g/kg—can be used. Laser therapy to the peripheral iris (iridoplasty) is also effective. Once the intraocular pressure has started to fall, topical 4% pilocarpine, 1 drop every 15 minutes for 1 hour and then four times a day, is used to reverse the underlying angle closure. The definitive treatment is laser peripheral iridotomy, which should also be performed prophylactically on the fellow eye. Cataract extraction is a possible alternative. If it is not possible to control the intraocular pressure medically, glaucoma drainage surgery as for uncontrolled open-angle glaucoma (see below) may be required.

B. Secondary

In secondary acute angle-closure glaucoma, systemic acetazolamide is also used, with or without osmotic agents. Further treatment is determined by the cause.

Prognosis

Untreated acute glaucoma results in severe and permanent visual loss within 2-5 days after onset of symptoms.

CHRONIC GLAUCOMA

Essentials of Diagnosis

- No symptoms in early stages.
- Gradual loss of peripheral vision over a period of years, resulting in tunnel vision.
- Insidious progression in older age groups.
- "Halos around lights" are present only in severe cases.
- Pathologic cupping of the optic disks usually associated with persistent elevation of intraocular pressure.

General Considerations

Chronic glaucoma is characterized by gradually progressive—over a period of months or years—excavation ("cupping") and pallor of the optic disk with loss of vision varying from slight constriction of the peripheral fields to complete blindness. In chronic open-angle glaucoma, the intraocular pressure is elevated due to abnormal drainage of aqueous through the trabecular meshwork. In chronic angle-closure glaucoma, this finding is due to obstruction of flow of aqueous into the anterior chamber angle. In normal-tension glaucoma, intraocular pressure is not elevated above the normal range but the same pattern of optic nerve damage occurs, probably due to vascular insufficiency that may also play a role in primary open-angle glaucoma.

The cause of the decreased rate of aqueous outflow in primary open-angle glaucoma has not been clearly established. A number of mutations, such as in the myocilin gene on chromosome 1, have been identified in a small proportion of cases. The disease is bilateral, and there is an increased prevalence in first-degree relatives of affected individuals and in diabetics. Primary open-angle glaucoma occurs at an earlier age, is more frequent in blacks, and may result in more severe optic nerve damage. Secondary open-angle glaucoma may result from uveitis or the effects of trauma. Elevation of intraocular pressure is also a complication of steroid therapy, whether it be topical, systemic, inhaled, or administered by nasal spray.

In the United States, it is estimated that 1-2% of people over 40 have glaucoma; about 25% of cases are undetected. Over 90% of cases are of the open-angle type, either primary open-angle or normal-tension glaucoma. Worldwide, about 50% of all cases of glaucoma are due to acute (see above) or chronic angle closure due to the very high prevalence of angle closure in eastern Asia.

Clinical Findings

Patients with chronic glaucoma have no symptoms initially. On examination, there may be slight cupping of the optic disk observed as an absolute increase—or an asymmetry between the two eyes—of the ratio of the diameter of the optic cup to the diameter of the whole optic disk (cup-disk ratio). (Cup-disk ratio of greater than 0.3 or asymmetry of cup-disk ratio of 0.2 or more is suggestive.) Changes in the retinal nerve fiber layer may be observed as an earlier finding in some patients. The visual fields gradually constrict, but central vision remains good until late in the disease.

Tonometry, ophthalmoscopic visualization of the optic nerve, and central visual field testing are the best studies for diagnosis and follow-up. The diagnosis depends upon identification of consistent abnormalities in at least two of these parameters. The normal range of intraocular pressure is 10-24 mm Hg. Except in acute cases, the diagnosis of glaucoma is not made on the basis of one tonometric measurement. Intraocular pressure is influenced by various factors, including posture and diurnal variation. In many individuals, elevated intraocular pressure is not associated with optic disk or visual field abnormalities. These ocular hypertensives are at increased risk of developing glaucomatous damage. Treatment to reduce intraocular pressure is justified if there is a moderate to high risk of the development of glaucoma. Risk is determined by several factors, including age, optic disk appearance, level of intraocular pressure, and corneal thickness. Conversely, a significant proportion of patients with glaucoma have normal intraocular pressure when it is first measured, and only repeated measurements identify the abnormally high pressure. Furthermore, in patients with normal-tension glaucoma, the intraocular pressure is always within the normal range despite repeated measurement, even with a glaucomatous optic disk and visual field abnormalities. There are many other causes of optic disk abnormalities or visual field changes that mimic glaucomatous damage, and visual field testing may prove unreliable in some patients, particularly the elderly. Taken together, these factors mean that the diagnosis of glaucoma is not always straightforward, hampering the effectiveness of screening programs.

Prevention

All persons over age 40 should have tonometric and ophthalmoscopic examinations every 2 years. In diabetics and in individuals with a family history of glaucoma, annual examination is indicated.

Treatment

Topical β -adrenergic blocking agents such as timolol 0.25% or 0.5%, carteolol 1%, levobunolol 0.5%, and metipranolol 0.3% solutions twice daily or timolol 0.5% gel once daily continue to be popular antiglaucoma agents. They are contraindicated in patients with reactive airway disease or heart failure. Betaxolol, 0.25% or 0.5%, a β -receptor selective blocking agent, is theoretically safer in reactive airway disease but less effective at reducing intraocular pressure. The prostaglandin analogs (latanoprost 0.005%, bimatoprost 0.03%, and travoprost 0.004% once daily at night or unoprostone isopropyl 0.15% twice daily) are increasingly used, either as first-line therapy or in addition to a β -blocker, because of their efficacy, the convenience of once-daily administration, and their lack of systemic side effects. All may produce conjunctival hyperemia, permanent darkening of the iris and eyebrow color, and eyelash growth. Latanoprost has been associated with reactivation of uveitis and macular edema. Brimonidine 0.2%, a selective α_2 agonist, and dorzolamide 2%, a topical carbonic anhydrase inhibitor, can also be used in addition to a β -blocker (twice daily) or as initial therapy when β -blockers are contraindicated (brimonidine twice daily and dorzolamide three times daily). Both are associated with allergic reactions.

Apraclonidine, 0.5-1%, another α_2 agonist, can be used three times a day to postpone the need for surgery in patients receiving maximal medical therapy, but long-term use is limited by drug reactions. It is more commonly used to control acute rises in intraocular pressure such as after laser therapy. Epinephrine, 0.5-1%, and the prodrug dipivefrin, 0.1%, are being used much less frequently because of adverse effects on the outcome of subsequent glaucoma surgery. Pilocarpine, 1-4% (and sometimes higher concentrations in patients with dark irides) four times a day, is little used because of the induced myopia in younger patients and the pupillary constriction that compromises vision in patients with cataract. Oral carbonic anhydrase inhibitors (eg, acetazolamide) may still be used on a long-term basis if topical therapy is inadequate and surgical or laser therapy is inappropriate.

Laser trabeculoplasty is used as an adjunct to topical therapy to defer surgery and is also advocated as primary treatment. Surgery is generally undertaken when intraocular pressure is inadequately controlled by medical and laser therapy, but it may also be used as primary treatment. Trabeculectomy remains the standard procedure. Adjunctive treatment with subconjunctival fluorouracil or mitomycin is used peri- or postoperatively in difficult cases. Viscocanalostomy and deep sclerectomy with collagen implant—two alternative procedures that avoid a full-thickness incision into the eye—may prove to be as effective as trabeculectomy.

Prognosis

Untreated chronic glaucoma that begins at age 40-45 will probably cause complete blindness by age 60-65. Early diagnosis and treatment can preserve useful vision throughout life. In primary open-angle glaucoma—and if treatment is required in ocular hypertension—the aim is to reduce intraocular pressure to a level that will adequately reduce progression of visual field loss. In the most serious cases, intraocular pressure must be reduced to less than 16 mm Hg. In normal-tension glaucoma, it may be necessary to achieve even lower intraocular pressure; surgery is nonetheless generally required.

UVEITIS

Uveitis means inflammation of the uveal tract, which is formed by the iris (iritis), ciliary body (cyclitis), and choroid (choroiditis). Inflammatory eye disease may also originate primarily in the retina (retinitis) or retinal blood vessels (retinal vasculitis).

Intraocular inflammation is classified as anterior uveitis, posterior uveitis, or panuveitis. Uveitis may also be termed acute or chronic and granulomatous or nongranulomatous. In most cases the pathogenesis of uveitis is primarily immunologic, but in immunodeficiency states infection may be the cause.

Clinical Findings

Anterior uveitis is characterized by inflammatory cells and flare within the aqueous. Cells may also be seen on the corneal endothelium as keratic precipitates (KPs). In granulomatous uveitis, these are large "mutton-fat" KPs, and iris nodules may be seen. In nongranulomatous uveitis, the KPs are smaller and iris nodules are not seen. Occasionally, granulomatous uveitis may initially masquerade as nongranulomatous disease. In severe anterior uveitis, there may be hypopyon (layered collection of white cells) and fibrin within the anterior chamber. In virtually all forms of anterior uveitis, the pupil is small, and with the development of posterior synechiae (adhesions between the iris and anterior lens capsule), it also becomes irregular.

Nongranulomatous anterior uveitis tends to present acutely with unilateral pain, redness, photophobia, and visual loss. Granulomatous anterior uveitis is more indolent, causing blurred vision in a mildly inflamed eye.

In posterior uveitis, there are cells in the vitreous. Inflammatory lesions may be present in the retina or choroid. Fresh lesions are yellow, with indistinct margins, whereas older lesions have more definite margins and are commonly pigmented. Retinal vessel sheathing may occur adjacent to such lesions or more diffusely. In severe cases, vitreous opacity precludes visualization of retinal details.

Posterior uveitis tends to present with gradual visual loss in a relatively quiet eye. Bilateral involvement is common. Visual loss may be due to vitreous haze and opacities, inflammatory lesions involving the macula, macular edema, retinal vein occlusion, or, rarely, associated optic neuropathy.

Etiology

The systemic disorders associated with acute nongranulomatous anterior uveitis are the HLA-B27-related conditions ankylosing spondylitis, reactive arthritis, psoriasis, ulcerative colitis, and Crohn's disease. Behcet's syndrome produces both anterior uveitis with recurrent hypopyon in 5% and posterior uveitis with retinal vein occlusions on occasion. Both herpes simplex and herpes zoster infections may cause nongranulomatous anterior uveitis.

Diseases producing granulomatous anterior uveitis also tend to be causes of posterior uveitis. These include sarcoidosis, tuberculosis, syphilis, toxoplasmosis, Vogt-Koyanagi-Harada syndrome (bilateral uveitis associated with alopecia, poliosis [depigmented eyelashes, eyebrows, or hair], vitiligo, and hearing loss), and sympathetic ophthalmia. Syphilis produces a characteristic "salt and pepper" fundus, often with surprisingly little visual loss unless there is also primary syphilitic optic atrophy. In congenital toxoplasmosis, there is usually evidence of previous episodes of retinochoroiditis. The principal agents responsible for ocular inflammation in AIDS are cytomegalovirus, herpes simplex and herpes zoster viruses, mycobacterium, cryptococcus, toxoplasma, and candida.

Autoimmune retinal vasculitis and pars planitis (intermediate uveitis) are idiopathic conditions that produce posterior uveitis.

Retinal detachment, intraocular tumors, and central nervous system lymphoma may all masquerade as uveitis.

Treatment

Anterior uveitis will usually respond to topical corticosteroids. Occasionally, periocular steroid injections or even systemic steroids may be required. Dilation of the pupil is important to relieve discomfort and prevent posterior synechiae.

Posterior uveitis more commonly requires systemic corticosteroid therapy and occasionally systemic immunosuppression with azathioprine or cyclosporine. Pupillary dilation is not usually necessary.

In all cases if an infectious cause is identified, specific antimicrobial therapy is indicated. In general, the prognosis for anterior uveitis, particularly the nongranulomatous type, is better than that for posterior uveitis.

CATARACT

Essentials of Diagnosis

- Blurred vision, progressive over months or years.
- No pain or redness.
- Lens opacities (may be grossly visible).

General Considerations

A cataract is a lens opacity. Cataracts are usually bilateral. They may be congenital (owing to intrauterine infections such as rubella and cytomegalovirus, or inborn errors of metabolism such as galactosemia); traumatic; or secondary to systemic disease (diabetes, myotonic dystrophy, atopic dermatitis), systemic or inhaled corticosteroid treatment, or uveitis. Senile cataract is by far the most common type; most persons over age 60 have some degree of lens opacity. Cigarette smoking increases the risk of cataract formation.

Clinical Findings

Even in its early stages, a cataract can be seen through a dilated pupil with an ophthalmoscope, a slit lamp, or an ordinary hand illuminator. As the cataract matures, the retina will become increasingly more difficult to visualize, until finally the fundus reflection is absent and the pupil is white.

Treatment

Functional visual impairment is the prime criterion for surgery. The cataract is usually removed by one of the techniques in which the delicate posterior lens capsule

remains (extracapsular). This may, however, call for subsequent laser treatment if the posterior capsule opacifies. With the development of ultrasonic fragmentation (phacoemulsification) of the lens nucleus, it is possible to perform cataract surgery through a small incision without suturing the wound, thus reducing the postoperative complication rate and accelerating visual rehabilitation.

It is routine practice to implant an intraocular lens at the time of surgery. This dispenses with the need for heavy cataract glasses or contact lenses. With improved intraocular lenses, the success rate is high. Multifocal intraocular lenses have been used with some success to reduce the need for both distance and reading glasses.

Prognosis

If surgery is indicated, lens extraction improves visual acuity in 95% of cases. The remainder either have preexisting retinal damage or develop perioperative or postoperative complications.

RETINAL DETACHMENT

Essentials of Diagnosis

- Blurred vision in one eye becoming progressively worse.
- No pain or redness.
- Detachment seen by ophthalmoscopy.

General Considerations

The primary event in rhegmatogenous retinal detachment is the development of a retinal tear or hole. This is usually spontaneous, related to changes in the vitreous, but may be secondary to trauma. Spontaneous detachment occurs most frequently in persons over 50 years of age. Myopia and cataract extraction are the two most common predisposing causes. Once there is a tear or hole in the retina, fluid vitreous is able to pass through the tear and lodge behind the sensory retina. This, combined with vitreous traction and the pull of gravity, results in progressive detachment. The superior temporal area is the most common site of detachment. The area involved rapidly increases, causing corresponding progressive visual loss. Central vision remains intact until the macula becomes detached.

The basis of traction retinal detachment is the development of preretinal fibrosis, such as in association with proliferative retinopathy secondary to diabetic retinopathy or retinal vein occlusion. Serous retinal detachment results from accumulation of subretinal fluid, such as in exudative age-related macular degeneration or secondary to choroidal tumors.

Clinical Findings

On ophthalmoscopic examination in rhegmatogenous retinal detachment, the retina is seen hanging in the vitreous like a gray cloud. One or more retinal tears will usually be found on further examination. In traction retinal detachment, there is irregular retinal elevation with fibrosis. With serous retinal detachment, the retina is dome-shaped and the subretinal fluid may shift position with changes in posture.

Treatment

All cases of retinal detachment must be referred immediately to an ophthalmologist. During transportation, the patient's head is positioned so that the detached portion of the retina will fall back with the aid of gravity. Treatment is directed at closing the tears. A permanent adhesion between the neurosensory retina, the retinal pigment epithelium, and the choroid is produced in the region of the tears by applying cryotherapy to the sclera or laser photocoagulation to the retina. To achieve apposition of the neurosensory retina to the retinal pigment epithelium while this adhesion is developing, an indentation may be made in the sclera with a silicone sponge or buckle; subretinal fluid may be drained via an incision in the sclera; and an expansile gas may be injected into the vitreous cavity. Certain types of uncomplicated retinal detachment may be treated by pneumatic retinopexy, in which an expansile gas is initially injected into the vitreous cavity followed by positioning of the patient's head to facilitate reattachment of the retina. Once the retina is repositioned, the tear is sealed by laser photocoagulation or cryotherapy. All the stages of pneumatic retinopexy can be performed under local anesthesia as an office procedure. The last stage is the same as is used to seal retinal tears without associated detachment as prophylaxis against recurrence.

In complicated retinal detachments—particularly those in which fibroproliferative tissue has developed on the surface of the retina or within the vitreous cavity, ie, traction retinal detachments—retinal reattachment can be accomplished only by removal of the vitreous, direct manipulation of the retina, and internal tamponade of the retina with air, expansile gases, or even silicone oil. (The presence of an expansile gas within the eye is a contraindication to air travel, mountaineering at high altitude, and nitrous oxide anesthesia. Such gases persist in the globe for weeks after surgery.) (See [Chapter 38](#).) Treatment of serous retinal detachments is determined by the underlying cause.

Prognosis

About 80% of uncomplicated rhegmatogenous retinal detachments can be cured with one operation, an additional 15% will need repeated operations, and the remainder never reattach. The prognosis is worse if the macula is detached or if the detachment is of long duration. Without treatment, retinal detachment often becomes total within 6 months. Spontaneous detachments are ultimately bilateral in up to 25% of cases.

VITREOUS HEMORRHAGE

Patients with vitreous hemorrhage complain of sudden visual loss, abrupt onset of floaters that may progressively increase in severity, or, occasionally, "bleeding within the eye." Visual acuity ranges from 20/20 to light perception only. The eye is not inflamed, and the clue to diagnosis is the inability to see fundal details clearly despite the presence of a clear lens. Causes of vitreous hemorrhage include diabetic retinopathy, retinal tears (with or without detachment), retinal vein occlusions, exudative age-related macular degeneration, blood dyscrasias, trauma, and subarachnoid hemorrhage. In all cases, examination by an ophthalmologist is essential. Retinal tears and detachments necessitate urgent treatment (see above).

AGE-RELATED MACULAR DEGENERATION

Age-related macular degeneration is the leading cause of permanent visual loss in the elderly. The exact cause is unknown, but the incidence increases with each decade over age 50 (to almost 30% by age 75). Other associations besides age include race (usually white), sex (slight female predominance), family history, and a history of cigarette smoking.

Age-related macular degeneration includes a broad spectrum of clinical and pathologic findings that can be classified into two groups: atrophic ("dry") and exudative ("wet"). Although both are progressive and usually bilateral, they differ in manifestations, prognosis, and management. The precursor to age-related macular degeneration is age-related maculopathy, of which the hallmark is the development of retinal drusen. Hard drusen appear ophthalmoscopically as discrete yellow deposits, usually in the macular region. Soft drusen are larger, paler, and less distinct. Large, confluent soft drusen are particularly associated with exudative age-related macular degeneration.

Atrophic degeneration is characterized by gradually progressive bilateral visual loss of moderate severity due to atrophy and degeneration of the outer retina, retinal pigment epithelium, Bruch's membrane, and choriocapillaris. In exudative degeneration, visual loss is of more rapid onset and greater severity, and the two eyes are frequently affected sequentially over a period of a few years. The exudative form accounts for about 90% of all cases of legal blindness due to this disorder. Impairment of the barrier function of Bruch's membrane (between the retinal pigment epithelium and the choriocapillaris) allows serous fluid or blood to leak into the retina to

produce elevation of the retinal pigment epithelium from Bruch's membrane (retinal pigment epithelial detachment) or separation of the neurosensory retina from the retinal pigment epithelium (serous retinal detachment). These changes may resolve spontaneously, with variable visual outcome, but are often associated with neovascularization arising from the choroidal vessels and extending between the retinal pigment epithelium and Bruch's membrane (subretinal neovascular membrane). This membrane produces permanent visual loss.

Sudden visual loss in patients with exudative age-related macular degeneration occurs at the time of pigment epithelial or sensory retinal detachment or hemorrhage from a subretinal neovascular membrane. All these changes may occur in previously undiagnosed patients, in patients known to have atrophic changes, and in the other eye of patients with exudative disease. Laser photocoagulation of subretinal neovascular membranes may delay the onset of permanent visual loss but only when the membrane is far enough away from the fovea to permit such treatment. Conventional laser photocoagulation of subfoveal neovascular membranes is associated with an inevitable immediate reduction in vision because of associated retinal damage. Photodynamic laser therapy (PDT) involves the intravenous injection of verteporfin activated by subsequent laser irradiation to produce cytotoxic derivatives, resulting in selective vascular damage. This limits visual loss, but repeated treatments are necessary and the cost is high. Various surgical techniques to excise subfoveal neovascular membranes—or to reposition the macula away from them—continue to be investigated. Radiotherapy for subretinal neovascular membranes is ineffective. Older patients developing sudden visual loss due to macular disease—particularly paracentral distortion or scotoma with preservation of central acuity—should be referred urgently to an ophthalmologist for assessment.

There is no specific treatment for atrophic age-related macular degeneration, but—as with the exudative form—patients often benefit from low vision aids. The disorder results in loss of central vision only. Peripheral fields and hence navigational vision are always maintained, though these may become impaired by cataract formation for which surgery may be helpful. The value of oral antioxidants and zinc in preventing visual loss in age-related macular degeneration continues to be assessed.

CENTRAL & BRANCH RETINAL VEIN OCCLUSIONS

The severity of visual loss in central retinal vein occlusion is variable. The visual impairment is commonly first noticed upon waking. Ophthalmoscopic signs include disk swelling, venous dilation and tortuosity, retinal hemorrhages, and cotton-wool spots.

In those with initially good acuity (20/60 or better), the visual prognosis is good. With poor initial acuity (20/200 or worse), extensive hemorrhages and multiple cotton-wool spots indicate widespread retinal ischemia, which can be confirmed by demonstrating extensive areas of capillary closure on fluorescein angiography. These eyes are at high risk of developing neovascular (rubeotic) glaucoma, typically within 3 months after venous occlusion, and should be monitored by an ophthalmologist so that laser panretinal photocoagulation can be undertaken if it occurs. Visual prognosis in such cases is poor. Improvement in vision has been reported in central retinal vein occlusion after direct injection of tissue plasminogen activator into the retinal venous system and incision of the sclera at the edge of the optic disk (radial optic neurotomy).

Branch retinal vein occlusions may present in a variety of ways. Sudden loss of vision may occur at the time of occlusion if the fovea is involved or some time afterward from vitreous hemorrhage due to retinal new vessels. More gradual visual loss may occur with development of macular edema or exudate. In a significant proportion, the occlusion is noted incidentally.

In acute branch retinal vein occlusion there are signs similar to those of central retinal vein occlusion but affecting only the retina drained by the obstructed vein. There is no specific treatment, but if retinal neovascularization develops, the affected area should be laser-photocoagulated. Macular edema may also respond to laser treatment.

All patients with retinal vein occlusion should be referred urgently to an ophthalmologist. In younger patients, an assessment for inherited coagulation defects is indicated. Hyperhomocystinemia and antiphospholipid antibodies may also be risk factors. Hyperviscosity syndromes are rarely associated with retinal vein occlusions but may worsen their prognosis. Branch retinal vein occlusion is an important feature of Behcet's syndrome.

CENTRAL & BRANCH RETINAL ARTERY OCCLUSIONS

Central retinal artery occlusion presents as sudden profound visual loss. Visual acuity is reduced to counting fingers or worse, and visual field is restricted to an island of vision in the temporal field. Ophthalmoscopy reveals pallid swelling of the retina, most obvious in the posterior segment, with a cherry-red spot at the fovea. The retinal arteries are attenuated, and "box-car" segmentation of blood in the veins may be seen. Occasionally, emboli are seen in the central retinal artery or its branches. The retinal swelling subsides over a period of 4-6 weeks, leaving a relatively normal retinal appearance but a pale optic disk and attenuated arterioles.

The patient is referred emergently to an ophthalmologist. If seen within a few hours after onset, emergency treatment—including laying the patient flat, ocular massage, high concentrations of inhaled oxygen, intravenous acetazolamide, and anterior chamber paracentesis—may influence the visual outcome. Thrombolysis, particularly by local intra-arterial injection but also intravenously, may improve overall outcome.

The main management problem is identifying any treatable underlying disorder. Giant cell arteritis must be excluded in all older patients, especially because of the risk—highest in the first few days—of involvement of the other eye. If giant cell arteritis is suspected, one should institute high-dose corticosteroids immediately and proceed promptly to temporal artery biopsy. Carotid and cardiac sources of emboli must also be considered in retinal artery occlusion and appropriate treatment given to reduce the risk of stroke (see [Chapter 12](#)). Internal carotid artery dissection should be considered when central retinal artery occlusion is associated with head or neck pain.

Branch retinal artery occlusion may also present with sudden loss of vision if the fovea is involved, but more commonly sudden loss of visual field is the presenting complaint. Fundal signs of retinal swelling and adjacent cotton-wool spots are limited to the area of retina supplied by the occluded vessel. Embolic causes are proportionately more common than in central retinal artery occlusion. Migraine, oral contraceptives, and vasculitis must also be considered. Congenital or acquired thrombophilia has been identified in patients with central and branch retinal artery occlusions. Patients with branch retinal artery occlusions should be referred urgently to an ophthalmologist.

AMAUROSIS FUGAX

Amaurosis fugax ("fleeting blindness") is usually caused by retinal emboli from ipsilateral carotid disease. The visual loss is usually described as a curtain passing vertically across the visual field with complete monocular visual loss lasting a few minutes and a similar curtain effect as the episode passes. In order to reduce the risk of stroke, patients with high-grade stenosis (70-99%) of the ipsilateral internal carotid artery should be considered for carotid endarterectomy. Patients with medium-grade (30-69%) or low-grade (up to 29%) stenosis are better treated medically with aspirin or other antiplatelet drugs. The most reliable method of evaluating carotid stenosis is intra-arterial angiography, but this is associated with a number of complications including stroke. The noninvasive techniques of duplex ultrasonography and magnetic resonance angiography are suitable screening methods. Emboli from cardiac sources may also be responsible for amaurosis fugax. Electrocardiography should be performed in all cases, particularly to identify atrial fibrillation. Echocardiography should be undertaken in young patients and in any patient with clinical evidence of a potential cardiac source of emboli. In younger patients without carotid or cardiac disease, amaurosis fugax may be due to choroidal or retinal vascular spasm, in which case calcium channel blockers such as slow-release nifedipine, 60 mg/d, appear to be effective. Antiphospholipid syndrome should be excluded.

Similar obscurations of vision may occur with poor ocular perfusion due to severe occlusive carotid disease or to aortic dissection. More transient episodes (lasting only a few seconds to 1 minute) affecting both eyes occur in patients with raised intracranial pressure. In all cases of episodic visual loss, early ophthalmologic consultation is advisable.

Donders RC: Clinical features of transient monocular blindness and the likelihood of atherosclerotic lesions of the internal carotid artery. J Neurol Neurosurg Psychiatry 2001;71:247. [\[PMID: 11459904\]](#)

RETINAL DISORDERS ASSOCIATED WITH SYSTEMIC DISEASES

Many systemic diseases are associated with retinal manifestations. These include diabetes mellitus, essential hypertension, preeclampsia-eclampsia of pregnancy, blood dyscrasias, and AIDS. The retinal changes caused by these disorders can be easily observed with an ophthalmoscope.

Diabetic Retinopathy

Diabetic retinopathy is the leading cause of new blindness among US adults aged 20-65. It is broadly classified as nonproliferative or proliferative.

Nonproliferative retinopathy shows dilation of veins, microaneurysms, retinal hemorrhages, retinal edema, and hard exudates. A major subgroup are those patients in whom visual loss develops owing to edema, exudates, or ischemia at the macula (diabetic maculopathy). This is the most common cause of legal blindness in maturity-onset diabetes.

Proliferative retinopathy is characterized by neovascularization, arising either from the optic disk or the major vascular arcades. Vitreous hemorrhage is a common sequela. Proliferation into the vitreous of blood vessels, with their associated fibrous component, leads to tractional retinal detachment. Without treatment, the visual prognosis with proliferative retinopathy is generally much worse than that with nonproliferative retinopathy. Severe proliferative retinopathy is often complicated by maculopathy.

Nonproliferative retinopathy is occasionally present at the time of diagnosis in type 2 diabetes. Treatment includes optimizing control of blood glucose and any associated hypertension or hyperlipidemia. Institution of intensive insulin therapy can be associated with temporary exacerbation of retinopathy, with multiple cotton-wool spots. Laser photocoagulation is helpful in the treatment of focal macular edema but may also be used when there is diffuse macular edema. The presence of macular edema can be detected only by stereoscopic examination of the retina or by fluorescein angiography. The level of visual acuity is a poor guide to the presence of treatable maculopathy—hence the need for regular ophthalmologic follow-up.

Proliferative retinopathy must be recognized early and treated by panretinal laser photocoagulation to prevent blindness. Neovascularization is all too often diagnosed only at the time of vitreous hemorrhage. In some patients, a "preproliferative" retinopathy may be identified. Whether panretinal laser photocoagulation should be undertaken at this time can be determined by the degree of retinal ischemia as assessed by fluorescein angiography.

Surgical treatment (vitrectomy) is being used increasingly either to remove vitreous hemorrhage and thus allow perioperative panretinal laser photocoagulation for the underlying retinal neovascularization, to deal with retinal detachments involving the macula, to manage rapidly progressive proliferative disease, or to treat persistent macular edema.

Patients with diabetes should have yearly ophthalmoscopic examination through dilated pupils. Examination by an ophthalmologist is advisable in type 1 diabetes of more than 5 years' duration; at the time of diagnosis in type 2 diabetes; in early pregnancy, prior to conception in women contemplating pregnancy, and every 4-8 weeks throughout pregnancy; if ocular symptoms develop; or if there are suspicious findings of retinopathy, especially neovascularization or macular exudates. Failure to diagnose diabetic retinopathy by ophthalmoscopic examination is common, particularly if the pupils are not dilated. The severity of diabetic retinopathy can be lessened by control of blood glucose levels, but good diabetic control is more important in preventing the development of retinopathy than in influencing its subsequent course. Proliferative diabetic retinopathy, especially after successful laser treatment, is not a contraindication to treatment with thrombolytic agents, aspirin, or warfarin unless there has been recent vitreous or preretinal hemorrhage.

Hypertensive Retinopathy

Systemic hypertension affects both the retinal and choroidal circulations. The clinical manifestations vary according to the degree and rapidity of rise in blood pressure and the underlying state of the ocular circulation. The most florid disease occurs in young patients with abrupt elevations of blood pressure, such as may occur in pheochromocytoma, malignant hypertension, or preeclampsia-eclampsia.

Chronic hypertension accelerates the development of atherosclerosis. The retinal arterioles become more tortuous and narrow and develop abnormal light reflexes ("silver-wiring" and "copper-wiring"). There is increased venous compression at the retinal arteriovenous crossings ("arteriovenous nicking"), an important factor predisposing to branch retinal vein occlusions. Flame-shaped hemorrhages occur in the nerve fiber layer of the retina.

Acute elevations of blood pressure result in loss of autoregulation in the retinal circulation, leading to the breakdown of endothelial integrity and occlusion of precapillary arterioles and capillaries. These pathologic changes are manifested as cotton-wool spots, retinal hemorrhages, retinal edema, and retinal exudates, often in a stellate appearance at the macula. In the choroid, vasoconstriction and ischemia result in serous retinal detachments and retinal pigment epithelial infarcts. These infarcts later develop into pigmented lesions that may be focal, linear, or wedge-shaped. The abnormalities in the choroidal circulation may also affect the optic nerve head, producing ischemic optic neuropathy with optic disk swelling. Malignant hypertensive retinopathy was the term previously used to describe the constellation of clinical signs resulting from the combination of abnormalities in the retinal, choroidal, and optic disk circulation. When there is such severe disease, there is likely to be permanent retinal, choroidal, or optic nerve damage. Precipitous reduction of blood pressure may exacerbate such damage.

Chatterjee S et al: Hypertension and the eye: changing perspectives. J Hum Hypertens 2002;16:667. [\[PMID: 12420190\]](#)

Blood Dyscrasias

In conditions characterized by thrombocytopenia or severe anemia, various types of hemorrhages occur in both the retina and choroid and may lead to visual loss. If macular hemorrhages have not occurred, it is possible to regain normal vision with treatment.

Proliferative retinopathy (sickle cell retinopathy) is particularly common in hemoglobin SC disease but may also occur with other hemoglobin S variants. Severe visual loss is rare. Retinal photocoagulation reduces the frequency of vitreous hemorrhage. Surgery is occasionally needed for unresolving vitreous hemorrhage or tractional retinal detachment.

AIDS

Cotton-wool spots, retinal hemorrhages, and microaneurysms are the most common ophthalmic abnormalities in AIDS patients.

Cytomegalovirus retinitis occurs when CD4 counts are below 50/uL. It is characterized by progressively enlarging yellowish-white patches of retinal opacification, which are accompanied by retinal hemorrhages; they usually begin adjacent to the major retinal vascular arcades. Patients are often asymptomatic until there is involvement of the fovea or optic nerve or until retinal detachment develops.

The commonly used agents are intravenous or intravitreal ganciclovir, foscarnet, and cidofovir, which has the significant advantage of a prolonged intracellular half-life such that no more than weekly administration is required. Major side effects are neutropenia with systemic ganciclovir and nephrotoxicity with foscarnet and cidofovir. Dosage of both ganciclovir and foscarnet is adjusted in renal failure. Oral probenecid and intravenous hydration are used to minimize nephrotoxicity from cidofovir. Oral valganciclovir and intravitreal fomivirsen are also effective. All the available agents are virostatic. Reactivation of disease and therefore eventually complete loss of vision can only be delayed rather than prevented.

Initial therapy is as follows: (1) intravenous—ganciclovir 5 mg/kg twice a day, foscarnet 60 mg/kg three times a day, or cidofovir 5 mg/kg once weekly, usually for 2 weeks; (2) oral—valganciclovir 900 mg twice daily; or (3) by local administration, using either intravitreal injection of ganciclovir, foscarnet, or fomivirsen or the sustained-release ganciclovir intravitreal implant. Intravitreal cidofovir is effective, but there is a high incidence of uveitis, low intraocular pressure, and ciliary body necrosis. Maintenance therapy can be conducted with lower-dose intravenous therapy (ganciclovir 3.75 mg/kg/d or foscarnet 60 mg/kg/d for 5 days each week, or cidofovir 5 mg/kg once every 2 weeks), with oral ganciclovir (3 g/d) or oral valganciclovir 900 mg once daily, or with intravitreal therapy. Local therapy tends to be more effective than systemic therapy and avoids systemic side effects, but there is a risk of intraocular complications, and the incidence of retinitis in the fellow eye and that of extraocular cytomegalovirus infection are higher. Unresponsive disease or reactivation during maintenance therapy can be managed by changing to a different agent or by use of combination therapy. Retinal detachment, either due to retinitis or as a complication of intravitreal therapy, requires vitrectomy and intravitreal silicone oil. Oral ganciclovir as prophylaxis against cytomegalovirus retinitis in patients with low CD4 counts or high CMV burdens has not been found to be worthwhile.

Antiretroviral therapy may result in reduction of HIV virus load and increase in CD4 counts, and even regression of CMV retinitis without the use of anticytomegalovirus therapy. If the CD4 count is maintained above 100/uL, it may be possible to discontinue maintenance anticytomegalovirus therapy. Highly active antiretroviral therapy (HAART) occasionally leads to "immune recovery" uveitis, which may lead to visual loss.

Other opportunistic ophthalmic infections occurring in AIDS patients include herpes simplex retinitis, toxoplasmic and candidal chorioretinitis, and herpes zoster ophthalmicus. Kaposi's sarcoma of the conjunctiva and orbital lymphoma may also be seen on rare occasions.

ANTERIOR ISCHEMIC OPTIC NEUROPATHY

Anterior ischemic optic neuropathy—due to inadequate perfusion of the posterior ciliary arteries that supply the anterior portion of the optic nerve—produces sudden visual loss, usually with an altitudinal field defect, and optic disk swelling. In older patients, it is often caused by giant cell arteritis, which necessitates high-dose systemic steroid treatment to prevent visual loss in the fellow eye. (See Central and Branch Retinal Artery Occlusions, above.) The predominant factor predisposing to nonarteritic anterior ischemic optic neuropathy is congenitally small optic disks. Other causative factors include systemic hypertension, diabetes, systemic vasculitis, and inherited coagulation defects or prothrombotic states. Anterior ischemic optic neuropathy has also been reported after ingestion of sildenafil.

Newman NJ et al: The Ischemic Optic Neuropathy Decompression Trial Research Group. The fellow eye in NAION: report from the ischemic optic neuropathy decompression trial follow-up study. Am J Ophthalmol 2002;134:317. [\[PMID: 12208242\]](#)

Pomeranz HD et al: Sildenafil-associated nonarteritic anterior ischemic optic neuropathy. Ophthalmology 2002;109:584. [\[PMID: 11874765\]](#)

OPTIC NEURITIS

Optic neuritis is characterized by unilateral loss of vision, which usually develops over a few days. Vision ranges from 20/30 to no perception of light. Commonly there is pain in the region of the eye, particularly on eye movements. Field loss is usually a central scotoma, but a wide range of monocular field defects are possible. There is marked loss of color vision and a relative afferent pupillary defect. In about two-thirds of cases, the optic nerve is normal during the acute stage (retrobulbar optic neuritis). In the remainder, the optic disk is swollen (papillitis) with occasional flame-shaped peripapillary hemorrhages. Visual acuity usually improves within 2-3 weeks and returns to 6/12 or better in 95% of previously unaffected eyes. In all cases, optic atrophy subsequently develops if there has been destruction of sufficient optic nerve fibers.

Optic neuritis is strongly associated with demyelinating disease, occurring in patients known to have multiple sclerosis during recurrence and as a first manifestation of the disease in others. Among patients with clinically isolated optic neuritis, about 60% will develop multiple sclerosis within 40 years. The major risk factors are female gender, multiple white matter lesions on brain MRI, and cerebrospinal fluid oligoclonal bands. In demyelinating optic neuritis, systemic steroid therapy accelerates visual recovery. Use in an individual patient is determined by the degree of visual loss, the state of the fellow eye, and the patient's visual requirements. In patients with a first episode of optic neuritis and multiple cerebral white matter lesions, long-term interferon therapy reduces the risk of subsequent development of multiple sclerosis by 25% at 2-3 years.

Optic neuritis also occurs with viral infections (including measles, mumps, influenza, and those caused by the varicella-zoster virus), with various autoimmune disorders, particularly systemic lupus erythematosus, and by spread of inflammation from meninges, orbital tissues, or paranasal sinuses.

Optic neuritis due to herpes zoster or systemic lupus erythematosus generally has a poorer prognosis and requires high-dose intravenous corticosteroid therapy. All patients with optic neuritis should be referred urgently for neuro-ophthalmologic assessment. Any patient with isolated optic neuritis in which visual recovery does not occur requires exclusion of a compressive lesion or an intrinsic optic nerve tumor.

Interferon beta-1a for optic neuritis patients at high risk for multiple sclerosis. Am J Ophthalmol 2001;132:463. [\[PMID: 11589865\]](#)

OPTIC DISK SWELLING

Optic disk swelling may result from intraocular disease, orbital and optic nerve lesions, severe hypertensive retinopathology, or raised intracranial pressure. Intraocular causes include central retinal vein occlusion, posterior uveitis, and posterior scleritis. Optic nerve lesions causing disk swelling include optic neuritis; anterior ischemic optic neuropathy; optic disk drusen (pseudopapilledema); optic nerve sheath meningioma; and nerve infiltration by sarcoidosis, leukemia, or lymphoma. Any orbital lesion causing nerve compression may produce disk swelling.

Papilledema (optic disk swelling due to raised intracranial pressure) is usually bilateral and most commonly produces enlargement of the blind spot without loss of acuity. Chronic papilledema, as in idiopathic intracranial hypertension and dural venous sinus occlusion, may be associated with progressive visual field loss and occasionally with profound loss of acuity. All patients with chronic papilledema must be monitored carefully—especially their visual fields—and optic nerve sheath fenestration or lumboperitoneal shunt is considered in those with progressive visual failure not controlled by medical therapy (weight loss where appropriate and acetazolamide).

Optic disk drusen are a possibility when disk swelling is not associated with any visual disturbance or symptoms of raised intracranial pressure. Exposed optic disk drusen may be obvious clinically or can be demonstrated by their autofluorescence. Buried drusen are best detected by orbital ultrasound or CT scanning. Other family members may be similarly affected.

OCULAR MOTOR PALSIES

In complete **third nerve paralysis**, there is ptosis with a divergent and slightly depressed eye. Extraocular movements are restricted in all directions except laterally (preserved lateral rectus function). Intact fourth nerve (superior oblique) function is detected by the presence of inward rotation on attempted depression of the eye.

Pupillary involvement (dilated pupil that does not react to accommodation or to light shone in either eye) is an important sign differentiating "surgical" from "medical" causes of isolated third nerve palsy. Compressive lesions of the third nerve—eg, aneurysm of the posterior communicating artery and uncus herniation due to a supratentorial mass lesion—characteristically have pupillary involvement. Patients with painful isolated third nerve palsy and pupillary involvement are assumed to have a posterior communicating artery aneurysm until this has been excluded. Medical causes of isolated third nerve palsy include diabetes, hypertension, syphilis, and giant cell arteritis.

Fourth nerve paralysis causes upward deviation of the eye with failure of depression on adduction. There is vertical diplopia that becomes most apparent on attempted reading and descending stairs. Many cases of isolated fourth nerve palsy are due to a congenital lesion. Trauma is a major cause of acquired—particularly bilateral—fourth nerve palsy, but cerebral neoplasms and medical causes such as in third nerve palsies should also be considered.

Sixth nerve paralysis causes convergent squint in the primary position with failure of abduction of the affected eye, producing horizontal diplopia that increases on gaze to the affected side and on looking into the distance. It is an important sign of raised intracranial pressure. Sixth nerve palsy may also be due to trauma, neoplasms, brain stem lesions, or medical causes.

An intracranial or intraorbital mass lesion should be considered in any patient with an isolated ocular motor palsy. In patients with isolated ocular motor nerve palsies presumed to be due to medical causes, brain MRI is performed if recovery has not begun within 3 months.

Ocular motor nerve palsies occurring in association with other neurologic signs may be due to lesions in the brain stem, the cavernous sinus, or in the orbit. Lesions around the cavernous sinus involve the upper divisions of the trigeminal nerve, the ocular motor nerves, and occasionally the optic chiasm. Orbital apex lesions involve the optic nerve and the ocular motor nerves.

Myasthenia and dysthyroid eye disease must always be considered in the differential diagnosis of disordered extraocular movements.

Lee AG et al: The evaluation of isolated third nerve palsy revisited: an update on the evolving role of magnetic resonance, computed tomography, and catheter angiography. *Surv Ophthalmol* 2002;47:137. [\[PMID: 11918895\]](#)

Peters GB 3rd et al: Cause and prognosis of nontraumatic sixth nerve palsies in young adults. *Ophthalmology* 2002; 109:1925. [\[PMID: 12359616\]](#)

DYSTHYROID EYE DISEASE

Dysthyroid eye disease is a clinical syndrome caused by deposition of mucopolysaccharides and infiltration with chronic inflammatory cells of the orbital tissues, particularly the extraocular muscles. Patients may have clinical or laboratory evidence of thyroid dysfunction, elevated thyroid autoantibodies, or no detectable abnormality outside the orbit. Radioiodine therapy and cigarette smoking increase its severity.

The primary clinical features are proptosis, lid retraction and lid lag, conjunctival chemosis and episcleral inflammation, and extraocular muscle abnormalities due to restriction of their actions. Resulting symptoms are cosmetic abnormalities, surface irritation, which usually responds to artificial tears, and diplopia, which should be treated conservatively (eg, with prisms) in the active stages of the disease and only by surgery when the disease has been static for at least 6 months.

The important complications are corneal exposure and optic nerve compression, both of which may lead to marked visual loss. Treatment is by urgent orbital decompression, either medically, with high-dose systemic steroids (prednisolone 80-100 mg/d)—although this is often of only short-term benefit—by radiotherapy, or by surgery, usually consisting of extensive removal of bone from the medial, inferior, and lateral walls of the orbit.

The optimal management of moderately severe dysthyroid eye disease without visual loss is controversial. Steroids and radiotherapy do not provide definite long-term benefit. Surgical decompression may be justified in patients with marked proptosis. Lateral tarsorrhaphy may be used for moderately severe corneal exposure. Other procedures are particularly useful for correcting lid retraction but should not be undertaken until the orbital disease is quiescent and orbital decompression or extraocular muscle surgery has been undertaken.

Gorman CA et al: The aftermath of orbital radiotherapy for Graves' ophthalmopathy. *Ophthalmology* 2002;109:2100. [\[PMID: 12414422\]](#)

ORBITAL CELLULITIS

Orbital cellulitis is manifested by an abrupt onset of fever, proptosis, restriction of extraocular movements, and swelling with redness of the lids. Infection of the paranasal sinuses is the usual underlying cause. Immediate treatment with intravenous antibiotics is necessary to prevent optic nerve damage and spread of infection to the cavernous sinuses, meninges, and brain. The response to antibiotics is usually excellent, but abscess formation may necessitate surgical drainage.

OCULAR TRAUMA

Conjunctival & Corneal Foreign Bodies

If a patient complains of "something in my eye" and gives a consistent history, a foreign body is usually present on the cornea or under the upper lid even though it may not be visible. Visual acuity should be tested before treatment is instituted, as a basis for comparison in the event of complications.

After a local anesthetic (eg, proparacaine, 0.5%) is instilled, the eye is examined with a hand flashlight, using oblique illumination, and loupe. Corneal foreign bodies may be made more apparent by the instillation of sterile fluorescein. They are then removed with a sterile wet cotton-tipped applicator. Polymyxin-bacitracin ophthalmic ointment should be instilled. It is not necessary to patch the eye, but the patient must be examined 24 hours later for secondary infection of the crater. If a corneal foreign body cannot be removed in this manner, the patient should be referred to an ophthalmologist.

Steel foreign bodies usually leave a diffuse rust ring. This requires excision of the affected tissue and is best done under local anesthesia using a slit lamp. **Caution:** Anesthetic drops should not be given to the patient for self-administration.

If there is no infection, a layer of corneal epithelial cells will line the crater within 24 hours. The intact corneal epithelium forms an effective barrier to infection, but once it is disturbed the cornea becomes extremely susceptible to infection. Early infection is manifested by a white necrotic area around the crater and a small amount of gray exudate. These patients are referred immediately to an ophthalmologist; untreated corneal infection may lead to loss of the eye.

In the case of a foreign body under the upper lid, a local anesthetic is instilled and the lid is everted by grasping the lashes gently and exerting pressure on the mid portion of the outer surface of the upper lid with an applicator. If a foreign body is present, it can easily be removed by passing a wet sterile cotton-tipped applicator across the conjunctival surface.

Intraocular Foreign Body

An intraocular foreign body requires emergency treatment by an ophthalmologist. Patients giving a history of "something hitting the eye"—particularly while hammering on metal or using grinding equipment—must be assessed for this possibility, especially when no corneal foreign body is seen, a corneal or scleral wound is apparent, or there is marked visual loss or media opacity. Such patients must be treated as for corneal laceration (see below) and referred without delay. Intraocular foreign bodies significantly increase the risk of intraocular infection.

Corneal Abrasions

A patient with a corneal abrasion complains of severe pain and photophobia. There is often a history of trauma to the eye, commonly involving a fingernail, piece of paper, or contact lens. Visual acuity is recorded, and the cornea and conjunctiva are examined with a light and loupe to rule out a foreign body. If an abrasion is suspected but cannot be seen, sterile fluorescein is instilled into the conjunctival sac: the area of corneal abrasion will stain a deeper green than the surrounding cornea.

Treatment includes polymyxin-bacitracin ophthalmic ointment and application of a bandage with firm pressure to prevent movement of the lid. The patient should rest at home, keeping the fellow eye closed, and should be observed the following day to be certain the cornea has healed. Recurrent corneal erosion may follow corneal

abrasions.

Contusions

Contusion injuries of the eye and surrounding structures may cause ecchymosis ("black eye"), subconjunctival hemorrhage, edema or rupture of the cornea, hemorrhage into the anterior chamber (hyphema), rupture of the root of the iris (iridodialysis), paralysis of the pupillary sphincter, paralysis of the muscles of accommodation, cataract, dislocation of the lens, vitreous hemorrhage, retinal hemorrhage and edema (most common in the macular area), detachment of the retina, rupture of the choroid, fracture of the orbital floor ("blowout fracture"), or optic nerve injury. Many of these injuries are immediately obvious; others may not become apparent for days or weeks. Patients with moderate to severe contusions should be seen by an ophthalmologist.

Any injury causing hyphema involves the danger of secondary hemorrhage, which may cause intractable glaucoma with permanent visual loss. Any patient with traumatic hyphema should be advised to rest until complete resolution has occurred. Daily ophthalmologic assessment is essential. Aspirin and any drugs inhibiting coagulation increase the risk of secondary hemorrhage and are to be avoided.

Burnstine MA: Clinical recommendations for repair of isolated orbital floor fractures: an evidence-based analysis. Ophthalmology 2002;109:1207. [\[PMID: 12093637\]](#)

Lacerations

A. Lids

If the lid margin is lacerated, the patient should be referred for specialized care, since permanent notching may result. Lacerations of the lower eyelid near the inner canthus often sever the lower canaliculus. Lid lacerations not involving the margin may be sutured like any skin laceration.

B. Conjunctiva

In lacerations of the conjunctiva, sutures are not necessary. In order to prevent infection, sulfonamides or other antibiotics are instilled into the eye until the laceration is healed.

C. Cornea or Sclera

Patients with suspected corneal or scleral lacerations must be seen promptly by an ophthalmologist. Manipulation is kept to a minimum, since pressure may result in extrusion of the intraocular contents. The eye is bandaged lightly and covered with a metal shield that rests on the orbital bones above and below. The patient should be instructed not to squeeze the eye shut and to remain still. The eye is routinely studied by x-ray, and CT scanning if necessary, to identify and localize any metallic intraocular foreign body. MRI is contraindicated owing to the risk of movement of the foreign body in the magnetic field.

ULTRAVIOLET KERATITIS (ACTINIC KERATITIS)

Ultraviolet burns of the cornea are usually caused by use of a sunlamp without eye protection, exposure to a welding arc, or exposure to the sun when skiing ("snow blindness"). There are no immediate symptoms, but about 6-12 hours later the patient complains of agonizing pain and severe photophobia. Slit-lamp examination after instillation of sterile fluorescein shows diffuse punctate staining of both corneas.

Treatment consists of binocular patching and instillation of 1-2 drops of 1% cyclopentolate (to relieve the discomfort of ciliary spasm). All patients recover within 24-48 hours without complications. Local anesthetics should not be prescribed.

Chemical Conjunctivitis & Keratitis

Chemical burns are treated by irrigation of the eyes with saline solution or plain water as soon as possible after exposure. Neutralization of an acid with an alkali or vice versa generates heat and may cause further damage. Alkali injuries are more serious and require prolonged irrigation, since alkalies are not precipitated by the proteins of the eye as are acids. It is important to remove any retained particulate matter such as is typically present in injuries involving cement and building plaster. This may require double eversion of the upper lid. The pupil should be dilated with 1% cyclopentolate, 1 drop twice a day, to relieve discomfort, and prophylactic topical antibiotics should be started. In moderate to severe injuries, intensive topical corticosteroids and topical and systemic vitamin C are also necessary. Complications include mucus deficiency, scarring of the cornea and conjunctiva, symblepharon (adhesions between the tarsal and bulbar conjunctiva), tear duct obstruction, and secondary infection.

PRINCIPLES OF TREATMENT OF OCULAR INFECTIONS

Before one can determine the drug of choice for treatment of ocular infection, the causative organisms must be identified, but in most instances empirical treatment is used in the first instance. In the treatment of conjunctivitis and for prophylaxis against ocular infection, it is preferable to use a drug that is not given systemically. Of the available local antibacterial agents, the sulfonamides are effective and inexpensive; sulfisoxazole and sodium sulfacetamide are examples. The sulfonamides have the added advantages of low allergenicity and effectiveness against the chlamydial group of organisms. They are available in ointment or solution form. Combined bacitracin-polymyxin ointment is often used prophylactically after corneal foreign body removal for the protection it affords against both gram-positive and gram-negative organisms.

Among the most effective broad-spectrum antibiotics for ophthalmic use are gentamicin, tobramycin, neomycin, and ciprofloxacin. These drugs have some effect against gram-negative as well as gram-positive organisms but are generally not effective against the pneumococcus, for which penicillin G or nafcillin (if beta-lactamase resistance is present) is required. Allergic reactions to neomycin are common. Other antibiotics frequently used are erythromycin, the tetracyclines, and the cephalosporins.

Method of Administration

Most ocular anti-infective drugs are administered locally. Ointments have greater therapeutic effectiveness than solutions, since contact can be maintained longer. However, they do cause blurring of vision; if this must be avoided, solutions should be used.

Systemic administration is required for all intraocular infections, orbital cellulitis, dacryocystitis, gonococcal keratoconjunctivitis, inclusion conjunctivitis, and severe external infection that does not respond to local treatment.

TECHNIQUES USED IN THE TREATMENT OF OCULAR DISORDERS

[Table 7-2](#) lists commonly used ophthalmic drugs and their indications and costs.

Instilling Medications

The patient is placed in a chair with head tilted back, both eyes open, and looking up. The lower lid is retracted slightly, and 2 drops of liquid are instilled into the lower cul-de-sac. The patient looks down while finger contact is maintained, so that the eyes are not squeezed shut. Ointments are instilled in the same general manner.

For self-medication, the same techniques are used except that medications are usually better instilled with the patient lying down.

Eye Bandage

Most eye bandages should be applied firmly enough to hold the lid securely against the cornea. An ordinary patch consisting of gauze-covered cotton is usually sufficient. Tape is applied from the cheek to the forehead.

Eyelid Taping

Eyelid taping, such as for corneal protection in facial palsy, is best achieved with 1-inch width transparent plastic adhesive tape (eg, Transpore or even Sellotape) placed horizontally over the closed eyelids from the side of the nose to the temple.

PRECAUTIONS IN MANAGEMENT OF OCULAR DISORDERS

Use of Local Anesthetics

Unsupervised self-administration of local anesthetics is dangerous because the patient may further injure an anesthetized eye without knowing it. The drug may also interfere with the normal healing process.

Pharmakakis NM et al: Corneal complications following abuse of topical anesthetics. Eur J Ophthalmol 2002;12:373. [PMID: 12474918]

Pupillary Dilation

Dilating the pupil can very occasionally precipitate acute glaucoma if the patient has a narrow anterior chamber angle and should be undertaken with caution if the anterior chamber is obviously shallow (readily determined by oblique illumination of the anterior segment of the eye). A short-acting mydriatic such as tropicamide should be used and the patient warned to report immediately if ocular discomfort or redness develops. Angle closure is more likely to occur if pilocarpine is used to overcome pupillary dilation than if the pupil is allowed to constrict naturally.

Pandit RJ et al: Mydriasis and glaucoma: exploding the myth. A systematic review. Diabet Med 2000;17:693. [PMID: 11110501]

Local Corticosteroid Therapy

Repeated use of local corticosteroids presents several hazards: herpes simplex (dendritic) keratitis, fungal infection, open-angle glaucoma, and cataract formation. Furthermore, perforation of the cornea may occur when the corticosteroids are used for herpes simplex keratitis.

Contaminated Eye Medications

Ophthalmic solutions are prepared with the same degree of care as fluids intended for intravenous administration, but once bottles are opened there is always a risk of contamination, particularly with solutions of tetracaine, proparacaine, fluorescein, and any preservative-free preparations. The most dangerous is fluorescein, as this solution is frequently contaminated with *P aeruginosa*, which can rapidly destroy the eye. Sterile fluorescein filter paper strips are now available and are recommended for use in place of fluorescein solutions.

Whether in plastic or glass containers, eye solutions should not remain in use for long periods after the bottle is opened. Four weeks after opening is an absolute maximal time to use a solution containing preservatives before discarding. Preservative-free preparations should be kept refrigerated and discarded within 1 week after opening.

If the eye has been injured accidentally or by surgical trauma, it is of the greatest importance to use freshly opened bottles of sterile medications or single-use eyedropper units.

Uchio E et al: Adenovirus detected by polymerase chain reaction in multidose eyedrop bottles used by patients with adenoviral keratoconjunctivitis. Am J Ophthalmol 2002;134:618. [PMID: 12383829]

Toxic & Hypersensitivity Reactions to Topical Therapy

Patients receiving long-term topical therapy may develop local toxic or hypersensitivity reactions to the active agent or preservatives, especially if there is inadequate tear secretion. Preservatives in contact lens cleaning solutions may produce similar problems. Burning and soreness are exacerbated by drop instillation or contact lens insertion; occasionally, fibrosis and scarring of the conjunctiva and cornea may occur.

An antibiotic instilled into the eye can sensitize the patient to that drug and cause an allergic reaction upon subsequent systemic administration.

Systemic Effects of Ocular Drugs

The systemic absorption of certain topical drugs (through the conjunctival vessels and lacrimal drainage system) must be considered when there is a systemic medical contraindication to the use of the drug. Ophthalmic solutions of the nonselective beta-blockers, eg, timolol, may worsen patients with congestive heart failure or asthma. Atropine ointment should be prescribed for children rather than the drops, since absorption of the 1% topical solution may be toxic. Phenylephrine eye drops may precipitate hypertensive crises and angina. Also to be considered are adverse interactions between systemically administered and ocular drugs. Using only 1 or 2 drops at a time and a few minutes of nasolacrimal occlusion or eyelid closure ensure maximum efficacy and decrease systemic side effects of topical agents.

Fraunfelder FW et al: Adverse systemic effects from pledgets of topical ocular phenylephrine 10%. Am J Ophthalmol 2002;134:624. [PMID: 12383833]

ADVERSE OCULAR EFFECTS OF SYSTEMIC DRUGS

Systemically administered drugs produce a wide variety of adverse effects on the visual system. Table 7-3 lists the major examples.

Flach AJ, Fraunfelder FW: Ocular and systemic side effects of drugs. In: Vaughan & Asbury's General Ophthalmology, 16th ed. Riordan-Eva P, Whitcher JP (editors). McGraw-Hill, 2004.

Table 7-1. The inflamed eye: Differential diagnosis of common causes.

	Acute Conjunctivitis	Acute Uveitis	Corneal Trauma or Acute Glaucoma ¹	Infection
Incidence	Extremely common	Common	Uncommon	Common
Discharge	Moderate to copious	None	None	Watery or purulent
Vision	No effect on vision	Often blurred	Markedly blurred	Usually blurred
Pain	Mild	Moderate	Severe	Moderate to severe
Conjunctival injection	Diffuse; more toward fornices	Mainly circumcorneal	Mainly circumcorneal	Mainly circumcorneal
Cornea	Clear	Usually clear	Steamy	Clarity change related to cause
Pupil size	Normal	Small	Moderately dilated and fixed	Normal
Pupillary light response	Normal	Poor	None	Normal
Intraocular pressure	Normal	Commonly low but may be elevated	Elevated	Normal
Smear	Causative organisms	No organisms	No organisms	Organisms found only in corneal ulcers due to infection

¹Angle-closure glaucoma.

Table 7-2. Topical ophthalmic agents.

Agent	Representative Cost/Size ¹	Sig	Indications
AGENTS FOR GLAUCOMA AND INTRAOCULAR HYPERTENSION			
Sympathomimetics			
Apraclonidine HCl 0.5% solution (Iopidine)	\$57.60/5 mL	1 drop three times daily	Reduction of intraocular pressure. Expensive. Reserve for treatment of resistant cases.
Apraclonidine HCl 1% solution (Iopidine)	\$9.55/unit dose 0.1 mL	1 drop 1 hour before and immediately after anterior segment laser surgery	To control or prevent elevations of intraocular pressure after laser trabeculoplasty or iridotomy.
Brimonidine tartrate 0.2% solution (Alphagan)	\$36.28/5 mL	1 drop two or three times daily	Reduction of intraocular pressure.
Dipivefrin HCl 0.1% solution (various) ²	\$14.07/5 mL	1 drop every 12 hours	Open-angle glaucoma.
Epinephrine HCl 0.25%, 0.5% (Epifrin), 1% and 2% solution (various) ³	1%: \$49.69/15 mL 2%: \$54.36/15 mL	1 drop twice daily	
Beta-adrenergic blocking agents			
Betaxolol HCl 0.5% solution (Betoptic) and 0.25% suspension (Betoptic S) ⁴	0.5%: \$50.64/10 mL	1 drop twice daily	Reduction of intraocular pressure.
Carteolol HCl 1% solution (Ocupress) ⁵	\$61.72/10 mL	1 drop twice daily	
Levobunolol HCl 0.25% and 0.5% solution (Betagan) ⁵	0.5%: \$32.29/10 mL	1 drop once or twice daily	
Metipranolol HCl 0.3% solution (OptiPranolol) ⁵	\$20.93/5 mL	1 drop twice daily	
Timolol 0.25% and 0.5% solution (Betimol) ⁵	0.5%: \$32.29/10 mL	1 drop once or twice daily	
Timolol maleate 0.25% and 0.5% solution (Timoptic) and 0.25% and 0.5% gel (Timoptic-XE) ⁵	0.5% solution: \$17.00/5 mL 0.5% gel: \$31.50/5 mL	1 drop once or twice daily	
Miotics			
Pilocarpine HCl (various) ⁶ (1-4%, 6%, 8%, 10%)	2%: \$11.80/15 mL	1 drop three or four times daily	Reduction of intraocular pressure, treatment of acute or chronic angle-closure glaucoma, and pupillary constriction.
Pilocarpine HCl 4% gel (Pilopine HS)	\$37.86/4 g	Apply 0.5-inch ribbon in lower conjunctival sac at bedtime. Replace each unit every 7 days.	
Pilocarpine 20 µg/h for 7 days, and 40 µg/h for 7 days ocular therapeutic system (Ocusert Pilo-20 and Ocusert Pilo-40) ⁷	40 µg/h: \$52.65/8 each		
Carbonic anhydrase inhibitor			
Dorzolamide HCl 2% solution (Trusopt)	\$26.94/5 mL \$53.91/10 mL	1 drop three times daily	Reduction of intraocular pressure.
Brinzolamide 1% suspension (Azopt)	\$31.44/5 mL \$62.94/10 mL	1 drop three times daily	
Prostaglandin analogs			
Bimatoprost 0.003% solution (Lumigan)	\$55.79/2.5 mL	1 drop once daily in the evening	Reduction of intraocular pressure.
Latanoprost 0.005% solution (Xalatan)	\$53.38/2.5 mL	1 drop once or twice daily in the evening	
Travoprost 0.004% solution (Travatan)	\$55.75/2.5 mL	1 drop once daily in the evening	
Unoprostone 0.15% solution (Rescula)	\$46.81/5 mL	1 drop twice daily	
ANTI-INFLAMMATORY AGENTS			
Nonsteroidal anti-inflammatory agents⁸			
Diclofenac sodium 0.1% solution (Voltaren)	\$51.79/5 mL	1 drop to affected eye four times daily beginning 24 hours after cataract surgery and continuing through first 2 postoperative weeks.	Treatment of postoperative inflammation following cataract extraction, and laser corneal surgery.
Flurbiprofen sodium 0.03% solution (various)	\$8.73/2.5 mL	1 drop every half hour beginning 2 hours before surgery.	Inhibition of intraoperative miosis. Treatment of cystoid macular edema and inflammation after cataract surgery.
Ketorolac tromethamine 0.5% solution (Acular)	\$56.26/5 mL	1 drop four times daily	Relief of ocular itching due to seasonal allergic conjunctivitis.
Corticosteroids⁹			
Dexamethasone sodium phosphate 0.1% solution (various)	\$16.51/5 mL	1 or 2 drops as often as indicated by severity. Use every hour during the day and every 2 hours during the night in severe inflammation. Taper off as inflammation decreases.	Treatment of steroid-responsive inflammatory conditions of anterior segment.
Dexamethasone sodium phosphate 0.05% ointment (various)	\$6.34/3.5 g	Apply thin coating on lower conjunctival sac three or four times daily.	
Fluorometholone 0.1% suspension (various) ¹⁰	\$26.20/10 mL	1 or 2 drops as often as indicated by severity. Use every hour during the day and every 2 hours during the night in severe inflammation. Taper off as inflammation decreases.	
Fluorometholone 0.25% suspension (FML Forte) ¹⁰	\$37.60/10 mL		
Fluorometholone 0.1% ointment (FML S.O.P.)	\$34.00/3.5 g	Apply thin coating on lower conjunctival sac three or four times daily.	
Medrysone 1% suspension (HMS)	\$33.24/10 mL	1 or 2 drops as often as indicated by severity of inflammation. Use every hour during the day and every 2 hours during the night in severe inflammation. Taper off as inflammation decreases.	
Prednisolone acetate 0.12% suspension (Pred Mild)	\$36.14/10 mL		
Prednisolone acetate 0.125% suspension (various)	\$24.66/5 mL		
Prednisolone sodium phosphate 0.125% solution (various)	\$36.96/10 mL \$18.56/5 mL		
Prednisolone acetate 1% suspension (various)	\$23.10/10 mL		
Prednisolone sodium phosphate 1% solution (various)	\$24.06/10 mL		
Rimexolone 1% suspension (Vexol)	\$25.74/5 mL		
Mast cell stabilizers			
Cromolyn sodium 4% solution (Crolom)	\$37.25/10 mL	1 drop four to six times daily	Allergic conjunctivitis.

Ketotifen fumerate 0.025% solution (Zaditor)	\$46.51/5 mL	1 drop two to four times daily	Allergic conjunctivitis.	
Lodoxamide tromethamine 0.1% solution (Alomide)	\$58.02/10 mL	1 or 2 drops four times daily (up to 3 months)	Vernal keratoconjunctivitis.	
Olopatadine hydrochloride 0.1% solution (Patanol)	\$70.25/5 mL	1 drop twice daily	Allergic conjunctivitis.	\$58.02/10 mL

ANTIBIOTIC OINTMENTS AND SOLUTIONS

Bacitracin 500 units/g ointment (various) ¹¹	\$4.28/3.5 g	Refer to package insert (instructions vary)	Infections involving lid, conjunctiva, or cornea.	
Chloramphenicol 0.5% (5 mg/mL) solution (various) ¹²	\$23.26/7.5 mL		As above, with both gram-positive and gram-negative coverage.	
Chloramphenicol 1% (10 mg/g) ointment (various) ¹²	\$21.55/3.5 g			
Ciprofloxacin HCl (various)	0.3% solution \$44.63/5 mL 0.3% ointment \$50.00/3.5 g			
Erythromycin 0.5% ointment (various) ¹³	\$5.62/3.5 g			
Gentamicin sulfate 0.3% solution (various)	\$8.17/5 mL			
Gentamicin sulfate 0.3% ointment (various)	\$19.67/3.5 g			
Ofloxacin 0.3% solution (Ocuflox)	\$39.55/5 mL			
Polymyxin B sulfate 500,000 units, powder for solution (Polymyxin B Sulfate Sterile) ¹⁴	\$8.64/500,000 units			
Tobramycin 0.3% solution (various)	\$15.00/5 mL			
Tobramycin 0.3% ointment (Tobrex)	\$47.50/3.5 g			

SULFONAMIDES

Sulfacetamide sodium 10% solution (various)	\$5.08/15 mL	1 or 2 drops every 1-3 hours	Conjunctivitis, corneal ulcer, and other superficial ocular infections due to susceptible microorganisms. Used as adjunct to systemic sulfonamide therapy in treatment of trachoma.	
Sulfacetamide sodium 10% ointment (various)	\$8.10/3.5 g	Apply small amount (0.5 inch) into lower conjunctival sac once to four times daily and at bedtime.		

Note: Many combination products containing antibiotics, antibiotics and steroids, or sulfonamides and steroids are available as solutions, suspensions, or ointment.

TOPICAL ANTIFUNGAL AGENTS

Natamycin 5% suspension (Natacyn)	\$131.04/15 mL	1 drop every 1-2 hours.	Fungal blepharitis, conjunctivitis, and keratitis caused by susceptible organisms. Drug of choice for <i>Fusarium solani keratitis</i> .	

TOPICAL ANTIVIRAL AGENTS

Ganciclovir 4.5 mg surgical insert (Vitrasert)	\$5000.00 each	1 implant every 5-8 months	Treatment of CMV retinitis in patients with AIDS.	
Trifluridine 1% solution (Viroptic)	\$99.01/7.5 mL	1 drop onto cornea every 2 hours while awake for a maximum daily dose of 9 drops until resolution occurs. Then an additional 7 days of 1 drop every 4 hours while awake (minimum five times daily)	Primary keratoconjunctivitis and recurrent epithelial keratitis due to HSV types 1 or 2. ¹⁵	
Vidarabine monohydrate 3% ointment (Vira-A)	\$27.05/3.5 g	0.5 inch of ointment into the lower conjunctival sac five times daily at 3-hour intervals.	Acute keratoconjunctivitis and recurrent epithelial keratitis due to HSV types 1 or 2. ¹⁵	

TOPICAL ANTIHISTAMINICS¹⁶

Levocabastine HCl 0.05% ophthalmic solution (Livostin)	\$81.29/10 mL	1 drop four times daily (up to 2 weeks)	Allergic conjunctivitis; temporary relief of seasonal allergic conjunctivitis.	

¹Cost to pharmacist (average wholesale price, generic when possible) for quantity listed. Source: *Drug Topics Red Book*, May 2003; Vol. 22, No. 5.

²Macular edema occurs in 30% of patients.

³May (rarely) increase blood pressure. **Caution:** Avoid in patients with sulfite hypersensitivity (some brands contain sulfite). ⁴Cardioselective (β₁) beta-blocker.

⁵Nonselective (β₁ and β₂) beta-blocker. Monitor all patients for systemic side effects, particularly exacerbation of asthma. ⁶Decreased night vision, headaches possible.

⁷Sustained-release preparation. Refrigerate.

⁸Cross-sensitivity to aspirin and other NSAIDs.

⁹Long-term use may increase intraocular pressure or cause cataracts.

¹⁰May be less likely to elevate intraocular pressure. ¹¹Little efficacy against gram-negative organisms (except neisseria).

¹²Aplastic anemia has been reported with prolonged ophthalmic use. Use only in serious infections for which less toxic drugs are ineffective or contraindicated.

¹³Also indicated for prophylaxis of ophthalmia neonatorum due to *N gonorrhoeae* or *C trachomatis*. Increasing resistance of *S pneumoniae* and *P aeruginosa* has been noted.

¹⁴No gram-positive coverage.

¹⁵Recurrences are common and call for additional 7-day treatment.

¹⁶Antihistamines (topical) are potential sensitizers and may produce local reactions.

TABLES
Table 7-2. Topical ophthalmic agents.

●

Table 7-3. Adverse ocular effects of systemic drugs.

Drug	Possible Side Effects
Respiratory drugs	
Oxygen	Retinopathy of prematurity.
Anticholinergic bronchodilators	Angle-closure glaucoma.
Cardiovascular system drugs	
Digitalis	Disturbances of color vision, scotomas, photopsia.
Quinidine	Optic neuritis (rare).
Thiazides (Diuril, etc)	Xanthopsia (yellow vision), myopia.
Carbonic anhydrase inhibitors (acetazolamide)	Ocular hypotony, transient myopia.
Amiodarone	Corneal deposits, optic neuropathy, thyroid ophthalmopathy.
Gastrointestinal drugs	
Anticholinergic agents	Risk of angle-closure glaucoma due to mydriasis. Blurring of vision due to cycloplegia (occasional).
Central nervous system drugs	
Barbiturates	Extraocular muscle palsies with diplopia, nystagmus, ptosis, cortical blindness.
Chloral hydrate	Diplopia, ptosis, miosis.
Phenothiazines	Deposits of pigment in conjunctiva, cornea, lens and retina. Oculogyric crises.
Amphetamines	Widening of palpebral fissure. Dilation of pupil, paralysis of ciliary muscle with loss of accommodation.
Monoamine oxidase inhibitors	Nystagmus, extraocular muscle palsies, optic atrophy.
Tricyclic agents	Dilation of pupil (risk of angle-closure glaucoma), cycloplegia.
Phenytoin	Nystagmus, diplopia, ptosis, slight blurring of vision (rare).
Neostigmine	Nystagmus, miosis.
Morphine	Miosis.
Haloperidol	Capsular cataract.
Lithium carbonate	Exophthalmos, oculogyric crisis, nystagmus.
Diazepam	Nystagmus.
Topiramate	Angle-closure glaucoma.
Paroxetine	Angle-closure glaucoma.
Hormonal agents	
Corticosteroids	Cataract (posterior subcapsular), local immunologic suppression, causing susceptibility to viral (herpes simplex), bacterial, and fungal infections; steroid-induced glaucoma.
Female sex hormones	Retinal artery occlusion, retinal vein occlusion, papilledema, ocular palsies with diplopia, nystagmus, optic neuropathy.
Tamoxifen	Crystalline retinal deposits.
Antibiotics	
Chloramphenicol	Optic neuritis and atrophy.
Streptomycin	Optic neuritis.
Tetracycline	Pseudotumor cerebri, transient myopia.
Antimalarial agents	
Chloroquine, etc	Macular changes, central scotomas, pigmentary degeneration of the retina, chloroquine keratopathy, ocular palsies, ptosis, ERG depression.
Amebicides	
Iodochlorhydroxyquin	Optic atrophy.
Chemotherapeutic agents	
Sulfonamides	Stevens-Johnson syndrome.
Ethambutol	Optic neuritis and atrophy.
Isoniazid	Optic neuritis and atrophy.
Heavy metals	
Gold salts	Deposits in the cornea and conjunctiva.
Lead compounds	Optic atrophy, papilledema, ocular palsies.
Chelating agents	
Penicillamine	Ocular pemphigoid, optic neuritis, ocular myasthenia.
Oral hypoglycemic agents	
Chlorpropamide	Transient change in refractive error, diplopia, Stevens-Johnson syndrome.
Vitamins	
Vitamin A	Papilledema, retinal hemorrhages, loss of eyebrows and eyelashes, nystagmus, diplopia, blurring of vision.
Vitamin D	Band-shaped keratopathy.
Antirheumatic agents	
Salicylates	Nystagmus, retinal hemorrhages, cortical blindness (rare).
Indomethacin	Corneal deposits.
Phenylbutazone	Retinal hemorrhages.
Dermatologic agent (or retinoid)	

Isotretinoin

Blepharoconjunctivitis, corneal opacities, decreased dark adaptation, decreased contact lens tolerance, teratogenic ocular abnormalities.

■ DISEASES OF THE EAR

HEARING LOSS

Classification & Epidemiology

A. Conductive Hearing Loss

Conductive hearing loss results from dysfunction of the external or middle ear. There are four mechanisms, each resulting in impairment of the passage of sound vibrations to the inner ear: (1) obstruction (eg, cerumen impaction), (2) mass loading (eg, middle ear effusion), (3) stiffness effect (eg, otosclerosis), and (4) discontinuity (eg, ossicular disruption). Conductive losses in adults are most commonly due to cerumen impaction or transient auditory tube dysfunction associated with upper respiratory tract infection. Persistent conductive losses usually result from chronic ear infection, trauma, or otosclerosis. Conductive hearing loss is generally correctable with medical or surgical therapy—or in some cases both.

B. Sensory Hearing Loss

Sensory hearing loss results from deterioration of the cochlea, usually due to loss of hair cells from the organ of Corti. Sensorineural losses in adults are common. A gradually progressive, predominantly high-frequency loss with advancing age (presbycusis) is typical. Other than aging effects, common causes of sensorineural loss include excessive noise exposure, head trauma, and systemic diseases such as diabetes mellitus. Sensory hearing loss is not correctable with medical or surgical therapy but often may be prevented or stabilized.

C. Neural Hearing Loss

Neural hearing loss occurs with lesions involving the eighth nerve, auditory nuclei, ascending tracts, or auditory cortex. It is the least common clinically recognized cause of hearing loss. Causes include acoustic neuroma, multiple sclerosis, and cerebrovascular disease.

Blanchfield BB et al: The severely to profoundly hearing-impaired population in the United States: prevalence estimates and demographics. J Am Acad Audiol 2001;12:183. [\[PMID: 11763876\]](#)

Karlsimose B et al: A randomised controlled trial of screening for adult hearing loss during preventive health checks. Br J Gen Pract 2001;51:351. [\[PMID: 11360697\]](#)

Evaluation of Hearing (Audiology)

In a quiet room, the hearing level may be estimated by having the patient repeat aloud words presented in a soft whisper, a normal spoken voice, or a shout. Tuning forks are useful in differentiating conductive from sensorineural losses. A 512-Hz tuning fork is employed, since frequencies below this level elicit a tactile response. In the **Weber test**, the tuning fork is placed on the forehead or front teeth. In conductive losses, the sound appears louder in the poorer-hearing ear, whereas in sensorineural losses it radiates to the better side. In the **Rinne test**, the tuning fork is placed alternately on the mastoid bone and in front of the ear canal. In conductive losses, bone conduction exceeds air conduction; in sensorineural losses, the opposite is true.

Formal audiometric studies are performed in a soundproofed room. Pure-tone thresholds in decibels (dB) are obtained over the range of 250-8000 Hz (the main speech frequencies are between 500 and 3000 Hz) for both air and bone conduction. Conductive losses create a gap between the air and bone thresholds, whereas in sensorineural losses both air and bone thresholds are equally diminished. The threshold of normal hearing is from 0 to 20 dB, which corresponds to the loudness of a soft whisper. Mild hearing loss is indicated by a threshold of 20-40 dB (soft spoken voice), moderate loss by a threshold of 40-60 dB (normal spoken voice), severe loss by a threshold of 60-80 dB (loud spoken voice), and profound loss by a threshold of 80 dB (shout). The clarity of hearing is often impaired in sensorineural hearing loss. This is evaluated by speech discrimination testing, which is reported as percentage correct (90-100% is normal). The site of the lesion responsible for sensorineural loss—whether it lies in the cochlea or in the central auditory system—may be determined with auditory brain stem-evoked responses.

Every patient who complains of a hearing loss should be referred for audiologic evaluation unless the cause is easily remediable (eg, cerumen impaction, otitis media). Audiologic screening is not recommended for adults with apparently normal hearing unless they are exposed to potentially injurious levels of noise or have reached the age of 65, after which screening evaluations should be done every few years.

Zadeh MH et al: Evaluation of hearing impairment. Compr Ther 2001;27:302. [\[PMID: 1765688\]](#)

Hearing Rehabilitation

Patients with hearing loss not correctable by medical therapy may benefit from hearing amplification. Contemporary hearing aids are comparatively free of distortion and have been miniaturized to the point where they often may be contained entirely within the ear canal. To optimize the benefit, a hearing aid must be carefully selected to conform to the nature of the hearing loss. Digitally programmable hearing aids are now becoming available that allow optimization of speech intelligibility and may be tuned to deal with difficult listening circumstances.

Much current interest is focused upon the development of semi-implantable and even fully implantable hearing aids. A variety of devices are under development that deliver vibrations—usually via either a rare earth magnet or a piezoceramic crystal—directly to the ossicular chain. Some of these devices are in clinical trials.

Aside from hearing aids, many assistive devices are available to improve comprehension in individual and group settings, to help with hearing television and radio programs, and for telephone communication. In individuals with profound sensory hearing loss, the cochlear implant—an electronic device that is surgically implanted to stimulate the auditory nerve—offers socially beneficial auditory rehabilitation to most adults with acquired deafness.

Caye-Thomasen P: Long-term results and experience with the first-generation semi-implantable electromagnetic hearing aid with ossicular replacement device for mixed hearing loss. Otol Neurotol 2002;23:904. [\[PMID: 12438854\]](#)

DISEASES OF THE AURICLE

Disorders of the external ear are for the most part dermatologic. Skin cancers due to sun exposure are common and may be treated with standard techniques. Traumatic auricular hematoma must be recognized and drained to prevent significant cosmetic deformity (cauliflower ear) resulting from dissolution of supporting cartilage. Similarly, cellulitis of the auricle must be treated promptly to prevent development of perichondritis and its resultant deformity. Relapsing polychondritis is a systemic disorder often associated with recurrent, frequently bilateral, painful episodes of auricular erythema and edema. Treatment with corticosteroids may help forestall cartilage dissolution. Respiratory compromise may occur as a result of progressive involvement of the tracheobronchial tree. Chondritis and perichondritis may be differentiated from auricular cellulitis by sparing of involvement of the lobule, which does not contain cartilage.

Chen S et al: Painful erythematous ear. Arch Dermatol 2000; 136:418. [\[PMID: 10724211\]](#)

DISEASES OF THE EAR CANAL

1. Cerumen Impaction

Cerumen is a protective secretion produced by the outer portion of the ear canal. In most individuals, the ear canal is self-cleansing. Recommended hygiene consists of cleaning the external opening with a washcloth over the index finger without entering the canal itself. In most cases, cerumen impaction is self-induced through

ill-advised attempts at cleaning the ear. It may be relieved with detergent ear drops (eg, 3% hydrogen peroxide; 6.5% carbamide peroxide), mechanical removal, suction, or irrigation. Irrigation is performed with water at body temperature to avoid a vestibular caloric response. The stream should be directed at the ear canal wall adjacent to the cerumen plug. Irrigation should be performed only when the tympanic membrane is known to be intact

Use of jet irrigators designed for cleaning teeth (eg, WaterPik) for wax removal should be avoided since they may result in tympanic membrane perforations. Following irrigation, the ear canal should be thoroughly dried (eg, by instilling isopropyl alcohol or using a hair blow-dryer on low-power setting) to reduce the likelihood of inducing external otitis. Specialty referral for cleaning under microscopic guidance is indicated when the impaction has not responded to routine measures or if the patient has a history of chronic otitis media or tympanic membrane perforation.

Browning G: Wax in ear. Clin Evid 2002;(7):490. [\[PMID: 12230675\]](#)

2. Foreign Bodies

Foreign bodies in the ear canal are more frequent in children than in adults. Firm materials may be removed with a loop or a hook, taking care not to displace the object medially toward the tympanic membrane; microscopic guidance is helpful. Aqueous irrigation should not be performed for organic foreign bodies (eg, beans, insects), because water may cause them to swell. Living insects are best immobilized before removal by filling the ear canal with lidocaine.

DiMuzio J Jr et al: Emergency department management of foreign bodies of the external ear canal in children. Otol Neurotol 2002;23:473. [\[PMID: 12170148\]](#)

3. External Otitis

External otitis presents with otalgia, frequently accompanied by pruritus and purulent discharge. There is often a history of recent water exposure or mechanical trauma (eg, scratching, cotton applicators). External otitis is usually caused by gram-negative rods (eg, *Pseudomonas*, *Proteus*) or fungi (eg, *Aspergillus*), which grow in the presence of excessive moisture

Examination reveals erythema and edema of the ear canal skin, often with a purulent exudate. Manipulation of the auricle often elicits pain. Because the lateral surface of the tympanic membrane is ear canal skin, it is often erythematous. However, in contrast to acute otitis media, it moves normally with pneumatic otoscopy. When the canal skin is very edematous, it may be impossible to visualize the tympanic membrane.

Fundamental to the treatment of external otitis is protection of the ear from additional moisture and avoidance of further mechanical injury by scratching. Otic drops containing a mixture of aminoglycoside antibiotic and anti-inflammatory corticosteroid in an acid vehicle are generally very effective (eg, neomycin sulfate, polymyxin B sulfate, and hydrocortisone). Purulent debris filling the ear canal should be gently removed to permit entry of the topical medication. Drops should be used abundantly (5 or more drops three or four times a day) to penetrate the depths of the canal. When substantial edema of the canal wall prevents entry of drops into the ear canal, a wick is placed to facilitate entry of the medication. In recalcitrant cases—particularly when cellulitis of the periauricular tissue has developed—oral fluoroquinolones (eg, ciprofloxacin, 500 mg twice daily for 1 week) are the drugs of choice because of their effectiveness against *Pseudomonas* species.

Denneny JC 3rd: Otological agents in the treatment of the draining ear. Am J Manag Care 2002;8(14 Suppl):S353. [\[PMID: 12408221\]](#)

Schapowal A: Otitis externa: a clinical overview. Ear Nose Throat J 2002;81(8 Suppl 1):21 [\[PMID: 12199185\]](#)

4. Pruritus

Pruritus of the external auditory canal, particularly at the meatus, is a common problem. While it may be associated with external otitis or with dermatologic conditions such as seborrheic dermatitis and psoriasis, most cases are self-induced either from excoriation or by overly zealous ear cleaning. To permit regeneration of the protective cerumen blanket, patients should be instructed to avoid use of soap and water or cotton swabs in the ear canal. Patients with excessively dry canal skin may benefit from application of mineral oil, which helps to counteract dryness and repel moisture. When an inflammatory component is present, topical application of a corticosteroid (eg, 0.1% triamcinolone) may be beneficial. It is axiomatic in persistent pruritus that the patient must cease scratching the ear. In stubborn cases, the fingernails must be kept short and the patient may need to wear cotton gloves at night to avoid manipulation during sleep. Symptomatic reduction of pruritus may be obtained by use of oral antihistamines (eg, diphenhydramine, 25 mg orally at bedtime). Topical application of isopropyl alcohol promptly relieves ear canal pruritus in many patients.

5. Malignant External Otitis

Persistent external otitis in the diabetic or immunocompromised patient may evolve into osteomyelitis of the skull base, often called malignant external otitis. Usually caused by *Pseudomonas aeruginosa*, osteomyelitis begins in the floor of the ear canal and may extend into the middle fossa floor, the clivus, and even the contralateral skull base. The patient usually presents with persistent foul aural discharge, granulations in the ear canal, deep otalgia, and progressive cranial nerve palsies involving nerves VI, VII, IX, X, XI, or XII. Diagnosis is confirmed by the demonstration of osseous erosion on CT and radionuclide scanning.

Treatment is chiefly medical, requiring prolonged antipseudomonal antibiotic administration, often for several months. Although intravenous therapy is often required, selected patients may be managed with the oral agent ciprofloxacin (500-1000 mg orally twice daily), which has proved effective against many of the causative *Pseudomonas* strains. To avoid relapse, antibiotic therapy should be continued, even in the asymptomatic patient, until gallium scanning indicates a marked reduction in the inflammatory process. Surgical debridement of infected bone is reserved for cases of deterioration despite medical therapy.

Walshe P et al: Malignant otitis externa—a high index of suspicion is still needed for diagnosis. Ir Med J 2002;95:14. [\[PMID: 11928781\]](#)

6. Exostoses & Osteomas

Bony overgrowths of the ear canal are a frequent incidental finding and occasionally have clinical significance. Clinically, they present as skin-covered mounds in the medial ear canal obscuring the tympanic membrane to a variable degree. Solitary osteomas are of no significance as long as they do not cause obstruction or infection. Multiple exostoses, which are generally acquired from repeated exposure to cold water, often progress and require surgical removal.

Kroon DF et al: Surfer's ear: external auditory exostoses are more prevalent in cold water surfers. Otolaryngol Head Neck Surg 2002;126:499. [\[PMID: 12075223\]](#)

7. Neoplasia

The most common neoplasm of the ear canal is squamous cell carcinoma. When an apparent otitis externa does not resolve on therapy, this should be suspected and biopsy performed. This disease carries a very high 5-year mortality rate because the tumor tends to invade the lymphatics of the cranial base and must be treated with wide surgical resection and radiation therapy. Adenomatous tumors, originating from the ceruminous glands, generally follow a more indolent course.

Nyrop M et al: Cancer of the external auditory canal. Arch Otolaryngol Head Neck Surg 2002;128:834. [\[PMID: 12117346\]](#)

DISEASES OF THE AUDITORY TUBE

1. Auditory Tube Dysfunction

The tube that connects the middle ear to the nasopharynx—the auditory tube, or eustachian tube—provides ventilation and drainage for the middle ear cleft. It is normally closed, opening only during the act of swallowing or yawning. When auditory tube function is compromised, air trapped within the middle ear becomes absorbed and negative pressure results. The most common causes of auditory tube dysfunction are diseases associated with edema of the tubal lining, such as viral upper respiratory tract infections and allergy. The patient usually reports a sense of fullness in the ear and mild to moderate impairment of hearing. When the tube is only partially blocked, swallowing or yawning may elicit a popping or crackling sound. Examination reveals retraction of the tympanic membrane and decreased mobility on pneumatic otoscopy. Following a viral illness, this disorder is usually transient, lasting days to weeks. Treatment with systemic and intranasal decongestants (eg, pseudoephedrine, 60 mg orally every 4 hours; oxymetazoline, 0.05% spray every 8-12 hours) combined with autoinflation by forced exhalation against closed nostrils may hasten relief. Autoinflation should not be recommended to patients with active intranasal infection, since this maneuver may precipitate middle ear infection. Allergic patients may also benefit from desensitization or intranasal corticosteroids (eg, beclomethasone dipropionate, two sprays in each nostril twice daily for 2-6 weeks). Air travel, rapid altitudinal change, and underwater diving should be avoided.

An overly patent auditory tube is a relatively uncommon problem that may be quite distressing. Typical complaints include fullness in the ear and autophony, an exaggerated ability to hear oneself breathe and speak. A patulous auditory tube may develop during rapid weight loss, or may be idiopathic. In contrast to a hypofunctioning auditory tube, the aural pressure is often made worse by exertion and may diminish during an upper respiratory tract infection. Although physical examination is usually normal, respiratory excursions of the tympanic membrane may occasionally be detected during vigorous breathing. Treatment includes

avoidance of decongestant products, insertion of a ventilating tube to reduce the outward stretch of the ear drum during phonation, and, rarely, surgical narrowing of the auditory tube.

van Heerbeek N: Therapeutic improvement of Eustachian tube function: a review. Clin Otolaryngol 2002;27:50. [\[PMID: 11903373\]](#)

2. Serous Otitis Media

When the auditory tube remains blocked for a prolonged period, the resultant negative pressure will result in transudation of fluid. This condition, known as serous otitis media, is especially common in children because their auditory tubes are narrower and more horizontal in orientation than adults. It is less common in adults, in whom it usually follows an upper respiratory tract infection or barotrauma. In an adult with persistent unilateral serous otitis media, nasopharyngeal carcinoma must be excluded. The tympanic membrane in serous otitis media is dull and hypomobile, occasionally accompanied by air bubbles in the middle ear and conductive hearing loss. The treatment of serous otitis media is similar to that for auditory tube dysfunction. A short course of oral corticosteroids (eg, prednisone, 40 mg/d for 7 days) has been advocated by some in the management of serous otitis media, as have oral antibiotics (eg, amoxicillin, 250 mg orally three times daily for 7 days)—or even a combination of the two. The role of these regimens remains controversial, but they are probably of little lasting benefit.

When medication fails to bring relief after several months, a ventilating tube placed through the tympanic membrane may restore hearing and alleviate the sense of aural fullness.

Williamson I: Otitis media with effusion. Clin Evid 2002; (8):511. [\[PMID: 12603897\]](#)

3. Barotrauma

Individuals with auditory tube dysfunction due either to congenital narrowness or to acquired mucosal edema may be unable to equalize the barometric stress exerted on the middle ear by air travel, rapid altitudinal change, or underwater diving. The problem is generally most acute during airplane descent, since the negative middle ear pressure tends to collapse and lock the auditory tube. Several measures are useful to enhance auditory tube function and avoid otic barotrauma. The patient should be advised to swallow, yawn, and autoinflate frequently during descent, which may be painful if the auditory tube collapses. Systemic decongestants (eg, pseudoephedrine, 60-120 mg) should be taken several hours before anticipated arrival time so that they will be maximally effective during descent. Topical decongestants such as 1% phenylephrine nasal spray should be administered 1 hour before arrival.

The treatment of acute negative middle ear pressure that persists on the ground is with decongestants and attempts at autoinflation. Myringotomy (creation of a small eardrum perforation) provides immediate relief and is appropriate in the setting of severe otalgia and hearing loss. Repeated episodes of barotrauma in persons who must fly frequently may be alleviated by insertion of ventilating tubes.

Underwater diving represents even a greater barometric stress to the ear than flying. The problem occurs most commonly during the descent phase, when pain develops within the first 15 feet if inflation of the middle ear via the auditory tube has not occurred. Divers must descend slowly and equilibrate in stages to avoid the development of severely negative pressures in the tympanum that may result in hemorrhage (hemotympanum) or perilymphatic fistulization. In the latter, the oval or round window ruptures, resulting in sensory hearing loss and acute vertigo. Emesis due to acute labyrinthine dysfunction can be very dangerous during an underwater dive. Sensory hearing loss or vertigo, which develops during the ascent phase of a saturation dive, may be the first (or only) symptom of decompression sickness. Immediate recompression will return intravascular gas bubbles to solution and restore the inner ear microcirculation. Patients should be warned to avoid diving when they have upper respiratory infections or episodes of nasal allergy. Tympanic membrane perforation is an absolute contraindication to diving, as the patient will experience an unbalanced thermal stimulus to the semicircular canals and may experience vertigo, disorientation, and even emesis. Finally, individuals with only one hearing ear should be discouraged from diving because of the significant risk of otologic injury.

DISEASES OF THE MIDDLE EAR

1. Acute Otitis Media

Acute otitis media is a bacterial infection of the mucosally lined air-containing spaces of the temporal bone. Purulent material forms not only within the middle ear cleft but also within the mastoid air cells and petrous apex when they are pneumatized. Acute otitis media is usually precipitated by a viral upper respiratory tract infection that causes auditory tube edema. This results in accumulation of fluid and mucus, which becomes secondarily infected by bacteria. The most common pathogens both in adults and in children are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Streptococcus pyogenes*.

Acute otitis media is most common in infants and children, though it may occur at any age. The patient presents with otalgia, aural pressure, decreased hearing, and often fever. The typical physical findings are erythema and decreased mobility of the tympanic membrane. Occasionally, bullae will be seen on the tympanic membrane. Although it is taught that this represents infection with *Mycoplasma pneumoniae*, most cases involve more common pathogens.

Rarely, when middle ear empyema is severe, the tympanic membrane can be seen to bulge outward. In such cases, tympanic membrane rupture is imminent. Rupture is accompanied by a sudden decrease in pain, followed by the onset of otorrhea. With appropriate therapy, spontaneous healing of the tympanic membrane occurs in most cases. When perforation persists, chronic otitis media frequently evolves. Mastoid tenderness often accompanies acute otitis media and is due to the presence of pus within the mastoid air cells. This alone does not indicate suppurative (surgical) mastoiditis.

The treatment of acute otitis media is specific antibiotic therapy, often combined with nasal decongestants. The first-choice antibiotic treatment is either amoxicillin (20-40 mg/kg/d) or erythromycin (50 mg/kg/d) plus sulfonamide (150 mg/kg/d) for 10 days. Alternatives useful in resistant cases are cefaclor (20-40 mg/kg/d) or amoxicillin-clavulanate (20-40 mg/kg/d) combinations.

Tympanocentesis for bacterial (aerobic and anaerobic) and fungal culture may be performed by any experienced physician. A 20-gauge spinal needle bent 90 degrees to the hub attached to a 3 mL syringe is inserted through the inferior portion of the tympanic membrane. Interposition of a pliable connecting tube between the needle and syringe permits an assistant to aspirate without inducing movement of the needle. Tympanocentesis is useful for otitis media in immunocompromised patients and when infection persists or recurs despite multiple courses of antibiotics.

Surgical drainage of the middle ear (myringotomy) is reserved for patients with severe otalgia or when complications of otitis (eg, mastoiditis, meningitis) have occurred.

Recurrent acute otitis media may be managed with long-term antibiotic prophylaxis. Single daily doses of sulfamethoxazole (500 mg) or amoxicillin (250 or 500 mg) are given over a period of 1-3 months. Failure of this regimen to control infection is an indication for insertion of ventilating tubes.

Snow JB Jr: Progress in the prevention of otitis media through immunization. Otol Neurotol 2002;23:1. [\[PMID: 11773835\]](#)

2. Chronic Otitis Media & Cholesteatoma

Chronic infection of the middle ear and mastoid generally develops as a consequence of recurrent acute otitis media, although it may follow other diseases and trauma. Perforation of the tympanic membrane is usually present. This may be accompanied by mucosal changes such as polypoid degeneration and granulation tissue and osseous changes such as osteitis and sclerosis. The bacteriology of chronic otitis media differs from that of acute otitis media. Common organisms include *P aeruginosa*, proteus species, *Staphylococcus aureus*, and mixed anaerobic infections. The clinical hallmark of chronic otitis media is purulent aural discharge. Drainage may be continuous or intermittent, with increased severity during upper respiratory tract infection or following water exposure. Pain is uncommon except during acute exacerbations. Conductive hearing loss results from destruction of the tympanic membrane and ossicular chain. The medical treatment of chronic otitis media includes regular removal of infected debris, use of earplugs to protect against water exposure, and topical antibiotic drops for exacerbations. The activity of ciprofloxacin against pseudomonas may help to dry a chronically discharging ear when given in a dosage of 500 mg orally twice a day for 1-6 weeks.

Definitive management is surgical in most cases. Tympanic membrane repair may be accomplished with temporalis muscle fascia or with homograft middle ear structures. Successful reconstruction of the tympanic membrane may be achieved in about 90% of cases, often with elimination of infection and significant

improvement in hearing. When the mastoid air cells are involved by irreversible infection, they should be exenterated through mastoidectomy.

Cholesteatoma is a special variety of chronic otitis media. The most common cause is prolonged auditory tube dysfunction, with resultant chronic negative middle ear pressure that draws inward the upper flaccid portion of the tympanic membrane. This creates a squamous epithelium-lined sac, which—when its neck becomes obstructed—may fill with desquamated keratin and become chronically infected. Cholesteatomas typically erode bone, with early penetration of the mastoid and destruction of the ossicular chain. Over time they may erode the inner ear, involve the facial nerve, and on rare occasions spread intracranially. Physical examination reveals an epitympanic retraction pocket or marginal tympanic membrane perforation that exudes keratin debris. The treatment of cholesteatoma is surgical marsupialization of the sac or its complete removal. This often requires creation of a "mastoid bowl" in which the ear canal and mastoid are joined into a large common cavity that must be periodically cleaned.

3. Complications of Otitis Media

Mastoiditis

Acute suppurative mastoiditis usually evolves following several weeks of inadequately treated acute otitis media. It is characterized by postauricular pain and erythema accompanied by a spiking fever. Radiography reveals coalescence of the mastoid air cells due to destruction of their bony septa. Initial treatment consists of intravenous antibiotics and myringotomy for culture and drainage. Failure of medical therapy indicates the need for surgical drainage (mastoidectomy).

Zapalac JS et al: Suppurative complications of acute otitis media in the era of antibiotic resistance. *Arch Otolaryngol Head Neck Surg* 2002;128:660. [\[PMID: 12049560\]](#)

Petrous Apicitis

The medial portion of the petrous bone between the inner ear and clivus may become a site of persistent infection when the drainage of its pneumatic cell tracts becomes blocked. This may cause foul discharge, deep ear and retro-orbital pain, and sixth nerve palsy (Gradenigo's syndrome); meningitis may be a complication. Treatment is with prolonged antibiotic therapy (based on culture results) and surgical drainage via petrous apicectomy.

Price T et al: Abducens nerve palsy as the sole presenting symptom of petrous apicitis. *J Laryngol Otol* 2002;116:726. [\[PMID: 12437811\]](#)

Otogenic Skull Base Osteomyelitis

Infections originating in the external or middle ear may result in osteomyelitis of the skull base, usually due to *P aeruginosa*. The diagnosis and management of this disease are discussed in the section on malignant external otitis.

Facial Paralysis

Facial palsy may be associated with either acute or chronic otitis media. In the acute setting, it results from inflammation of the seventh nerve in its middle ear segment, perhaps mediated through bacterially secreted neurotoxins. Treatment consists of myringotomy for drainage and culture, followed by intravenous antibiotics (based on culture results). The use of corticosteroids is controversial. The prognosis is excellent, with complete recovery in the vast majority of cases.

Facial palsy associated with chronic otitis media usually evolves slowly due to chronic pressure on the seventh nerve in the middle ear or mastoid by cholesteatoma. Treatment requires surgical correction of the underlying disease. The prognosis is less favorable than for facial palsy associated with acute otitis media.

Yetiser S et al: Facial nerve paralysis due to chronic otitis media. *Otol Neurotol* 2002;23:580. [\[PMID: 12170164\]](#)

Sigmoid Sinus Thrombosis

Trapped infection within the mastoid air cells adjacent to the sigmoid sinus may cause septic thrombophlebitis. This is heralded by signs of systemic sepsis (spiking fevers, chills), at times accompanied by signs of increased intracranial pressure (headache, lethargy, nausea and vomiting, papilledema). Diagnosis can be made noninvasively by magnetic resonance venography. Treatment is with intravenous antibiotics (based on culture results), surgical drainage, and—when embolization is suspected—ligation of the internal jugular vein in the neck.

Bradley DT et al: Otogenic sigmoid sinus thrombosis: what is the role of anticoagulation? *Laryngoscope* 2002;112:1726. [\[PMID: 12368604\]](#)

Central Nervous System Infection

Otogenic meningitis is by far the most common intracranial complication of ear infection. In the setting of acute suppurative otitis media, it arises from hematogenous spread of bacteria, most commonly *H influenzae* and *S pneumoniae*. In chronic otitis media, it results either from passage of infections along preformed pathways such as the petrosquamous suture line or from direct extension of disease through the dural plates of the petrous pyramid.

Epidural abscesses arise from direct extension of disease in the setting of chronic infection. They are usually asymptomatic but may present with deep local pain, headache, and low-grade fever. They are often discovered as an incidental finding at surgery. Brain abscess may arise in the temporal lobe or cerebellum as a result of septic thrombophlebitis adjacent to an epidural abscess. The predominant causative organisms are *S aureus*, *S pyogenes*, and *S pneumoniae*. Rupture into the subarachnoid space results in meningitis and often death.

Manolidis S: Dural herniations, encephaloceles: an index of neglected chronic otitis media and further complications. *Am J Otolaryngol* 2002;23:203. [\[PMID: 12105784\]](#)

Sennaroglu L et al: Otogenic brain abscess: review of 41 cases. *Otolaryngol Head Neck Surg* 2000;123:751. [\[PMID: 112974\]](#)

4. Otosclerosis

Otosclerosis is a progressive disease with a marked familial tendency that affects bone surrounding the inner ear. Lesions involving the footplate of the stapes result in increased impedance to the passage of sound through the ossicular chain, producing conductive hearing loss. This may be corrected through surgical replacement of the stapes with a prosthesis (stapedectomy). When otosclerotic lesions impinge on the cochlea, permanent sensory hearing loss occurs. Some evidence suggests that this level of hearing loss may be stabilized by treatment with oral sodium fluoride over prolonged periods of time (Florical—8.3 mg sodium fluoride and 364 mg calcium carbonate—two tablets orally each morning). Fluorides have minimal adverse effects other than occasional mild gastric irritation, which may be eliminated by ingesting the drug with meals.

House HP et al: Stapedectomy versus stapedotomy: comparison of results with long-term follow-up. *Laryngoscope* 2002; 112:2046. [\[PMID: 12439178\]](#)

5. Trauma to the Middle Ear

Tympanic membrane perforation may result from impact injury or explosive acoustic trauma. Spontaneous healing occurs in the great majority of cases. Persistent perforation may result from secondary infection brought on by exposure to water. Patients should be advised to wear earplugs while swimming or bathing during the healing period. Hemorrhage behind an intact tympanic membrane (hemotympanum) may follow blunt trauma or extreme barotrauma. Spontaneous resolution over several weeks is the usual course. When a conductive hearing loss greater than 30 dB persists for more than 3 months following trauma, disruption of the ossicular chain should be suspected. Middle ear exploration with reconstruction of the ossicular chain, combined with repair of the tympanic membrane when required, will

usually restore hearing.

Brodie HA et al: Management of complications from 820 temporal bone fractures. Am J Otol 1997;18:188. [\[PMID: 9093676\]](#)

6. Middle Ear Neoplasia

Primary middle ear tumors are rare. Glomus tumors arise either in the middle ear (glomus tympanicum) or in the jugular bulb with upward erosion into the hypotympanum (glomus jugulare). They present clinically with pulsatile tinnitus and hearing loss. A vascular mass may be visible behind an intact tympanic membrane. Large glomus jugulare tumors are often associated with multiple cranial neuropathies, especially involving nerves VII, IX, X, XI, and XII. Treatment may require surgery, radiotherapy, or both.

Leonetti JP et al: Malignancy of the temporal bone. Otolaryngol Clin North Am 2002;35:405. [\[PMID: 12391626\]](#)

EARACHE

External otitis and acute otitis media are the two most common causes of earache. In external otitis, there is often a recent history of swimming, Q-tip use, or physical trauma, while in acute otitis media there is usually an antecedent or concurrent upper respiratory infection. The physical findings also differ. In external otitis, the ear canal skin is erythematous, while in acute otitis media this generally occurs only if the tympanic membrane has ruptured, spilling purulent material into the ear canal. Also, in external otitis the tympanic membrane may be erythematous, but it retains its mobility owing to the normal aeration of the middle ear cavity. Pain out of proportion to the physical findings may be due to herpes zoster oticus, especially when vesicles appear in the ear canal or concha. Chronic otitis media is usually not painful except during acute exacerbations. Persistent pain and discharge from the ear suggest osteomyelitis of the skull base or cancer.

The sensory innervation of the ear is derived from the trigeminal, facial, glossopharyngeal, vagal, and upper cervical nerves. Because of this rich innervation, referred otalgia is quite frequent. Temporomandibular joint dysfunction is a common cause of ear pain. It is often made worse by chewing or psychogenic grinding of the teeth (bruxism) and may be associated with dental malocclusion. Management includes soft diet, local heat to the masticatory muscles, massage, analgesics, and dental referral. Repeated episodes of severe lancinating otalgia may occur in glossopharyngeal neuralgia. Treatment with carbamazepine (100-300 mg orally every 8 hours) often confers substantial symptomatic relief. Severe glossopharyngeal neuralgia, which is refractory to medical management, may respond to microvascular decompression of the ninth nerve. Infections and neoplasia that involve the oropharynx, hypopharynx, and larynx frequently cause otalgia. Persistent earache demands specialty referral to exclude cancer of the upper aerodigestive tract.

DISEASES OF THE INNER EAR

1. Sensory Hearing Loss

Diseases of the cochlea result in sensory hearing loss, a condition that is usually irreversible. Most cochlear diseases result in bilateral symmetric hearing loss. The presence of unilateral or asymmetric sensorineural hearing loss suggests a lesion proximal to the cochlea. Lesions affecting the eighth nerve and central auditory system are discussed in the section on neural hearing loss. The primary goals in the management of sensory hearing loss are prevention of further losses and functional improvement with amplification and auditory rehabilitation.

Presbycusis

Presbycusis, the most frequent cause of sensory hearing loss, is the progressive, predominantly high-frequency symmetric hearing loss of advancing age. It is difficult to separate the various etiologic factors (eg, noise trauma) that may contribute to presbycusis, but genetic predisposition appears to play a role. Most patients notice a loss of speech discrimination that is especially pronounced in noisy environments. About 25% of people between the ages of 65 and 75 years and almost 50% of those over 75 experience hearing difficulties.

Marcincuk MC et al: Geriatric hearing loss. Understanding the causes and providing appropriate treatment. Geriatrics 2002;57:44, 48, 55 passim. [\[PMID: 11974390\]](#)

Noise Trauma

Noise trauma is the second most common cause of sensory hearing loss. Sounds exceeding 85 dB are potentially injurious to the cochlea, especially with prolonged exposures. The loss typically begins in the high frequencies (especially 4000 Hz) and progresses to involve the speech frequencies with continuing exposure. Among the more common sources of injurious noise are industrial machinery, weapons, and excessively loud music. In recent years, monitoring of noise levels in the workplace by regulatory agencies has led to preventive programs that have reduced the frequency of occupational losses. Individuals of all ages, especially those with existing hearing losses, should wear earplugs when exposed to moderately loud noises and specially designed earmuffs when exposed to explosive noises.

Hager LD: Hearing protection. Didn't hear it coming . . . noise and hearing in industrial accidents. Occup Health Saf 2002;71:196. [\[PMID: 12369364\]](#)

Palmer KT et al: Occupational exposure to noise and the attributable burden of hearing difficulties in Great Britain. Occup Environ Med 2002;59:634. [\[PMID: 12205239\]](#)

Physical Trauma

Head trauma has effects on the inner ear similar to those of severe acoustic trauma. Some degree of sensory hearing loss may occur following simple concussion and is frequent after skull fracture. Deployment of air bags during an automobile accident has been associated with hearing loss.

Bonelli A et al: Airbag and hearing loss: our experience. Rev Laryngol Otol Rhinol (Bord) 2002;123:53. [\[PMID: 12201003\]](#)

Segal S et al: Dynamics of sensorineural hearing loss after head trauma. Otol Neurotol 2002;23:312. [\[PMID: 11981387\]](#)

Ototoxicity

Ototoxic substances may affect both the auditory and vestibular systems. The most common ototoxic medications are salicylates, aminoglycosides, loop diuretics, and several antineoplastic agents, notably cisplatin. The latter three categories may cause irreversible hearing loss even when administered in therapeutic doses. When using these medications, it is important to identify high-risk patients such as those with preexisting hearing losses or renal insufficiency. Patients simultaneously receiving multiple ototoxic agents are at particular risk owing to ototoxic synergy. Useful measures to reduce the risk of ototoxic injury include serial audiometry and monitoring of serum peak and trough levels and substitution of equivalent nonototoxic drugs whenever possible.

It is possible for topical agents that enter the middle ear to be absorbed into the inner ear via the round window. When the tympanic membrane is perforated, use of potentially ototoxic ear drops (eg, neomycin, gentamicin) is best avoided.

Tange RA: Eardrops and aminoglycoside ototoxicity revisited. Adverse Drug React Toxicol Rev 2001;20:164. [\[PMID: 11668866\]](#)

Wu WJ et al: Recent advances in understanding aminoglycoside ototoxicity and its prevention. Audiol Neurotol 2002;7:171. [\[PMID: 12053140\]](#)

Sudden Sensory Hearing Loss

Sudden loss of hearing in one ear may occur at any age but is more common in the elderly. It most probably is the result of sudden vascular occlusion of the internal auditory artery or of a viral inner ear infection. Prognosis is mixed, with many patients suffering permanent deafness in the involved ear while others have complete recovery. Although the subject is controversial, oral corticosteroids are felt by many to improve the odds of recovery. A common regimen is prednisone, 80 mg/d, followed by a tapering dose over a 10-day period.

Tucci DL et al: Treatment of sudden sensorineural hearing loss with systemic steroids and valacyclovir. Otol Neurotol 2002;23:301. [\[PMID: 11981385\]](#)

[12574765\]](#)

Hereditary Hearing Loss

Sensory hearing loss with onset during adult life often runs in families. The mode of inheritance may be either autosomal dominant or recessive. The age at onset, the rate of progression of hearing loss, and the audiometric pattern (high-frequency, low-frequency, or flat) can often be predicted by studying family members. In recent years, great strides have been made in identifying the molecular genetic errors associated with hereditary hearing loss, and several dozen specific mutations have now been characterized.

Gurtler N et al: Etiology of syndromic and nonsyndromic sensorineural hearing loss. *Otolaryngol Clin North Am* 2002;35:891. [\[PMID: 12487088\]](#)

Autoimmune Hearing Loss

Sensory hearing loss may be associated with a wide array of systemic autoimmune disorders such as systemic lupus erythematosus, Wegener's granulomatosis, and Cogan's syndrome (hearing loss, keratitis, aortitis). The loss is most often bilateral and progressive. The hearing level often fluctuates, with periods of deterioration alternating with partial or even complete remission. The tendency is for the gradual evolution of permanent hearing loss, which usually stabilizes with some remaining auditory function but occasionally proceeds to complete deafness. Vestibular dysfunction, particularly dysequilibrium and postural instability, may accompany the auditory symptoms. A syndrome resembling Meniere's disease may also occur with intermittent attacks of severe vertigo.

In the majority of cases, the autoimmune pattern of audiovestibular dysfunction presents in the absence of recognized systemic autoimmune disease. Use of laboratory tests to screen for autoimmune disease (eg, antinuclear antibody, rheumatoid factor, erythrocyte sedimentation rate) may be informative. Specific tests of immune reactivity against inner ear antigens (anticochlear antibodies, lymphocyte transformation tests) are available but are currently of interest for research purposes only. Responsiveness to oral corticosteroid treatment is helpful in making the diagnosis and constitutes first-line therapy. If stabilization of hearing becomes dependent on long-term corticosteroid use, steroid-sparing immunosuppressive regimens (eg, methotrexate, 7.5 mg three times a week) may become necessary.

Ryan AF et al: Immune-mediated hearing loss: basic mechanisms and options for therapy. *Acta Otolaryngol Suppl* 2002; 548:38. [\[PMID: 12211356\]](#)

Other Causes of Sensory Hearing Loss

There are numerous less common causes of sensory hearing loss. Metabolic derangements (eg, diabetes, hypothyroidism, hyperlipidemia, and renal failure), infections (eg, measles, mumps, syphilis), and physical factors (eg, radiation therapy) are some of the chief examples. Identification of metabolic or infectious sensory hearing losses is especially important, as these may occasionally be reversible with medical therapy. Meniere's syndrome and labyrinthitis are discussed in the section on vestibular disorders.

Duck SW et al: Interaction between hypertension and diabetes mellitus in the pathogenesis of sensorineural hearing loss. *Laryngoscope* 1997;107(12 Part 1):1596. [\[PMID: 9396671\]](#)

2. Tinnitus

Tinnitus is the perception of abnormal ear or head noises. Persistent tinnitus usually indicates the presence of sensory hearing loss. Intermittent periods of mild, high-pitched tinnitus lasting for several minutes are common in normal-hearing persons. When severe and persistent, tinnitus may interfere with sleep and the ability to concentrate, resulting in considerable psychologic distress.

The most important treatment of tinnitus is avoidance of exposure to excessive noise, ototoxic agents, and other factors that may cause cochlear damage. Masking the tinnitus with music or through amplification of normal sounds with a hearing aid may also bring some relief. Although intravenous treatment with antiarrhythmic drugs (eg, lidocaine) suppresses tinnitus in some individuals, evidence suggests no benefit with oral agents that are potentially suitable for long-term symptom relief. Among the numerous drugs that have been tried, oral antidepressants (eg, nortriptyline at an initial dosage of 50 mg orally at bedtime) have proved to be the most efficacious.

Pulsatile tinnitus—often described by the patient as listening to one's own heartbeat—should be distinguished from tonal tinnitus. Though often ascribed to conductive hearing loss, this symptom may be far more serious and indicates a vascular abnormality such as glomus tumor, carotid vaso-occlusive disease, arteriovenous malformation, or aneurysm. MR angiography should be considered to establish the diagnosis.

A staccato "clicking" tinnitus may result from middle ear muscle spasm, sometimes associated with palatal myoclonus. The patient typically perceives a rapid series of popping noises, lasting seconds to a few minutes, accompanied by a fluttering feeling in the ear.

Henry JA et al: Comparison of tinnitus masking and tinnitus retraining therapy. *J Am Acad Audiol* 2002;13:559. [\[PMID: 12503924\]](#)

Tonkin J: Tinnitus. More can be done than most GPs think. *Aust Fam Physician* 2002;31:712. [\[PMID: 12189660\]](#)

3. Hyperacusis

Excessive sensitivity to sound may occur in normal-hearing individuals either for psychologic reasons or in association with ear disease. Patients with cochlear dysfunction commonly experience recruitment, an abnormal sensitivity to loud sounds despite a reduced sensitivity to softer ones. Fitting hearing aids and other amplification devices to patients with recruitment requires use of compression circuitry to avoid uncomfortable overamplification. For normal-hearing individuals with hyperacusis, use of an earplug in noisy environments is often beneficial.

Katzenell U et al: Hyperacusis: review and clinical guidelines. *Otol Neurotol* 2001;22:321. [\[PMID: 11347634\]](#)

4. Vertigo ([Table 8-1](#))

Vertigo is the cardinal symptom of vestibular disease. It is either a sensation of motion when there is no motion or an exaggerated sense of motion in response to a given bodily movement. Thus, vertigo is not just "spinning" but may present, for example, as a sense of tumbling, of falling forward or backward, or of the ground rolling beneath one's feet ("earthquake-like"). It should be distinguished from imbalance, light-headedness, and syncope, all of which are usually nonvestibular in origin. The vertigo that results from peripheral vestibulopathy is usually of sudden onset, may be so severe that the patient is unable to walk or stand, and is frequently accompanied by nausea and vomiting. Tinnitus and hearing loss may be associated and provide strong support for a peripheral origin.

A minimal physical examination of the patient with vertigo includes the Romberg test, an evaluation of gait, and observation for the presence of nystagmus. In peripheral lesions, nystagmus is usually horizontal with a rotatory component; the fast phase usually beats away from the diseased side. Visual fixation tends to inhibit nystagmus except in very acute peripheral lesions or with central nervous system disease. The Nylen-Barany maneuvers are performed as follows: Put the patient in a sitting position on the examination table with the head turned to the right. Quickly lower the patient to the supine position with the head extending over the edge and placed 30 degrees lower than the body. Watch for nystagmus for 30 seconds. Repeat with the head turned to the left. Lastly, perform the maneuver without turning the head.

These maneuvers are intended to induce positioning nystagmus but are of limited use when the patient is able to visually fixate. This objection may be overcome either by placing +2-diopter lenses (Fresnel glasses) over the eyes or by making observations in the dark by means of electronystagmographic recording. The Fukuda test, in which the patient walks in place with eyes closed, is useful for detecting subtle defects. A positive response is observed when the patient rotates, usually toward the side of the diseased labyrinth. Vertigo arising from central lesions tends to develop gradually and then become progressively more severe and debilitating. Nystagmus is not always present but can occur in any direction and may be dissociated in the two eyes. The associated nystagmus is often nonfatigable, vertical rather than horizontal in orientation, without latency, and unsuppressed by visual fixation. Electronystagmography is useful in documenting these characteristics. The evaluation of central audiovestibular dysfunction usually requires imaging of the brain with MRI.

Episodic vertigo can occur in patients with diplopia from external ophthalmoplegia and is maximal when the patient looks in the direction where the separation of images is greatest. Cerebral lesions involving the temporal cortex may also produce vertigo, which is sometimes the initial symptom of a seizure. Finally, vertigo may be a feature of a number of systemic disorders and can occur as a side effect of certain anticonvulsant, antibiotic, hypnotic, analgesic, and tranquilizing drugs or of alcohol.

Laboratory investigations such as audiologic evaluation, caloric stimulation, electronystagmography, CT scan or MRI, and brain stem auditory evoked potential studies are indicated in patients with persistent vertigo or when central nervous system disease is suspected. These studies will help to distinguish between central and

peripheral lesions and to identify causes requiring specific therapy. Electronystagmography consists of objective recording of the nystagmus induced by head and body movements, gaze, and caloric stimulation. It is helpful in quantifying the degree of vestibular hypofunction and may help with the differentiation between peripheral and central lesions. Computer-driven rotatory chairs and posturography platforms offer improved diagnostic abilities but are not widely available.

Vertigo Syndromes Due to Peripheral Lesions

A. Endolymphatic Hydrops (Meniere's Syndrome)

Meniere's syndrome results from distention of the endolymphatic compartment of the inner ear. The primary lesion appears to be in the endolymphatic sac, which is thought to be responsible for endolymph filtration and excretion. Although a precise cause of hydrops cannot be established in most cases, two known causes are syphilis and head trauma. The classic syndrome consists of episodic vertigo, usually lasting 1-8 hours; low-frequency sensorineural hearing loss, often fluctuating; tinnitus, usually low-tone and "blowing" in quality; and a sensation of aural pressure. Symptoms wax and wane as the endolymphatic pressure rises and falls. Caloric testing commonly reveals loss or impairment of thermally induced nystagmus on the involved side.

Episodic vertigo resembling that of Meniere's syndrome but without accompanying auditory symptoms is known as recurrent vestibulopathy. The pathogenic mechanism of this symptom complex is unknown in most cases, though a few patients suffer from a variant of migraine. Others will go on to develop the classic syndrome of endolymphatic hydrops.

B. Labyrinthitis

Patients with labyrinthitis suffer from acute onset of continuous, usually severe vertigo lasting several days to a week, accompanied by hearing loss and tinnitus. During a recovery period that lasts for several weeks, rapid head movements may bring on transient vertigo. Hearing may return to normal or remain permanently impaired in the involved ear. The cause of labyrinthitis is unknown, although it frequently follows an upper respiratory tract infection.

C. Positioning Vertigo

This form of vertigo is usually peripheral in origin. Transient vertigo following changes in head position is a frequent complaint. The term "positioning vertigo" is more accurate than "positional vertigo" because it is provoked by changes in head position rather than by the maintenance of a particular posture. Use of the term "*benign positional/ vertigo*" is discouraged except for cases known to be unassociated with central nervous system disorders. True positional vertigo suggests either vertebrobasilar insufficiency or dysfunction of the cervical spine.

The typical symptoms of positioning vertigo occur in clusters that persist for several days. Typically with peripheral lesions, there is a latency period of several seconds following a head movement before symptoms develop, and they subside within 10-60 seconds. Constant repetition of the positional change leads to habituation. In central lesions, there is no latent period, fatigability, or habituation of the sign and symptoms. Single-session physical therapy protocols, based on the theory that peripheral positioning vertigo results from free-floating otoconia within a semicircular canal, have recently been developed. These strive to reposition the offending crystals through a series of head manipulations. New surgical procedures are also being explored which, by interrupting the posterior semicircular canal, attempt to prevent the exaggerated response to angular head motion.

D. Vestibular Neuronitis

In vestibular neuronitis, a paroxysmal, usually single attack of vertigo occurs without accompanying impairment of auditory function and may persist for several days to weeks before clearing. Examination reveals nystagmus and absent responses to caloric stimulation on one or both sides. The cause of the disorder is unclear. Treatment is symptomatic.

E. Traumatic Vertigo

The most common cause of vertigo following head injury is labyrinthine concussion. Symptoms generally diminish within several days but may linger for a month or more. Basilar skull fractures that traverse the inner ear usually result in severe vertigo lasting several days to a week and deafness in the involved ear. Chronic posttraumatic vertigo may result from cupulolithiasis. This occurs when traumatically detached statoconia (otoconia) settle on the ampulla of the posterior semicircular canal and cause an excessive degree of cupular deflection in response to head motion. Clinically, this presents as episodic positioning vertigo.

F. Perilymphatic Fistula

Leakage of perilymphatic fluid from the inner ear into the tympanic cavity via the round or oval window is often discussed as a cause of vertigo and sensory hearing loss but is actually very rare. Most cases result from either physical injury (eg, blunt head trauma, hand slap to ear), extreme barotrauma during airflight, scuba diving, etc, or vigorous Valsalva maneuver (eg, during weight lifting). Treatment may require middle ear exploration and window sealing with a tissue graft; however, this is seldom indicated without a clear-cut history of a precipitating traumatic event.

G. Cervical Vertigo

Position receptors located in the facets of the cervical spine are important physiologically in the coordination of head and eye movements. Cervical proprioceptive dysfunction is a common cause of vertigo triggered by neck movements. This disturbance often commences after neck injury, particularly hyperextension. An association also exists with degenerative cervical spine disease. Although symptoms vary, vertigo may be triggered by assuming a particular head position as opposed to moving to a new head position (the latter typical of labyrinthine dysfunction). Management consists of neck movement exercises to the extent permitted by orthopedic considerations.

H. Migrainous Vertigo

Episodic vertigo is frequently associated with a migraine type of headache. Most commonly, the vertigo is temporally related to the headache and lasts up to several hours. Some patients experience a positioning vertigo pattern. Occasionally, vertigo occurs independently of the head pain. The importance of recognizing this association is that antimigraine pharmacotherapy often relieves the vestibular symptoms.

Vertigo Syndromes Due to Central Lesions

Central nervous system causes of vertigo include brain stem vascular disease, arteriovenous malformations, tumor of the brain stem and cerebellum, multiple sclerosis, and vertebrobasilar migraine. Vertigo of central origin often becomes unremitting and disabling. The associated nystagmus is often nonfatigable, vertical rather than horizontal in orientation, without latency, and unsuppressed by visual fixation. Electronystagmography is useful in documenting these characteristics. There are commonly other signs of brain stem dysfunction (eg, cranial nerve palsies; motor, sensory, or cerebellar deficits in the limbs) or of increased intracranial pressure. Auditory function is generally spared. The underlying cause should be treated.

Baloh RW: Episodic vertigo: central nervous system causes. Curr Opin Neurol 2002;15:17. [\[PMID: 11796946\]](#)

Management of the Patient with Vertigo

Few specific treatments for labyrinthine disorders have been designed to reverse a known pathogenic mechanism. In Meniere's disease, treatment is intended to lower endolymphatic pressure. A low-salt diet (< 2 g sodium daily), at times supplemented by diuretics, adequately controls symptoms in the great majority of patients. A typical diuretic regimen is hydrochlorothiazide, 50-100 mg daily. Other specific treatments are antibiotics as required and surgical repair of perilymphatic fistulas.

Symptomatic treatment is useful in the vertiginous patient to lessen the abnormal sensation and to alleviate vegetative symptoms such as nausea and vomiting. The

most common drug classes employed are the antihistamines, anticholinergics, and sedative-hypnotics. Ample evidence exists that vestibular suppressant medications adversely affect the process of central compensation following acute vestibular disease. For this reason, these drugs should be used only for brief periods. Generally, they are best administered to patients with prominent vegetative symptoms and are best tapered and halted when symptoms are resolved, usually within 1-2 weeks.

In acute severe vertigo, vestibular suppressants such as diazepam, 2.5-5 mg sublingually, orally, or intravenously, may abate an attack. Relief from nausea and vomiting usually requires an antiemetic delivered intramuscularly or by rectal suppository (eg, prochlorperazine, 10 mg intramuscularly, or 25 mg rectally every 6 hours). Less severe vertigo may often be successfully alleviated with antihistamines such as meclizine, 25 mg, or cyclizine or dimenhydrinate, 25-50 mg, orally every 6 hours. Scopolamine, administered in low dosage transdermally (0.5 mg/d), has proved beneficial to many patients with recurrent vertigo, although side effects (dry mouth, blurred vision, urinary obstruction) often limit its utility. Sometimes employing one-half or even one-fourth of a patch may allow therapeutic effect without the usual adverse consequences. A combination of drugs sometimes helps when the response to one drug is disappointing.

Bed rest may reduce the severity of acute vertigo. Conversely, in chronic or recurrent vertigo, one of the most important therapies is exercise. Physical activity substantially enhances the central nervous system's ability to compensate for labyrinthine dysfunction and should be encouraged once nausea and vomiting have resolved. In general, the patient should be instructed to repeatedly perform maneuvers that provoke vertigo—up to the point of nausea or fatigue—in an effort to habituate them. Patients with vertigo and imbalance refractory to conventional therapy may benefit from a formal rehabilitation program under the guidance of a physical therapist. Substantial success has been reported in such patients through use of customized habituation protocols and specialized equipment, including tilt tables. Recently, use of a series of head maneuvers (theoretically intended to reposition free-floating otolithic particles) has gained popularity in the management of positioning vertigo. Such protocols have been shown to be at least as effective as vestibular habituation exercises, and they are less time-consuming.

For patients with recalcitrant vertigo or clusters of attacks, specialty referral may be useful. Prednisone has been used for clusters refractory to diuretics, low-salt diet, and vestibular suppressants.

Permanent therapy in medically refractory unilateral peripheral vestibular dysfunction is selective chemical destruction of the vestibular hair cell population by infusion of ototoxins transtympanically into the middle ear. Absorption into perilymph occurs via the round window. The most frequently used drug is gentamicin (80 mg/mL diluted 50:50 with bicarbonate), which is injected into the middle ear via a spinal needle. Results in patients with Meniere's syndrome have been impressive, with about 80-90% of patients relieved of severe episodic vertigo. A recent innovation in the management of endolymphatic hydrops (Meniere's disease) is a device that applies intermittent pressure pulses to the inner ear via a tympanostomy tube. Preliminary results for this minimally invasive technique have been promising.

Surgical remedies are reserved for those who remain substantially disabled despite a prolonged and varied trial of medical therapy and exercises. Selective section of the vestibular portion of the eighth nerve brings relief of vertigo in over 90% of such patients. Surgical removal of the semicircular canals (labyrinthectomy) is also highly effective but is appropriate only for patients with little or no hearing in the involved ear.

DISEASES OF THE CENTRAL AUDITORY & VESTIBULAR SYSTEMS (TABLE 8-1)

Lesions of the eighth cranial nerve and central audiovestibular pathways produce neural hearing loss and vertigo. One characteristic of neural hearing loss is deterioration of speech discrimination out of proportion to the decrease in pure tone thresholds. Another is auditory adaptation, wherein a steady tone appears to the listener to decay and eventually disappear. Auditory evoked responses are useful in distinguishing cochlear from neural losses and may give insight into the site of lesions within the central pathways.

The evaluation of central audiovestibular disorders usually requires imaging of the internal auditory canal, cerebellopontine angle, and brain with enhanced MRI.

1. Vestibular Schwannoma (Acoustic Neuroma)

Eighth nerve schwannomas are among the most common of intracranial tumors. These benign lesions arise within the internal auditory canal and gradually grow to involve the cerebellopontine angle, eventually compressing the pons and resulting in hydrocephalus. Their typical auditory symptoms are unilateral hearing loss with a deterioration of speech discrimination exceeding that predicted by the degree of pure tone loss. Nonclassic presentations, such as sudden unilateral hearing loss, are fairly common. Any individual with a unilateral or asymmetric sensorineural hearing loss should be evaluated for an intracranial mass lesion. Vestibular dysfunction more often takes the form of continuous dysequilibrium than episodic vertigo. Other lesions of the cerebellopontine angle such as meningioma and epidermoids may have similar audiovestibular manifestations. Diagnosis is made by enhanced MRI, though auditory evoked responses may have a role in screening. Microsurgical excision is most often indicated, though small tumors in older individuals may be managed with stereotactic radiotherapy or simply followed with serial imaging studies.

2. Vascular Compromise

Vertebrobasilar insufficiency is a common cause of vertigo in the elderly. It is often triggered by changes in posture or extension of the neck. Reduced flow in the vertebrobasilar system may be demonstrated noninvasively through magnetic resonance angiography. Empirical treatment is with vasodilators and aspirin.

Vascular loops that impinge upon the brain stem root entry zone of cranial nerves have been shown to cause dysfunction. Widely recognized examples are hemifacial spasm and tic douloureux. It has been suggested that hearing loss, tinnitus, and disabling positioning vertigo may result from a vascular loop abutting the eighth nerve.

Fujita N et al: Usefulness of MR angiography in cases of central vertigo. Auris Nasus Larynx 2002;29:247. [\[PMID: 12167445\]](#)

3. Multiple Sclerosis

Patients with multiple sclerosis may suffer from episodic vertigo and chronic imbalance. Hearing loss in this disease is most commonly unilateral and of rapid onset. Spontaneous recovery may occur.

Alpini D et al: Vertigo and multiple sclerosis: aspects of differential diagnosis. Neurol Sci 2001;22(Suppl 2):S84. [\[PMID: 11794485\]](#)

OTOLOGIC MANIFESTATIONS OF AIDS

The otologic manifestations of AIDS are protean. The pinna and external auditory canal may be affected by Kaposi's sarcoma as well as persistent and potentially invasive fungal infections, particularly due to *Aspergillus fumigatus*. The most common middle ear manifestation of AIDS is serous otitis media due to auditory tube dysfunction arising from adenoidal hypertrophy (HIV lymphadenopathy), recurrent mucosal viral infections, or an obstructing nasopharyngeal tumor (eg, lymphoma). For middle ear effusions, ventilating tubes are seldom helpful and may trigger profuse watery otorrhea. Acute otitis media is usually caused by the typical bacterial organisms that occur in nonimmunocompromised patients, though *Pneumocystis jiroveci* (formerly *P carinii*) otitis has been reported. Sensorineural hearing loss is common and in some cases appears to result from viral central nervous system infection. In cases of progressive hearing loss, it is important to evaluate for cryptococcal meningitis and syphilis. Acute facial paralysis due to herpes zoster infection (Ramsay Hunt's syndrome) is quite common and follows a clinical course similar to that in nonimmunocompromised patients. Treatment is primarily with high-dose acyclovir. Corticosteroids may also be effective.

■ DISEASES OF THE NOSE & PARANASAL SINUSES

INFECTIONS OF THE NOSE & PARANASAL SINUSES

1. Viral Rhinitis (Common Cold)

The nonspecific symptoms of the ubiquitous common cold are present in the early phases of many diseases that affect the upper aerodigestive tract. Because there are numerous serologic types of rhinoviruses, adenoviruses, and other viruses, patients remain susceptible throughout life. Headache, nasal congestion, watery rhinorrhea, sneezing, and a scratchy throat accompanied by general malaise are typical in viral infections. Nasal examination usually shows reddened, edematous mucosa and a watery discharge. The presence of purulent nasal discharge suggests bacterial infection.

There is no curative treatment for a cold. There is a common misperception among patients that antibiotics are helpful. Supportive measures such as decongestants (pseudoephedrine, 30-60 mg every 4-6 hours or 120 mg twice daily) may provide some relief of rhinorrhea and nasal obstruction.

Nasal sprays such as oxymetazoline or phenylephrine are rapidly effective. They should not be used for more than a few days at a time, since chronic use leads to a rebound congestion that is often worse than the original symptoms. This chronic nasal stuffiness is known as rhinitis medicamentosa. Treatment requires complete cessation of the sprays. This triggers a period of severe nasal congestion that usually lasts 1-2 weeks. Topical intranasal corticosteroids (flunisolide, two sprays in each nostril twice daily) or a short tapering course of oral prednisone may help during the process of withdrawal.

Other than transient middle ear effusion, complications of viral rhinitis are unusual. Secondary bacterial infection may occur and is suggested by persistence of symptoms beyond a week accompanied both by purulent green or yellow nasal secretions and unilateral facial or tooth pain. The most common pathogens are the same as those responsible for acute otitis media, ie, *Streptococcus pneumoniae*, other streptococci, *Haemophilus influenzae*, *Staphylococcus aureus*, and *Moraxella catarrhalis*. (See Acute Sinusitis, below.)

Steinman MA, et al: Predictors of broad-spectrum antibiotic prescribing for acute respiratory tract infections in adult primary care. JAMA 2003;289:719. [\[PMID: 12585950\]](#)

2. Acute Sinusitis

Acute sinus infections are uncommon compared with viral rhinitis, but they still affect over 14% of the population, accounting for over \$2 billion in health care expenditures for sinusitis annually. Because sinusitis usually has followed an acute respiratory infection and because media advertisements often use the term "sinusitis" when "rhinitis" would be more accurate, it is understandable that patients and clinicians alike sometimes confuse these entities. Sinusitis is suggested when symptoms have persevered for more than a week and pain is reported unilaterally, either as toothache or as pain over the maxillary sinus. Objective signs include a change of secretions from watery or mucoid to purulent green or yellow, or (occasionally) visible swelling or erythema over a sinus.

Sinusitis usually is a result of impaired mucociliary clearance and obstruction of the osteomeatal complex. Diseases that swell the nasal mucous membrane, such as viral or allergic rhinitis, are usually the underlying cause. Edematous mucosa causes obstruction of the sinus drainage tract, resulting in the accumulation of mucous secretion in the sinus cavity that becomes secondarily infected by bacteria. The typical pathogens of bacterial sinusitis are the same as those that cause acute otitis media: *S pneumoniae*, other streptococci, *H influenzae*, and, less commonly, *S aureus* and *M catarrhalis*. It should be kept in mind that about 25% of healthy asymptomatic individuals may, if sinus aspirates are cultured, harbor such bacteria as well.

Clinical Findings

A. Symptoms and Signs

Because the maxillary sinus is the largest of the paranasal sinuses and its ostia into the nose is superiorly placed, thereby failing to take advantage of gravity, it is the most commonly affected sinus. Pain and pressure over the cheek are the usual symptoms. Pain may refer to the upper incisor and canine teeth via branches of the trigeminal nerve, which traverse the floor of the sinus. It is not uncommon for maxillary sinusitis to result from dental infection, and teeth that are tender should be carefully examined for signs of abscess. Discolored nasal discharge and poor response to decongestants may also suggest sinusitis. Other possible causes for facial pain, such as trigeminal neuralgia and optic neuritis, should be kept in mind as well.

Acute ethmoiditis in adults is usually accompanied by maxillary sinusitis. In such cases, the symptoms of maxillary sinusitis generally predominate. Ethmoidal infection presents with pain and pressure over the high lateral wall of the nose that may radiate to the orbit. Periorbital cellulitis may be present.

Sphenoid sinusitis is usually seen in the setting of pansinusitis. The patient may complain of a headache "in the middle of the head" and often points to the vertex. Sixth nerve palsy may occur as the abducens nerve courses just lateral to the sinus.

Acute frontal sinusitis usually causes pain and tenderness of the forehead. This is most easily elicited by palpation of the orbital roof just below the medial end of the eyebrow. Palpation here is more accurate than percussion of the supraorbital area or forehead.

B. Imaging

It is usually possible to make the diagnosis of sinusitis on clinical grounds alone. Although more sensitive than clinical examination, routine radiographs are not cost-effective and are not recommended by the Agency for Health Care Policy and Research. However, they may be helpful when clinically based criteria are difficult to evaluate. The hallmarks of acute sinusitis radiologically are soft tissue density without bone destruction. An air-fluid level may also be seen.

Limited coronal CT scans have largely replaced conventional sinus films. CT is no more expensive, is more sensitive to both inflammatory changes and bone destruction (which would raise the possibility of an underlying tumor), and by identifying anatomic blockage of the osteomeatal complex may also help guide endoscopic sinus surgery in recurrent or chronic sinusitis. In critically ill intubated patients, where the prevalence of nosocomial sinusitis is as high as 40%, CT identification and subsequent antibiotic treatment appear to reduce the incidence of bronchopneumonia. Occasionally, a CT scan may be indicated to demonstrate that a patient with midface pain does *not* have sinusitis.

While reasonably sensitive, CT scans are not specific. Sinus abnormalities can be seen in the majority of patients with an upper respiratory infection, while only 2% develop bacterial sinusitis. Thus, sinusitis is a clinical diagnosis for which CT may be helpful in confirming, denying, or monitoring.

If malignancy is suspected, MRI with gadolinium should be ordered instead of CT. MRI will distinguish tumor from inflammation and inspissated mucus far better than CT, as well as better delineating tumor extent with respect to adjacent structures such as the orbit, skull base, and palate. Bone destruction can be demonstrated as well by MRI as by CT.

Treatment

Two-thirds of untreated patients will improve symptomatically within 2 weeks. Administration of antibiotics does, however, reduce by 50% the incidence of clinical failure and, coupled with clinical criteria-based diagnosis, represents the most cost-effective treatment strategy. Symptoms may be improved with oral or nasal decongestants

(or both)—eg, oral pseudoephedrine, 30-120 mg per dose, up to 240 mg/d; nasal oxymetazoline, 0.05%; or xylometazoline, 0.05-0.1%, one or two sprays in each nostril every 6-8 hours for up to 3 days.

Double-blinded studies exist to support any of the following antibiotic choices:

Amoxicillin (500 mg orally three times a day), possibly with clavulanate (125 mg three times a day)

Trimethoprim-sulfamethoxazole (4 mg/kg TMP and 20 mg/kg SMZ twice daily; available as tablets with 80 or 160 mg TMP and 160 or 800 mg SMZ)

Cephalexin (250-500 mg orally four times a day)

Cefuroxime (250 mg orally twice daily)

Cefaclor (250 mg orally three times a day)

Cefixime (400 mg orally daily)

Quinolones, such as ciprofloxacin (500 mg twice daily), levofloxacin (500 mg once daily), moxifloxacin (400 mg once daily), and sparfloxacin (200 mg once daily after an initial dose of 400 mg).

Macrolides, such as azithromycin (500 mg once daily, possibly for only three days) or clarithromycin (500 mg orally twice daily, for 14 days)

Usually, amoxicillin or trimethoprim-sulfamethoxazole is adequate and most cost-effective and covers the common pathogens discussed earlier. Treatment is usually for 10 days (or as stated above), though longer courses are sometimes required to prevent relapses. Recurrent sinusitis or sinusitis that does not appear to respond clinically warrants evaluation by a specialist. Selection of antibiotics is usually empiric, but if symptoms persist, obtaining a culture endoscopically or via maxillary sinus puncture may help narrow the choice based on culture and sensitivity tests. Resistance by *Haemophilus influenzae* and *Streptococcus pneumoniae* is a public health concern. Culture may also be helpful in nosocomial sinusitis, where the bacterial spectrum may be less typical and the potential complications greater.

Failure of sinusitis to resolve after an adequate course of oral antibiotics may necessitate hospital admission for intravenous antibiotics and possible surgical drainage. Frontal sinusitis that does not promptly respond to outpatient care should be managed aggressively, because the posterior sinus wall is adjacent to the dura and because undertreated infection may lead to intracranial extension. If intravenous antibiotics fail to ameliorate symptoms, it may be necessary to surgically drill a small opening into the floor of the frontal sinus to drain and irrigate the sinus. Persistent maxillary empyema may be cultured and relieved with a needle inserted through the lateral wall of the nose or anterior wall of the antrum through the gingivobuccal sulcus.

Complications

Local complications of sinusitis include osteomyelitis and mucocoele. Mucocoeles, a consequence of long-standing ductal obstruction, are more common in the supraorbital ethmoids and frontal sinuses and may become secondarily infected. They appear radiologically as a smoothly expanded sinus filled with homogeneous soft tissue density. Treatment is surgical, requiring either drainage of the mucocoele intranasally or its complete excision with fat ablation of the sinus cavity.

Osteomyelitis requires prolonged antibiotics as well as removal of necrotic bone. The frontal sinus is most commonly affected, with bone involvement suggested by a tender puffy swelling of the forehead. Following treatment, secondary cosmetic reconstructive procedures may be necessary.

Intracranial complications of sinusitis occur either through hematogenous spread, as in cavernous sinus thrombosis and meningitis, or by direct extension, as in epidural and intraparenchymal brain abscesses. Fortunately, they are rare today. Cavernous sinus thrombosis is heralded by ophthalmoplegia, chemosis, and visual loss. Frontal epidural abscess is usually quiescent. It may be detected on CT scan, a study recommended in all cases of atypical or complicated sinusitis.

It should always be kept in mind that paranasal sinus cancer is in the differential diagnosis of sinusitis. The presence of bone destruction radiologically, cranial neuropathies (especially V₂), persistent pain, epistaxis, or a prolonged clinical course should raise the suspicion of possible cancer.

3. Nasal Vestibulitis

Inflammation of the nasal vestibule commonly results from folliculitis of the hairs that line this orifice. Systemic antibiotics effective against *S aureus* (such as dicloxacillin, 250 mg orally four times daily for 7-10 days) are indicated. Topical mupirocin (applied two or three times daily) may be a helpful addition. If recurrent, the addition of rifampin (10 mg/kg orally twice daily for the last 4 days of treatment) may eliminate the *S aureus* carrier state. If a furuncle exists, it should be incised and drained, preferably intranasally. Adequate treatment of these infections is important to prevent retrograde spread of infection through valveless veins into the cavernous sinus and intracranial structures.

4. Rhinocerebral Mucormycosis

Although mucormycosis is rare, any clinician seeing patients in a primary care setting must be aware of its presenting symptoms and signs. The fungus (mucor, absidia, rhizopus) spreads rapidly through vascular channels and may be lethal if not detected early. Patients with mucormycosis almost invariably have an underlying disease, often diabetes mellitus or end-stage renal disease. It also occurs following bone marrow transplantation, in patients with lymphoma, in patients who are immunosuppressed for other reasons, and in patients receiving deferoxamine (a metal chelator). Occasional cases have been reported in patients with AIDS, though aspergillus is more common in this setting. The initial symptoms may be similar to those of bacterial sinusitis, although facial pain is often more severe. Examination of the nasal mucosa is likely to show black, necrotic eschar adherent to the inferior turbinate, though this may not be present in early stages. Cranial neuropathies and black necrotic skin overlying the ethmoid sinuses are advanced signs. Early diagnosis requires suspicion of the disease and nasal or sinus biopsy, which reveals broad nonseptate hyphae within tissues. Because CT or MRI may initially show only soft tissue changes, intervention should be based on the clinical setting and not on radiologic demonstration of bony destruction or intracranial changes.

Mucormycosis represents a medical and surgical emergency. Once recognized, prompt wide surgical debridement and amphotericin B by intravenous infusion are indicated. Lipid-based amphotericin B may be used in patients who have renal insufficiency or develop it secondary to nephrotoxic doses of nonlipid amphotericin. When there appears to be sufficiently little orbital involvement that orbital preservation is a realistic therapeutic objective, conservative debridement of the orbit may be supplemented with adjunctive amphotericin B irrigation. Close management of the underlying disease is also of great importance. Even with early diagnosis and immediate appropriate intervention, the prognosis is guarded. In diabetics, the mortality rate is about 20%; in patients with renal failure, it is over 50%; and in AIDS, it is close to 100%.

ALLERGIC RHINITIS

The symptoms of "hay fever" are similar to those of viral rhinitis but are usually persistent and show seasonal variation. Nasal symptoms are often accompanied by eye irritation, which causes pruritus, erythema, and excessive tearing. Numerous allergens may cause these symptoms: pollens are most common in the spring, grasses in the summer, and ragweed in the fall. Dust and household mites may produce year-round symptoms.

On physical examination, the mucosa of the turbinates is usually pale or violaceous because of venous engorgement. This is in contrast to the erythema of viral rhinitis. Nasal polyps, which are yellowish boggy masses of hypertrophic mucosa, may be seen.

Treatment of allergic and perennial rhinitis has improved in recent years. Numerous over-the-counter antihistamines, such as brompheniramine or chlorpheniramine (4 mg orally every 6-8 hours, or 8-12 mg orally every 8-12 hours as a sustained-release tablet) and clemastine (1.34-2.68 mg orally twice daily) offer the benefit of reduced cost though usually associated with higher rates of drowsiness compared with the newer prescription antihistamines. These oral H₁ receptor antagonists include cetirizine (10 mg orally once daily), fexofenadine (60 mg orally twice daily or 120 mg once daily), and loratadine (10 mg orally once daily). Fexofenadine appears to be nonsedating; the other two minimally sedating. Also shown to be effective in randomized trials are ebastine (10-20 mg orally once daily) and misolastine (10 mg once daily). Two H₁ receptor antagonist antihistamine nasal sprays have also been shown to be effective in randomized trials: levocabastine (0.2 mg twice daily) and azelastine (two sprays per nostril, 1.1 mg/d).

Intranasal corticosteroid sprays are a mainstay of treatment of allergic rhinitis. Evidence-based literature reviews show that these are more effective—and frequently less expensive—than nonsedating antihistamines. Patients should be reminded that there may be a delay in onset of relief of 1-2 weeks. Steroid sprays may also shrink nasal polyps, thereby providing an improved nasal airway and delaying or eliminating the indications for endoscopic sinus surgery. Available preparations include beclomethasone (42 ug/spray twice daily each nostril), flunisolide (25 ug/spray twice daily each nostril), mometasone furoate (200 ug once daily per nostril), and fluticasone propionate (200 ug once daily per nostril). The latter two synthetic glucocorticoids appear to have higher topical potencies and lipid solubility and reduced systemic bioavailability, suggesting possible practical advantages.

In addition to intranasal corticosteroid sprays and antihistamines, including H₁ receptor antagonists, recent literature supports the use of antileukotriene medications in allergic rhinitis. There are proinflammatory effects of cysteinyl leukotrienes in upper and lower airway disease, including asthma, allergic rhinitis, and hyperplastic sinusitis and polyposis. Improved nasal rhinorrhea, sneezing, and congestion are seen with the use of leukotriene receptor antagonists, often in conjunction with antihistamines.

Maintaining an allergen-free environment by covering pillows and mattresses with plastic covers, substituting synthetic materials (foam mattress, acrylics) for animal products (wool, horsehair), and removing dust-collecting household fixtures (carpets, drapes, bedspreads, wicker) is worth the attempt to help more troubled patients. Air purifiers and dust filters (such as Bionaire models) may also aid in maintaining an allergen-free environment. When symptoms are extremely bothersome, a search for offending allergens may prove helpful. This can either be done by skin testing or by serum RAST testing. Desensitization by gradually increasing subdermal exposure to identified allergens may be tried in selected patients, with variable results.

Adjunctive options include intranasal anticholinergic agents such as ipratropium bromide 0.03% sprays (42 ug per nostril three times daily) when rhinorrhea is a major symptom and intranasal cromolyn spray prior to the onset of seasonal symptoms.

OLFACTORY DYSFUNCTION

The physiology of olfaction is less well understood than that of the other special senses. The taste of foods is strongly affected by our sense of smell, and studies have shown a moderate correlation between taste discrimination ability and odor discrimination ability. In the past few years, discovery of the family of odor-receptor genes as well as inositol phosphate and cyclic nucleotide signaling pathways has led to a molecular basis of olfactory reception. Clinically, odorant molecules traverse the nasal vault to reach the cribriform area and become soluble in the mucus overlying the exposed dendrites of receptor cells. Anatomic blockage of the nares is the most common cause of olfactory dysfunction (hyposmia or anosmia). Polyps, septal deformities, and nasal tumors may prevent air from reaching the area of the cribriform plate high in the nose where these receptors are located. Transient olfactory dysfunction often accompanies the common cold, nasal allergies, and perennial rhinitis. About 20% of olfactory dysfunction is idiopathic, although it often follows a viral illness. Some have suggested administering large doses of vitamin A and zinc to such patients, although little evidence supports their use. Central nervous system neoplasms, especially those that involve the olfactory groove or temporal lobe, may affect olfaction. Head trauma accounts for less than 5% of cases of hyposmia. Absent, diminished, or distorted smell or taste has been reported in a wide variety of endocrine, nutritional, and nervous disorders. In particular, olfactory dysfunction in Parkinson's disease and Alzheimer's disease has been the subject of recent research. A great many medications have also been implicated.

Evaluation of olfactory dysfunction should include a thorough history of systemic illnesses and medication use as well as a physical examination focusing on the nose and nervous system. Most clinical offices are not set up to test olfaction, but such feats may at times be worthwhile if only to assess whether a patient possesses any sense of smell at all. Odor identification and discrimination can be tested using standardized choices (see references). Odor threshold can be tested using increasing concentrations of various materials. In permanent hyposmia, counseling should be offered about seasoning foods with spices (eg, pepper) that stimulate the trigeminal as well as olfactory chemoreceptors and about safety issues such as the use of smoke alarms and electric rather than gas home appliances.

EPISTAXIS

Bleeding from Kiesselbach's plexus, a vascular plexus on the anterior nasal septum, is by far the most common type of epistaxis encountered. Predisposing factors include nasal trauma (nose picking, foreign bodies, forceful nose blowing), rhinitis, drying of the nasal mucosa from low humidity, deviation of the nasal septum, alcohol use, and antiplatelet medications. Most cases of anterior epistaxis may be successfully treated by direct pressure on the bleeding site. The nasal alae should be firmly compressed for at least 10 minutes. Venous pressure is reduced in the sitting position, and leaning forward lessens the swallowing of blood. Short-acting topical nasal decongestants (eg, phenylephrine, 0.125-1% solution, one or two sprays), which act as vasoconstrictors, may also be helpful. When the bleeding does not readily subside, the nose should be examined, using good illumination and suction, in an attempt to locate the bleeding site. Topical 4% cocaine applied either as a spray or on a cotton strip serves both as an anesthetic and as a vasoconstricting agent. If cocaine is unavailable, a topical decongestant (eg, oxymetazoline) and a topical anesthetic (eg, tetracaine) provide equivalent results. When visible, the bleeding site may be cauterized with silver nitrate, diathermy, or electrocautery. A supplemental patch of Surgicel or Gelfoam may be helpful.

Occasionally, a site of bleeding may be inaccessible to direct control, or attempts at direct control may be unsuccessful. In such cases there are a number of alternatives. When the site of bleeding is anterior, anterior packing will usually suffice. There are a number of ways to do this, such as with several feet of lubricated iodoform packing systematically placed in the floor of the nose and then the vault of the nose, or with various manufactured foam packs or nasal balloons.

About 5% of nasal bleeding originates in the posterior nasal cavity. This requires placement of a pack to occlude the choana before placement of a pack anteriorly. Because this is uncomfortable for the patient and because it requires oxygen supplementation to prevent hypoxia, hospitalization for several days is indicated. Narcotic analgesics are needed to reduce the considerable discomfort and elevated blood pressure caused by a posterior pack. Ligation of the nasal arterial supply (internal maxillary artery and ethmoid arteries) is an alternative to posterior nasal packing, as is endovascular embolization of the internal maxillary artery. This is certainly necessary when packing fails to control life-threatening hemorrhage. On rare occasions, ligation of the external carotid artery may be necessary.

After control of epistaxis, the patient is advised to avoid vigorous exercise for several days. Avoidance of hot or spicy foods and tobacco is also advisable, as they may cause vasodilation. Avoiding nasal trauma, including nose picking, is an obvious necessity. Lubrication with petroleum jelly or bacitracin ointment and increased home humidity may also be useful ancillary measures.

It is important in all patients with epistaxis to consider underlying causes of the bleeding. Laboratory assessment of bleeding parameters may be indicated, especially in recurrent cases. Other causes of recurrent epistaxis, such as hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome), should also be considered. Similarly, once the acute episode has passed, careful examination of the nose and paranasal sinuses to rule out neoplasia is wise.

Patients presenting with epistaxis often have higher blood pressures than control patients. Continued management of patients with epistaxis should therefore include follow-up investigation of possible hypertension.

NASAL TRAUMA

The nasal pyramid is the most frequently fractured bone in the body. Fracture is suggested by crepitance or palpably mobile bony segments. Epistaxis and pain are common, as are soft tissue hematomas ("black eye"). It is important to make certain that there is no palpable step-off of the infraorbital rim, which would indicate the presence of a zygomatic complex fracture. Radiologic confirmation may at times be helpful but is not necessary in uncomplicated nasal fractures. It is also important to assess for possible concomitant additional facial, pulmonary, or intracranial injuries when the circumstances of injury are suggestive, as in the case of automobile and motorcycle accidents.

Treatment is aimed at maintaining long-term nasal airway patency and nasal aesthetics. Closed reduction, using topical 4% cocaine and locally injected 1% lidocaine, should be attempted within 1 week of injury. In the presence of marked nasal swelling, it is best to wait several days for the edema to subside before undertaking reduction. Persistent functional or cosmetic defects may be repaired by delayed reconstructive nasal surgery.

Intranasal examination should be performed in all cases to rule out septal hematoma, which appears as a widening of the anterior septum, visible just posterior to the columella. The septal cartilage receives its only nutrition from its closely adherent mucoperichondrium. An untreated subperichondrial hematoma will result in loss of the nasal cartilage with resultant saddlenose deformity. Septal hematomas may become infected, with *S aureus* the predominant organism. Treatment consists of incision and drainage via an intranasal septal mucosal incision. It is important to be sure that both sides of the septal cartilage are adequately drained. A small Penrose drain sutured in place is helpful. Antibiotics should be given and the drained fluid sent for culture.

TUMORS & GRANULOMATOUS DISEASE

1. Benign Nasal Tumors

Nasal Polyps

Nasal polyps are pale, edematous, mucosally covered masses commonly seen in patients with allergic rhinitis, but compelling evidence argues against a purely allergic pathogenesis. They may result in chronic nasal obstruction and a diminished sense of smell. In patients with nasal polyps and a history of asthma, aspirin should be avoided as it may precipitate a severe episode of bronchospasm. The presence of polyps in children should suggest the possibility of cystic fibrosis.

Initial treatment with topical nasal steroids (see Allergic Rhinitis section for specific drugs) for 1-3 months is usually successful for small polyps and may reduce the need for operation. A short course of oral corticosteroids (eg, prednisone, 6-day course using twenty-one 5-mg tablets: 30 mg on day 1 and tapering by 5 mg each day) may also be of benefit. When medical management is unsuccessful, polyps should be removed surgically. In healthy persons, this is a minor outpatient procedure. In recurrent cases or when surgery itself is associated with increased risk (such as in asthmatics), a more complete procedure, such as ethmoidectomy, may be advisable. In recurrent polyposis, it may be necessary to remove polyps from the ethmoid, sphenoid, and maxillary sinuses to provide longer-lasting relief.

Inverted Papilloma

Inverted papillomas are benign tumors that usually arise in the common wall between the nose and maxillary sinus. They present with unilateral nasal obstruction and occasionally hemorrhage. Because squamous cell carcinoma is seen in about 10% of inverted or schneiderian papillomas, complete excision is strongly recommended. This usually requires a medial maxillectomy, but in selected cases an endoscopic approach may be possible. Because recurrence rates for inverted papilloma are reported to be as high as 20%, subsequent clinical and radiologic follow-up is imperative. All excised tissue (not just a portion) should be carefully reviewed by the pathologist to be sure no carcinoma is present.

Juvenile Angiofibroma

These highly vascular tumors arise in the nasopharynx, typically in adolescent males. Initially, they cause nasal obstruction and hemorrhage. Any adolescent male with recurrent epistaxis should be evaluated for an angiofibroma. Though benign, these tumors expand locally from the pterygopalatine fossa at the pterygoid canal and extend into the pterygoid base, the greater wing of the sphenoid, the nasal cavity, and the paranasal sinuses. They may involve the skull base, usually extradurally, and extend into the superior clivus. Treatment consists of preoperative embolization followed by surgical excision via an approach appropriate for the tumor extent. Small angiofibromas may occasionally be resected endoscopically. Extensive ones may require skull base approaches. Recurrences are not uncommon and should be resected if possible. Unresectable recurrences that do not appear to grow significantly may be followed radiologically with serial MR scans in expectation of possible eventual involution stabilization or involution of tumor. Low-dose (30 Gy) irradiation may be helpful in nonresectable, continually growing tumors.

2. Malignant Nasopharyngeal & Paranasal Sinus Tumors

Unfortunately, malignant tumors of the nose, nasopharynx, and paranasal sinuses tend to remain asymptomatic until late in their course. Although the prognosis is poor for advanced tumors, results of treatment of resectable tumors of paranasal sinus origin have improved with the wider use of skull base resections and intensity-modulated radiation therapy. Cure rates are often 45-60%. Early symptoms are nonspecific, mimicking those of rhinitis or sinusitis. Unilateral nasal obstruction and discharge are common, with pain and recurrent hemorrhage often clues to the diagnosis of cancer. Any patient with unilateral or persistent nasal symptoms should be thoroughly evaluated. A high index of suspicion remains a key to the earlier diagnosis of these tumors. Patients often present with advanced symptoms such as proptosis, expansion of a cheek, or ill-fitting maxillary dentures. Malar hypesthesia, due to involvement of the infraorbital nerve, is common in maxillary sinus tumors. Biopsy is necessary for definitive diagnosis, and MRI is the best imaging study to delineate the extent of disease and plan appropriate surgery and radiation.

Squamous cell carcinoma is the most common cancer found. It is especially common in the nasopharynx, where it obstructs the auditory tube and results in serous otitis media. Nasopharyngeal carcinoma (poorly differentiated squamous cell carcinoma, nonkeratinizing squamous cell carcinoma, or lymphoepithelioma) is usually associated with elevated IgA antibody to the viral capsid antigen of the Epstein-Barr virus. It is particularly common in patients of southern Chinese descent. Any adult with persistent serous otitis media, especially when unilateral, requires careful evaluation of the nasopharynx. Adenocarcinomas, mucosal melanomas, sarcomas, and non-Hodgkin's lymphomas are less commonly encountered neoplasms of this area.

Treatment depends on the tumor type and the extent of disease. Nasopharyngeal carcinoma at this time is best treated by concomitant radiation and cisplatin followed by adjuvant chemotherapy with cisplatin and fluorouracil—this protocol significantly decreased local, nodal, and distant failures and increased progression-free and overall survival. Locally recurrent nasopharyngeal carcinoma may in selected cases be treated with repeat irradiation protocols or surgery with moderate success and a high degree of concern about local wound healing. Other squamous cell carcinomas are best treated—when resectable—with a combination of surgery and irradiation. Numerous protocols investigating the role of chemotherapy are under evaluation. Cranial base surgery appears to be an effective modality in improving the overall prognosis in paranasal sinus malignancies eroding the ethmoid roof.

3. Wegener's Granulomatosis, NK Cell & T Cell EBV-Positive Lymphoma, & Sarcoidosis

The nose and paranasal sinuses are involved in over 90% of cases of Wegener's granulomatosis. It is often not realized that involvement at these sites is more common than involvement of lungs or kidneys. Examination shows bloodstained crusts and friable mucosa. Biopsy classically shows necrotizing granulomas and vasculitis, but the diagnosis may be difficult. Sarcoidosis also commonly involves the paranasal sinuses and is clinically similar to other chronic sinonasal inflammatory processes. Biopsy shows noncaseating granulomas.

Polymorphic reticulosis (midline malignant reticulosis, idiopathic midline destructive disease, lethal midline granuloma), as the multitude of apt descriptive terms suggest, is not well understood but appears to be a nasal lymphoma. In contrast to Wegener's granulomatosis, involvement is limited to the mid- face, and there may be extensive bone destruction. Its progression in time to a lymphoma is being described with increasing frequency.

Many destructive lesions of the mucosa and nasal structures labeled as polymorphic reticulosis are in fact non-Hodgkin's lymphoma of either NK cell or T cell origin. Immunophenotyping, especially for CD56 expression, is essential in the histologic evaluation. Even when apparently localized, these lymphomas have a poor prognosis, with progression and death within a year the rule.

■ DISEASES OF THE ORAL CAVITY & PHARYNX

LEUKOPLAKIA, ERYTHROPLAKIA, ORAL LICHEN PLANUS, & ORAL CANCER

Leukoplakia is any white lesion that, unlike oral candidiasis, cannot be removed by rubbing the mucosal surface. These areas are usually small but may be several centimeters in diameter. Histologically, they are often hyperkeratoses occurring in response to chronic irritation (eg, from dentures, tobacco, lichen planus); about 2-6%, however, represent either dysplasia or early invasive squamous cell carcinoma.

Erythroplakia is similar to leukoplakia except that it has a definite erythematous component. The distinction is important, since about 90% of cases of erythroplakia are either dysplasia or carcinoma. Squamous cell carcinoma accounts for 90% of oral cancer. Alcohol and tobacco are the major epidemiologic risk factors. The differential diagnosis may include oral candidiasis, necrotizing sialometaplasia, pseudoepitheliomatous hyperplasia, median rhomboid glossitis, and vesiculoerosive inflammatory disease such as erosive lichen planus. This should not be confused with the brown-black gingival melanin pigmentation—diffuse or speckled—common in nonwhites, blue-black embedded fragments of dental amalgam, or other systemic disorders associated with general pigmentation (neurofibromatosis, familial polyposis, Addison's disease). Intraoral melanoma is extremely rare.

Oral lichen planus is a relatively common (0.5-2% of the population) chronic inflammatory autoimmune disease that may be difficult to diagnose clinically because of its

numerous distinct phenotypic subtypes. For example, the reticular pattern may mimic candidiasis or hyperkeratosis, while the erosive pattern may mimic squamous cell carcinoma. Management begins with distinguishing it from other oral lesions; this usually requires biopsy. Therapy is aimed at managing pain and discomfort. Steroids have been used widely both locally and systemically. Cyclosporines and retinoids have also been used. Many think there is a low rate (1%) of squamous cell carcinoma arising within lichen planus (in addition to the possibility of clinical misdiagnosis).

Any erythroplakic or enlarging leukoplakic area should have an incisional biopsy or an exfoliative cytologic examination. Specialty referral should be sought early both for diagnosis and treatment. Intraoral staining with 1% toluidine blue may aid in selection of the most suspicious biopsy site. A systematic intraoral examination—including the lateral tongue, floor of the mouth, gingiva, buccal area, palate, and tonsillar fossae—and palpation of the neck for enlarged lymph nodes should be part of any general physical examination, especially in patients over 45 who smoke tobacco or drink immoderately. Indirect or fiberoptic examination of the nasopharynx, oropharynx, hypopharynx, and larynx by an otolaryngologist-head and neck surgeon or radiation oncologist should also be considered for such patients when there is unexplained or persistent throat or ear pain, oral or nasal bleeding, or oral erythroplakia. Fine-needle aspiration biopsy may be indicated if an enlarged lymph node is found.

Early detection of squamous cell carcinoma is the key to successful management. Lesions less than 4 mm in depth have a low propensity to metastasize. Most patients in whom the tumor is detected before it is 2 cm in diameter are cured. Small lesions are best treated with surgical excision, often with a laser. Radiation is an alternative but is associated with xerostomia, osteonecrosis of the mandible, and inability to use a curative dose again in the treatment field. Large tumors nevertheless are usually treated with a combination of resection and irradiation. Reconstruction, if required, is done at the time of resection and can involve the use of myocutaneous flaps or vascularized free flaps with or without bone.

Molecular and genetic analysis of premalignant and malignant tissue has produced increasing evidence of genetic instability (including microsatellite instability, cell cycle-regulatory gene *P16* and *P14* deletions and hypermethylation, and mutations in *P53*), and clonal alterations, such as loss of retinoic acid beta-receptor expression, occur during the early stage of aerodigestive tract carcinogenesis. These molecular and epidemiologic studies provide the foundation on which clinical trials have been designed to evaluate the role of retinoids and other compounds in the reversal of premalignancy and the possible reduction in the 4-7% annual rate of second primary tumors.

A number of clinical trials have suggested a role for beta-carotene, vitamin E, and retinoids in producing regression of leukoplakia and reducing the incidence of recurrent squamous cell carcinomas. Retinoids suppress head and neck and lung carcinogenesis in animal models and inhibit carcinogenesis in individuals with premalignant lesions. They also seem to reduce the incidence of second primary cancers in head and neck and lung cancer patients previously treated for a primary. Sudbo has demonstrated clearly that aneuploidy in leukoplakic lesions is associated with an increased propensity to develop malignancy. It is expected that increased screening for gross genomic instability will become more widely used in the future.

CANDIDIASIS

Oral candidiasis (thrush) is usually painful and looks like creamy-white curd-like patches overlying erythematous mucosa. Because these white areas are easily rubbed off (eg, by a tongue depressor)—unlike leukoplakia or lichen planus—only the underlying irregular erythema may be seen. Oral candidiasis is commonly encountered among denture wearers; in debilitated patients, diabetes patients, anemia patients, and patients undergoing chemotherapy or local irradiation; and in patients receiving corticosteroids or broad-spectrum antibiotics. Candidiasis is often seen as the first manifestation of HIV infection. Angular cheilitis is another manifestation of candidiasis, though it is also seen in nutritional deficiencies.

The diagnosis is made clinically. A wet preparation using potassium hydroxide will reveal spores and may show nonseptate mycelia. Biopsy will show intraepithelial pseudomycelia of *Candida albicans*.

Effective antifungal therapy may be achieved with any of the following: fluconazole (100 mg daily for 7-14 days), ketoconazole (200-400 mg with breakfast [requires acidic gastric environment for absorption] for 7-14 days), clotrimazole troches (10 mg dissolved orally five times daily), or nystatin vaginal troches (100,000 units dissolved orally five times daily) or mouth rinses (500,000 units [5 mL of 100,000 units/mL] held in the mouth before swallowing three times daily). Shorter-duration therapy has proved effective, using fluconazole. In patients with HIV infection, however, longer courses may be needed, and itraconazole (200 mg orally daily) may be indicated in fluconazole-refractory cases. In addition, 0.12% chlorhexidine or half-strength hydrogen peroxide mouth rinses may provide local relief. Nystatin powder (100,000 units/g) applied to dentures three or four times daily for several weeks may help denture wearers.

GLOSSITIS, GLOSSODYNIA, DYSGEUSIA, & BURNING MOUTH SYNDROME

Inflammation of the tongue with loss of filiform papillae leads to a red, smooth-surfaced tongue (glossitis). Rarely painful, it may be secondary to nutritional deficiencies (eg, niacin, riboflavin, iron, or vitamin E), drug reactions, dehydration, irritants, and possibly autoimmune reactions or psoriasis. If the primary cause cannot be identified and corrected, empirical nutritional replacement therapy may be of value.

Glossodynia is burning and pain of the tongue; it may occur with or without glossitis. It has been associated with diabetes, drugs (eg, diuretics), tobacco, xerostomia, and candidiasis as well as the listed causes of glossitis. Periodontal disease is not apt to be a factor. Treating possible underlying causes, changing chronic medications to alternative ones, and smoking cessation may resolve symptoms. Glossodynia is benign, and reassurance that there is no infection or tumor is likely to be appreciated. Anxiolytic medications and evaluation of possible psychologic status may be considered as well. Recent data support the hypothesis that symptoms which cannot be related to a specific medication or other cause may be neuropathic in origin, suggesting an empirical trial of gabapentin for symptom control.

INTRAORAL ULCERATIVE LESIONS

1. Necrotizing Ulcerative Gingivitis (Trench Mouth, Vincent's Infection)

Necrotizing ulcerative gingivitis, often caused by an infection of both spirochetes and fusiform bacilli, is common in young adults under stress (classically at examination time). Underlying systemic diseases may also predispose to this disorder. Clinically, there is painful acute gingival inflammation and necrosis, often with bleeding, halitosis, fever, and cervical lymphadenopathy. Warm half-strength peroxide rinses and oral penicillin (250 mg three times daily for 10 days) may help. Dental gingival curettage may prove necessary.

Necrotizing ulcerative periodontitis is discussed later in this chapter in the section on AIDS.

Worle B et al: Chronic ulcerative stomatitis. Br J Dermatol 1997;137:262. [\[PMID: 9292078\]](#)

2. Aphthous Ulcer (Canker Sore, Ulcerative Stomatitis)

Aphthous ulcers are very common and easy to recognize. Their cause remains uncertain, though an association with human herpesvirus 6 has been suggested. Found on nonkeratinized mucosa (eg, buccal and labial mucosa and not gingiva or palate), they may be single or multiple, are usually recurrent, and appear as painful small (usually 1-2 mm, but sometimes 1-2 cm) round ulcerations with yellow-gray fibrinoid centers surrounded by red halos. The painful stage lasts 7-10 days; healing is completed in 1-3 weeks.

Treatment is nonspecific. Topical steroids (triamcinolone acetonide, 0.1%, or fluocinonide ointment, 0.05%) in an adhesive base (Orabase Plain) do appear to provide symptomatic relief. Other topical therapies shown to be effective in controlled studies include diclofenac 3% in hyaluronan 2.5%, doxymycine-cyanoacrylate, mouthwashes containing the enzymes amyloglucosidase and glucose oxidase, and amlexanox 5% oral paste. A 1-week tapering course of prednisone (40-60 mg/d) has also been used successfully.

Large or persistent areas of ulcerative stomatitis may be secondary to erythema multiforme or drug allergies, acute herpes simplex, pemphigus, pemphigoid, bullous lichen planus, Behcet's disease, or inflammatory bowel disease. Squamous cell carcinoma may occasionally present in this fashion. When the diagnosis is not clear, incisional biopsy is indicated.

Tilliss TS et al: Differential diagnosis: is it herpes or aphthous? J Contemp Dent Pract 2002;3:1. [\[PMID: 12167909\]](#)

3. Herpetic Stomatitis

Herpetic gingivostomatitis is common, mild, and short-lived and requires no intervention in most adults. In immunocompromised individuals, however, reactivation of herpes simplex virus infection is frequent and may be severe. Clinically, there is initial burning, followed by typical small vesicles that rupture and form scabs. Acyclovir (200-800 mg five times daily for 7-14 days) may shorten the course and reduce postherpetic pain. Differential diagnosis includes ulcerative stomatitis (see above), erythema multiforme, syphilitic chancre, and carcinoma. Coxsackievirus-caused lesions (grayish white tonsillar and palatal ulcers of herpangina or buccal and lip ulcers in hand-foot-and-mouth disease) are seen more commonly in children under age 6.

PHARYNGITIS & TONSILLITIS

Pharyngitis and tonsillitis account for over 10% of all office visits to primary care clinicians and 50% of outpatient antibiotic use. The most appropriate management continues to be debated because some of the issues are deceptively complex, but consensus has increased in recent years. The main concern is determining who is likely to have a group A β -hemolytic streptococcal infection (GABHS), as this can lead to subsequent complications such as rheumatic fever and glomerular nephritis. A second public health policy concern is reducing the extraordinary cost (both in dollars and in the development of antibiotic-resistant *Streptococcus pneumoniae*) in the United States associated with unnecessary and unrecommended antibiotic use. Questions now being asked: Is there still a role for culturing a sore throat, or have the rapid antigen tests supplanted this procedure under most circumstances? Are clinical criteria alone a sufficient basis for decisions about which patients should be given antibiotics? Should any patient receive any antibiotic other than penicillin (or erythromycin if penicillin-allergic)? For how long should treatment be continued? Numerous well-done studies in the past few years as well as increasing experience with rapid laboratory tests for detection of streptococci (eliminating the delay caused by culturing) appear to make a consensus approach more possible.

The clinical features most suggestive of group A β -hemolytic streptococcal pharyngitis include fever over 38 °C, tender anterior cervical adenopathy, lack of a cough, and a pharyngotonsillar exudate. These four features (the Centor criteria), when present, strongly suggest GABHS, and some would treat regardless of laboratory results. When three of the four are present, laboratory sensitivity of rapid antigen testing exceeds 90%. When only one criterion is present, GABHS is unlikely. Sore throat may be severe, withodynophagia, tender adenopathy, and a scarlatiniform rash. An elevated white count and left shift are also possible. Hoarseness, cough, and coryza are not suggestive of this disease.

Marked lymphadenopathy and a shaggy white-purple tonsillar exudate, often extending into the nasopharynx, suggest mononucleosis, especially if present in a young adult. Hepatosplenomegaly and a positive heterophil agglutination test or elevated anti-EBV titer are corroborative. However, about one-third of patients with infectious mononucleosis have secondary streptococcal tonsillitis, requiring treatment. Ampicillin should routinely be avoided if mononucleosis is suspected because it induces a rash. Diphtheria (extremely rare but described in the alcoholic population) presents with low-grade fever and an ill patient with a gray tonsillar pseudomembrane.

The most common pathogens other than group A β -hemolytic streptococci in the differential diagnosis of "sore throat" are viruses, *Neisseria gonorrhoeae*, mycoplasma, and *Chlamydia trachomatis*. Rhinorrhea and lack of exudate would suggest a virus, but in practice it is not possible to confidently distinguish viral upper respiratory infection from group A β -hemolytic streptococcal infection on clinical grounds alone. Infections with *Corynebacterium diphtheriae*, anaerobic streptococci, and *Corynebacterium haemolyticum* (which responds better to erythromycin than penicillin) may also mimic pharyngitis due to group A β -hemolytic streptococci.

Treatment strategies for pharyngitis and tonsillitis range from "treat all comers" to "test all comers, reserving treatment for those with positive results." Issues that affect this decision include the reliability of cultures and rapid tests for streptococci (latex agglutination antigen tests and solid-phase enzyme immunoassays [ELISA]), the incidence of pharyngitis not due to group A β -hemolytic streptococci in the community, patient follow-up and medical compliance, and cost. The advantage of the "treat all" approach is the initial short-term cost, savings from elimination of diagnostic tests, and prevention of rheumatic fever, but such an approach necessarily causes the highest rate of antibiotic use and side effects and therefore overall the highest cost. At the other extreme is the "culture all" approach, which is associated with the fewest side effects but is dependent on excellent and rapid follow-up to prevent postinfectious complications. The sensitivity of current GABHS rapid antigen tests is now excellent, exceeding 90% in appropriately selected patients. It thus appears appropriate to screen for the four Centor criteria and use them in one of the following ways: (1) test patients who satisfy two or more criteria, and treat only those with positive results; (2) test those who satisfy two or three criteria, and treat both those with positive results and all patients who satisfy all four criteria without testing them; or (3) test nobody and treat all who satisfy three or four criteria. Routine cultures are not needed. Webb and colleagues, using this approach, found no increase in rates of complications among 7500 patients annually, about 75% of whom had high-specificity antigen tests without culture confirmation of negative results.

Given the availability of many well-documented studies in recent years, it should be possible to determine the most appropriate way to treat a sore throat. The Infectious Diseases Society of America recommends laboratory confirmation of the clinical diagnosis by means of either throat culture or a rapid antigen detection test. The American College of Physicians- American Society of Internal Medicine (ACP-ASIM), in collaboration with the Centers for Disease Control and Prevention, advocates use of a clinical algorithm alone—in lieu of microbiologic testing—for confirmation of the diagnosis in adults for whom the suspicion of streptococcal infection is high. Others examine the assumptions of the ACP-ASIM guideline for using a clinical algorithm alone and question whether those recommendations will achieve the stated objective of dramatically decreasing excess antibiotic use. Convincing clinical trials are needed before clinicians are likely to abandon long-held teachings (even if different physicians appear to have been taught different strategies) regarding diagnosis and management of group A streptococcal pharyngitis.

Thirty years ago, a single injection of benzathine penicillin or procaine penicillin was standard antibiotic treatment. This remains effective, but the injections are painful.

If compliance is an issue, it may be the best choice. Oral treatment is also effective. Antibiotic choice aims to reduce the already low (10-20%) incidence of treatment failures (positive culture after treatment despite symptomatic resolution) and recurrences. A review of recent controlled studies suggests that penicillin V potassium (250 mg orally three times daily or 500 mg twice daily for 10 days) or cefuroxime axetil (250 mg orally twice daily for 5-10 days) are both effective. The efficacy of a 5-day regimen of penicillin V appears to be similar to that of a 10-day course, with a 94% clinical response rate and an 84% streptococcal eradication rate. Erythromycin (active against mycoplasma and chlamydia) is a reasonable alternative to penicillin in allergic patients. Cephalosporins are somewhat more effective than penicillin in producing bacteriologic cures; 5-day administration has been successful for cefpodoxime and cefuroxime. The macrolide antibiotics have also been reported to be successful in shorter-duration regimens. Azithromycin (500 mg once daily), because of its long half-life, need be taken for only 3 days.

Adequate antibiotic treatment usually avoids the streptococcal complications of scarlet fever, glomerulonephritis, rheumatic myocarditis, and local abscess formation.

Antibiotics for treatment failures are also somewhat controversial. Surprisingly, penicillin-tolerant strains are not isolated more frequently in those who fail treatment than in those treated successfully with penicillin. The reasons for failure appear to be complex, and a second course of treatment with the same drug is not unreasonable. Alternatives to penicillin include cefuroxime and other cephalosporins, dicloxacillin (which is β -lactamase-resistant), and amoxicillin with clavulanate. When there is a history of penicillin allergy, alternatives should be used, such as erythromycin. Erythromycin resistance—with failure rates of about 25% is an increasing problem in many areas. In cases of severe penicillin allergy, cephalosporins should be avoided as the cross-reaction is common (8% or more).

Ancillary treatment of pharyngitis includes analgesics and anti-inflammatory agents, such as aspirin or acetaminophen. Some patients find that salt water gargling is soothing. In severe cases, anesthetic gargles and lozenges (eg, benzocaine) may provide additional symptomatic relief. Occasionally, odynophagia is so intense that hospitalization for intravenous hydration and antibiotics is necessary.

PERITONSILLAR ABSCESS & CELLULITIS

When infection penetrates the tonsillar capsule and involves the surrounding tissues, peritonsillar cellulitis results. Peritonsillar abscess and cellulitis present with severe sore throat, odynophagia, trismus, medial deviation of the soft palate and peritonsillar fold, and an abnormal muffled ("hot potato") voice. Following therapy, peritonsillar cellulitis usually either resolves over several days or evolves into peritonsillar abscess. The existence of an abscess may be confirmed by aspirating pus from the peritonsillar fold just superior and medial to the upper pole of the tonsil. A No. 19 or No. 21 needle should be passed no deeper than 1 cm, because the internal carotid artery passes posterior and deep to the tonsillar fossa. There is controversy about the best way to treat peritonsillar abscesses. Some incise and drain the area and continue with parenteral antibiotics, whereas others aspirate only and follow as an outpatient. To drain the abscess and avoid recurrence, it may be appropriate to consider immediate tonsillectomy (quinsy tonsillectomy). About 10% of patients with peritonsillar abscess exhibit relative indications for tonsillectomy. All three approaches are rational and have support in the literature. Regardless, one must be sure the abscess is adequately drained, since complications such as extension to the retropharyngeal, deep neck, and posterior mediastinal spaces are possible. Bacteria may also be aspirated into the lungs, resulting in pneumonia. While there is controversy about whether a single abscess is sufficient indication for tonsillectomy, most would agree that patients with recurrent abscesses should have their tonsils removed.

TONSILLECTOMY

Despite the frequency with which tonsillectomy is performed, the indications for the procedure remain controversial. Most would agree that airway obstruction causing sleep apnea or cor pulmonale is an absolute indication for tonsillectomy. Similarly, persistent marked tonsillar asymmetry should prompt an excisional biopsy to rule out lymphoma. Relative indications include recurrent streptococcal tonsillitis, causing considerable loss of time from school or work, recurrent peritonsillar abscess, and chronic tonsillitis.

Tonsillectomy is not an entirely benign procedure. The pros and cons of tonsillectomy need to be discussed with each prospective patient. Postoperative bleeding occurs in 2-4% of cases and on rare occasions can lead to laryngospasm and airway obstruction. Pain may be considerable, especially in the adult. Protracted emesis or fever may also occasionally occur. Secondary bleeding 5-8 days postoperatively is far more common than bleeding in the first 24 hours. There is increasing economic pressure for these procedures to be done as outpatient surgery. At present it seems clear that outpatient tonsillectomy is usually safe when followed by a 6-hour period of uneventful observation, but individual circumstances may mandate hospitalization.

Although reports in the 1970s suggested an association of tonsillectomy with Hodgkin's disease, careful review of this literature reveals no conclusively causative association.

DEEP NECK INFECTIONS

Deep neck abscesses usually present with marked neck pain and swelling in a toxic febrile patient. They are emergencies because they may rapidly compromise the airway. They may also spread to the mediastinum or cause septicemia. Most commonly, they originate from odontogenic infections. Other causes include suppurative lymphadenitis, direct spread of pharyngeal infection, penetrating trauma, pharyngoesophageal foreign bodies, cervical osteomyelitis, and intravenous injection of the internal jugular vein, especially in drug abusers. Recurrent deep neck infection may suggest an underlying congenital lesion such as a branchial cleft cyst.

Fundamentals of treatment include securing the airway, intravenous antibiotics, and incision and drainage. In highly selected patients without airway compromise, needle aspiration and catheter drainage or even conservative management without antibiotics alone has been reported to be successful in uniloculated abscesses. The airway may be secured, when indicated, either by intubation or tracheotomy. Tracheotomy is preferable in the patients with substantial pharyngeal edema, since attempts at intubation may precipitate acute airway obstruction. Bleeding in association with a deep neck abscess suggests the possibility of carotid artery or internal jugular vein involvement and requires prompt neck exploration both for drainage of pus and for vascular control.

Contrast-enhanced CT usually augments the clinical examination in defining the extent of the infection. It often will distinguish inflammation (requiring antibiotics) from abscess (requiring drainage) and define for the surgeon the extent of an abscess. CT with MRI may also identify thrombophlebitis of the internal jugular vein secondary to oropharyngeal inflammation. This condition, known as Lemierre's syndrome, may be associated with septic emboli and requires prompt institution of antibiotics appropriate for *Fusobacterium necrophorum* as well as the more usual upper airway pathogens. The presence of pulmonary infiltrates (or septic arthritis) in the setting of a neck abscess should lead one to suspect Lemierre's syndrome.

Ludwig's angina is the most commonly encountered neck space infection. It is a cellulitis of the sublingual and submaxillary spaces, often arising from infection of the tooth roots that extend below the mylohyoid line of the mandible. Clinically, there is edema and erythema of the upper neck under the chin and often of the floor of the mouth. The tongue may be displaced upward and backward by the posterior spread of cellulitis. This may lead to occlusion of the airway and necessitate tracheotomy. Microbiologic isolates include streptococci, staphylococci, bacteroides, and fusobacteria. Usual doses of penicillin plus metronidazole, ampicillin-sulbactam, clindamycin, or selective cephalosporins are good initial choices. Culture and sensitivity data will then refine the choice. Dental consultation is advisable. External

drainage via bilateral submental incisions is required if the airway is threatened or when medical therapy has not reversed the process.

■ DISEASES OF THE SALIVARY GLANDS

The salivary glands are divided into the two large parotid glands, two submandibular glands, several sublingual glands, and 600-1000 minor salivary glands located throughout the upper aerodigestive tract.

ACUTE INFLAMMATORY SALIVARY GLAND DISORDERS

1. Sialadenitis

Acute bacterial sialadenitis in the adult most commonly affects either the parotid or submandibular gland. It typically presents with acute swelling of the gland, increased pain and swelling with meals, and tenderness and erythema of the duct opening. Pus often can be massaged from the duct. Sialadenitis often occurs in the setting of dehydration or in association with chronic illness. Underlying Sjogren's syndrome may contribute. Ductal obstruction, often by an inspissated mucous plug, is followed by salivary stasis and secondary infection. The most common organism recovered from purulent draining saliva is *S aureus*. Treatment consists of intravenous antibiotics such as nafcillin (1 g intravenously every 4-6 hours) and measures to increase salivary flow, including hydration, warm compresses, sialagogues (eg, lemon drops), and massage of the gland. Usually one can switch to an oral agent based on clinical and microbiologic improvement to complete a 10-day course. Failure of the process to resolve on this regimen suggests abscess formation, ductal stricture, stone, or tumor causing obstruction. Ultrasound or CT scan may be helpful in establishing the diagnosis. Sialography is best avoided in acute cases.

Yousem DM et al: Major salivary gland imaging. *Radiology* 2000;216:19. [\[PMID: 10887223\]](#)

2. Sialolithiasis

Calculus formation is more common in Wharton's duct (draining the submandibular glands) than in Stensen's duct (draining the parotid glands). Clinically, a patient may note postprandial pain and local swelling, often with a history of recurrent acute sialadenitis. Stones in Wharton's duct are usually large and radiopaque, whereas those in Stensen's duct are usually radiolucent and smaller. Those very close to the orifice of Wharton's duct may be palpated manually in the anterior floor of the mouth and removed intraorally by dilating or incising the distal duct. The duct proximal to the stone must be temporarily clamped (using, for instance, a single throw of a suture) to keep manipulation of the stone from pushing it back toward the submandibular gland. Those more than 1.5-2 cm from the duct are too close to the lingual nerve to be removed safely in this manner. Similarly, dilation of Stensen's duct, located on the buccal surface opposite the second maxillary molar, may relieve distal stricture or allow a small stone to pass. The location of the facial nerve makes intraoral retrieval of more proximal parotid stones unsafe.

Repeated episodes of sialadenitis invariably lead to stricture and chronic infection. If the obstruction cannot be safely removed or dilated, excision of the gland may be necessary. In recent years there has been increased success with endoscopic techniques both to diagnose and remove salivary stones, with success rates for calculus removal in excess of 80%.

CHRONIC INFLAMMATORY & INFILTRATIVE DISORDERS OF THE SALIVARY GLANDS

Numerous infiltrative disorders may cause unilateral or bilateral parotid gland enlargement. Sjogren's disease and sarcoidosis are examples of lymphoepithelial and granulomatous diseases that may affect the salivary glands. Metabolic disorders, including alcoholism, diabetes mellitus, and vitamin deficiencies, may also cause diffuse enlargement. Several drugs have been associated with parotid enlargement, including thioureas, iodine, and drugs with cholinergic effects (eg, phenothiazines), which stimulate salivary flow and cause more viscous saliva.

SALIVARY GLAND TUMORS

Approximately 80% of salivary gland tumors occur in the parotid gland. In adults, about 80% of these are benign. In the submandibular triangle, it is sometimes difficult to distinguish a primary submandibular gland tumor from a metastatic submandibular space node. Only 50-60% of primary submandibular tumors are benign. Tumors of the minor salivary glands are most likely to be malignant, with adenoid cystic carcinoma predominating.

Most parotid tumors present as an asymptomatic mass in the superficial part of the gland. Their presence may have been noted by the patient for months or years. Facial nerve involvement correlates strongly with malignancy. Tumors may extend deep to the plane of the facial nerve or may originate in the parapharyngeal space. In such cases, medial deviation of the soft palate is visible on intraoral examination. MRI and CT scans have largely replaced sialography in defining the extent of tumor.

When the clinician encounters a patient with an otherwise asymptomatic salivary gland mass where tumor is the most likely diagnosis, the choice is whether to simply excise the mass via a parotidectomy with facial nerve dissection or submandibular gland excision or to obtain a fine-needle aspiration (FNA) biopsy first. Although the accuracy of FNA biopsy for malignancy has been reported to be quite high, results vary among institutions. If a negative FNA biopsy would lead to a decision not to proceed to surgery, then it should be considered. Poor overall health of the patient and the possibility of inflammatory disease as the cause of the mass are situations where FNA biopsy might be helpful. In otherwise straightforward nonrecurrent cases, excision is indicated. In benign and small low-grade malignant tumors, no additional treatment is needed. Postoperative irradiation is required for larger and high-grade cancers.

■ DISEASES OF THE LARYNX

DYSPHONIA, HOARSENESS, & STRIDOR

The primary symptoms of laryngeal disease are hoarseness and stridor. Hoarseness is caused by an abnormal flow of air past the vocal cords. The voice is "breathy" when too much air passes incompletely apposed vocal cords, as in unilateral vocal cord paralysis. The voice is harsh when turbulence is created by irregularity of the vocal cords, as in laryngitis or a mass lesion. Stridor, a high-pitched sound, is produced by lesions that narrow the airway. Airway narrowing above the vocal cords produces predominantly inspiratory stridor. Airway narrowing below the vocal cord level produces either expiratory or mixed stridor.

Evaluation of an abnormal voice begins with obtaining a history of the circumstances preceding its onset and an examination of the airway. This may include indirect or flexible laryngoscopy and at times videostrobolaryngoscopy. Especially when the patient has a history of tobacco use, laryngeal cancer or lung cancer (leading to paralysis of a recurrent laryngeal nerve) must be strongly considered. Laryngitis, voice abuse, and vocal cord nodules are among the most common causes of hoarseness.

COMMON LARYNGEAL DISORDERS

1. Epiglottitis

Epiglottitis (or, more correctly, supraglottitis) in adults should be suspected when a patient presents with a rapidly developing sore throat or when odynophagia (pain on swallowing) is out of proportion to apparently minimal oropharyngeal findings on examination. It may be viral or bacterial in origin. Unlike in children, indirect laryngoscopy is generally safe and may demonstrate a swollen, erythematous epiglottis. Initial treatment is hospitalization for intravenous antibiotics—eg, ceftizoxime, 1-2 g intravenously every 8-12 hours, or cefuroxime, 750-1500 mg intravenously every 8 hours, and dexamethasone, usually 4-10 mg as initial bolus, then 4 mg intravenously every 6 hours—and observation of the airway. Steroids may be tapered as symptoms and signs resolve. Similarly, substitution of oral antibiotics may be appropriate to complete a 10-day course. When epiglottitis is recognized early in the adult, it is usually possible to avoid intubation. Indications for intubation are dyspnea or rapid pace of sore throat (where progression to airway compromise may occur before the effects of steroids and antibiotics take hold). If the patient is not intubated, prudence would suggest monitoring oxygen saturation with continuous pulse oximetry and initial admission to an intensive care unit.

Sack JL et al: Identifying acute epiglottitis in adults. High degree of awareness, close monitoring are key. Postgrad Med 2002; 112:81. [\[PMID: 12146095\]](#)

2. Laryngeal Papillomas

Papillomas are common lesions of the larynx and other sites where ciliated and squamous epithelia meet. Unlike oral papillomas, laryngeal papillomas are likely to be symptomatic, with hoarseness that progresses to stridor over weeks to months. The disease is more common in children. Repeated laser excisions via microdirect laryngoscopy are often needed to control the disease. Tracheotomy should be avoided, if possible, since it introduces an additional squamociliary junction where papillomas appear to preferentially grow. Interferon treatment has been under investigation.

Kimberlin DW: Pharmacotherapy of recurrent respiratory papillomatosis. Expert Opin Pharmacother 2002;3:1091. [\[PMID: 12150688\]](#)

3. Acute Laryngitis

Acute laryngitis is probably the most common cause of hoarseness, which may persist for a week or so after other symptoms of an upper respiratory infection have cleared. The patient should be warned to avoid vigorous use of the voice (singing, shouting) while laryngitis is present, since this may foster the formation of vocal nodules. Although thought to be usually viral in origin, both *Moraxella catarrhalis* and *Haemophilus influenzae* may be isolated from the nasopharynx at higher than expected frequencies. Erythromycin may reduce the severity of hoarseness and cough.

Spiegel JR et al: Acute laryngitis. Ear Nose Throat J 2000;79:488. [\[PMID: 10935296\]](#)

4. Gastroesophageal Reflux & Hoarseness

Gastroesophageal reflux into the larynx (laryngopharyngeal reflux) should be considered a possible cause of chronic hoarseness if other causes of abnormal laryngeal airflow (such as tumor) have been excluded by indirect or direct laryngoscopy. Gastroesophageal reflux disease (GERD) has also been implicated as a contributing factor to other symptoms such as throat clearing, throat discomfort, chronic cough, a sensation of postnasal drip, and esophageal spasm, as well as in many cases of posterior laryngitis and some cases of asthma. As less than half of patients with documented laryngopharyngeal reflux have typical symptoms of heartburn and regurgitation, the lack of such symptoms should not be construed as eliminating this cause.

Management should initially exclude other causes of hoarseness, laryngitis, or chronic cough; consultation with an otolaryngologist is advisable. Many next advocate an empiric trial of a proton pump inhibitor at twice-daily dosing (eg, omeprazole 20 mg twice daily) for 2-3 months as a practical alternative to an initial pH study. If symptoms improve and cessation of therapy leads to symptoms again, then a proton pump inhibitor is resumed at the lowest dose effective for remission, usually daily but at times on a demand basis. Although H₂ receptor antagonists are an alternative to proton pump inhibitors, they are generally both less clinically effective and less cost-effective. Nonresponders should undergo pH testing and manometry. Twenty-four-hour pH monitoring of the pharynx should best document laryngopharyngeal reflux and is advocated by some as the initial management step, but it is costly, more difficult, and less available than lower esophageal monitoring alone. Lower esophageal pH monitoring does not correlate well with laryngopharyngeal reflux symptoms.

TUMORS OF THE LARYNX

1. Benign Tumors of the Larynx

Vocal cord nodules are smooth, paired lesions that form at the junction of the anterior one-third and posterior two-thirds of the vocal cords. They are a common cause of hoarseness resulting from vocal abuse. In adults, they are referred to as "singer's nodules"; in children, "screamer's nodules." Treatment requires modification of voice habits, and referral to a speech therapist is indicated. Recalcitrant nodules may require surgical excision.

Polypoid changes in the vocal cords may result from vocal abuse, smoking, chemical industrial irritants, or hypothyroidism. Attention to the underlying problem may resolve the polypoid changes. Inhaled steroid spray (eg, beclomethasone, 42 ug/spray, or dexamethasone, 84 ug/spray, two or three times a day) may hasten resolution. At times, removal of the hyperplastic vocal cord mucosa may be indicated.

A common but often unrecognized cause of hoarseness is contact ulcers on the vocal processes of the arytenoid cartilages secondary to esophageal reflux. Treatment may be with H₂ receptor blockers or proton pump inhibitors (see Gastroesophageal Reflux and Hoarseness, above). Intubation granulomas may also be seen posteriorly between the vocal processes.

2. Laryngeal Leukoplakia

Leukoplakia is a frequent cause of hoarseness, most commonly arising in smokers. Direct laryngoscopy with biopsy is advised. Histologic examination usually demonstrates mild, moderate, or severe dysplasia. Cessation of smoking may reverse dysplastic changes. A certain percentage of patients—estimated to be less than 5% of those with mild dysplasia and about 35-60% of those with severe dysplasia—will subsequently develop squamous cell carcinoma. In some cases, invasive squamous cell carcinoma is present in the initial biopsy.

3. Squamous Cell Carcinoma of the Larynx

Squamous cell carcinoma is the most common cancer seen in the larynx. It occurs predominantly in heavy smokers, with alcohol an apparent cocarcinogen. It is most common between ages 50 and 70. Hoarseness is the usual presenting symptom. Any patient with hoarseness that has persisted beyond 2-3 weeks should be evaluated by indirect laryngoscopy. Odynophagia, hemoptysis, weight loss, referred otalgia, vocal cord immobility, and cervical adenopathy suggest more advanced disease.

Early squamous cell carcinoma (certainly T1 and T2 lesions) may be treated with either surgery (endoscopic excision or vertical partial laryngectomy) or irradiation with excellent cure rates in excess of 90% and equally satisfactory patient-reported satisfaction. Selected T2 and highly selected T3 lesions may be treated with conservation surgery. For larger tumors, organ preservation approaches, usually consisting of irradiation and concomitant chemotherapy, are often recommended. Total laryngectomy is necessary for many large tumors and for most irradiation failures. A number of partial laryngectomy procedures are sometimes considered for selected smaller and intermediate-sized tumors. Treatment of glottic (vocal cord) tumors in which a cord is paralyzed and for supraglottic tumors includes treatment of the neck because of the high risk of neck node involvement. The use of tracheoesophageal valves following total laryngectomy restores useful speech for most patients.

VOCAL CORD PARALYSIS

Most cases of vocal cord paralysis result from involvement of a recurrent laryngeal nerve; others arise more proximally along the vagus nerve itself. Common causes of recurrent laryngeal nerve involvement include thyroid surgery (and occasionally thyroid cancer), other neck surgery (anterior discectomy and carotid endarterectomy), and mediastinal or apical involvement by lung cancer. Skull base tumors often involve cranial nerves IX, X, and XI. Occasionally, no cause can be identified. When either no cause is found or the paresis follows surgical trauma in which the nerve was not divided, spontaneous recovery commonly occurs, usually within a year.

Unlike unilateral cord paralysis, which produces a breathy hoarseness, bilateral cord paralysis usually causes inspiratory and expiratory stridor if acute, in which case intervention to create an emergency airway may be needed. If insidious in onset, it may be asymptomatic at rest, including a normal voice, though there is usually dyspnea on exertion. Causes of bilateral cord paralysis include thyroid surgery, esophageal cancer, and ventricular shunt malfunction. Unilateral or bilateral cord immobility may also be seen in cricoarytenoid arthritis secondary to advanced rheumatoid arthritis, intubation injuries, glottic and subglottic stenosis, and, of course, laryngeal cancer. The goal of intervention is the creation of a safe airway with minimal reduction in voice quality and airway protection from aspiration. A number of cord lateralization procedures have been advocated as a means of removing the tracheotomy tube.

Surgical management of persistent or irrecoverable symptomatic unilateral vocal cord paralysis has evolved over the last several decades. The primary goal is medialization of the paralyzed cord in order to rehabilitate the voice. Additional goals include eliminating aspiration, improving diet, and aiding in the subsequent decannulation of individuals with glottic insufficiency. Success has been reported for years with injection medialization using predominantly Teflon, but other materials as well have been used, such as fat or Gelfoam. An alternative to injection medialization of the vocal fold is to medialize the soft tissue and arytenoid via a small incision overlying the thyroid cartilage under local anesthesia. A section of the cartilage is removed, providing access to the soft tissue of the larynx and the arytenoid cartilage. An implant is inserted that displaces this soft tissue and arytenoid medially.

■ TRACHEOTOMY & CRICOTHYROTOMY

There are two primary indications for tracheotomy: airway obstruction at or above the level of the larynx and respiratory failure requiring prolonged mechanical ventilation. In an acute emergency, cricothyrotomy secures an airway more rapidly than tracheotomy, with fewer potential immediate complications such as pneumothorax and hemorrhage. Although classically it has been recommended that one should change a cricothyrotomy to a tracheotomy as soon as it is convenient and safe, recent studies have questioned this if decannulation can be expected soon. Percutaneous dilation tracheotomy as an elective bedside (or ICU) procedure has undergone scrutiny in recent years as an alternative to tracheotomy. In experienced hands the various methods of percutaneous dilation tracheotomy have been documented to be safe, though complications do occur. When a patient is not intubated, simultaneous bronchoscopy may reduce complications. The major cost reduction comes from not using the main operating room. Bedside tracheotomy (in the ICU) achieves similar cost reduction and is advocated by some as slightly less costly than the percutaneous dilation procedure.

The most common indication for elective tracheotomy is the need for prolonged mechanical ventilation. There is no firm rule about how many days a patient must be intubated before conversion to tracheotomy should be advised. The incidence of serious complications such as subglottic stenosis increases with extended endotracheal intubation. As soon as it is apparent that the patient will require protracted ventilatory support, tracheotomy should replace the endotracheal tube. Less frequent indications for tracheotomy are life-threatening aspiration pneumonia, the need to improve pulmonary toilet to correct problems related to insufficient clearing of tracheobronchial secretions, and sleep apnea.

Posttracheotomy care requires humidified air to prevent secretions from crusting and occluding the inner cannula of the tracheotomy tube. The tracheotomy tube should be cleaned several times daily. The most frequent early complication of tracheotomy is dislodgment of the tracheotomy tube. Surgical creation of an inferiorly based tracheal flap sutured to the inferior neck skin may make reinsertion of a dislodged tube easier. It should be recalled that the act of swallowing requires elevation of the larynx, which is prevented by tracheotomy. Therefore, frequent tracheal and bronchial suctioning is often required to clear the aspirated saliva as well as the increased tracheobronchial secretions. Care of the skin around the stoma is important to prevent maceration and secondary infection.

■ FOREIGN BODIES IN THE UPPER AERODIGESTIVE TRACT

FOREIGN BODIES OF THE TRACHEA & BRONCHI

Aspiration of foreign bodies occurs less frequently in adults than in children. The elderly and denture wearers appear to be at greatest risk. Wider familiarity with the Heimlich maneuver has reduced deaths. If the maneuver is unsuccessful, cricothyrotomy may be necessary. Plain chest radiographs may reveal a radiopaque foreign body. Detection of radiolucent foreign bodies may be aided by inspiration-expiration films that demonstrate air trapping distal to the obstructed segment. Atelectasis and pneumonia may occur later.

Tracheal and bronchial foreign bodies should be removed under general anesthesia by a skilled endoscopist working with an experienced anesthesiologist.

Debeljak A et al: Bronchoscopic removal of foreign bodies in adults: experience with 62 patients from 1974-1998. Eur Respir J 1999;14:792. [\[PMID: 10573222\]](#)

ESOPHAGEAL FOREIGN BODIES

Foreign bodies in the esophagus create urgent but not life-threatening situations as long as the airway is not compromised. There is probably time to consult an experienced clinician for management. Patients are likely to have difficulty handling secretions and may be spitting out their saliva. It is a useful diagnostic sign of complete obstruction if the patient is drooling or cannot handle secretions. They may often point to the exact level of the obstruction. Indirect laryngoscopy often shows pooling of saliva at the esophageal inlet. Plain films may detect radiopaque foreign bodies such as chicken bones. Coins tend to align in the coronal plane in the esophagus and sagittally in the trachea. If a foreign body is suspected, a barium swallow may help make the diagnosis.

The treatment of an esophageal foreign body depends very much on identification of its nature. In children, swallowed nonfood objects are common, and treatment options include esophageal bougienage dislodgment or Foley catheter displacement for coins, endoscopic removal under general anesthesia, and observation insofar as about 20% of objects will pass spontaneously. The cost and the complications associated with each of these approaches have been studied, suggesting that bougienage is most appropriate for coins, but considerable debate exists. In adults, however, food foreign bodies are more common, and there is the greater possibility of underlying esophageal pathology. Endoscopic removal and examination is usually best, via flexible esophagoscopy or rigid laryngoscopy-esophagoscopy. Obstruction may sometimes occur from a metal stent placed in the treatment of esophageal cancer.

■ DISEASES PRESENTING AS NECK MASSES

The differential diagnosis of neck masses is heavily dependent on the location in the neck, the age of the patient, and the presence of associated disease processes. Rapid growth and tenderness suggest an inflammatory process, while firm, painless, and slowly enlarging masses are often neoplastic. In young adults, most neck masses are benign (branchial cleft cyst, thyroglossal duct cyst, reactive lymphadenitis), though malignancy should always be considered (lymphoma, metastatic thyroid carcinoma). Lymphadenopathy is common in HIV-positive individuals, but a growing or dominant mass may well be malignant. In adults over 40, cancer is the most common cause of persistent neck mass. A metastasis from squamous cell carcinoma arising within the mouth, pharynx, larynx, or upper esophagus should be suspected, especially if there is a history of tobacco or significant alcohol use. Especially among patients younger than 30 or older than 70, lymphoma should be considered. In any case, a comprehensive otolaryngologic examination is needed. Cytologic evaluation of the neck mass via fine-needle aspiration biopsy is likely to be the next step if an obvious primary tumor is not visible or palpable on physical examination.

CONGENITAL LESIONS PRESENTING AS NECK MASSES IN ADULTS

1. Branchial Cleft Cysts

Branchial cleft cysts usually present as a soft cystic mass along the anterior border of the sternocleidomastoid muscle. These lesions are usually recognized in the second or third decades of life, often when they suddenly swell or become infected. To prevent recurrent infection and possible carcinoma, they should be completely excised, along with their fistulous tracts.

First branchial cleft cysts present high in the neck, sometimes just below the ear. A fistulous connection with the floor of the external auditory canal may be present. Second branchial cleft cysts, which are far more common, may communicate with the tonsillar fossa. Third branchial cleft cysts, which may communicate with the piriform sinus, are rare.

Schwetschenau E et al: The adult neck mass. Am Fam Physician 2002;66:831. [\[PMID: 12322776\]](#)

2. Thyroglossal Duct Cysts

Thyroglossal duct cysts occur along the embryologic course of the thyroid's descent from the tuberculum impar of the tongue base to its usual position in the low neck. Although they may occur at any age, they are commonest before age 20. They present as a midline neck mass, often just below the hyoid bone, that moves with

swallowing. Surgical excision is recommended to prevent recurrent infection. This requires removal of the entire fistulous tract along with the middle portion of the hyoid bone.

INFECTIOUS & INFLAMMATORY NECK MASSES

1. Reactive Cervical Lymphadenopathy

Normal lymph nodes in the neck are usually less than 1 cm in length. Infections involving the pharynx, salivary glands, and scalp often cause tender enlargement of neck nodes. Enlarged nodes are common in HIV-infected persons. Except for the occasional node that suppurates and requires incision and drainage, treatment is directed against the underlying infection. An enlarged node unassociated with an obvious infection should be further evaluated, especially if the patient has a history of smoking or alcohol use (common etiologic factors in head and neck squamous cell carcinoma) or a history of cancer. Other common indications for fine-needle aspiration biopsy of a node include its persistence or continued enlargement. Common causes of cervical adenopathy include tumor (squamous cell carcinoma, lymphoma, occasional metastases from non-head and neck sites) and infection (eg, reactive nodes, mycobacteria [discussed below], and cat scratch disease). Rare causes of adenopathy include Kikuchi's disease (histiocytic necrotizing lymphadenitis) and autoimmune adenopathy.

Murakami K et al: Cat scratch disease: analysis of 130 seropositive cases. J Infect Chemother 2002;8:349. [PMID: 12525897]

Ridder GJ et al: Role of cat-scratch disease in lymphadenopathy in the head and neck. Clin Infect Dis 2002;35:643. [PMID: 12203159]

2. Tuberculous & Nontuberculous Mycobacterial Lymphadenitis

Granulomatous neck masses are not uncommon. The differential diagnosis includes mycobacterial adenitis, sarcoidosis, and cat-scratch disease due to *Bartonella henselae*. Although mycobacterial adenitis can extend to the skin and drain externally (as described for atypical mycobacteria and referred to as scrofula), this late presentation is no longer common. The usual presentation of granulomatous disease in the neck is simply single or matted nodes. Fine-needle aspiration is usually the best initial diagnostic approach: cytology, smear for acid-fast bacilli, culture, sensitivity test, and polymerase chain reaction (PCR) can all be done.

Mycobacterial lymphadenitis is on the rise both in immunocompromised and immunocompetent individuals. Identification of *Mycobacterium tuberculosis* can usually be confirmed by a combination of FNA smear and culture in a suspected patient, but excisional biopsy of a node may be needed. PCR from FNA (or from excised tissue) is the single most sensitive test and is particularly useful when conventional methods have not been diagnostic but clinical impression remains consistent for tuberculous infection.

Short-course therapy (6 months) consisting of an initial 4 months of streptomycin, isoniazid, rifampin, and pyrazinamide followed by 2 months of rifampin is the current recommended treatment for tuberculous lymphadenopathy. For atypical (nontuberculous) lymphadenopathy, treatment depends on sensitivity results of culture, but antibiotics likely to be useful include 6 months of isoniazid and rifampin and, for at least the first 2 months, ethambutol—all in standard dosages (see [Table 9-14](#)). Some would totally excise the involved nodes prior to chemotherapy, depending on location and other factors.

Gong G et al: Nested PCR for diagnosis of tuberculous lymphadenitis and PCR-SSCP for identification of rifampicin resistance in fine-needle aspirates. Diagn Cytopathol 2002;26:228. [PMID: 11933268]

Nataraj G et al: Correlation of fine needle aspiration cytology, smear and culture in tuberculous lymphadenitis: a prospective study. J Postgrad Med 2002;48:113. [PMID: 12215692]

3. Lyme Disease

Lyme disease, caused by the spirochete *Borrelia burgdorferi* and transmitted by ticks of the *Ixodes* genus, may have protean manifestation, but over 75% of patients have symptoms involving the head and neck. Facial paralysis, dysesthesias, dysgeusia, or other cranial neuropathies are most common. Headache, pain, and cervical lymphadenopathy may occur. See [Chapter 34](#) for a more thorough discussion.

TUMOR METASTASES

In older adults, 80% of firm, persistent, and enlarging neck masses are metastatic in origin. The great majority of these arise from squamous cell carcinoma of the upper aerodigestive tract. A complete head and neck examination may reveal the tumor of origin, but examination under anesthesia with direct laryngoscopy, esophagoscopy, and bronchoscopy is usually required to fully evaluate the tumor and exclude second primaries.

It is often helpful to obtain a cytologic diagnosis if initial head and neck examination fails to reveal the primary tumor. An open biopsy should be done only when neither physical examination by an experienced clinician specializing in head and neck cancer nor fine-needle aspiration biopsy performed by an experienced cytopathologist yields a diagnosis. In such a setting, one should strongly consider obtaining an MRI or PET scan prior to open biopsy, as these methods may yield valuable information about a possible presumed primary site or another site for FNA.

Other than thyroid carcinoma, non-squamous cell metastases to the neck are infrequent. While tumors not involving the head and neck seldom metastasize to the middle or upper neck, the supraclavicular region is quite often involved by lung and breast tumors. Infradiaphragmatic tumors, with the exception of renal cell carcinoma, rarely metastasize to the neck.

LYMPHOMA

About 10% of lymphomas present in the head and neck. Lymphoma arising in AIDS patients is an increasing concern. Multiple rubbery nodes, especially in the young adult, are suggestive of this disease. A thorough physical examination may demonstrate other sites of nodal or organ involvement. Fine needle aspiration may be diagnostic, but open biopsy is often required.

Jayaram G et al: Fine needle aspiration cytology of lymph nodes in HIV-infected individuals. Acta Cytol 2000;44:960. [PMID: 11127753]

■ OTOLARYNGOLOGIC MANIFESTATIONS OF HIV INFECTION (SEE ALSO [CHAPTER 31](#).)

ORAL CAVITY & PHARYNX

The evaluation of oral lesions is critically important in HIV-infected individuals and in patients at risk for HIV infection. Oral candidiasis and hairy leukoplakia, each occurring in 10-20% of HIV-infected patients, are frequently the presenting signs of HIV disease. Kaposi's sarcoma (prevalence about 1%) may similarly be the first indication of HIV infection—as may necrotizing ulcerative periodontitis (occurring in 2-5%), but less predictively. The course of candidiasis and hairy leukoplakia in known HIV-infected patients may correlate with the degree of immune suppression and overall disease progression, heralding the subsequent development of AIDS. For these reasons, oral lesions are useful in staging HIV disease and in designing entry criteria and end points for antiretroviral clinical trials. The United States Department of Health Services Clinical Practice Guideline for Evaluation and Management of Early HIV Infection recommends examination of the oral mucosa with each physician visit as well as dental examination at least every 6 months.

When CD4 cell counts drop below 200/uL, the incidence of intraoral lesions rises dramatically. In the past few years, the severity of these lesions has lessened, but their incidence has increased. Candidiasis is common and may require treatment for longer than the usual 1-week course with fluconazole (100 mg daily) or ketoconazole (200-400 mg daily). Clotrimazole and topical nystatin are less effective. Itraconazole (200 mg daily) is often helpful in fluconazole-resistant cases, or some cases due to non-*albicans* species, which are frequently azole-unresponsive. Giant intraoral ulcers have been seen in some patients.

Hairy leukoplakia occurring on the lateral border of the tongue is another common early finding. It may develop quickly and appears as slightly raised leukoplakic areas with a corrugated or "hairy" surface. Histologically, parakeratosis and koilocytes are seen with little or no underlying inflammation. Among HIV-positive patients with oral lesions, hairy leukoplakia was seen in 19% in one study. Clinical response following administration of zidovudine or acyclovir has been reported, and treatment is under active investigation. The appearance of hairy leukoplakia may herald subsequent more ominous manifestations of AIDS.

Kaposi's sarcoma is most common on the hard palate but may be seen anywhere in the oral cavity and pharynx. It usually appears as a raised violaceous lesion beneath an intact mucosa, although it may be ulcerated, erythematous, and bleeding. Radiation therapy may control the tumor. A brisk mucositis can be expected following radiation therapy.

In addition to Kaposi's sarcoma, an increased incidence of non-Hodgkin's lymphoma is seen in AIDS. An increase in squamous cell carcinoma is also seen in the homosexual population, perhaps related to HIV infection.

THE NECK

Persistent generalized lymphadenopathy is extremely common in HIV infection. A tender or growing node may represent secondary infection, lymphoma, or other tumor. Fine-needle aspiration for culture and cytology is the best initial diagnostic step. Open biopsy will often be needed if granulomatous disease or lymphoma is suspected, though fine-needle aspiration biopsy may be diagnostic of *M tuberculosis* infection in seropositive patients.

Parotid cysts and benign lymphoepithelial lesions in HIV-positive patients may be seen, often in association with cervical adenopathy.

PARANASAL SINUSES

Sinusitis is common in HIV infection and the causative organisms are diverse. The same pathogens encountered in nonimmunocompromised patients remain the most common. Early sinus irrigation, with aspirates sent for cytologic examination as well as fungal, viral, legionella, and aerobic and anaerobic culture may be helpful in severe cases. Guaifenesin (600 mg orally four times daily), a mucolytic agent, may offer some adjunctive symptomatic relief. Functional endoscopic surgery to provide sinus drainage is often helpful.

Invasive aspergillus sinusitis is an increasingly reported complication in AIDS. Though this infection is more indolent than mucormycosis, most patients with AIDS and aspergillus sinusitis die as a result of intracranial extension.

■ COMMON MANIFESTATIONS OF LUNG DISEASE

DYSPNEA

Dyspnea is a common symptom. It is analogous to pain in that sensory input from multiple sites is integrated in the cerebral cortex. In general, dyspnea increases with the level of functional impairment as measured by spirometry. However, there is only a weak correlation between the severity of dyspnea and quantitative measures of airflow limitation or exercise tolerance.

Several pathophysiologic processes contribute to dyspnea. The most important is the increased respiratory effort that accompanies many different diseases: airflow obstruction (asthma; chronic obstructive pulmonary disease [COPD]), changes in pulmonary compliance (interstitial fibrosis, congestive heart failure) or chest wall compliance (obesity, pleural disease), intrinsic respiratory muscle weakness (inanition, neuromuscular disease, chronic respiratory failure), or the weakness conveyed by the mechanical disadvantage of hyperinflation (asthma or emphysema). Dyspnea is magnified by increased respiratory drive. Acute hypercapnia is therefore a potent stimulus to dyspnea. Hypoxemia is often only a weak stimulus to dyspnea. In mechanically ventilated patients, failure to provide adequate inspiratory flow rates to patients with heightened respiratory drive commonly results in dyspnea that may present as agitation. Stimulation of irritant receptors in the airways intensifies dyspnea, while stimulation of pulmonary stretch receptors decreases it.

Clinical Findings

The history should focus on onset and timing of symptoms, the patient's position at onset of symptoms, the relationship of symptoms to activity, and any factors that may improve or exacerbate symptoms. The clinician can assess dyspnea and response to treatment with a ten-point numeric rating scale by asking the patient, "On a scale of zero to ten, with zero being no shortness of breath and ten being the worst shortness of breath you can imagine, how short of breath are you?" Exertional dyspnea should be quantified, but the absolute level of exertion that precipitates dyspnea is less important than acute changes in the threshold level of activity. Complete allergic, occupational, and smoking histories are essential.

Acute dyspnea has a short list of causes, most of which are readily identified: asthma, pulmonary infection, pulmonary edema, pneumothorax, pulmonary embolus, metabolic acidosis, or acute respiratory distress syndrome (ARDS). Severe acute respiratory syndrome (SARS) is an important new disease that is discussed in [Chapter 32](#). Panic attacks may present as a respiratory complaint. Orthopnea (dyspnea on recumbency) and nocturnal dyspnea suggest asthma, gastroesophageal reflux disease (GERD), left ventricular dysfunction, or obstructive sleep apnea. Rapid onset of severe dyspnea when supine suggests phrenic nerve impairment and diaphragmatic paralysis. Platypnea (dyspnea that worsens in the upright position) is a rare complaint associated with arteriovenous malformations at the lung bases or with hepatopulmonary syndrome, resulting in increased shunting and hypoxemia in the upright position (orthodeoxia).

Chronic dyspnea is invariably progressive. Symptoms often first appear during exertion; patients learn to limit their activity to accommodate their diminished pulmonary reserve until dyspnea occurs with minimal activity or at rest. Episodic dyspnea suggests congestive heart failure, asthma, acute or chronic bronchitis, or recurrent pulmonary emboli. Constant dyspnea is most commonly due to COPD but may indicate interstitial lung disease (eg, pulmonary fibrosis), pulmonary vascular disease, or fixed airflow obstruction from severe asthma.

Dyspnea is increasingly being recognized as a major issue in the care of dying patients, and clinicians typically undertreat this symptom.

Evaluation should include a complete blood count, renal function tests, chest radiograph, spirometry, and noninvasive oximetry. Patients over 40 years of age or with a family history of early coronary disease should have an electrocardiogram. Arterial blood gases, measurement of lung volumes, ventilation/perfusion scanning, echocardiography, and cardiopulmonary exercise testing are reserved for cases that elude diagnosis on initial evaluation.

Treatment

In patients with advanced lung disease, the responsible condition may be easily identified but treatment only partially effective. Oxygen improves survival in those who are hypoxemic and can improve the exercise tolerance of all patients. Its effect on dyspnea is variable. Anxiety can play an important role in the distress caused by dyspnea and may be relieved by judicious use of benzodiazepines such as lorazepam, 0.5-1 mg orally every 4-6 hours. Pulmonary rehabilitation can improve respiratory function and train patients in energy conservation and breathing techniques that help moderate their sense of respiratory effort. Opioids reduce respiratory drive and blunt dyspnea. They can be titrated safely even in patients with advanced lung disease. Finally, fresh air or a fan may offer additional relief. Smokers with progressive exertional dyspnea should know that they can limit future loss of function through smoking cessation.

COUGH

Cough is an important physiologic mechanism that defends against respiratory pathogens and helps to clear the tracheobronchial tree of mucus, foreign particles, and noxious aerosols. Excessive cough is one of the most common symptoms for which patients seek medical care and may represent up to one-third of a pulmonologist's outpatient practice referrals. Persistent severe cough, seen in interstitial lung disease or bronchiectasis, may impair respiration as well as disrupt sleep and social functioning. Bronchospasm (brought on by repetitive forced exhalation), syncope, rib fractures, and urinary incontinence are all potential complications. A reduced or absent cough, seen in some postoperative patients or those with neuromuscular disease, will reduce clearance of secretions and may impair oxygenation.

Cough may be voluntary or involuntary. Involuntary cough is stimulated by vagal afferent receptors in the trachea, especially at the carina, and the larynx but also from others throughout the head and neck. Stimulation of cough receptors may be mechanical, as in cases of aspiration, or irritative.

Clinical Findings

It is important to distinguish acute (< 3 weeks) from chronic cough. Acute cough most commonly follows viral or bacterial upper respiratory tract infection. Within 2 days after onset of the common cold, 85% of untreated patients cough; 26% are still coughing 14 days later; in a few, cough will persist for 6-8 weeks. Many patients with persistent cough following upper respiratory tract infection have underlying asthma. Other causes of acute cough include aspiration, pneumonia, pulmonary embolism, and pulmonary edema.

The most common cause of chronic cough is a low-grade chronic bronchitis secondary to exposure to tobacco smoke, though smokers do not commonly seek medical attention for this problem. Over 90% of nonsmokers presenting for evaluation of chronic cough suffer from postnasal drip, gastroesophageal reflux disease, or asthma (even without other symptoms). Angiotensin-converting enzyme (ACE) inhibitors have become another common cause. In primary care settings, single causes predominate.

The character and timing of chronic cough and the presence or absence of sputum production do not permit an etiologic diagnosis and should not be used as the sole basis for empirical therapy. The history and physical examination should attempt to identify anatomic locations of the afferent limb of the cough reflex in light of the common causes listed above. A nasal discharge, frequent need to clear the throat, and mucoid or mucopurulent secretions in the posterior pharynx suggest postnasal drip. Sinus radiographs may be diagnostic of acute or chronic sinusitis. Wheezing on chest auscultation or airflow obstruction on pulmonary function tests suggests asthma. In cough-variant asthma, methacholine bronchoprovocation testing may be positive in the absence of clinical findings of asthma. Gastroesophageal reflux disease is an important cause of chronic cough but is associated with the fewest clinical clues. Patients may complain of heartburn or regurgitation, but cough may be the only symptom. Barium swallow is specific but insensitive, and esophageal pH monitoring may be necessary. Chest radiographs are best reserved for cough in smokers and patients with hemoptysis or constitutional symptoms such as fever and weight loss.

Treatment

The first step is to eliminate irritant exposures such as tobacco smoke (primary or secondary) and occupational agents and to discontinue medications such as ACE inhibitors or beta-blockers, including eyedrops. Cough due to ACE inhibitors should subside within 1-4 days after discontinuing the medication, though it may take

weeks to months. Postnasal drip syndrome due to allergic rhinitis that does not respond to antihistamines should be treated with intranasal steroids. Chronic sinusitis may require prolonged antibiotics directed against *Haemophilus influenzae*. Cough caused by asthma that does not respond after 2 weeks of bronchodilators and corticosteroids suggests another contributing condition. Cough due to gastroesophageal reflux disease is difficult to treat, since H₂ blockers may not be adequate. Most practitioners now initiate antitussive therapy for gastroesophageal reflux disease with proton pump inhibitors. Patients whose cough began after an upper respiratory tract infection usually respond to treatment with an antihistamine-decongestant combination or treatment for asthma.

HEMOPTYSIS

Hemoptysis is the expectoration of blood that originates below the vocal cords. It is commonly classified as trivial, mild, or massive—the latter defined as more than 200-600 mL in 24 hours. The dividing lines are arbitrary, since the amount of blood is rarely quantified with precision. Massive hemoptysis can be usefully defined as any amount that is hemodynamically significant or threatens ventilation, in which case the initial management goal is not diagnostic but therapeutic.

The lungs are supplied with a dual circulation. The pulmonary arteries arise from the right ventricle to supply the pulmonary parenchyma in a low-pressure circuit. The bronchial arteries arise from the aorta or intercostal arteries and carry blood under systemic pressure to the airways, blood vessels, hila, and visceral pleura. The bronchial arterial circulation represents only 1-2% of total pulmonary blood flow but is frequently the source of hemoptysis. It is a high-pressure circuit that provides the blood supply to the airways and lesions within those airways, and flow can increase dramatically under conditions of chronic inflammation—eg, chronic bronchiectasis.

The causes of hemoptysis can be classified anatomically. Blood may arise from the airways in chronic bronchitis, bronchiectasis, and bronchogenic carcinoma; from the pulmonary vasculature in left ventricular failure, mitral stenosis, pulmonary emboli, and arteriovenous malformations; or from the pulmonary parenchyma in pneumonia, inhalation of crack cocaine, or autoimmune diseases such as Goodpasture's disease or Wegener's granulomatosis. Iatrogenic hemorrhage may follow transbronchial lung biopsies, anticoagulation, or pulmonary artery rupture due to distal placement of a balloon-tipped catheter.

Clinical Findings

Blood-tinged sputum in the setting of acute bronchitis in an otherwise healthy nonsmoker does not warrant an extensive diagnostic evaluation if the hemoptysis subsides with resolution of the infection. However, hemoptysis is frequently a sign of serious disease, especially in patients with a high prior probability of underlying pulmonary pathology. The goal of the history is to identify patients at risk for one of the disorders listed above. Pertinent features are tobacco use, duration of symptoms, and the presence of respiratory infection. Nonpulmonary sources of hemorrhage—from the nose or the gastrointestinal tract—should be ruled out.

Laboratory evaluation should include a chest radiograph and complete blood count, including platelet count. Renal function tests, urinalysis, and coagulation studies are appropriate in specific circumstances. Flexible bronchoscopy reveals endobronchial cancer in 3-6% of patients with hemoptysis who have a normal (nonlateralizing) chest radiograph. Nearly all of these patients are smokers over the age of 40, and most will have had symptoms for more than a week. Bronchoscopy is indicated in such patients. High-resolution CT of the chest is complementary to bronchoscopy. It can diagnose unsuspected bronchiectasis and arteriovenous malformations and will show central endobronchial lesions in many cases. It is the test of choice for suspected small peripheral malignancies.

Treatment

The management of mild hemoptysis consists of identifying and treating the specific cause. Massive hemoptysis is life-threatening. The airway must be protected, ventilation ensured, and effective circulation maintained. If the location of the bleeding site is known, the patient should be placed in the decubitus position with the involved lung dependent. Uncontrollable hemorrhage warrants rigid bronchoscopy and surgical consultation. In stable patients, flexible bronchoscopy may localize the site of bleeding, and angiography can embolize the involved bronchial arteries. Embolization is effective initially in 85% of cases, though rebleeding may occur in up to 20% of patients over the following year. The anterior spinal artery arises from the bronchial artery in up to 5% of people, and paraplegia may result if it is inadvertently cannulated.

■ APPROACH TO THE PATIENT

PHYSICAL EXAMINATION

Examination of the patient with suspected pulmonary disease includes inspection, palpation, percussion, and auscultation of the chest. An efficient approach begins with observing the pattern of breathing, auscultation of the chest, and inspection for extrapulmonary signs of pulmonary disease. More detailed examination follows from initial findings.

The pattern of breathing refers to the respiratory rate and rhythm, the depth of breathing or tidal volume, and the relative amount of time spent in inspiration and expiration. Normal values are a rate of 12-14 breaths per minute, tidal volumes of 5 mL/kg, and a ratio of inspiratory to expiratory time of 2:3. **Tachypnea** is an increased rate of breathing and is commonly associated with a decrease in tidal volume. The rhythm is normally regular, with a sigh (1.5-2 times normal tidal volume) every 90 breaths or so to prevent collapse of alveoli and atelectasis. Alterations in the rhythm of breathing include rapid, shallow breathing, seen in restrictive lung disease and as a precursor to respiratory failure; Kussmaul breathing, rapid large-volume breathing indicating intense stimulation of the respiratory center, seen in metabolic acidosis; and Cheyne-Stokes respiration, a rhythmic waxing and waning of both rate and tidal volumes that includes regular periods of apnea. This pattern is seen in patients with end-stage left ventricular failure or neurologic disease and in many normal subjects at high altitude, especially during sleep.

During normal quiet breathing, the primary muscle of respiration is the diaphragm. Movement of the chest wall is minimal. The use of accessory muscles of respiration, the intercostal and sternocleidomastoid muscles, indicates high work of breathing. At rest, the use of accessory muscles is a sign of significant pulmonary impairment. As the diaphragm contracts, it pushes the abdominal contents down. Hence, the chest and abdominal wall normally expand simultaneously. Expansion of the chest but collapse of the abdomen on inspiration indicates weakness of the diaphragm. The chest normally expands symmetrically. Asymmetric expansion suggests unilateral volume loss, as in atelectasis or pleural effusion, unilateral airway obstruction, asymmetric pulmonary or pleural fibrosis, or splinting from chest pain.

The examiner may palpate as follows: the trachea at the suprasternal notch, to detect shifts in the mediastinum; on the posterior chest wall, to gauge fremitus and the transmission through the lungs of vibrations of spoken words; and on the anterior chest wall to assess the cardiac impulse. All these maneuvers are characterized by low interobserver agreement.

Chest percussion identifies dull areas that correspond to lung consolidation or pleural effusion or hyperresonant areas suggesting emphysema or pneumothorax. Percussion has a low sensitivity (10-20% in several studies) compared with chest radiographs to detect abnormalities. Specificity is high (85-99%). Since an insensitive test is a poor screening examination, percussion and palpation are not necessary in every patient. These techniques do serve as important confirmatory tests in specific patients when the prior probability of a finding is increased. For example, in a patient with a suspected tension pneumothorax, the finding of tracheal shift and hyperresonance can be lifesaving, permitting immediate decompression of the affected side.

Auscultation of the chest depends on a reliable and consistent classification of auditory findings. Normal lung sounds heard over the periphery of the lung are called **vesicular**. They have a gentle, rustling quality heard throughout inspiration that fades during expiration. Normal sounds heard over the suprasternal notch are called tracheal or **bronchial** lung sounds. They are louder, higher-pitched, and have a hollow quality that tends to be louder on expiration. Bronchial lung sounds heard over the periphery of the lung are abnormal and imply consolidation. Globally diminished lung sounds are an important finding predictive of significant airflow obstruction.

Abnormal lung sounds ("adventitious" breath sounds) may be continuous (> 80 ms in duration) or discontinuous (< 20 ms). Continuous lung sounds are divided into **wheezes**, which are high-pitched, musical, and have a distinct whistling quality; and **rhonchi**, which are lower-pitched, sonorous, and may have a gurgling quality. Wheezes occur in the setting of bronchospasm, mucosal edema, or excessive secretions. In each case, the airway is narrowed to the point where adjacent airway walls flutter as airflow is limited. Rhonchi originate in the larger airways when excessive secretions and abnormal airway collapsibility cause repetitive rupture of fluid films. Rhonchi frequently clear after cough.

Discontinuous lung sounds are called **crackles**—brief, discrete, nonmusical sounds with a popping quality. Fine crackles are soft, high-pitched, and crisp (< 10 ms in duration). They are formed by the explosive opening of small airways previously held closed by surface forces and are heard in interstitial diseases or early pulmonary edema. Coarse crackles are louder, lower-pitched, and slightly longer in duration (< 20 ms) and probably result from gas bubbling through fluid. Coarse crackles are heard in pneumonia, obstructive lung disease, and late pulmonary edema.

Interobserver agreement regarding auscultatory findings is good. The clinical usefulness of these findings is also well established. The presence of wheezes on physical examination is a powerful predictor of obstructive lung disease. The absence of wheezes is not helpful since patients may have significant airflow limitation without wheezing. Such patients will have globally diminished lung sounds as the clinical clue to their obstructive lung disease. Normal lung sounds exclude significant airway obstruction. The timing and character of crackles can reliably distinguish different pulmonary disorders. Fine, late inspiratory crackles suggest pulmonary fibrosis, while early coarse crackles suggest pneumonia or heart failure.

Extrapulmonary signs of intrinsic pulmonary disease include digital clubbing, cyanosis, elevation of central venous pressures, and lower extremity edema.

Digital clubbing refers to structural changes at the base of the nails that include softening of the nail bed and loss of the normal 150-degree angle between the nail and the cuticle. The distal phalanx is convex and enlarged: its thickness is equal to or greater than the thickness of the distal interphalangeal joint. Symmetric clubbing may be a normal variant but more commonly is a sign of underlying disease. Clubbing is seen in patients with chronic infections of the lungs and pleura (lung abscess, empyema, bronchiectasis, cystic fibrosis), malignancies of the lungs and pleura, chronic interstitial lung disease (idiopathic pulmonary fibrosis), and arteriovenous malformations. It does not normally accompany asthma or COPD; when seen in the latter, one should suspect concomitant lung cancer. It is observed less often in small-cell cancer than in other histologic types. Clubbing is not specific to pulmonary disorders; it is also seen in cyanotic congenital heart disease, infective endocarditis, cirrhosis, and inflammatory bowel disease. **Hypertrophic pulmonary osteoarthropathy** is a syndrome of digital clubbing, chronic proliferative periostitis of the long bones, and synovitis. It is seen in the same conditions as digital clubbing but is particularly common in bronchogenic carcinoma. The cause of clubbing and hypertrophic osteoarthropathy is not known with certainty, but the disorder may reflect platelet clumping and local release of platelet-derived growth factor at the nail bed. Both clubbing and osteoarthropathy may resolve with appropriate treatment of the underlying disease. **Cyanosis** is a blue or bluish-gray discoloration of the skin and mucous membranes caused by increased amounts ($> 5 \text{ g/dL}$) of unsaturated hemoglobin in capillary blood. Since the oxygen saturation at which cyanosis becomes clinically apparent is a function of hemoglobin concentration, anemia may prevent cyanosis from appearing while polycythemia may lead to cyanosis in the setting of mild hypoxemia. Cyanosis is therefore not a reliable indicator of hypoxemia but should prompt direct measurement of arterial PO_2 or of hemoglobin saturation.

Estimation of **central venous pressure** (CVP) and assessment of lower extremity edema are indirect measures of pulmonary hypertension, the major cardiovascular complication of chronic lung disease. Estimation of CVP can be done with precision in many patients. Elevated CVP is a pathologic finding associated with impaired ventricular function, pericardial effusion or restriction, valvular heart disease, and chronic obstructive or restrictive lung disease. Peripheral edema is a nonspecific finding that, in the setting of chronic lung disease, suggests right ventricular failure.

PULMONARY FUNCTION TESTS

Standard pulmonary function tests measure airflow rates, lung volumes, and the ability of the lung to transfer gas across the alveolar-capillary membrane. Indications for pulmonary function testing include assessment of the type and extent of lung dysfunction; diagnosis of causes of dyspnea and cough; detection of early evidence of lung dysfunction; longitudinal surveillance in occupational settings; follow-up of response to therapy; preoperative assessment; and disability evaluation.

Contraindications to pulmonary function testing include acute severe asthma, respiratory distress, angina aggravated by testing, pneumothorax, ongoing hemoptysis, and active tuberculosis. Many test results are effort-dependent, and some patients may be too impaired to make a maximal effort. Suboptimal effort limits validity and is a common cause of misinterpretation of results. All pulmonary function tests are measured against predicted values derived from large studies of healthy subjects. In general, these predictions vary with age, gender, height and, to a lesser extent, weight and ethnicity.

Spirometry (see box) and measurement of lung volumes allow measurement of the presence and severity of obstructive and restrictive pulmonary dysfunction. Obstructive dysfunction is marked by a reduction in airflow rates judged by a fall in the ratio of FEV_1 (forced expiratory volume in the first second) to FVC (forced vital capacity). Causes include asthma, COPD (chronic bronchitis and emphysema), bronchiectasis, bronchiolitis, and upper airway obstruction. Restrictive dysfunction is marked by a reduction in lung volumes with a normal to increased FEV_1/FVC ratio. Severity is graded by the reduction in total lung capacity. A reduced FVC suggests pulmonary restriction but is not diagnostic. Causes include decreased lung compliance from infiltrative disorders such as pulmonary fibrosis; reduced muscle strength from phrenic nerve injury, diaphragm dysfunction, or neuromuscular disease; pleural disease, including large pleural effusion or marked pleural thickening; and prior lung resection. The flow-volume loop combines the maximal expiratory and inspiratory flow-volume curves and is especially helpful in determining the site of airway obstruction. (See Figure 9-1.)

Spirometry is adequate for evaluation of most patients with suspected respiratory disease. If airflow obstruction is evident, spirometry is repeated 10-20 minutes after an inhaled bronchodilator is administered. This doubles the cost of the study. The absence of improvement in spirometry after inhaled bronchodilator in the pulmonary function laboratory does *not* preclude a successful clinical response to bronchodilator therapy. Measurements of lung volumes and diffusing capacity are useful in selected patients, but these tests are expensive and should not be ordered routinely with spirometry.

Measurement of the single-breath **diffusing capacity** for carbon monoxide (D_Lco), which reflects the ability of the lung to transfer gas across the alveolar/capillary interface, is particularly helpful in evaluation of patients with diffuse infiltrative lung disease or emphysema. The total pulmonary diffusing capacity (D_L) depends upon the diffusion properties of the alveolar-capillary membrane and the amount of hemoglobin occupying the pulmonary capillaries. The diffusing capacity should therefore be corrected for the blood hemoglobin concentration.*

Elevated D_Lco is observed in pulmonary hemorrhage and may be seen in acute congestive heart failure and asthma due to an increase in pulmonary capillary blood volume. A diffusing capacity of 6 mL CO/mm Hg or more below the predicted value in women or 8.1 mL CO/mm Hg in men is considered abnormally low (Intermountain Thoracic Society guidelines). Reporting the ratio of measured diffusing capacity to alveolar volume ($\text{D}_\text{Lco}/\text{V}_\text{A}$) is helpful, because a diminished diffusing capacity may only reflect a reduction in lung volume. In patients with emphysema, the diffusing capacity is characteristically low, the alveolar volume normal or increased, and the $\text{D}_\text{Lco}/\text{V}_\text{A}$ ratio is low. In patients with diffuse infiltrative lung disease, both the diffusing capacity and the alveolar volume are characteristically reduced, and the $\text{D}_\text{Lco}/\text{V}_\text{A}$ ratio is normal or low.

$$^*Corrected\ D_LCO = Measured\ D_LCO \times \frac{[Hb] + 10.22}{1.7[Hb]}$$
 where [Hb] is the measured hemoglobin concentration (g/dL).

In patients with AIDS, D_LCO is a highly sensitive screening test for the presence of pulmonary disease, especially *Pneumocystis jiroveci* pneumonia, but it lacks specificity. A normal D_LCO in an AIDS patient is strong evidence against pneumocystis pneumonia. An abnormal result indicates the need for further diagnostic evaluation. Routine measurement of D_LCO and other pulmonary function in AIDS patients with pulmonary disease is not advised, because of expense and lack of specificity.

Arterial blood gas analysis is indicated whenever a clinically important acid-base disturbance, hypoxemia, or hypercapnia is suspected. **Oximetry** provides an inexpensive, noninvasive alternative means of monitoring hemoglobin saturation with oxygen. Oximeters monitor oxygen saturation and not oxygen tension. [Figure 9-2](#) displays the normal relationship between oxygen saturation and partial pressure of oxygen in blood. This relationship is not linear. The clinical accuracy of pulse oximeters is reduced in such conditions as severe anemia (< 5 g/dL hemoglobin), the presence of abnormal hemoglobin moieties (carboxyhemoglobin, methemoglobin, fetal hemoglobin), the presence of intravascular dyes, motion artifact, and lack of pulsatile arterial blood flow (hypotension, hypothermia, cardiac arrest, simultaneous use of a blood pressure cuff, and cardiopulmonary bypass). The normal arterial PO_2 falls with increasing altitude ([Table 9-1](#)).

Nonspecific **bronchial provocation testing** may aid the evaluation of suspected asthma, when baseline spirometry is normal, and in unexplained cough. The subject inhales a nebulized solution containing methacholine or histamine. These agents cause bronchial smooth muscle constriction in asthmatics at much lower doses than in nonasthmatics. If the FEV_1 falls by more than 20% at a dose of 16 mg/mL or less, the test is positive. Bronchial provocation testing is 95% sensitive for the diagnosis of asthma. A negative result therefore makes asthma unlikely. Specificity is lower—about 70—since false positives may occur in several common conditions, including COPD, congestive heart failure, recent viral respiratory infection, cystic fibrosis, and sarcoidosis.

Cardiopulmonary Exercise Stress Testing

Cardiopulmonary exercise testing is usually performed to evaluate patients with unexplained exertional dyspnea. A bicycle ergometer or treadmill is used. Minute ventilation, expired oxygen and carbon dioxide tension, heart rate, blood pressure, and respiratory rate are monitored. The exercise protocol is determined by the indications for the test and the ability of the patient to exercise. Complications are rare.

Mottram CD: Exercise testing. Respir Care Clin N Am 1997;3:247. [\[PMID: 9390911\]](#)

Bronchoscopy

Flexible fiberoptic bronchoscopy is an essential tool in the diagnosis and management of many pulmonary diseases. Bronchoscopy is indicated for evaluation of the airway, diagnosis and staging of bronchogenic carcinoma, evaluation of hemoptysis, and diagnosis of pulmonary infections. It allows transbronchial lung biopsy, bronchoalveolar lavage, and removal of retained secretions and foreign bodies from the airway. The procedure is contraindicated in severe bronchospasm and a bleeding diathesis. Complications include hemorrhage, fever, and a transient hypoxemia. The rate of major complications is less than 1%, and deaths are rare. The rate of major complications jumps to about 7% when transbronchial lung biopsy is performed. Hospitalization for fiberoptic bronchoscopy is not necessary.

Rigid bronchoscopy is performed for massive bleeding, extraction of large obstructing objects (foreign bodies, blood clots, tumor masses, broncholiths), biopsy of tracheal or main stem bronchus tumors and bronchial carcinoids, and facilitation of laser therapy. Unlike fiberoptic bronchoscopy, which can usually be performed with only topical anesthesia and low-dose conscious sedation (a narcotic or a benzodiazepine, or both), rigid bronchoscopy usually requires general anesthesia.

■ DISORDERS OF THE AIRWAYS

Airway disorders have diverse causes but share certain common pathophysiologic and clinical features. Airflow limitation is characteristic and frequently causes dyspnea and cough. Other symptoms are common and typically disease-specific. Disorders of the airways can be classified as those which involve the upper airways—loosely defined as those above and including the vocal cords—and those which involve the lower airways.

DISORDERS OF THE UPPER AIRWAYS

Upper airway obstruction may occur acutely or present as a chronic condition. **Acute upper airway obstruction** can be immediately life-threatening and must be relieved promptly to avoid asphyxia. Causes of acute upper airway obstruction include foreign body aspiration, laryngospasm, laryngeal edema from airway burns, angioedema, trauma to the larynx or pharynx, infections (Ludwig's angina, pharyngeal or retropharyngeal abscess, acute epiglottitis), and acute allergic laryngitis.

Chronic obstruction of the upper airway may be caused by carcinoma of the pharynx or larynx, laryngeal or subglottic stenosis, laryngeal granulomas or webs, or bilateral vocal cord paralysis. Laryngeal or subglottic stenosis may become evident weeks or months following a period of translaryngeal endotracheal intubation. Inspiratory stridor, intercostal retractions on inspiration, a palpable inspiratory thrill over the larynx, and wheezing localized to the neck or trachea on auscultation are characteristic findings. Flow-volume loops may show flow limitations characteristic of obstruction. Soft tissue radiographs of the neck may show supra- or infraglottic narrowing. CT and MRI scans can reveal exact sites of obstruction. Flexible endoscopy may be diagnostic, but caution is necessary to avoid exacerbating upper airway edema and precipitating critical airway narrowing.

Vocal cord dysfunction syndrome is a condition characterized by paradoxical vocal cord adduction, resulting in both acute and chronic upper airway obstruction. It can cause dyspnea and wheezing that may present as asthma; it may be distinguished from asthma by the lack of response to bronchodilator therapy, normal spirometry immediately after an attack, spirometric evidence of upper airway obstruction, a negative bronchial provocation test, or direct visualization of adduction of the vocal cords on both inspiration and expiration. Bronchodilators are of no therapeutic benefit. Treatment consists of speech therapy.

Bacharier LB et al: Vocal cord dysfunction: A practical approach to diagnosis. J Respir Dis 2001;22:93.

Noble VE et al: Stridor. J Emerg Med 2000;19:183. [\[PMID: 10903470\]](#)

DISORDERS OF THE LOWER AIRWAYS

Tracheal obstruction may be intrathoracic (below the suprasternal notch) or extrathoracic. Fixed tracheal obstruction may be caused by acquired or congenital tracheal stenosis, primary or secondary tracheal neoplasms, extrinsic compression (tumors of the lung, thymus, or thyroid; lymphadenopathy; congenital vascular rings; aneurysms, etc), foreign body aspiration, tracheal granulomas and papillomas, and tracheal trauma.

Acquired **tracheal stenosis** is usually secondary to previous tracheotomy or endotracheal intubation. Dyspnea, cough, and inability to clear pulmonary secretions occur weeks to months after tracheal decannulation or extubation. Physical findings may be absent until tracheal diameter is reduced 50% or more, when wheezing, a palpable tracheal thrill, and harsh breath sounds may be detected. The diagnosis is usually confirmed by plain films or CT of the trachea. Complications include recurring pulmonary infection and life-threatening respiratory failure. Management is directed toward ensuring adequate ventilation and oxygenation and avoiding manipulative procedures that may increase edema of the tracheal mucosa. Surgical reconstruction, endotracheal stent placement, or laser photoresection may be required.

Bronchial obstruction may be caused by retained pulmonary secretions, aspiration, foreign bodies, bronchogenic carcinoma, compression by extrinsic masses, and tumors metastatic to the airway. Clinical and radiographic findings vary depending on the location of the obstruction and the degree of airway narrowing. Symptoms include dyspnea, cough, wheezing, and, if infection is present, fever and chills. A history of recurrent pneumonia in the same lobe or segment or slow resolution (> 3

months) of pneumonia on successive radiographs suggests the possibility of bronchial obstruction and the need for bronchoscopy. Complete obstruction of a main stem bronchus may be obvious on physical examination (asymmetric chest expansion, mediastinal shift, absence of breath sounds on the affected side, and dullness to percussion), but partial obstruction is often difficult or impossible to detect. Prolonged expiration and localized wheezing may be the only clues. Segmental or subsegmental bronchial obstruction may produce no abnormalities on physical examination.

Roentgenographic findings include **atelectasis** (local parenchymal collapse), postobstructive infiltrates, and air trapping caused by unidirectional expiratory obstruction. CT scanning may demonstrate the nature and the exact location of obstruction of the central bronchi. MRI may be superior to CT for delineating the extent of the underlying disease in the hilum, but it is usually reserved for cases in which CT findings are equivocal. Bronchoscopy is the definitive diagnostic study, particularly if tumor or foreign body aspiration is suspected. The finding of tubular breath sounds on physical examination or an air bronchogram on chest radiograph in an area of atelectasis rules out complete airway obstruction. Bronchoscopy is unlikely to be of therapeutic benefit in this situation.

Right middle lobe syndrome is recurrent or persistent atelectasis of the right middle lobe. This collapse is related to the relatively long length and narrow diameter of the right middle lobe bronchus and the oval ("fish mouth") opening to the lobe, in the setting of impaired collateral ventilation. Fiberoptic bronchoscopy or CT scan is often necessary to rule out obstructing tumor. Foreign body or other benign causes are common.

Kwon KY et al: Middle lobe syndrome: a clinicopathological study of 21 patients. Hum Pathol 1995;26:302. [\[PMID: 7890282\]](#)

ASTHMA

Essentials of Diagnosis

- Episodic or chronic symptoms of airflow obstruction: breathlessness, cough, wheezing, and chest tightness.
- Symptoms frequently worse at night or in the early morning.
- Prolonged expiration and diffuse wheezes on physical examination.
- Limitation of airflow on pulmonary function testing or positive bronchoprovocation challenge.
- Complete or partial reversibility of airflow obstruction, either spontaneously or following bronchodilator therapy.

General Considerations

Asthma is a common disease, affecting approximately 5% of the population. Men and women appear to be equally affected. Each year, approximately 470,000 hospital admissions and 5000 deaths in the United States are attributed to asthma. Hospitalization rates have been highest among blacks and children, and death rates for asthma are consistently highest among blacks aged 15-24 years. Prevalence, hospitalizations, and fatal asthma have all increased in the United States over the past 20 years.

Definition & Pathogenesis

Asthma is a chronic inflammatory disorder of the airways. The histopathologic features include denudation of airway epithelium, collagen deposition beneath the basement membrane, airway edema, mast cell activation, and inflammatory cell infiltration with neutrophils, eosinophils, and lymphocytes (especially T lymphocytes). Hypertrophy of bronchial smooth muscle and hypertrophy of mucous glands with plugging of small airways with thick mucus can occur. This airway inflammation underlies disease chronicity and contributes to airway hyperresponsiveness, airflow limitation, and respiratory symptoms (including recurrent episodes of wheezing, breathlessness, chest tightness, and cough, particularly during the nighttime and early morning hours).

A genetic predisposition to asthma is recognized. The strongest identifiable predisposing factor for the development of asthma is atopy. Exposure of sensitive patients to inhaled allergens increases airway inflammation, airway hyperresponsiveness, and symptoms. Patients may develop symptoms immediately (immediate asthmatic response) or 4-6 hours after their exposures (late asthmatic response). Common aeroallergens include house dust mites (often found in pillows, mattresses, upholstered furniture, carpets, and drapes), cockroaches, cats, and seasonal pollens. Substantially reducing exposure reduces pathologic findings and clinical symptoms.

Nonspecific precipitants of asthma include exercise, upper respiratory tract infections, rhinitis, sinusitis, postnasal drip, aspiration, gastroesophageal reflux, changes in the weather, and stress. Exposure to environmental tobacco smoke increases asthma symptoms and the need for medications and reduces lung function. Increased air levels of respirable particles, ozone, SO₂, and NO₂ precipitate asthma symptoms and increase emergency department visits and hospitalizations. Selected individuals may experience asthma symptoms after exposure to aspirin, nonsteroidal anti-inflammatory drugs, or tartrazine dyes. Certain other medications may also precipitate asthma symptoms ([Table 9-28](#)). Occupational asthma is triggered by various agents in the workplace and may occur weeks to years after initial exposure and sensitization. Women may experience catamenial asthma at predictable times during the menstrual cycle. Exercise-induced bronchoconstriction usually begins within 3 minutes after the end of exercise, peaks within 10-15 minutes and then resolves by 60 minutes. This phenomenon is thought to be a consequence of the airways' attempt to warm and humidify an increased volume of expired air during exercise. "Cardiac asthma" is wheezing precipitated by uncompensated congestive heart failure.

Clinical Findings

Symptoms and signs vary widely from patient to patient as well as individually over time. General clinical findings in stable asthma patients are listed below; findings seen during asthma exacerbations are listed in [Table 9-3](#).

A. Symptoms and Signs

Asthma is characterized by episodic wheezing, difficulty in breathing, chest tightness, and cough. The frequency of asthma symptoms is highly variable. Some patients may have only a chronic dry cough and others a productive cough. Some patients have infrequent, brief attacks of asthma and others may suffer nearly continuous symptoms. Asthma symptoms may occur spontaneously or may be precipitated or exacerbated by many different triggers as discussed above. Asthma symptoms are frequently worse at night; circadian variations in bronchomotor tone and bronchial reactivity reach their nadir between 3 and 4 AM, increasing symptoms of bronchoconstriction.

Some physical findings increase the probability of asthma. Nasal mucosal swelling, increased nasal secretions, and nasal polyps are often seen in patients with allergic asthma. Eczema, atopic dermatitis, or other manifestations of allergic skin disorders may also be present. Hunched shoulders and use of accessory muscles of respiration suggest an increased work of breathing. Chest examination may be normal between exacerbations in patients with mild asthma. Wheezing during normal breathing or a prolonged forced expiratory phase correlates well with the presence of airflow obstruction. Wheezing during forced expiration does not. During severe asthma exacerbations, airflow may be too limited to produce wheezing, and the only diagnostic clue on auscultation may be globally reduced breath sounds with prolonged expiration.

B. Pulmonary Function Testing

Clinicians are able to identify airflow obstruction on examination, but they have limited ability to assess it or to predict whether it is reversible. The evaluation for asthma should therefore include spirometry (FEV₁, FVC, FEV₁/FVC) before and after the administration of a short-acting bronchodilator. These measurements help determine the presence and extent of airflow obstruction and whether it is immediately reversible. Airflow obstruction is indicated by a reduced FEV₁/FVC ratio (< 75%). In severe airflow obstruction with significant air trapping, the FVC may also be reduced, resulting in a pattern that suggests a restrictive ventilatory defect. Significant reversibility of airflow obstruction is defined by an increase of ≥ 12% and 200 mL in FEV₁ or ≥ 15% and 200 mL in FVC after inhaling a short-acting bronchodilator. However, the absence of improvement in airflow after administration of a bronchodilator is not proof of irreversible airflow obstruction.

Peak expiratory flow (PEF) meters are handheld devices designed as home monitoring tools. PEF monitoring can establish peak flow variability, quantify asthma severity, and provide both the patient and the clinician with objective measurements on which to base treatment decisions. There are conflicting data about whether measuring PEF improves asthma outcomes, but doing so is recommended as part of a comprehensive approach to asthma management in Expert Panel Report 2 of the National Asthma Education and Prevention Program (NAEPP) of the National Heart, Lung and Blood Institute.

Predicted values for PEF vary with age, height, and gender but are poorly standardized. Comparison with reference values is less helpful than comparison with the patient's best baseline. PEF shows diurnal variation. It is generally lowest on first awakening and highest several hours before the midpoint of the waking day. PEF should be measured in the morning before the administration of a bronchodilator and in the afternoon after taking a bronchodilator. A 20% change in PEF values from morning to afternoon or from day to day suggests inadequately controlled asthma. PEF values less than 200 L/min indicate severe airflow obstruction.

Bronchial provocation testing with histamine or methacholine—or exercise challenge testing—may be useful when asthma is suspected and spirometry is nondiagnostic. Bronchial provocation is not generally recommended if the FEV₁ is less than 65% of predicted. A positive test is defined as a decrease in FEV₁ of at

least 20% at exposure to a concentration of 16 mg/mL or less. A negative test has a negative predictive value for asthma of 95%.

Arterial blood gas measurements may be normal during a mild asthma exacerbation, but respiratory alkalosis and an increase in the alveolar-arterial oxygen difference (A-a DO₂) are common. During severe exacerbations, hypoxemia develops and the PaCO₂ returns to normal. The combination of an increased PaCO₂ and respiratory acidosis is a harbinger of respiratory failure and may indicate the need for mechanical ventilation.

C. Additional Testing

Routine chest radiographs in patients with asthma usually show only hyperinflation. Other findings may include bronchial wall thickening and diminished peripheral lung vascular shadows. Chest radiographs are indicated when pneumonia, another disorder mimicking asthma, or a complication of asthma such as pneumothorax is suspected. The diagnostic usefulness of measurements of biologic markers of inflammation such as cell counts and mediator titers in blood and sputum is being investigated. Skin testing or in vitro testing to assess sensitivity to relevant environmental allergens may be useful in patients with persistent asthma. Evaluations for paranasal sinus disease or gastroesophageal reflux should be considered in patients with pertinent symptoms and in those who have severe or refractory asthma.

Complications

Complications of asthma include exhaustion, dehydration, airway infection, cor pulmonale, and tussive syncope. Pneumothorax occurs but is rare. Acute hypercapnic and hypoxic respiratory failure occur in severe disease.

Differential Diagnosis

Disorders that mimic asthma typically fall into one of three categories: upper and lower airway disorders, systemic vasculitides, and psychiatric disorders. It is prudent to consider these conditions in patients who have atypical asthma symptoms or response to therapy. Upper airway disorders that mimic asthma include vocal cord paralysis, vocal cord dysfunction syndrome, foreign body aspiration, laryngotracheal masses, tracheal narrowing, tracheomalacia, and airway edema as in the setting of angioedema or inhalation injury. Lower airway disorders include nonasthmatic chronic obstructive pulmonary disease (chronic bronchitis or emphysema), bronchiectasis, allergic bronchopulmonary mycosis, cystic fibrosis, eosinophilic pneumonia, and bronchiolitis obliterans. Systemic vasculitides that often have an asthmatic component include Churg-Strauss syndrome and other systemic vasculitides with pulmonary involvement. Psychiatric causes include conversion disorders, which have been variably referred to as functional asthma, emotional laryngeal wheezing, vocal cord dysfunction, or episodic laryngeal dyskinesia. Munchausen syndrome or malingering may rarely explain the patient's complaints.

Classification of Asthma Severity

The Expert Panel of the NAEPP has developed asthma classification schemes which are useful in directing asthma therapy and identifying patients at high risk of developing life-threatening asthma attacks. [Table 9-2](#) is used to classify the severity of chronic, stable asthma; [Table 9-3](#) to classify severity of asthma exacerbations. A patient's clinical features before treatment are used to classify the patient. The presence of only one of the severity features is sufficient to place a patient in that category; patients should be assigned to the most severe grade in which any feature occurs.

Approach to Long-Term Treatment

The goals of asthma therapy are to minimize chronic symptoms that impair normal activity (including exercise), to prevent recurrent exacerbations, to minimize the need for emergency department visits or hospitalizations, and to maintain near-normal pulmonary function. These goals should be met while providing optimal pharmacotherapy with the fewest adverse effects and while meeting patients' and families' expectations of satisfaction with asthma care.

Current approaches to persistent asthma focus on daily anti-inflammatory therapy with inhaled corticosteroids. Treatment algorithms are based on both the severity of a patient's baseline asthma and the severity of asthma exacerbations. Expert Panel Report 2 from the NAEPP recommends a stepwise approach to therapy ([Table 9-4](#)). The amount of medication and frequency of dosing are dictated by asthma severity and directed toward suppression of increasing airway inflammation. To establish prompt control, therapy should be initiated early at a higher intensity level than anticipated for chronic therapy. Pharmacotherapy can then be cautiously stepped down once asthma control is achieved and sustained; this allows for identification of the minimum medication necessary to maintain long-term control.

Pharmacologic Agents for Asthma

Asthma medications can be divided into long-term control and quick-relief medications. Long-term control medications are taken daily to achieve and maintain control of persistent asthma. These agents—also known as maintenance, controller, or preventive medications—act primarily to attenuate airway inflammation. Quick-relief medications are taken to promote prompt reversal of acute airflow obstruction and relief of accompanying symptoms by direct relaxation of bronchial smooth muscle.

Many asthma medications can be administered orally or by inhalation. Inhalation of an appropriate agent offers the advantage of delivery of high concentrations of medication directly to the target organ. This results in a more rapid onset of pulmonary effects as well as fewer systemic effects compared with oral administration of the same dose. Metered-dose inhalers (MDIs) propelled by chlorofluorocarbons (CFCs) have been the most widely used delivery system, but non-CFC propellant systems and dry powder inhalers are available. These alternatives are effective and well tolerated. Proper MDI technique and the use of an inhalation chamber improve drug delivery to the lung and decrease oropharyngeal deposition. Nebulizer therapy is reserved for acutely ill patients and those who cannot use MDIs because of difficulties with coordination or cooperation.

A. Long-Term Control Medications

Anti-inflammatory agents, long-acting bronchodilators, and leukotriene modifiers comprise the important medications in this group of agents (see [Table 9-5](#)). Other classes of agents are mentioned briefly below.

1. Corticosteroids—Corticosteroids are the most potent and consistently effective anti-inflammatory agents currently available. They reduce both acute and chronic inflammation, resulting in fewer asthma symptoms, improvement in airflow, decreased airway hyperresponsiveness, fewer asthma exacerbations, and less airway remodeling. These agents may also potentiate the action of beta-adrenergic agonists.

Inhaled corticosteroids are preferred for the long-term control of asthma and are first-line agents for patients with persistent asthma. Patients with persistent symptoms or asthma exacerbations who are not taking inhaled corticosteroids should be started on an inhaled corticosteroid; symptomatic patients already taking an inhaled corticosteroid should have the dose increased. Dosages for inhaled corticosteroids vary depending on the specific agent and delivery device. The most important determinants of agent selection and appropriate dosing are the patient's status and response to treatment. For most patients, twice-daily dosing provides adequate control of asthma. Once-daily dosing may be sufficient in selected patients with mild persistent asthma. Maximum responses from inhaled corticosteroids may not be observed for months. The use of an inhalation chamber coupled with mouth washing after inhalation decreases local side effects (cough, dysphonia, oropharyngeal candidiasis) and systemic absorption. Systemic effects (adrenal suppression, osteoporosis, skin thinning, easy bruising, and cataracts) may occur with high-dose inhalation therapy.

Systemic corticosteroids (oral or parenteral) are most effective in achieving prompt control of asthma during exacerbations or when initiating long-term asthma therapy. In patients with severe persistent asthma, systemic corticosteroids are often required for the long-term suppression of symptoms. Repeated efforts should be made to reduce the dose to the minimum needed to control symptoms. Alternate-day treatment is preferred to daily treatment. Rapid discontinuation of systemic corticosteroids after chronic use may precipitate adrenal insufficiency. Concurrent treatment with calcium supplements and vitamin D should be initiated to prevent steroid-induced bone mineral loss in long-term administration. Bisphosphonates may offer additional protection to these patients (see [Table 26-18](#)).

2. Long-acting bronchodilators—

a. Mediator inhibitors—Cromolyn sodium and nedocromil are long-term control medications that prevent asthma symptoms and improve airway function in patients with mild persistent asthma or exercise-induced asthma. Both of these agents modulate mast cell mediator release and eosinophil recruitment and inhibit both early and late asthmatic responses to allergen challenge and exercise-induced bronchospasm. The clinical response to these agents is less predictable than the response to inhaled corticosteroids. Nedocromil may help reduce the dose requirements for inhaled corticosteroids. Both agents have excellent safety profiles.

b. Beta-adrenergic agents—Long-acting β_2 agonists provide bronchodilation for up to 12 hours after a single dose. However, because their onset of action is delayed, they are not effective—and should not be used—in the treatment of acute bronchoconstriction. Salmeterol and formoterol are the two agents in this class available in the United States. They are indicated for long-term prevention of asthma symptoms and nocturnal symptoms and for prevention of exercise-induced bronchospasm. They should not be used in place of anti-inflammatory therapy. When added to standard doses of inhaled corticosteroids, salmeterol provides control equivalent to what is achieved by doubling the inhaled corticosteroid dose. Side effects are minimal at standard doses.

c. Phosphodiesterase inhibitors—Theophylline provides mild bronchodilation in asthmatics. This drug may also have anti-inflammatory properties, enhance mucociliary clearance, and strengthen diaphragmatic contractility. Sustained-release theophylline preparations are effective in controlling nocturnal asthma and are

usually reserved for use as adjuvant therapy in patients with moderate or severe persistent asthma. They can also be used as alternative long-term preventive therapy in patients with mild persistent asthma. Theophylline serum concentrations need to be monitored closely owing to the drug's narrow toxic-therapeutic range, individual differences in metabolism, and the effects of many factors on drug absorption and metabolism. Decreases in theophylline clearance accompany the use of cimetidine, macrolide and quinolone antibiotics, and oral contraceptives. Increases in theophylline clearance are caused by rifampin, phenytoin, barbiturates, and tobacco.

Adverse effects at therapeutic doses include insomnia, upset stomach, aggravation of dyspepsia and gastroesophageal reflux symptoms, and urination difficulties in elderly men with prostatism. Dose-related toxicities are common and include nausea, vomiting, tachyarrhythmias, headache, seizures, hyperglycemia and hypokalemia.

3. Leukotriene modifiers—This is the newest class of medications for long-term control of asthma. Leukotrienes are potent biochemical mediators that contribute to airway obstruction and asthma symptoms by contracting airway smooth muscle, increasing vascular permeability and mucus secretion, and attracting and activating airway inflammatory cells. Zileuton is a 5-lipoxygenase inhibitor that decreases leukotriene production, and zafirlukast and montelukast are cysteinyl leukotriene receptor antagonists. They cause modest improvements in lung function and reductions in asthma symptoms and lessen the need for beta-agonist rescue therapy. These agents may be considered as alternatives to low-dose inhaled corticosteroids in patients with mild persistent asthma. Zileuton can cause reversible elevations in plasma aminotransferase levels, and a small number of patients who have taken montelukast or zafirlukast subsequently have been diagnosed with Churg-Strauss syndrome.

4. Desensitization—Immunotherapy for specific allergens may be considered in selected asthma patients who have exacerbations of asthma symptoms when exposed to allergens to which they are sensitive and who do not respond to environmental control measures or other forms of conventional therapy. Studies show a reduction in asthma symptoms in patients treated with single-allergen immunotherapy. Because of the risk of immunotherapy-induced bronchoconstriction, it should be administered only in a setting where such complications can be treated.

5. Miscellaneous agents—Oral sustained-release β_2 agonists are reserved for patients with bothersome nocturnal asthma symptoms or moderate to severe persistent asthma who do not respond to other therapies. Corticosteroid-sparing anti-inflammatory agents such as troleandomycin, methotrexate, cyclosporine, intravenous immunoglobulin, and gold should be used only in selected severe asthmatics. These and other agents have variable benefit and worrisome toxicities.

B. Quick-Relief Medications

Short-acting bronchodilators and systemic corticosteroids comprise the important medications in this group of agents ([Table 9-6](#)).

1. Beta-adrenergic agents—Short-acting inhaled beta-adrenergic agonists are clearly the most effective bronchodilators during exacerbations. Beta-adrenergic agonists should be used in all patients to treat acute symptoms. These agents relax airway smooth muscle and cause a prompt increase in airflow and reduction of symptoms. Administration before exercise effectively prevents exercise-induced bronchoconstriction. There is no convincing evidence to support the use of one agent over another. However, β_2 -selective agents produce less cardiac stimulation than those with mixed β_1 and β_2 activities. Currently available short-acting β_2 -selective adrenergic agonists include albuterol, bitolterol, pirbuterol, and terbutaline.

Inhaled beta-adrenergic agonist therapy is as effective as oral or parenteral therapy in relaxing airway smooth muscle and improving acute asthma and offers the advantages of rapid onset of action (< 5 minutes) with fewer systemic side effects. Repetitive administration produces incremental bronchodilation. Intravenous and subcutaneous routes of administration should be reserved for patients who because of age or mechanical factors are unable to inhale medications.

One or two inhalations of a short-acting inhaled β_2 agonist from a metered-dose inhaler is usually sufficient for mild to moderate symptoms; severe exacerbations may require up to four inhalations every few hours. Administration by wet nebulization does not offer more effective delivery than metered-dose inhalers; it is perceived to be more effective because it is given in higher doses. With most β_2 agonists, the recommended dose by nebulizer for acute asthma (albuterol, 2.5 mg) is 25-30 times that delivered by a single activation of the metered-dose inhaler (albuterol, 0.09 mg). This difference suggests that the standard use of inhalations from a metered-dose inhaler will often be insufficient in the setting of an acute exacerbation. Equivalent bronchodilation can be achieved by either high doses (6-12 puffs) of a β_2 agonist by metered-dose inhaler with an inhalation chamber or by nebulizer therapy. Nebulizer therapy may be more effective in patients who are unable to coordinate inhalation of medication from a metered-dose inhaler because of age, agitation, or severity of the exacerbation.

Scheduled daily use of β_2 agonists is not generally recommended. Increased use (more than one canister a month) or lack of expected effect indicates diminished asthma control and dictates the need for additional long-term control therapy.

2. Anticholinergics—Anticholinergic agents reverse vagally mediated bronchospasm but not allergen- or exercise-induced bronchospasm. They may decrease mucous gland hypersecretion seen in asthma. Ipratropium bromide, a quaternary derivative of atropine free of atropine's side-effects, is the only available agent. This drug reverses acute bronchospasm and is the inhaled alternative for patients with intolerance to β_2 agonists. Ipratropium bromide may be a useful adjunct to inhaled short-acting β_2 agonists and considered in patients with moderate to severe asthma exacerbations. High doses of inhaled ipratropium bromide (0.5 mg) cause additional bronchodilation in some patients with severe airway obstruction, but the long-term role in management of asthma has not been clarified. It is the drug of choice for bronchospasm due to beta-blocker medications.

3. Phosphodiesterase inhibitors—Methylxanthines are not recommended for therapy of asthma exacerbations. Aminophylline has clearly been shown to be less effective than β_2 agonists when used as single-drug therapy for acute asthma and adds little except toxicity to the acute bronchodilator effects achieved by nebulized metaproterenol alone. In patients currently taking a theophylline-containing preparation, the serum theophylline concentration should be determined to exclude theophylline toxicity.

4. Glucocorticoids—Systemic corticosteroids are effective primary treatment for patients with moderate to severe exacerbations or for patients who fail to respond promptly and completely to inhaled β_2 -agonist therapy. They are one of the mainstays of the treatment of patients with severe asthma. These medications speed the resolution of airflow obstruction and reduce the rate of relapse. Delays in administering corticosteroids may result in delayed benefits from these important agents. Therefore, oral corticosteroids should be available for early administration at home in many patients with moderate to severe asthma.

It may be prudent to administer corticosteroids to critically ill patients via the intravenous route in order to avoid concerns about altered gastrointestinal absorption in these patients. The minimal effective dose of systemic corticosteroids for asthma patients has not been identified. Outpatient prednisone "burst" therapy is 0.5-1 mg/kg/d (typically 40-60 mg) as a single or in two divided doses for 3-10 days. Severe exacerbations requiring hospitalization typically require 1 mg/kg of prednisone equivalent every 6-12 hours for 48 hours or until the FEV₁ (or PEF) returns to 50% of predicted (or 50% of baseline). The dose is then decreased to 60-80 mg/d until the PEF reaches 70% of predicted or personal best. No clear advantage has been found for higher doses of corticosteroids in severe exacerbations.

5. Antimicrobials—Antibiotics have no role in routine asthma exacerbations. They may be useful if bacterial respiratory tract infections are thought to contribute. Thus, patients with fever and purulent sputum and evidence of pneumonia or bacterial sinusitis are reasonable candidates.

Approach to Treatment of Asthma Exacerbations

The principal goals in the treatment of asthma exacerbations are correction of hypoxemia, reversal of airflow obstruction, and reduction of the likelihood of recurrence of obstruction. Early intervention may lessen the severity and duration of an exacerbation. Of paramount importance is correction of hypoxemia through the use of supplemental oxygen. At the same time, rapid reversal of airflow obstruction should be attempted by repetitive or continuous administration of an inhaled short-acting β_2 agonist and the early administration of systemic corticosteroids to patients with moderate to severe asthma exacerbations or to patients who fail to respond promptly and completely to an inhaled short-acting β_2 agonist.

Serial measurements of lung function to quantify the severity of airflow obstruction and its response to treatment are especially useful. The improvement in FEV₁ after 30 minutes of treatment correlates significantly with a broad range of indices of the severity of asthma exacerbations. Serial measurement of airflow in the emergency department is an important factor in disposition and may reduce the rate of hospital admissions for asthma exacerbations.

The postexacerbation care plan is an important aspect of management. Regardless of the severity, all patients should be provided with necessary medications and education in how to use them, instruction in self-assessment, a follow-up appointment, and instruction in an action plan for managing recurrence.

Approach to Treatment of Mild Asthma Exacerbations

Mild asthma exacerbations are characterized by only minor changes in airway function (PEF > 80%) and minimal symptoms and signs of airway dysfunction ([Table 9-3](#)). The majority of exacerbations can be managed with home-based therapies. Most patients respond quickly and fully to an inhaled short-acting β_2 agonist alone. However, an inhaled short-acting β_2 agonist may need to be continued every 3-4 hours for 24-48 hours. For mild exacerbations in patients already taking an inhaled

corticosteroid, authorities recommend doubling the dose until peak flow returns to predicted or personal best. In patients not already taking an inhaled corticosteroid, initiation of this agent should be considered. A course of oral corticosteroids may be necessary for mild exacerbations that persist despite an increase in the dose of inhaled corticosteroids.

Approach to Treatment of Moderate & Severe Asthma Exacerbations

Some patients with moderate asthma exacerbations can be managed at home with the telephone assistance of a clinician. However, most such patients require a more comprehensive evaluation and treatment program such as that outlined below for severe asthma exacerbations. A course of oral corticosteroids is usually necessary.

Owing to the life-threatening nature of severe exacerbations of asthma, treatment should be started immediately once the exacerbation is recognized. All patients with a severe exacerbation should immediately receive oxygen, high doses of an inhaled short-acting β_2 agonist, and systemic corticosteroids. A brief history pertinent to the exacerbation can be completed while treatment is given. More detailed assessments, including laboratory studies, usually add little in the early phase of evaluation and management and should be delayed until after initial therapy has been completed.

Asphyxia is a common cause of death, and oxygen therapy is therefore very important. Supplemental oxygen should be given to maintain an $\text{SaO}_2 > 90\%$ or a $\text{PaO}_2 > 60$ mm Hg. Oxygen-induced hypoventilation is very rare, and concern for hypercapnia should never delay correction of hypoxemia.

Frequent high-dose delivery of an inhaled short-acting β_2 agonist is indicated and is usually well tolerated in the setting of severe airway obstruction. Some studies suggest that continuous therapy is more efficacious than intermittent administration of these agents, but there is no clear consensus as long as similar doses are administered. At least three metered-dose inhaler or nebulizer treatments should be given in the first hour of therapy. Thereafter, the frequency of administration varies according to the improvement in airflow and associated symptoms and the occurrence of side effects.

Systemic corticosteroids are administered as detailed above. Mucolytic agents (eg, acetylcysteine, potassium iodide) may worsen cough or airflow obstruction. Anxiolytic and hypnotic drugs are contraindicated in critically ill asthma patients because of their respiratory depressant effects.

Repeat assessment of patients with severe exacerbations should be made after the initial dose of inhaled bronchodilator and after three doses of inhaled bronchodilators (60-90 minutes after initiating treatment). The response to initial treatment is a better predictor of the need for hospitalization than is the severity of an exacerbation on presentation. The decision to hospitalize a patient should be based on the duration and severity of symptoms, severity of airflow obstruction, course and severity of prior exacerbations, medication use at the time of the exacerbation, access to medical care and medications, adequacy of social support and home conditions, and presence of psychiatric illness. In general, discharge to home is appropriate if the PEF or FEV_1 has returned to $\geq 70\%$ of predicted or personal best and symptoms are minimal or absent. Patients with a rapid response to treatment should be observed for 30 minutes after the most recent dose of bronchodilator to ensure stability of response before discharge to home.

A small minority of patients will not respond well to treatment and will show signs of impending respiratory failure due to a combination of worsening airflow obstruction and respiratory muscle fatigue (Table 9-3). Such patients can deteriorate rapidly and thus should be monitored in a critical care setting. Intubation of an acutely ill asthma patient is technically difficult and is best done semielectively, before the crisis of a respiratory arrest. At the time of intubation, close attention should be given to maintaining intravascular volume because hypotension commonly accompanies the administration of sedation and the initiation of positive-pressure ventilation in patients dehydrated due to poor recent oral intake and high insensible losses.

The main goals of mechanical ventilation are to ensure adequate oxygen and avoid barotrauma. Controlled hypoventilation with permissive hypercapnia is often required to limit airway pressures. Frequent high-dose delivery of inhaled short-acting β_2 agonists should be continued along with anti-inflammatory agents as discussed above. Many questions remain regarding the optimal delivery of inhaled β_2 agonists to intubated, mechanically ventilated patients. Further studies are needed to determine the comparative efficacy of metered-dose inhalers and nebulizers, optimal ventilator settings to use during drug delivery, ideal site along the ventilator circuit for introduction of the delivery system, and maximal acceptable drug doses. Magnesium sulfate reduces airflow obstruction in acute severe asthma ($\text{FEV}_1 < 25\%$ of predicted), but the improvement appears to be too slight to convey clinical benefit. Unconventional therapies such as helium-oxygen mixtures and inhalational anesthetic agents are of unclear benefit but may be appropriate in selected patients.

Assessment, Monitoring, & Prevention

Periodic assessments and ongoing monitoring of asthma are essential to determine if the goals of therapy are being met. Clinical assessment and patient self-assessment are the primary methods for monitoring asthma. Patients should be given a written action plan based on symptoms and signs or expiratory flow rates. An action plan is especially important for patients with moderate to severe asthma or those with a history of severe exacerbations. Patients should be taught to recognize symptoms—especially patterns indicating inadequate asthma control or predicting the need for additional therapy. The written asthma action plan should direct the asthma patient to adjust medications in response to particular signs, symptoms, and peak flow measurements and should state when to seek medical help.

Spirometry is recommended at the time of initial assessment, once treatment is initiated and symptoms and peak flows have stabilized, and at least every 1-2 years thereafter. Regular follow-up visits (at least every 6 months, or more frequently based on patient status) are essential to help maintain asthma control and to reevaluate medication requirements. Patients with persistent asthma should receive the pneumococcal vaccine (Pneumovax) and annual influenza vaccinations.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD)

Essentials of Diagnosis

- History of cigarette smoking.
- Chronic cough and sputum production (in chronic bronchitis) and dyspnea (in emphysema).
- Rhonchi, decreased intensity of breath sounds, and prolonged expiration on physical examination.
- Airflow limitation on pulmonary function testing that is not fully reversible and most often progressive.

General Considerations

Chronic obstructive pulmonary disease (COPD) is a disease state characterized by the presence of airflow obstruction due to chronic bronchitis or emphysema; the airflow obstruction is generally progressive, may be accompanied by airway hyperreactivity, and may be partially reversible (American Thoracic Society). The National Heart, Lung, and Blood Institute (NHLBI) estimates that 14 million Americans have been diagnosed with COPD; an equal number is thought to be afflicted but remains undiagnosed. Grouped together, COPD and asthma now represent the fourth leading cause of death in the United States, with over 100,000 deaths reported annually. The death rate from COPD is increasing rapidly, especially among elderly men.

Most patients with COPD have features of both emphysema and chronic bronchitis. **Chronic bronchitis** is a clinical diagnosis defined by excessive secretion of bronchial mucus and is manifested by productive cough for 3 months or more in at least 2 consecutive years in the absence of any other disease that might account for this symptom. **Emphysema** is a pathologic diagnosis that denotes abnormal permanent enlargement of air spaces distal to the terminal bronchiole, with destruction of their walls and without obvious fibrosis.

Cigarette smoking is clearly the most important cause of COPD. Nearly all smokers suffer an accelerated decline in lung function that is dose- and duration-dependent. Fifteen percent develop progressively disabling symptoms in their 40s and 50s. It is estimated that 80% of patients seen for COPD have significant exposure to tobacco smoke. The remaining 20% frequently have a combination of exposures to environmental tobacco smoke, occupational dusts and chemicals, and indoor air pollution from biomass fuel used for cooking and heating in poorly ventilated buildings. Outdoor air pollution, airway infection, familial factors, and allergy have also been

implicated in chronic bronchitis, and hereditary factors (deficiency of α_1 -antiprotease) have been implicated in COPD. The pathogenesis of emphysema may involve excessive lysis of elastin and other structural proteins in the lung matrix by elastase and other proteases derived from lung neutrophils, macrophages, and mononuclear cells. Atopy and the tendency for bronchoconstriction to develop in response to nonspecific airway stimuli may be important risks for COPD.

Clinical Findings

A. Symptoms and Signs

Patients with COPD characteristically present in the fifth or sixth decade of life complaining of excessive cough, sputum production, and shortness of breath. Symptoms have often been present for 10 years or more. Dyspnea is noted initially only on heavy exertion, but as the condition progresses it occurs with mild activity. In severe disease, dyspnea occurs at rest. A hallmark of COPD is frequent exacerbations of illness that result in absence from work and eventual disability. Pneumonia, pulmonary hypertension, cor pulmonale, and chronic respiratory failure characterize the late stage of COPD. Death usually occurs during an exacerbation of illness in association with acute respiratory failure.

Clinical findings may be completely absent early in the course of COPD. As the disease progresses, two symptom patterns tend to emerge, historically referred to as "pink puffers" and "blue bloaters" ([Table 9-7](#)). These patterns have been thought to represent pure forms of emphysema and bronchitis, respectively, but this is a simplification of the anatomy and pathophysiology. Most COPD patients have pathologic evidence of both disorders, and their clinical course may reflect other factors such as central control of ventilation and concomitant sleep-disordered breathing.

B. Laboratory Findings

Spirometry provides objective information about pulmonary function and assesses the results of therapy. Pulmonary function tests early in the course of COPD reveal only evidence of abnormal closing volume and reduced midexpiratory flow rate. Reductions in FEV_1 and in the ratio of forced expiratory volume to vital capacity ($FEV_1\%$ or FEV_1/FVC ratio) occur later. In severe disease, the forced vital capacity is markedly reduced. Lung volume measurements reveal an increase in the total lung capacity (TLC), a marked increase in the residual volume (RV), and an elevation of the RV/TLC ratio, indicative of air trapping, particularly in emphysema.

Arterial blood gas measurements characteristically show no abnormalities early in COPD other than an increased A-a DO_2 . Indeed, they are unnecessary unless (1) hypoxemia or hypercapnia is suspected, (2) the FEV_1 is < 40% of predicted, or (3) there are clinical signs of right heart failure. Hypoxemia occurs in advanced disease, particularly when chronic bronchitis predominates. Compensated respiratory acidosis occurs in patients with chronic respiratory failure, particularly in chronic bronchitis, with worsening of acidemia during acute exacerbations.

Examination of the sputum may reveal *Streptococcus pneumoniae*, *Haemophilus influenzae*, or *Moraxella catarrhalis*. Positive sputum cultures are poorly correlated with acute exacerbations, and research techniques demonstrate evidence of preceding viral infection in a majority of patients with exacerbations. The ECG may show sinus tachycardia, and in advanced disease, chronic pulmonary hypertension may produce electrocardiographic abnormalities typical of cor pulmonale. Supraventricular arrhythmias (multifocal atrial tachycardia, atrial flutter, and atrial fibrillation) and ventricular irritability also occur.

C. Imaging

When emphysema is the main clinical feature, hyperinflation is apparent. Parenchymal bullae or subpleural blebs are pathognomonic of emphysema. Radiographs of patients with chronic bronchitis may show only nonspecific peribronchial and perivascular markings. Pulmonary hypertension becomes evident as enlargement of central pulmonary arteries in advanced disease. Doppler echocardiography is an effective way to estimate pulmonary artery pressure if pulmonary hypertension is suspected.

Differential Diagnosis

Clinical, roentgenographic, and laboratory findings should enable the clinician to distinguish COPD from other obstructive pulmonary disorders such as bronchial asthma, bronchiectasis, cystic fibrosis, bronchopulmonary mycosis, and central airflow obstruction. Simple asthma is characterized by complete or near-complete reversibility of airflow obstruction. Bronchiectasis is distinguished from COPD by features such as recurrent pneumonia and hemoptysis, digital clubbing, and radiographic abnormalities. Patients with severe α_1 -antiprotease deficiency are recognized by the appearance of panacinar, bibasilar emphysema early in life, usually in the third or fourth decade, and hepatic cirrhosis and hepatocellular carcinoma may occur. Cystic fibrosis occurs in children and younger adults. Rarely, mechanical obstruction of the central airways simulates COPD. Flow-volume loops may help separate patients with central airway obstruction from those with diffuse intrathoracic airway obstruction characteristic of COPD.

Complications

Acute bronchitis, pneumonia, pulmonary thromboembolism, and concomitant left ventricular failure may worsen otherwise stable COPD. Pulmonary hypertension, cor pulmonale, and chronic respiratory failure are common in advanced COPD. Spontaneous pneumothorax occurs in a small fraction of patients with emphysema. Hemoptysis may result from chronic bronchitis or may signal bronchogenic carcinoma.

Prevention

COPD is largely preventable through elimination of chronic exposure to tobacco smoke. Smokers with early evidence of airflow limitation can alter their disease by smoking cessation. Smoking cessation slows the decline in FEV_1 in middle-aged smokers with mild airways obstruction. Vaccination against influenza and pneumococcal infection may also be of benefit.

Treatment

Standards for the management of patients with COPD have been published by the American Thoracic Society and the Global Initiative for Obstructive Lung Disease (GOLD), a joint expert committee of the NHLBI and the World Health Organization. See [Chapter 38](#) for a discussion of air travel in patients with lung disease.

A. Ambulatory Patients

1. Smoking cessation—The single most important intervention in smokers with COPD is to encourage smoking cessation. Simply telling a patient to quit succeeds 5% of the time. The Lung Health Study reported 22% sustained abstinence at 5 years in their intervention group (behavior modification plus nicotine gum). Nicotine transdermal patch, nicotine gum, and bupropion increase cessation rates in motivated smokers (see [Chapter 1](#)).

2. Oxygen therapy—The only drug therapy that is documented to alter the natural history of COPD is supplemental oxygen in those patients with resting hypoxemia. Proved benefits of home oxygen therapy in advanced COPD include longer survival, reduced hospitalization needs, and better quality of life. Oxygen by nasal prongs must be given at least 15 hours a day unless therapy is intended only for exercise or sleep. Survival in hypoxemic patients with COPD treated with supplemental oxygen therapy is directly proportionate to the number of hours per day oxygen is administered: in patients treated with continuous oxygen, the survival after 36 months is about 65%—significantly better than the survival rate of about 45% in those who are treated with only nocturnal oxygen.

Requirements for Medicare coverage for a patient's home use of oxygen and oxygen equipment are listed in [Table 9-8](#). Arterial blood gas analysis is preferable to ear or pulse oximetry to guide initial oxygen therapy. Hypoxemic patients with pulmonary hypertension, chronic cor pulmonale, erythrocytosis, impaired cognitive function, exercise intolerance, nocturnal restlessness, or morning headache are particularly likely to benefit from home oxygen therapy.

Home oxygen may be supplied by liquid oxygen systems (LOX), compressed gas cylinders, or oxygen concentrators. Most patients benefit from having both stationary and portable systems. For most patients, a flow rate of 1-3 L/min achieves a PaO_2 greater than 55 mm Hg. The monthly cost of home oxygen therapy ranges from \$300.00 to \$500.00 or more, being higher for liquid oxygen systems. Medicare covers approximately 80% of home oxygen expenses. **Transtracheal oxygen** is an alternative method of delivery and may be useful for patients who require higher flows of oxygen than can be delivered via the nose or who are experiencing troublesome side effects such as nasal drying or epistaxis from nasal delivery of oxygen. Reservoir nasal cannulas or "pendants" and demand (pulse) oxygen delivery systems are also available to conserve oxygen.

3. Bronchodilators—Bronchodilators are the most important agents in the pharmacologic management of patients with COPD. Bronchodilators do not alter the inexorable decline in lung function that is a hallmark of the disease, but they offer improvement in symptoms, exercise tolerance, and overall health status. Aggressiveness of bronchodilator therapy should be matched to the severity of the patient's disease. In patients who experience no symptomatic improvement, bronchodilators should be discontinued.

The two most commonly prescribed bronchodilators are the anticholinergic ipratropium bromide and short-acting β_2 agonists (eg, albuterol, metaproterenol), delivered by metered-dose inhaler or as an inhalation solution by nebulizer. Ipratropium bromide is generally preferred to the short-acting β_2 agonists as a first-line agent because of its longer duration of action and absence of sympathomimetic side effects. Some studies have suggested that ipratropium achieves superior bronchodilation

in COPD patients. Typical doses are two to four puffs (36-72 ug) every 6 hours. There is a dose response above this level without additional side effects. Short-acting β_2 agonists are less expensive and have a more rapid onset of action, commonly leading to greater patient satisfaction. At maximal doses, β_2 agonists have bronchodilator action equivalent to that of ipratropium but may cause tachycardia, tremor, or hypokalemia. There does not appear to be any advantage of scheduled use of short-acting β_2 agonists compared with as-needed administration. Use of both short-acting β_2 agonists and anticholinergics at submaximal doses leads to improved bronchodilation compared with either agent alone but does not improve dyspnea.

Long-acting β_2 agonists (eg, formoterol, salmeterol) and anticholinergics (tiotropium) appear to achieve bronchodilation that is equivalent or superior to what is experienced with ipratropium in addition to similar improvements on health status. They are currently more expensive than short-acting agents. Their role in management of stable COPD is an area of active research.

Oral **theophylline** is a third-line agent in COPD patients who fail to achieve adequate symptom control with anticholinergics and β_2 agonists. Sustained-release theophylline improves arterial oxygen hemoglobin saturation during sleep in COPD patients and is a first-line agent for those with sleep-related breathing disorders. Theophylline has fallen out of favor because of its narrow therapeutic window and the availability of potent inhaled bronchodilators. Nonetheless, theophylline does improve dyspnea, exercise performance, and pulmonary function in many stable COPD patients. Its benefits may result from anti-inflammatory properties and extrapulmonary effects on diaphragm strength, myocardial contractility, and renal function.

4. Corticosteroids—Apart from acute exacerbations, COPD is not generally a steroid-responsive disease. Only 10% of stable outpatients with COPD given oral corticosteroids will have a greater than 20% increase in FEV₁ compared with patients receiving placebo. Since there are no clear predictors of which patients will respond, empirical trials of oral (equivalent to 0.5 mg/kg/d of prednisone for 14-21 days) and inhaled (6-12 weeks of therapy) corticosteroids are common. Such trials should be guided by the following principles: The baseline FEV₁ should be stable, ie, not measured during an exacerbation, and documented on maximal bronchodilator therapy. The postbronchodilator FEV₁ value is considered the appropriate baseline. The drug should be discontinued unless there is a 20% or greater increase in FEV₁ after the trial of therapy. Patients who feel better without spirometric evidence of improvement are nonresponders. Responders to oral agents are usually switched to inhaled corticosteroids, but there are few data to guide this practice. COPD patients should not be treated with inhaled corticosteroids just because these agents lack the toxicity of oral preparations.

Several large clinical trials have reported no effect of inhaled corticosteroids on the characteristic decline in lung function experienced by COPD patients. Some clinical trials have reported a small reduction in the frequency of COPD exacerbations and an increase in self-reported functional status in patients treated with inhaled agents. Typically, these effects are small and occur with long-term, high-dose inhaled therapy.

5. Antibiotics—Antibiotics are commonly prescribed to outpatients with COPD for the following indications: (1) to treat an acute exacerbation, (2) to treat acute bronchitis, and (3) to prevent acute exacerbations of chronic bronchitis (prophylactic antibiotics). There is evidence from clinical studies that antibiotics improve outcomes slightly in the first two situations. There is no convincing evidence to support the use of prophylactic antibiotics in patients with COPD. Patients with a flare of COPD associated with dyspnea and a change in the quantity or character of sputum benefit the most from antibiotic therapy. Common agents include trimethoprim-sulfamethoxazole (160/800 mg every 12 hours), amoxicillin or amoxicillin-clavulanate (500 mg every 8 hours), or doxycycline (100 mg every 12 hours) given for 7-10 days. There are few controlled trials of antibiotics in severe COPD exacerbations; prompt administration of parenteral antibiotics seems reasonable as long as the decision is reevaluated frequently.

6. Other measures—In patients with chronic bronchitis, increased mobilization of secretions may be accomplished through the use of adequate systemic hydration, effective cough training methods, or use of a hand-held flutter device and postural drainage, sometimes with chest percussion or vibration. Postural drainage and chest percussion should be used only in selected patients with excessive amounts of retained secretions that cannot be cleared by coughing and other methods; these measures are of no benefit in pure emphysema. Expectorant-mucolytic therapy has generally been regarded as unhelpful in patients with chronic bronchitis. Cough suppressants and sedatives should be avoided as routine measures.

Human α_1 -antitrypsin is available for replacement therapy in emphysema due to congenital deficiency of α_1 -antitrypsin. Patients over 18 years of age with airflow obstruction by spirometry and levels less than 11 $\mu\text{mol/L}$ are potential candidates for replacement therapy. α_1 -Antitrypsin is administered intravenously in a dose of 60 mg/kg body weight once weekly.

Graded aerobic physical exercise programs (eg, walking 20 minutes three times weekly, or bicycling) are helpful to prevent deterioration of physical condition and to improve the patient's ability to carry out daily activities. Training of inspiratory muscles by inspiring against progressively larger resistive loads improves exercise tolerance in some but not all patients. Pursed-lip breathing to slow the rate of breathing and abdominal breathing exercises to relieve fatigue of accessory muscles of respiration may reduce dyspnea in some patients.

Severe dyspnea in spite of optimal medical management may warrant a clinical trial of an opioid. Sedative-hypnotic drugs (eg, diazepam, 5 mg three times daily) are controversial in intractable dyspnea but may benefit very anxious patients. Intermittent negative-pressure (cuirass) ventilation and transnasal positive-pressure ventilation at home to rest the respiratory muscles are promising approaches to improve respiratory muscle function and reduce dyspnea in patients with severe COPD. A bilevel transnasal ventilation system has been reported to reduce dyspnea in ambulatory patients with severe COPD, but the long-term benefits of this approach and compliance with it have not been defined.

B. Hospitalized Patients

Hospitalization is indicated for acute worsening of COPD that fails to respond to measures for ambulatory patients. Patients with acute respiratory failure or complications such as cor pulmonale and pneumothorax should also be hospitalized.

Management of the hospitalized patient with an acute exacerbation of COPD includes supplemental oxygen, inhaled ipratropium bromide and inhaled β_2 agonists, and broad-spectrum antibiotics, corticosteroids, and, in selected cases, chest physiotherapy. Theophylline should not be initiated in the acute setting, but patients taking theophylline prior to acute hospitalization should have their theophylline serum levels measured and maintained in the therapeutic range. Oxygen therapy should not be withheld for fear of worsening respiratory acidemia; hypoxemia is more detrimental than hypercapnia. Cor pulmonale usually responds to measures that reduce pulmonary artery pressure, such as supplemental oxygen and correction of acidemia; bed rest, salt restriction, and diuretics may add some benefit. Cardiac arrhythmias, particularly multifocal atrial tachycardia, usually respond to aggressive treatment of COPD itself. Atrial flutter may require DC cardioversion after initiation of the above therapy. If progressive respiratory failure ensues, tracheal intubation and mechanical ventilation are necessary. In clinical trials of COPD patients with hypercapnic acute respiratory failure, noninvasive positive-pressure ventilation (NPPV) delivered via face mask reduced the need for intubation and shortened ICU lengths of stay. Other studies have suggested a lower risk of nosocomial infections and less use of antibiotics in COPD patients treated with NPPV. These benefits do not appear to extend to hypoxemic respiratory failure or to patients with acute lung injury or ARDS.

C. Surgery for COPD

1. Lung transplantation—Experience with both single and bilateral sequential lung transplantation for severe COPD is extensive. Requirements for lung transplantation are severe lung disease, limited activities of daily living, exhaustion of medical therapy, ambulatory status, potential for pulmonary rehabilitation, limited life expectancy without transplantation, adequate function of other organ systems, and a good social support system. Average total charges for lung transplantation through the end of the first postoperative year exceed \$250,000. The two-year survival rate after lung transplantation for COPD is 75%. Complications include acute rejection, opportunistic infection, and obliterative bronchiolitis. Substantial improvements in pulmonary function and exercise performance have been noted after transplantation.

2. Lung volume reduction surgery (reduction pneumoplasty)—This is an experimental surgical approach to relief of dyspnea and improvement in exercise tolerance in patients with advanced diffuse emphysema and lung hyperinflation. Bilateral resection of 20-30% of lung volume in selected patients results in modest improvements in pulmonary function, exercise performance, and dyspnea. The duration of any improvement as well as any mortality benefit remains uncertain. Prolonged air leaks occur in up to one-half of patients postoperatively. Mortality rates in centers with the largest experience with lung volume reduction surgery range from 4% to 10%.

The National Emphysema Treatment Trial (NETT) is an ongoing randomized, multicenter clinical trial comparing lung volume reduction surgery with medical treatment. In October 2001, the safety monitoring board closed enrollment in the trial to patients with an FEV₁ < 20% predicted *and* either a homogeneous distribution of emphysema or a D_{Lco} < 20% of predicted due to excess mortality in the patients randomized to surgery. Additional results await completion of the trial.

3. Bullectomy—Bullectomy is an older surgical procedure for palliation of severe dyspnea in patients with severe bullous emphysema. In this procedure, the surgeon removes a very large emphysematous bulla that demonstrates no ventilation or perfusion on lung scanning and compresses adjacent lung that has preserved function. Bullectomy can now be performed with a CO₂ laser via thoracoscopy.

Prognosis

The outlook for patients with clinically significant COPD is poor. The median survival time of patients with severe COPD ($FEV_1 = 1$ L) is about 4 years. The degree of pulmonary dysfunction (as measured by FEV_1) at the time the patient is first seen is probably the most important predictor of survival. Comprehensive care programs, cessation of smoking, and supplemental oxygen may reduce the rate of decline of pulmonary function, but therapy with bronchodilators and other approaches probably has little, if any, impact on the natural course of COPD.

Dyspnea at the end of life can be extremely uncomfortable and distressing to the patient and family. Dyspnea can be effectively managed with a combination of medications and mechanical interventions (see Dyspnea, Treatment, above). As patients near the end of life, meticulous attention to palliative care is essential. (See [Chapter 5](#).)

BRONCHIECTASIS

Bronchiectasis is a congenital or acquired disorder of the large bronchi characterized by permanent, abnormal dilation and destruction of bronchial walls. It may be caused by recurrent inflammation or infection of the airways and may be localized or diffuse. Cystic fibrosis causes about half of all cases of bronchiectasis. Other causes include lung infection (tuberculosis, fungal infections, lung abscess, pneumonia), abnormal lung defense mechanisms (humoral immunodeficiency, α_1 -antiprotease deficiency with cigarette smoking, mucociliary clearance disorders, rheumatic diseases), and localized airway obstruction (foreign body, tumor, mucoid impaction). Immunodeficiency states that may lead to bronchiectasis include congenital or acquired panhypogammaglobulinemia; common variable immunodeficiency; selective IgA, IgM, and IgG subclass deficiencies; and acquired immunodeficiency from cytotoxic therapy, AIDS, lymphoma, multiple myeloma, leukemia, and chronic renal and hepatic diseases. However, most patients with bronchiectasis have panhypergammaglobulinemia, presumably reflecting an immune system response to chronic airway infection. Acquired primary bronchiectasis is now uncommon in the United States because of improved control of bronchopulmonary infections.

Symptoms of bronchiectasis include chronic cough, production of copious amounts of purulent sputum, hemoptysis, and recurrent pneumonia. Weight loss, anemia, and other systemic manifestations are common. Physical findings are nonspecific, but persistent crackles at the lung bases are common. Clubbing is infrequent in mild cases but is common in severe disease. Copious, foul-smelling, purulent sputum is characteristic. Obstructive pulmonary dysfunction with hypoxemia is seen in moderate or severe disease. Radiographic abnormalities include crowded bronchial markings related to peribronchial fibrosis and small cystic spaces at the base of the lungs. High-resolution CT is the diagnostic study of choice.

Treatment of acute exacerbations consists of antibiotics (selected on the basis of sputum smears and cultures), daily chest physiotherapy with postural drainage and chest percussion, and inhaled bronchodilators. Hand-held flutter valve devices may be as effective as chest physiotherapy in clearing secretions. Empirical oral antibiotic therapy for 10-14 days with amoxicillin or amoxicillin-clavulanate (500 mg every 8 hours), ampicillin or tetracycline (250-500 mg four times daily), or trimethoprim-sulfamethoxazole (160/800 mg every 12 hours) is reasonable therapy in an acute exacerbation if a specific bacterial pathogen cannot be isolated. Preventive or suppressive treatment is sometimes given to stable outpatients with bronchiectasis who have copious purulent sputum. Clinical trial data to guide this practice are scant. Common regimens include high-dose (3 g/d) amoxicillin or alternating cycles of the antibiotics listed above given orally for 2-4 weeks. Inhaled aerosolized aminoglycosides clearly reduce colonization by pseudomonas species. In patients with underlying cystic fibrosis, inhaled antibiotics improve FEV_1 and reduce hospitalizations, but these benefits are not consistently seen in the non-cystic fibrosis population. Complications of bronchiectasis include hemoptysis, cor pulmonale, amyloidosis, and secondary visceral abscesses at distant sites (eg, brain). Bronchoscopy is sometimes necessary to evaluate hemoptysis, remove retained secretions, and rule out obstructing airway lesions. Surgical resection is reserved for the few patients with localized bronchiectasis and adequate pulmonary function who fail to respond to conservative management. Surgery is also indicated for massive hemoptysis.

ALLERGIC BRONCHOPULMONARY MYCOSIS

Allergic bronchopulmonary mycosis is a pulmonary hypersensitivity disorder caused by allergy to fungal antigens that colonize the tracheobronchial tree. It usually occurs in atopic asthmatic individuals who are 20-40 years of age, in response to antigens of aspergillus species. For this reason, the disorder is commonly referred to as allergic bronchopulmonary aspergillosis. Primary criteria for the diagnosis include (1) a clinical history of asthma, (2) peripheral eosinophilia, (3) immediate skin reactivity to aspergillus antigen, (4) precipitating antibodies to aspergillus antigen, (5) elevated serum IgE levels, (6) pulmonary infiltrates (transient or fixed), and (7) central bronchiectasis. If the first six of these seven primary criteria are present, the diagnosis is almost certain. Secondary diagnostic criteria include identification of aspergillus in sputum, a history of brown-flecked sputum, and late skin reactivity to aspergillus antigen. High-dose prednisone (0.5-1 mg/kg orally per day) for at least 2 months is the treatment of choice, and the response in early disease is usually excellent. Depending on the overall clinical situation, prednisone can then be cautiously tapered. Relapses are frequent, and protracted or repeated treatment with corticosteroids is not uncommon. Patients with corticosteroid-dependent disease may benefit from itraconazole (200 mg orally once or twice daily) without added toxicity. Bronchodilators ([Table 9-6](#)) are also helpful. Complications include hemoptysis, severe bronchiectasis, and pulmonary fibrosis.

CYSTIC FIBROSIS

Essentials of Diagnosis

- Chronic or recurrent cough, sputum production, dyspnea, and wheezing.
- Recurrent infections or chronic colonization of the airways with nontypeable *Haemophilus influenzae*, mucoid and nonmucoid *Pseudomonas aeruginosa*, *Staphylococcus aureus*, or *Burkholderia cepacia*.
- Pancreatic insufficiency, recurrent pancreatitis, distal intestinal obstruction syndrome, chronic hepatic disease, nutritional deficiencies, or male urogenital abnormalities.
- Bronchiectasis and scarring on chest radiographs.
- Airflow obstruction on spirometry.
- Sweat chloride concentration above 60 meq/L on two occasions or mutations in genes known to cause cystic fibrosis.

General Considerations

Cystic fibrosis is the most common cause of severe chronic lung disease in young adults and the most common fatal hereditary disorder of Caucasians in the United States. It is an autosomal recessive disorder affecting about one in 3200 Caucasians; one in 25 is a carrier. Cystic fibrosis is caused by abnormalities in a membrane chloride channel (the cystic fibrosis transmembrane conductance regulator [CFTR] protein) that results in altered chloride transport and water flux across the apical surface of epithelial cells. Almost all exocrine glands produce an abnormal mucus that obstructs glands and ducts. Obstruction results in glandular dilation and damage

to tissue. In the respiratory tract, inadequate hydration of the tracheobronchial epithelium impairs mucociliary function. High concentrations of DNA in airway secretions (due to chronic airways inflammation and autolysis of neutrophils) increase sputum viscosity. Over 800 mutations in the gene that encodes CFTR have been described, and at least 230 mutations are known to be associated with clinical abnormalities. The mutation referred to as $\Delta F508$ accounts for about 60% of cases of cystic fibrosis.

About one-third of the nearly 30,000 cystic fibrosis patients in the United States are adults. Because of the wide range of alterations seen in the CFTR protein structure and function, adults with cystic fibrosis may present with a variety of pulmonary and nonpulmonary manifestations. Pulmonary manifestations in adults include acute and chronic bronchitis, bronchiectasis, pneumonia, atelectasis, and peribronchial and parenchymal scarring. Pneumothorax and hemoptysis are common. Hypoxemia, hypercapnia, and cor pulmonale occur in advanced cases. Biliary cirrhosis and gallstones may occur. Nearly all men with cystic fibrosis have congenital bilateral absence of the vas deferens with azoospermia. Patients with cystic fibrosis have an increased risk of malignancies of the gastrointestinal tract, osteopenia, and arthropathies.

Clinical Findings

A. Symptoms and Signs

Cystic fibrosis should be suspected in a young adult presenting with a history of chronic lung disease (especially bronchiectasis), pancreatitis, or infertility. Cough, sputum production, decreased exercise tolerance, and recurrent hemoptysis are typical complaints. Patients also often complain of facial (sinus) pain or pressure and purulent nasal discharge. Steatorrhea, diarrhea, and abdominal pain are also common. Digital clubbing, increased anteroposterior chest diameter, hyperresonance to percussion, and apical crackles are noted on physical examination. Sinus tenderness, purulent nasal secretions, and nasal polyps may also be seen.

B. Laboratory Findings

Arterial blood gas studies often reveal hypoxemia and, in advanced disease, a chronic, compensated respiratory acidosis. Pulmonary function studies show a mixed obstructive and restrictive pattern. There is a reduction in forced vital capacity, airflow rates, and total lung capacity. Air trapping (high ratio of residual volume to total lung capacity) and reduction in pulmonary diffusing capacity are common.

C. Imaging

Hyperinflation is seen early in the disease process. Peribronchial cuffing, mucus plugging, bronchiectasis (ring shadows and cysts), increased interstitial markings, small rounded peripheral opacities, and focal atelectasis may be seen separately or in various combinations. Pneumothorax can also be seen. Thin-section CT scanning may confirm the presence of bronchiectasis.

D. Diagnosis

The quantitative pilocarpine iontophoresis sweat test reveals elevated sodium and chloride levels (> 60 meq/L) in the sweat of patients with cystic fibrosis. Two tests on different days are required for accurate diagnosis. Facilities must perform enough tests to maintain laboratory proficiency and quality. A normal sweat chloride test does not exclude the diagnosis. Genotyping or other alternative diagnostic studies (such as measurement of nasal membrane potential difference, semen analysis, or assessment of pancreatic function) should be pursued if the test is repeatedly negative but there is a high clinical suspicion of cystic fibrosis. Standard genotyping is a limited diagnostic tool because it screens for only a fraction of the known cystic fibrosis mutations.

Treatment

Early recognition and comprehensive multidisciplinary therapy improve symptom control and the chances of survival and amelioration of symptoms. Referral to a regional cystic fibrosis center is strongly recommended. Conventional treatment programs focus on the following areas: clearance and reduction of lower airway secretions, reversal of bronchoconstriction, treatment of respiratory tract infections and airway bacterial burden, pancreatic enzyme replacement, and nutritional and psychosocial support (including genetic and occupational counseling).

Clearance of lower airway secretions can be promoted by postural drainage, chest percussion or vibration techniques, positive expiratory pressure (PEP) or flutter valve breathing devices, directed cough, and other breathing techniques; these approaches require detailed patient instruction by experienced personnel. Sputum viscosity in cystic fibrosis is increased by the large quantities of extracellular DNA that result from chronic airways inflammation and autolysis of neutrophils. Inhaled recombinant human deoxyribonuclease (rhDNase) cleaves extracellular DNA in sputum. When administered chronically at a daily nebulized dose of 2.5 mg, this therapy leads to improved FEV₁ and reduces the risk of cystic fibrosis-related respiratory exacerbations and the need for intravenous antibiotics. Pharyngitis, laryngitis, and voice alterations are common adverse effects. Annual cost exceeds \$12,000. Antibiotics are used to treat active airway infections based on results of culture and susceptibility testing of sputum. *S aureus* (including methicillin-resistant strains) and a mucoid variant of *P aeruginosa* are commonly present. *Haemophilus influenzae*, *Stenotrophomonas maltophilia*, and *Burkholderia cepacia*—the latter a highly drug-resistant organism—are occasionally isolated. The use of aerosolized antibiotics (inhalational tobramycin solution and others) for prophylaxis or treatment of lower respiratory tract infections is sometimes helpful. Although some studies of inhaled antibiotics demonstrate reduced exacerbations and increased FEV₁ in patients chronically infected with *P aeruginosa*, there is concern about the emergence of drug-resistant organisms, equipment contamination with *B cepacia*, and side effects such as bronchospasm.

Inhaled bronchodilators (eg, albuterol, two puffs every 4 hours as needed) should be considered in patients who demonstrate an increase of at least 12% in FEV₁ after an inhaled bronchodilator. Vaccination against pneumococcal infection and annual influenza vaccination are advised. Screening of family members and genetic counseling are suggested.

Lung transplantation is currently the only definitive treatment for advanced cystic fibrosis. Double-lung or heart-lung transplantation is required. A few transplant centers offer living lobar lung transplantation to selected patients. The 3-year survival rate following transplantation for cystic fibrosis is about 55%.

Investigational therapies for cystic fibrosis include anti-inflammatory agents (eg, ibuprofen, pentoxifylline, antiproteases, azithromycin), protein modification agents (eg, milrinone, phenylbutyrate), ion transport agents (eg, amiloride), and gene therapy.

Prognosis

The longevity of patients with cystic fibrosis is increasing, and the median survival age is now 31 years. Death occurs from pulmonary complications (eg, pneumonia, pneumothorax, or hemoptysis) or as a result of terminal chronic respiratory failure and cor pulmonale.

BRONCHIOLITIS

Bronchiolitis is nonspecific inflammation of terminal and respiratory bronchioles. In children, bronchiolitis is a common and often severe acute respiratory illness, usually caused by respiratory syncytial virus. Acute infectious bronchiolitis is rare in adults. In adults, bronchiolitis is a chronic, frequently progressive nonspecific response to injury of the distal small airways.

Bronchiolitis has two pathologic variants, either of which may be associated with obliteration of bronchioles (bronchiolitis obliterans). **Constrictive bronchiolitis** is characterized by chronic inflammation, concentric scarring, and smooth muscle hypertrophy causing luminal obstruction. These patients have airflow obstruction on spirometry, minimal radiographic abnormalities, and a progressive clinical course unresponsive to corticosteroids. **Proliferative bronchiolitis** occurs when intraluminal polyps consisting of fibroblasts, foamy macrophages, and lymphocytes partially or completely obstruct the bronchioles. When this exudate extends to the alveolar space, the pattern is referred to as bronchiolitis obliterans with organizing pneumonia (BOOP). Patients with proliferative bronchiolitis may have obstruction or restriction on pulmonary function testing. Radiographic infiltrates are common. The disease is frequently responsive to corticosteroids.

The most common clinical patterns are described below.

Toxic fume bronchiolitis obliterans follows 1-3 weeks after exposure to oxides of nitrogen, phosgene, and other noxious gases. The chest radiograph shows diffuse nonspecific alveolar or "ground-glass" densities.

Postinfectious bronchiolitis obliterans is a late response to mycoplasmal or viral lung infection in adults and has a highly variable radiographic appearance.

Bronchiolitis obliterans may also occur in association with rheumatoid arthritis, polymyositis, and dermatomyositis. Penicillamine therapy has been implicated as a

possible cause of bronchiolitis obliterans in patients with rheumatoid arthritis. Bronchiolitis obliterans occurs in up to 70% of patients following lung transplantation and 10% of patients undergoing allogeneic bone marrow transplantation, the latter occurring in the setting of chronic graft-versus-host disease.

Idiopathic bronchiolitis obliterans with organizing pneumonia (BOOP), also referred to as **cryptogenic organizing pneumonia**, affects men and women equally. Most patients are between the ages of 50 and 70. Dry cough, dyspnea, and a flu-like illness, ranging in duration from a few days to several months, are typical. Fever and weight loss are common. Physical examination demonstrates crackles in most patients, and wheezing is present in about a third. Clubbing is uncommon. Pulmonary function studies demonstrate restrictive dysfunction and hypoxemia. The chest radiograph typically shows patchy, bilateral, ground glass or alveolar infiltrates. Solitary pneumonia-like infiltrates and a diffuse interstitial pattern have also been described (see [Table 9-19](#)).

BOOP is usually a difficult diagnosis to make on clinical grounds alone. The presence of fever and weight loss, abrupt onset of symptoms (often following an upper respiratory tract infection), a relatively short duration of symptoms, the absence of clubbing, and the presence of alveolar infiltrates help the clinician distinguish this entity from idiopathic interstitial pneumonia. However, open lung biopsy may be necessary. Buds of loose connective tissue and inflammatory cells fill alveoli and distal bronchioles. Corticosteroid therapy is effective in two-thirds of cases, often abruptly. Relapses are common if corticosteroids are stopped prematurely, and most patients require at least 6 months of therapy. Prednisone is usually given initially in doses of 1 mg/kg/d for 2-3 months. The dose is then tapered slowly to 20-40 mg/d, depending on response, and eventually to an alternate-day regimen.

Two well-described disorders are not usually associated with obliteration of bronchioles. **Respiratory bronchiolitis** is a disorder of small airways in cigarette smokers. Clinically and radiographically, this disorder resembles desquamative interstitial pneumonia (DIP). (See [Table 9-19](#).) Cough, dyspnea, and crackles on chest auscultation are typical. However, the reduction in lung compliance seen in pulmonary fibrosis is not found in this disorder. The condition may be recognized only on open lung biopsy, which demonstrates characteristic metaplasia of terminal and respiratory bronchioles and filling of respiratory and terminal bronchioles, alveolar ducts, and alveoli by pigmented alveolar macrophages. The prognosis is good if the patient stops smoking.

Diffuse panbronchiolitis is an idiopathic disorder of respiratory bronchioles frequently diagnosed in Japan. The condition appears to be less common in the United States or Europe. Men are affected about twice as often as women and are most often between ages 20 and 80. About two-thirds of patients are nonsmokers. The large majority have a history of chronic pansinusitis. Marked dyspnea, cough, and sputum production are cardinal features. Crackles and rhonchi are noted on physical examination. Pulmonary function tests reveal obstructive abnormalities. The chest radiograph shows a distinct pattern of diffuse small nodular shadows and hyperinflation. Open lung biopsy is necessary for diagnosis.

■ PULMONARY INFECTIONS

PNEUMONIA

Lower respiratory tract infections continue to be a major health problem despite advances in the identification of etiologic organisms and the availability of potent new antimicrobial drugs. In addition, there is still much controversy regarding diagnostic approaches and treatment choices for pneumonia.

Microorganisms gain access to the lower respiratory tract by aspiration of oropharyngeal secretions and associated bacterial flora, inhalation of infected aerosols, and hematogenous dissemination. The consequences of seeding the lower respiratory tract with microorganisms depend on the size of the inoculum, the virulence of the microorganism, and host susceptibility. Characteristics of pneumonia caused by specific agents and appropriate antimicrobial therapy are presented in [Table 9-9](#). Pneumonias are typically classified as being either community-acquired or hospital-acquired (nosocomial). Anaerobic pneumonias and lung abscess can occur in both settings and warrant separate consideration.

This section sets forth the evaluation and management of immunocompetent hosts separately from the approach to the evaluation and management of pulmonary infiltrates in immunocompromised hosts—defined as patients with HIV disease, absolute neutrophil counts < 1000/uL, current or recent exposure to myelosuppressive or immunosuppressive drugs, or those currently taking prednisone in a dosage of over 5 mg/d.

1. Community-Acquired Pneumonia

Essentials of Diagnosis

- Symptoms and signs of an acute lung infection: fever or hypothermia, cough with or without sputum, dyspnea, chest discomfort, sweats or rigors.
- Bronchial breath sounds or rales are frequent auscultatory findings.
- Parenchymal infiltrate on chest radiograph.
- Occurs outside of the hospital or less than 48 hours after admission in a patient who is not hospitalized or residing in a long-term care facility for more than 14 days before the onset of symptoms.

General Considerations

Community-acquired pneumonia is a common disorder, with approximately 2-3 million cases diagnosed each year in the United States. It is the most deadly infectious disease in the United States and the sixth leading cause of death. Mortality is estimated to be approximately 14% among hospitalized patients and less than 1% for patients who do not require hospitalization. Important risk factors for increased morbidity and mortality from community-acquired pneumonia include advanced age, alcoholism, comorbid medical conditions, altered mental status, respiratory rate = 30 breaths/min, hypotension (defined by systolic blood pressure < 90 mm Hg or diastolic blood pressure < 60 mm Hg), and BUN > 30 mg/dL.

A predictor of patient risk and mortality from community-acquired pneumonia has been developed and validated by the Pneumonia Patient Outcomes Research Team (PORT). The PORT prediction scheme utilizes 19 clinical variables to stratify patients into five mortality risk classes. (See [Table 9-10](#).) Patients under 50 years of age without those comorbid conditions and specific physical examination abnormalities listed in [Table 9-10](#) are assigned to risk class I. All other patients are assigned to risk categories based on the scoring system in [Table 9-11](#). Thirty-day mortality by category is listed in [Table 9-11](#). The PORT model can be used along with clinical judgment in the initial decision about whether to hospitalize a patient with community-acquired pneumonia.

In immunocompetent patients, the history, physical examination, radiographs, and sputum examination are neither sensitive nor specific for identifying the microbiologic cause of community-acquired pneumonia. While helpful in selected patients, these modalities do not consistently differentiate bacterial from viral causes or distinguish "typical" from "atypical" causes. As a result, the American Thoracic Society recommends empirical treatment based on epidemiologic data. In contrast, practice guidelines proposed by the Infectious Disease Society of America advocate systematic use of the microbiology laboratory in an attempt to administer pathogen-directed antimicrobial therapy whenever possible, especially in hospitalized patients.

Definition & Pathogenesis

Community-acquired pneumonia begins outside of the hospital or is diagnosed within 48 hours after admission to the hospital in a patient who has not resided in a long-term care facility for 14 days or more before the onset of symptoms.

Pulmonary defense mechanisms (cough reflex, mucociliary clearance system, immune responses) normally prevent the development of lower respiratory tract infections following aspiration of oropharyngeal secretions containing bacteria or inhalation of infected aerosols. Community-acquired pneumonia occurs when there is a defect in one or more of the normal host defense mechanisms or when a very large infectious inoculum or a highly virulent pathogen overwhelms the host.

Prospective studies have failed to identify the cause of community-acquired pneumonia in 40-60% of cases; two or more causes are identified in up to 5% of cases. Bacteria are more commonly identified than viruses. The most common bacterial pathogen identified in most studies of community-acquired pneumonia is *Streptococcus pneumoniae*, accounting for approximately two-thirds of bacterial isolates. Other common bacterial pathogens include *Haemophilus influenzae*, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *Staphylococcus aureus*, *Neisseria meningitidis*, *Moraxella catarrhalis*, *Klebsiella pneumoniae*, other gram-negative rods, and legionella species. Common viral causes of community-acquired pneumonia include influenza virus, respiratory syncytial virus, adenovirus, and parainfluenza virus. A detailed assessment of epidemiologic risk factors may aid in diagnosing pneumonias due to the following causes: *Chlamydia psittaci* (psittacosis), *Coxiella burnetii* (Q fever), *Francisella tularensis* (tularemia), endemic fungi (blastomyces, coccidioides, histoplasma), and sin nombre virus (hantavirus pulmonary syndrome).

Clinical Findings

A. Symptoms and Signs

Most patients with community-acquired pneumonia experience an acute or subacute onset of fever, cough with or without sputum production, and dyspnea. Other common symptoms include rigors, sweats, chills, chest discomfort, pleurisy, hemoptysis, fatigue, myalgias, anorexia, headache, and abdominal pain.

Common physical findings include fever or hypothermia, tachypnea, tachycardia, and mild arterial oxygen desaturation. Many patients will appear acutely ill. Chest examination is often remarkable for altered breath sounds and rales. Dullness to percussion may be present if a parapneumonic pleural effusion is present.

The differential diagnosis of lower respiratory tract symptoms and signs is extensive and includes upper respiratory tract infections, reactive airway diseases, congestive heart failure, bronchiolitis obliterans organizing pneumonia, lung cancer, pulmonary vasculitis, pulmonary thromboembolic disease, and atelectasis.

B. Laboratory Findings

Controversy surrounds the role of Gram stain and culture analysis of expectorated sputum in patients with community-acquired pneumonia. Most reports suggest that these tests have poor positive and negative predictive value in most patients. Some argue, however, that the tests should still be performed to try to identify etiologic organisms in the hope of reducing microbial resistance to drugs, unnecessary drug costs, and avoidable side effects of empirical antibiotic therapy. Expert panel guidelines suggest that sputum Gram stain should be attempted in all patients with community-acquired pneumonia and that sputum culture should be obtained for all patients who require hospitalization. Sputum should be obtained before antibiotics are initiated except in a case of suspected antibiotic failure. The specimen is obtained by deep cough and should be grossly purulent. Culture should be performed only if the specimen meets strict cytologic criteria (except for detection of legionella or mycobacteria).

Additional testing is generally recommended for patients who require hospitalization: preantibiotic blood cultures (at least two sets with needle sticks at separate sites), arterial blood gases, complete blood count with differential, and a chemistry panel (including serum glucose, electrolytes, urea nitrogen, creatinine, bilirubin, and liver enzymes). The results of these tests help assess the severity of the disease and guide evaluation and therapy. HIV serology should be obtained from all hospitalized patients.

C. Imaging

Chest radiography may confirm the diagnosis and detect associated lung diseases. It can also be used to help assess severity and response to therapy over time. Radiographic findings can range from patchy airspace infiltrates to lobar consolidation with air bronchograms to diffuse alveolar or interstitial infiltrates. Additional findings can include pleural effusions and cavitation. No pattern of radiographic abnormalities is pathognomonic of a specific cause of pneumonia.

Progression of pulmonary infiltrates during antibiotic therapy or lack of radiographic improvement over time are poor prognostic signs and also raise concerns about secondary or alternative pulmonary processes. Clearing of pulmonary infiltrates in patients with community-acquired pneumonia can take 6 weeks or longer and is usually fastest in young patients, nonsmokers, and those with only single lobe involvement.

D. Special Examinations

Sputum induction is reserved for patients who cannot provide expectorated sputum samples or who may have *Pneumocystis jiroveci* or *Mycobacterium tuberculosis* pneumonia. Transtracheal aspiration, fiberoptic bronchoscopy, and transthoracic needle aspiration techniques to obtain samples of lower respiratory secretions or tissues are reserved for selected patients.

Thoracentesis with pleural fluid analysis (stains, cultures; glucose, lactate dehydrogenase, and total protein levels; leukocyte count with differential; pH determination) should be performed on most patients with pleural effusions to assist in diagnosis of the etiologic agent and assess for empyema or complicated parapneumonic process. Serologic assays, polymerase chain reaction tests, specialized culture tests, and other new diagnostic tests for organisms such as legionella, *Mycoplasma pneumoniae*, and *Chlamydia pneumoniae* are performed when these diagnoses are suspected. Limitations of many of these tests include delay in obtaining test results and poor sensitivity and specificity.

Treatment

Antimicrobial therapy should be initiated promptly after the diagnosis of pneumonia is established and appropriate specimens are obtained, especially in patients who require hospitalization. Delays in obtaining diagnostic specimens or the results of testing should not preclude the early administration of antibiotics to acutely ill patients. Decisions regarding hospitalization should be based on prognostic criteria as outlined above in the section on general considerations. Treatment recommendations can be divided into those for patients who can be treated as outpatients and those for patients who require hospitalization.

Special consideration must be given to emerging resistance of *Streptococcus pneumoniae* strains to penicillin. Intermediate resistance to penicillin is defined as an MIC of 0.1-1 ug/mL. Strains with high-level resistance usually require an MIC = 2 ug/mL for penicillin. Resistance to other antibiotics (beta-lactams, trimethoprim-sulfamethoxazole, macrolides, others) often accompanies resistance to penicillin. The prevalence of resistance varies by patient group, geographic region, and over time. Local resistance pattern data should therefore guide empirical therapy of suspected or documented *S pneumoniae* infections until specific susceptibility test results are available.

A. Treatment of Outpatients

Empirical antibiotic options for patients with community-acquired pneumonia who do not require hospitalization include the following: (1) Macrolides (clarithromycin, 500 mg orally twice a day, or azithromycin, 500 mg orally as a first dose and then 250 mg once a day for 4 days). (2) Doxycycline (100 mg orally twice a day). (3) Fluoroquinolones (with enhanced activity against *S pneumoniae*, such as gatifloxacin, 400 mg orally once a day, levofloxacin 500 mg orally once a day, or moxifloxacin 400 mg orally once a day). Some experts prefer doxycycline or macrolides for patients under 50 years of age without comorbidities and a fluoroquinolone for patients with comorbidities or who are older than 50 years of age. Alternatives include erythromycin (250-500 mg orally four times daily), amoxicillin-potassium clavulanate—especially for suspected aspiration pneumonia— 500 mg orally three times a day or 875 mg orally twice a day, and some second- and third-generation cephalosporins such as cefuroxime axetil (250-500 mg orally twice a day), cefpodoxime proxetil (100-200 mg orally twice a day), or cefprozil (250-500 mg orally twice a day).

There are limited data to guide recommendations for duration of treatment. The decision is influenced by the severity of illness, the etiologic agent, response to therapy, other medical problems, and complications. Therapy until the patient is afebrile for at least 72 hours is usually sufficient for pneumonia due to *S pneumoniae*. A minimum of 2 weeks of therapy is appropriate for pneumonia due to *S aureus*, *P aeruginosa*, klebsiella, anaerobes, *M pneumoniae*, *C pneumoniae*, or legionella species.

B. Treatment of Hospitalized Patients

Empirical antibiotic options for patients with community-acquired pneumonia who require hospitalization can be divided into those for patients who can be cared for on a general medical ward and those for patients who require care in an intensive care unit. Patients who only require general medical ward care usually respond to an extended-spectrum beta-lactam (such as ceftriaxone or cefotaxime) with a macrolide (clarithromycin or azithromycin is preferred if *H influenzae* infection is suspected) or a fluoroquinolone (with enhanced activity against *S pneumoniae*) such as gatifloxacin, levofloxacin, or moxifloxacin. Alternatives include a beta-lactam/beta-lactamase inhibitor (ampicillin-sulbactam or piperacillin-tazobactam) with a macrolide.

Patients requiring admission to the intensive care unit require a macrolide or a fluoroquinolone (with enhanced activity against *S pneumoniae*) plus an extended-spectrum cephalosporin (ceftriaxone, cefotaxime) or a beta-lactam/beta-lactamase inhibitor (ampicillin-sulbactam or piperacillin-tazobactam). Patients with penicillin allergies can be treated with a fluoroquinolone (with enhanced activity against *S pneumoniae*) with or without clindamycin. Patients with suspected aspiration pneumonia should receive a fluoroquinolone (with enhanced activity against *S pneumoniae*) with or without clindamycin, metronidazole, or a beta-lactam/beta-lactamase inhibitor. Patients with structural lung diseases such as bronchiectasis or cystic fibrosis benefit from empirical therapy with an antipseudomonal penicillin, carbapenem, or cefepime plus a fluoroquinolone (including high-dose ciprofloxacin) until sputum culture and sensitivity results are available. Expanded discussions of specific antibiotics are provided in [Chapter 37](#).

Almost all patients who are admitted to a hospital for therapy of community-acquired pneumonia receive intravenous antibiotics. Despite this preference, no studies demonstrate superior outcomes when hospitalized patients are treated intravenously instead of orally if patients can tolerate oral therapy and the drug is well absorbed. Duration of antibiotic treatment is the same as for outpatients with community-acquired pneumonia.

Prevention

Polyvalent pneumococcal vaccine (containing capsular polysaccharide antigens of 23 common strains of *S pneumoniae*) has the potential to prevent or lessen the severity of the majority of pneumococcal infections in immunocompetent patients. Indications for pneumococcal vaccination include the following: age = 65 years or any chronic illness that increases the risk of community-acquired pneumonia (see [Chapter 30](#)). Immunocompromised patients and those at highest risk of fatal pneumococcal infections should receive a single revaccination 6 years after the first vaccination. Immunocompetent persons 65 years of age or older should receive a second dose of vaccine if the patient first received the vaccine 6 or more years previously and was under 65 years old at the time of vaccination.

The influenza vaccine is effective in preventing severe disease due to influenza virus with a resulting positive impact on both primary influenza pneumonia and secondary bacterial pneumonias. The influenza vaccine is administered annually to persons at risk for complications of influenza infection (age = 65 years, residents of chronic care facilities, patients with pulmonary or cardiovascular disorders, patients recently hospitalized with chronic metabolic disorders) as well as health care workers and others who are able to transmit influenza to high-risk patients.

Hospitalized patients who would benefit from pneumococcal and influenza vaccines should be vaccinated during hospitalization. The vaccines can be given simultaneously, and there are no contraindications to use immediately after an episode of pneumonia.

2. Hospital-Acquired Pneumonia

Essentials of Diagnosis

- Occurs more than 48 hours after admission to the hospital and excludes any infection present at the time of admission.
- At least two of the following: fever, cough, leukocytosis, purulent sputum.
- New or progressive parenchymal infiltrate on chest radiograph.
- Especially common in patients requiring intensive care or mechanical ventilation.

General Considerations

Hospital-acquired (nosocomial) pneumonia is an important cause of morbidity and mortality despite the widespread use of preventive measures, advances in diagnostic testing, and potent new antimicrobial agents. Nosocomial pneumonia is the second most common cause of hospital-acquired infection and is the leading cause of deaths due to nosocomial infections with mortality rates ranging from 20% to 50%. While the majority of cases occur in patients who are not in the intensive care unit, the highest risk patients are those in such units or who are being mechanically ventilated; these patients also experience higher morbidity and mortality from nosocomial pneumonias.

Definition & Pathogenesis

Hospital-acquired pneumonia is defined as pneumonia developing more than 48 hours after admission to the hospital. Ventilator-associated pneumonia develops in a mechanically ventilated patient more than 48 hours after intubation.

Colonization of the pharynx and possibly the stomach with bacteria is the most important step in the pathogenesis of nosocomial pneumonia. Pharyngeal colonization is promoted by exogenous factors (instrumentation of the upper airway with nasogastric and endotracheal tubes, contamination by dirty hands and equipment, and treatment with broad-spectrum antibiotics that promote the emergence of drug-resistant organisms) and patient factors (malnutrition, advanced age, altered consciousness, swallowing disorders, and underlying pulmonary and systemic diseases). Aspiration of infected pharyngeal or gastric secretions delivers bacteria directly to the lower airway. Impaired cellular and mechanical defense mechanisms in the lungs of hospitalized patients raise the risk of infection after aspiration has occurred. Tracheal intubation increases the risk of lower respiratory infection by mechanical obstruction of the trachea, impairment of mucociliary clearance, trauma to the mucociliary escalator system, and interference with coughing. Tight adherence of bacteria such as *Pseudomonas* to the tracheal epithelium and the biofilm that lines the endotracheal tube makes clearance of these organisms from the lower airway difficult. Less important pathogenetic mechanisms of nosocomial pneumonia include inhalation of contaminated aerosols and hematogenous dissemination of microorganisms.

The role of the stomach in the pathogenesis of nosocomial pneumonia remains controversial. Observational studies have suggested that elevations of gastric pH due to antacids, H₂-receptor antagonists or enteral feeding is associated with gastric microbial overgrowth, tracheobronchial colonization, and nosocomial pneumonia. Sucralfate, a cytoprotective agent that does not alter gastric pH, is associated with a trend toward a lower incidence of ventilator-associated pneumonia.

The most common organisms responsible for nosocomial pneumonia are *Pseudomonas aeruginosa*, *Staphylococcus aureus*, enterobacter, *Klebsiella pneumoniae*, and *Escherichia coli*. *Proteus*, *Serratia marcescens*, *H influenzae*, and streptococci account for most of the remaining cases. Infection by *P aeruginosa* and acinetobacter tend to cause pneumonia in the most debilitated patients, those with previous antibiotic therapy, and those requiring mechanical ventilation. Anaerobic organisms (bacteroides, anaerobic streptococci, fusobacterium) may also cause pneumonia in the hospitalized patient; when isolated, they are commonly part of a polymicrobial flora. Mycobacteria, fungi, chlamydiae, viruses, rickettsiae, and protozoal organisms are uncommon causes of nosocomial pneumonia.

Clinical Findings

A. Symptoms and Signs

The symptoms and signs associated with nosocomial pneumonia are non-specific; however, one or more clinical findings (fever, leukocytosis, purulent sputum, and a new or progressive pulmonary infiltrate on chest radiograph) are present in most patients. Other findings associated with nosocomial pneumonia include those listed above for community-acquired pneumonia.

The differential diagnosis of new lower respiratory tract symptoms and signs in hospitalized patients includes congestive heart failure, atelectasis, aspiration, acute respiratory distress syndrome, pulmonary thromboembolism, pulmonary hemorrhage, and drug reactions.

B. Laboratory Findings

The minimum evaluation for suspected nosocomial pneumonia includes blood cultures from two different sites and an arterial blood gas or pulse oximetry determination. Blood cultures can identify the pathogen in up to 20% of all patients with nosocomial pneumonia; positivity is associated with increased risk for complications and other sites of infection. The assessment of oxygenation helps define the severity of illness and determines the need for supplemental oxygen. Blood counts and clinical chemistry tests are not helpful in establishing a specific diagnosis of nosocomial pneumonia; however, they can help define the severity of illness and identify complications. Thoracentesis for pleural fluid analysis (stains, cultures; glucose, lactate dehydrogenase, and total protein levels; leukocyte count with differential; pH determination) should be performed in patients with pleural effusions.

Examination of sputum is attended by the same disadvantages as in community-acquired pneumonia. Gram stains and cultures of sputum are neither sensitive nor specific in the diagnosis of nosocomial pneumonia. The identification of a bacterial organism by culture of sputum does not prove that the organism is a lower respiratory tract pathogen. However, it can be used to help identify antibiotic sensitivity patterns of bacteria and as a guide to therapy. If nosocomial pneumonia from *Legionella pneumophila* is suspected, direct fluorescent antibody staining can be performed. Sputum stains and cultures for mycobacteria and certain fungi may be diagnostic.

C. Imaging

Radiographic findings are nonspecific and can range from patchy airspace infiltrates to lobar consolidation with air bronchograms to diffuse alveolar or interstitial infiltrates. Additional findings can include pleural effusions and cavitation. Progression of pulmonary infiltrates during antibiotic therapy and lack of radiographic improvement over time are poor prognostic signs and also raise concerns about secondary or alternative pulmonary processes. Clearing of pulmonary infiltrates can take 6 weeks or longer.

D. Special Examinations

Endotracheal aspiration using a sterile suction catheter and fiberoptic bronchoscopy with bronchoalveolar lavage or a protected specimen brush can be used to obtain lower respiratory tract secretions for analysis, most commonly in patients with ventilator-associated pneumonias. Endotracheal aspiration cultures have significant negative predictive value but limited positive predictive value in the diagnosis of specific etiologic agents in patients with nosocomial pneumonia. A recent clinical trial of an invasive diagnostic approach using quantitative culture of bronchoalveolar lavage samples or protected specimen brush samples in patients suspected of having ventilator-associated pneumonia reported significantly less antibiotic use, earlier attenuation of organ dysfunction, and fewer deaths at 14 days in the invasive management group.

Treatment

Treatment of nosocomial pneumonia, like treatment of community-acquired pneumonia, is usually empirical. Because of the high mortality rate, therapy should be started as soon as pneumonia is suspected. Initial regimens must be broad in spectrum and tailored to the specific clinical setting. There is no uniform consensus on the best regimens.

Recommendations for the treatment of hospital-acquired pneumonia have been proposed by many organizations, including the American Thoracic Society. Initial empirical therapy with antibiotics is determined by the severity of illness, risk factors, and the length of hospitalization. Empirical therapy for mild to moderate nosocomial pneumonia in a patient without unusual risk factors or a patient with severe early-onset (within 5 days after hospitalization) hospital-acquired pneumonia may consist of a second-generation cephalosporin, a nonantipseudomonal third-generation cephalosporin, or a combination of a beta-lactam and beta-lactamase inhibitor.

Empirical therapy for patients with severe, late-onset (= 5 days after hospitalization) hospital-acquired pneumonia or with ICU- or ventilator-associated pneumonia should include a combination of antibiotics directed against the most virulent organisms, particularly *P aeruginosa*, acinetobacter species, and enterobacter species. The antibiotic regimen should include an aminoglycoside or fluoroquinolone plus one of the following: an antipseudomonal penicillin, an antipseudomonal cephalosporin, a carbapenem, or aztreonam—aztreonam alone with an aminoglycoside will be inadequate if coverage for gram-positive organisms or *H influenzae* is required. Vancomycin is added if infection with methicillin-resistant *S aureus* infection is of concern (especially in patients with coma, head trauma, diabetes mellitus, or renal failure, or who are in the ICU). Anaerobic coverage with clindamycin or a beta-lactam/beta-lactamase inhibitor combination may be added for patients who have risk factors for anaerobic pneumonia, including aspiration, recent thoracoabdominal surgery, or an obstructing airway lesion. A macrolide is added when patients are at risk for legionella infection, such as those receiving high-dose corticosteroids. After results of sputum, blood, and pleural fluid cultures have been obtained, it may be possible to switch to a regimen with a narrower spectrum. Duration of antibiotic therapy should be individualized based on the pathogen, severity of illness, response to therapy, and comorbid conditions. Therapy for gram-negative bacterial pneumonia should continue for at least 14-21 days.

Expanded discussions of specific antibiotics are provided in [Chapter 37](#). Antibiotic dosage suggestions are provided in [Chapter 37](#).

3. Anaerobic Pneumonia & Lung Abscess

Essentials of Diagnosis

- History of or predisposition to aspiration.
- Indolent symptoms, including fever, weight loss, malaise.
- Poor dentition.
- Foul-smelling purulent sputum (in many patients).
- Infiltrate in dependent lung zone, with single or multiple areas of cavitation or pleural effusion.

General Considerations

Aspiration of small amounts of oropharyngeal secretions occurs during sleep in normal individuals but rarely causes disease. Sequelae of aspiration of larger amounts of material include nocturnal asthma, chemical pneumonitis, mechanical obstruction of airways by particulate matter, bronchiectasis, and pleuropulmonary infection. Individuals predisposed to disease induced by aspiration include those with depressed levels of consciousness due to drug or alcohol use, seizures, general anesthesia, or central nervous system disease; those with impaired deglutition due to esophageal disease or neurologic disorders; and those with tracheal or nasogastric tubes, which disrupt the mechanical defenses of the airways.

Periodontal disease and poor dental hygiene, which increase the number of anaerobic bacteria in aspirated material, is associated with a greater likelihood of anaerobic pleuropulmonary infection. Aspiration of infected oropharyngeal contents initially leads to pneumonia in dependent lung zones, such as the posterior segments of the upper lobes and superior and basilar segments of the lower lobes. Body position at the time of aspiration determines which lung zones are dependent. The onset of symptoms is insidious. By the time the patient seeks medical attention, necrotizing pneumonia, lung abscess, or empyema may be apparent.

Most aspiration patients with necrotizing pneumonia, lung abscess, and empyema are found to be infected with multiple species of anaerobic bacteria. Most of the remainder are infected with both anaerobic and aerobic bacteria. *Prevotella melaninogenica*, peptostreptococcus, *Fusobacterium nucleatum*, and bacteroides species are commonly isolated anaerobic bacteria.

Clinical Findings

A. Symptoms and Signs

Patients with anaerobic pleuropulmonary infection usually present with constitutional symptoms such as fever, weight loss, and malaise. Cough with expectoration of foul-smelling purulent sputum suggests anaerobic infection, though the absence of productive cough does not rule out such an infection. Dentition is often poor. Patients are rarely edentulous; if so, an obstructing bronchial lesion is usually present.

B. Laboratory Findings

Expectorated sputum is inappropriate for culture of anaerobic organisms because of contaminating mouth flora. Representative material for culture can be obtained only by transthoracic aspiration, thoracentesis, or bronchoscopy with a protected brush. Transthoracic aspiration is rarely indicated, because drainage occurs via the bronchus and anaerobic pleuropulmonary infections usually respond well to empirical therapy.

C. Imaging

The different types of anaerobic pleuropulmonary infection are distinguished on the basis of their radiographic appearance. **Lung abscess** appears as a thick-walled solitary cavity surrounded by consolidation. An air-fluid level is usually present. Other causes of cavitary lung disease (tuberculosis, mycosis, cancer, infarction, Wegener's granulomatosis) should be excluded. **Necrotizing pneumonia** is distinguished by multiple areas of cavitation within an area of consolidation. **Empyema** is characterized by the presence of purulent pleural fluid and may accompany either of the other two radiographic findings. Ultrasonography is of value in locating fluid and may also reveal pleural loculations.

Treatment

Penicillins have been the standard treatment for anaerobic pleuropulmonary infections. However, an increasing number of anaerobic organisms produce beta-lactamases, and up to 20% of patients do not respond to penicillins. Improved responses have been documented with clindamycin (600 mg intravenously every 8 hours until improvement, then 300 mg orally every 6 hours) or amoxicillin-clavulanate (875 mg orally every 12 hours). Penicillin (amoxicillin, 500 mg every 8 hours, or penicillin G, 1-2 million units intravenously every 4-6 hours) plus metronidazole (500 mg orally or intravenously every 8-12 hours) is another option. Antibiotic therapy should be continued until the chest radiograph improves, a process that may take a month or more; patients with lung abscesses should be treated until radiographic resolution of the abscess cavity is demonstrated. Anaerobic pleuropulmonary disease requires adequate drainage with tube thoracostomy for the treatment of empyema. Open pleural drainage is sometimes necessary because of the propensity of these infections to produce loculations in the pleural space.

PULMONARY INFILTRATES IN THE IMMUNOCOMPROMISED HOST

Pulmonary infiltrates in immunocompromised patients may arise from infectious or noninfectious causes. Infection may be due to bacterial, mycobacterial, fungal, protozoal, helminthic, or viral pathogens. Noninfectious processes such as pulmonary edema, alveolar hemorrhage, drug reactions, pulmonary thromboembolic disease, malignancy, and radiation pneumonitis may mimic infection.

Although almost any pathogen can cause pneumonia in a compromised host, two clinical tools help the clinician narrow the differential diagnosis. The first is knowledge of the underlying immunologic defect. Specific immunologic defects are associated with particular infections. Defects in humoral immunity predispose to bacterial infections; defects in cellular immunity lead to infections with viruses, fungi, mycobacteria, and protozoa. Neutropenia and impaired granulocyte function predispose to

infections from *S aureus*, aspergillus, gram-negative bacilli, and candida. Second, the time course of infection also provides clues to the etiology of pneumonia in immunocompromised patients. A fulminant pneumonia is often caused by bacterial infection, whereas an insidious pneumonia is more apt to be caused by viral, fungal, protozoal, or mycobacterial infection. Pneumonia occurring within 2-4 weeks after organ transplantation is usually bacterial, whereas several months or more after transplantation *P jiroveci*, viruses (eg, CMV), and fungi (eg, aspergillus) are encountered more often.

Chest radiography is rarely helpful in narrowing the differential diagnosis. Examination of expectorated sputum for bacteria, fungi, mycobacteria, legionella, and *P jiroveci* is important and may preclude the need for expensive, invasive diagnostic procedures. Sputum induction is often necessary for diagnosis. The sensitivity of induced sputum for detection of *P jiroveci* depends upon institutional expertise, number of specimens analyzed, and detection methods.

Routine evaluation frequently fails to identify a causative organism. The clinician may begin empirical antimicrobial therapy and proceed to invasive procedures such as bronchoscopy, transthoracic needle aspiration, or open lung biopsy. The approach to management must be based on the severity of the pulmonary infection, the underlying disease, the risks of empirical therapy, and local expertise and experience with diagnostic procedures. Bronchoalveolar lavage using the flexible bronchoscope is a safe and effective method for obtaining representative pulmonary secretions for microbiologic studies. It involves less risk of bleeding and other complications than bronchial brushing and transbronchial biopsy. Bronchoalveolar lavage is especially suitable for the diagnosis of *P jiroveci* pneumonia in patients with AIDS when induced sputum analysis is negative. Open lung biopsy, now often performed by video-assisted thoracoscopy, provides the best opportunity for diagnosis of pulmonary infiltrates in the immunocompromised host. However, a specific diagnosis is obtained in only about two-thirds of cases, and the information obtained rarely affects the outcome. Therefore, empirical treatment is often preferred.

White P: Evaluation of pulmonary infiltrates in critically ill patients with cancer and marrow transplant. Crit Care Clin 2001;17:647. [PMID: 11525052]

PULMONARY TUBERCULOSIS

Essentials of Diagnosis

- Fatigue, weight loss, fever, night sweats, and cough.
- Pulmonary infiltrates on chest radiograph, most often apical.
- Positive tuberculin skin test reaction (most cases).
- Acid-fast bacilli on smear of sputum or sputum culture positive for *Mycobacterium tuberculosis*.

General Considerations

Tuberculosis is one of the world's most widespread and deadly illnesses. *Mycobacterium tuberculosis*, the organism that causes tuberculosis infection and disease, infects an estimated 20-43% of the world's population. Each year, 3 million people worldwide die from the disease. In the United States, it is estimated that 15 million people are infected with *M tuberculosis*. Tuberculosis occurs disproportionately among disadvantaged populations such as the malnourished, homeless, and those living in overcrowded and substandard housing. There is an increased occurrence of tuberculosis among HIV-positive individuals.

Infection with *M tuberculosis* begins when a susceptible person inhales airborne droplet nuclei containing viable organisms. Tubercle bacilli that reach the alveoli are ingested by alveolar macrophages. Infection follows if the inoculum escapes alveolar macrophage microbicidal activity. Once infection is established, lymphatic and hematogenous dissemination of tuberculosis typically occurs before the development of an effective immune response. This stage of infection, **primary tuberculosis**, is usually clinically and radiographically silent. In most persons with intact cell-mediated immunity, T cells and macrophages surround the organisms in granulomas that limit their multiplication and spread. The infection is contained but not eradicated, since viable organisms may lie dormant within granulomas for years to decades.

Individuals with this **latent tuberculosis infection** do not have active disease and cannot transmit the organism to others. However, reactivation of disease may occur if the host's immune defenses are impaired. Approximately 10% of individuals with latent tuberculosis infection who are not given preventive therapy will develop active tuberculosis in their lifetime; half of these cases occur in the 2 years following primary infection. Up to 50% of HIV-infected patients will develop active tuberculosis within 2 years after infection with tuberculosis. Diverse conditions such as gastrectomy, silicosis, and diabetes mellitus and disorders associated with immunosuppression (eg, HIV infection or therapy with corticosteroids or other immunosuppressive drugs) are associated with an increased risk of reactivation.

In approximately 5% of cases, the immune response is inadequate and the host develops **progressive primary tuberculosis**, accompanied by both pulmonary and constitutional symptoms that are described below. Standard teaching has held that 90% of tuberculosis in adults represents activation of latent disease. New diagnostic technologies such as DNA fingerprinting suggest that as many as one-third of new cases of tuberculosis in urban populations are primary infections resulting from person-to-person transmission.

The percentage of patients with atypical presentations—particularly elderly patients, patients with HIV infection, and those in nursing homes—has increased. Extrapulmonary tuberculosis is especially common in patients with HIV infection, who often display lymphadenitis or miliary disease.

Strains of *M tuberculosis* resistant to one or more first-line antituberculous drugs are being encountered with increasing frequency. Risk factors for drug resistance include immigration from parts of the world with a high prevalence of drug-resistant tuberculosis, close and prolonged contact with individuals with drug-resistant tuberculosis, unsuccessful previous therapy, and patient noncompliance. Resistance to one or more antituberculous drugs has been found in 15% of tuberculosis patients in the United States. Outbreaks of multidrug-resistant tuberculosis in hospitals and correctional facilities in Florida and New York have been associated with mortality rates of 70-90% and median survival rates of 4-16 weeks.

Clinical Findings

A. Symptoms and Signs

The patient with pulmonary tuberculosis typically presents with slowly progressive constitutional symptoms of malaise, anorexia, weight loss, fever, and night sweats. Chronic cough is the most common pulmonary symptom. It may be dry at first but typically becomes productive of purulent sputum as the disease progresses. Blood-streaked sputum is common, but significant hemoptysis is rarely a presenting symptom; life-threatening hemoptysis may occur in advanced disease. Dyspnea is unusual unless there is extensive disease. Rarely, the patient is asymptomatic. On physical examination, the patient appears chronically ill and malnourished. On chest examination, there are no physical findings specific for tuberculosis infection. The examination may be normal or may reveal classic findings such as posttussive apical rales.

B. Laboratory Findings

Definitive diagnosis depends on recovery of *M tuberculosis* from cultures or identification of the organism by DNA or RNA amplification techniques. Three consecutive morning sputum specimens are advised. Sputum induction may be helpful in patients who cannot voluntarily produce satisfactory specimens. Fluorochrome staining with rhodamine-auramine of concentrated, digested sputum specimens is performed initially as a screening method, with confirmation by the Kinyoun or Ziehl-Neelsen stains. Demonstration of acid-fast bacilli on sputum smear does not confirm a diagnosis of tuberculosis, since saprophytic nontuberculous mycobacteria may colonize the airways and rarely may cause pulmonary disease.

In patients thought to have tuberculosis despite negative sputum smears, fiberoptic bronchoscopy can be considered. Bronchial washings are helpful; however, transbronchial lung biopsies increase the diagnostic yield. Postbronchoscopy expectorated sputum specimens may also be useful. Early morning aspiration of gastric contents after an overnight fast is an alternative to bronchoscopy but is suitable only for culture and not for stained smear, because nontuberculous mycobacteria may be present in the stomach in the absence of tuberculous infection. *M tuberculosis* may be cultured from blood in up to 15% of patients with tuberculosis.

Cultures on solid media to identify *M tuberculosis* may require 12 weeks. Liquid medium culture systems allow detection of mycobacterial growth in several days. Once mycobacteria have been grown in culture, nucleic acid probes or high-performance liquid chromatography can be used to identify the species within hours. The results of nucleic acid (DNA and RNA) amplification tests for tuberculosis should be interpreted in the clinical context and on the basis of local laboratory performance. Drug susceptibility testing of culture isolates is considered routine for the first isolate of *M tuberculosis*, when a treatment regimen is failing, and when sputum cultures remain positive after 2 months of therapy.

DNA fingerprinting using the restriction fragment length polymorphism analysis is available to identify individual strains of *M tuberculosis*, thereby revealing if infection has been transmitted from person to person. In addition, this method can be used to detect laboratory cross-contamination.

Needle biopsy of the pleura reveals granulomatous inflammation in approximately 60% of patients with pleural effusions caused by *M tuberculosis*. Pleural fluid cultures for *M tuberculosis* are positive in less than 25% of cases of pleural tuberculosis. Culture of three pleural biopsy specimens combined with microscopic examination of a pleural biopsy yields a diagnosis in up to 90% of patients with pleural tuberculosis.

C. Imaging

Radiographic abnormalities in primary tuberculosis include small homogeneous infiltrates, hilar and paratracheal lymph node enlargement, and segmental atelectasis. Pleural effusion may be present, especially in adults, sometimes as the sole radiographic abnormality. Cavitation may be seen with progressive primary tuberculosis. Ghon (calcified primary focus) and Ranke (calcified hilar lymph node) complexes are seen in a minority of patients and represent residual evidence of healed primary tuberculosis.

Reactivation tuberculosis is associated with various radiographic manifestations, including fibrocavitary apical disease, nodules, and pneumonic infiltrates. The usual location is in the apical or posterior segments of the upper lobes or in the superior segments of the lower lobes; up to 30% of patients may present with radiographic evidence of disease in other locations. This is especially true in elderly patients, in whom lower lobe infiltrates with or without pleural effusion are encountered with increasing frequency. Lower lung tuberculosis may masquerade as pneumonia or lung cancer. A "miliary" pattern (diffuse small nodular densities) can be seen with hematologic or lymphatic dissemination of the organism. Resolution of reactivation tuberculosis leaves characteristic radiographic findings. Dense nodules in the pulmonary hila, with or without obvious calcification, upper lobe fibronodular scarring, and bronchiectasis with volume loss are common findings.

In patients with early HIV infection, the radiographic features of tuberculosis resemble those in patients without HIV infection. In contrast, atypical radiographic features predominate in patients with late- stage HIV infection. These patients often display lower lung zone, diffuse, or miliary infiltrates, pleural effusions, and involvement of hilar and, in particular, mediastinal lymph nodes.

D. Special Examinations

The **tuberculin skin test** identifies individuals who have been infected with *M tuberculosis* but does not distinguish between active and latent infection. The test is used to evaluate a person who has symptoms of tuberculosis, an asymptomatic person who may be infected with *M tuberculosis* (eg, after contact exposure), or to establish the prevalence of tuberculous infection in a population. Routine testing of individuals at low risk for tuberculosis is not recommended. The Mantoux test is the preferred method: 0.1 mL of purified protein derivative (PPD) containing 5 tuberculin units is injected intradermally on the volar surface of the forearm using a 27-gauge needle on a tuberculin syringe. The transverse width in millimeters of induration at the skin test site should be measured after 48-72 hours. [Table 9-12](#) summarizes the CDC criteria for interpretation of the Mantoux tuberculin skin test. A **tuberculin skin test conversion** is defined as an increase of = 10 mm of induration within a 2-year period regardless of patient age.

In general, it takes 2-10 weeks after tuberculosis infection for a person to develop an immune response to PPD. Both false-positive and false-negative results occur. False-positive tuberculin skin test reactions occur in persons previously vaccinated against MTB with BCG (extract of *Mycobacterium bovis*) and in those infected with nontuberculous mycobacteria. False-negative tuberculin skin test reactions may result from improper testing technique, concurrent infections, malnutrition, advanced age, immunologic disorders, lymphoreticular malignancies, corticosteroid therapy, chronic renal failure, HIV infection, and fulminant tuberculosis. Some individuals with latent tuberculosis infection may have a negative skin test reaction when tested many years after exposure.

Serial testing may create a false impression of skin test conversion. Dormant mycobacterial sensitivity is sometimes restored by the antigenic challenge of the initial skin test. This phenomenon is called "boosting." A two-step testing procedure is used to reduce the likelihood that a boosted tuberculin reaction will be misinterpreted as a recent infection. Following a negative tuberculin skin test, the person is retested in 1-3 weeks. If the second test is negative, the person is uninfected or anergic; if positive, a boosted reaction is likely. Two-step testing should be used for the initial tuberculin skin testing of individuals who will be tested repeatedly, such as health care workers. Anergy testing is not recommended for routine use to distinguish a true-negative result from anergy. Poor anergy test standardization and lack of outcome data limit the evaluation of its effectiveness. Interpretation of the tuberculin skin test in persons who have previously received BCG vaccination is the same as in those who have not had BCG.

Novel in vitro methods promise significant changes in the identification of persons with latent *M tuberculosis* infection. Potential advantages of in vitro testing include reduced variability and subjectivity associated with placing and reading the PPD, fewer false-positive results from prior BCG vaccination, and better discrimination of positive responses due to nontuberculous mycobacteria.

Persons with concomitant HIV and tuberculosis infection usually respond best when the HIV infection is treated concurrently. In some cases, prolonged antituberculous therapy may be warranted. Therefore, all patients with tuberculosis infection should be tested for HIV within 2 months after diagnosis.

Treatment

A. General Measures

The goals of therapy are to eliminate all tubercle bacilli from an infected individual while avoiding the emergence of clinically significant drug resistance. The basic principles of antituberculous treatment are (1) to administer multiple drugs to which the organisms are susceptible; (2) to add at least two new antituberculous agents to a regimen when treatment failure is suspected; (3) to provide the safest, most effective therapy in the shortest period of time; and (4) to ensure adherence to therapy.

All suspected and confirmed cases of tuberculosis should be reported promptly to local and state public health authorities. Public health departments will perform case investigations on sources and patient contacts to determine if other individuals with untreated, infectious tuberculosis are present in the community. They can identify infected contacts eligible for treatment of latent tuberculous infection, and ensure that a plan for monitoring adherence to therapy is established for each patient with tuberculosis. Patients with tuberculosis should be treated by physicians who are skilled in the management of this infection. Clinical expertise is especially important in cases of drug-resistant tuberculosis.

Nonadherence to antituberculous treatment is a major cause of treatment failure, continued transmission of tuberculosis, and the development of drug resistance. Adherence to treatment can be improved by providing detailed patient education about tuberculosis and its treatment in addition to a case manager who oversees all aspects of an individual patient's care. **Directly observed therapy (DOT)**, which requires that a health care worker physically observe the patient ingest antituberculous medications in the home, clinic, hospital, or elsewhere, also improves adherence to treatment. The importance of direct observation of therapy cannot be overemphasized. The Centers for Disease Control and Prevention recommends DOT for all patients with drug-resistant tuberculosis and for those receiving intermittent (twice- or thrice-weekly) therapy.

Hospitalization for initial therapy of tuberculosis is not necessary for most patients. It should be considered if a patient is incapable of self-care or is likely to expose new, susceptible individuals to tuberculosis. Hospitalized patients with active disease require a private room with appropriate ventilation until tubercle bacilli are no longer found in their sputum ("smear-negative") on three consecutive smears taken on separate days.

Additional treatment considerations can be found in [Chapter 33](#). Characteristics of antituberculous drugs are provided in [Chapter 37](#). More complete information can be obtained from the Centers for Disease Control and Prevention's Division of Tuberculosis Elimination Web site at <http://www.cdc.gov/nchstp/tb/>.

B. Treatment of Tuberculosis for HIV-Negative Persons

Most patients with previously untreated pulmonary tuberculosis can be effectively treated with either a 6-month or a 9-month regimen, though the 6-month regimen is preferred. The initial phase of a 6-month regimen consists of 2 months of daily isoniazid, rifampin, pyrazinamide, and ethambutol. Once the isolate is determined to be isoniazid-sensitive, ethambutol may be discontinued. If the MTB isolate is susceptible to isoniazid and rifampin, the second phase of therapy consists of isoniazid and rifampin for a minimum of 4 additional months, with treatment to extend at least 3 months beyond documentation of conversion of sputum cultures to negative for MTB. If directly observed therapy is used, medications may be given intermittently using one of three regimens: (1) Daily isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months, followed by isoniazid and rifampin two or three times each week for 4 months if susceptibility to isoniazid and rifampin is demonstrated. (2) Daily isoniazid, rifampin, pyrazinamide, and ethambutol for 2 weeks, then administration of the same agents twice weekly for 6 weeks followed by administration of isoniazid and rifampin twice each week for 4 months if susceptibility to isoniazid and rifampin is demonstrated. (3) Thrice-weekly administration of isoniazid, rifampin, pyrazinamide, and ethambutol for 6 months.

Patients who cannot or should not (eg, pregnant women) take pyrazinamide should receive daily isoniazid and rifampin along with ethambutol for 4-8 weeks. If susceptibility to isoniazid and rifampin is demonstrated or drug resistance is unlikely, ethambutol can be discontinued and isoniazid and rifampin may be given twice a week for a total of 9 months of therapy. If drug resistance is a concern, patients should receive isoniazid, rifampin, and ethambutol for 9 months. Patients with smear- and culture-negative disease (eg, pulmonary tuberculosis diagnosed on clinical grounds) and patients for whom drug susceptibility testing is not available can be treated with 6 months of isoniazid and rifampin combined with pyrazinamide for the first 2 months. This regimen assumes low prevalence of drug resistance. Previous guidelines have used streptomycin interchangeably with ethambutol. Increasing worldwide streptomycin resistance has made this drug less useful as empirical therapy.

When a twice-weekly or thrice-weekly regimen is used instead of a daily regimen, the dosages of isoniazid, pyrazinamide, and ethambutol or streptomycin must be increased. Recommended dosages for the initial treatment of tuberculosis are listed in [Table 9-14](#). Fixed-dose combinations of isoniazid and rifampin (Rifamate) and of isoniazid, rifampin, and pyrazinamide (Rifater) are available to simplify treatment. Single tablets improve compliance but are more expensive than the individual drugs

purchased separately.

C. Treatment of Tuberculosis in HIV-Positive Persons

Management of tuberculosis is rendered even more complex in patients with concomitant HIV disease. Experts in the management of both tuberculosis and HIV disease should be involved in the care of such patients. The Centers for Disease Control and Prevention (CDC) has published detailed recommendations for the treatment of tuberculosis in HIV-positive patients. This document can be obtained by accessing the CDC Web site at <http://www.cdc.gov/mmwr/preview/mmwrhtml/00055357.htm>.

The basic approach to HIV-positive patients with tuberculosis is similar to that detailed above for patients without HIV disease. Additional considerations in HIV-positive patients include (1) longer duration of therapy and (2) drug interactions between rifamycin derivatives such as rifampin and rifabutin, used to treat tuberculosis, and some of the protease inhibitors and nonnucleoside reverse transcriptase inhibitors (NNRTIs), used to treat HIV. Directly observed therapy should be used for all HIV-positive tuberculosis patients. Pyridoxine (vitamin B₆), 25-50 mg orally each day, should be administered to all HIV-positive patients being treated with isoniazid to reduce central and peripheral nervous system side effects.

D. Treatment of Drug-Resistant Tuberculosis

Patients with drug-resistant MTB infection require careful supervision and management. Clinicians who are unfamiliar with the treatment of drug-resistant tuberculosis should seek expert advice. Tuberculosis resistant only to isoniazid can be successfully treated with a 6-month regimen of rifampin, pyrazinamide, and ethambutol or streptomycin or a 12-month regimen of rifampin and ethambutol. When isoniazid resistance is documented during a 9-month regimen without pyrazinamide, isoniazid should be discontinued. If ethambutol was part of the initial regimen, rifampin and ethambutol should be continued for a minimum of 12 months. If ethambutol was not part of the initial regimen, susceptibility tests should be repeated and two other drugs to which the organism is susceptible should be added. Treatment of MTB isolates resistant to agents other than isoniazid and treatment of drug resistance in HIV patients require expert consultation.

Multidrug-resistant tuberculosis (MDRTB) calls for an individualized daily directly observed treatment plan under the supervision of a clinician experienced in the management of this entity. Treatment regimens are based on the patient's overall status and the results of susceptibility studies. Most MDRTB isolates are resistant to at least isoniazid and rifampin and require a minimum of three drugs to which the organism is susceptible. These regimens are continued until culture conversion is documented, and then a two-drug regimen is then continued for at least another 12 months. Some experts recommend at least 18-24 months of a three-drug regimen.

E. Treatment of Extrapulmonary Tuberculosis

In most cases, regimens that are effective for treating pulmonary tuberculosis are also effective for treating extrapulmonary disease. However, many experts recommend 9 months of therapy when miliary, meningeal, or bone and joint disease is present. Treatment of skeletal tuberculosis is enhanced by early surgical drainage and debridement of necrotic bone. Corticosteroid therapy has been shown to help prevent cardiac constriction from tuberculous pericarditis and to reduce neurologic complications from tuberculous meningitis.

F. Treatment of Pregnant or Lactating Women

Tuberculosis in pregnancy is usually treated with isoniazid, rifampin, and ethambutol. Ethambutol can be excluded if isoniazid resistance is unlikely. Therapy is continued for 9 months. Since the risk of teratogenicity with pyrazinamide has not been clearly defined, pyrazinamide should be used only if resistance to other drugs is documented and susceptibility to pyrazinamide is likely. Streptomycin is contraindicated in pregnancy because it may cause congenital deafness. Pregnant women taking isoniazid should receive pyridoxine (vitamin B₆), 10-25 mg orally once a day, to prevent peripheral neuropathy.

Small concentrations of antituberculous drugs are present in breast milk and are not known to be harmful to nursing newborns. Therefore, breast feeding is not contraindicated while receiving antituberculous therapy.

G. Treatment Monitoring

Adults should have measurements of serum bilirubin, hepatic enzymes, urea nitrogen, creatinine, and a complete blood count (including platelets) before starting chemotherapy for tuberculosis. Visual acuity and red-green color vision tests are recommended before initiation of ethambutol and serum uric acid before starting pyrazinamide. Audiometry should be performed if streptomycin therapy is initiated.

Routine monitoring of laboratory tests for evidence of drug toxicity during therapy is not recommended. Monthly questioning for symptoms of drug toxicity is advised. Patients should be educated about common side effects of antituberculous medications and instructed to seek medical attention should these symptoms occur. Monthly follow-up of outpatients is recommended, including sputum smear and culture for *M tuberculosis* until cultures convert to negative. Patients with negative sputum cultures after 2 months of treatment should have at least one additional sputum smear and culture performed at the end of therapy. Patients with MDRTB should have sputum cultures performed monthly during the entire course of treatment. A chest radiograph at the end of therapy provides a useful baseline for any future films. BR>

Patients whose cultures do not become negative or whose symptoms do not resolve despite 3 months of therapy should be evaluated for drug-resistant organisms and for nonadherence to the treatment regimen. Directly observed therapy is required for the remainder of the treatment regimen, and the addition of at least two drugs not previously given should be considered pending repeat drug susceptibility testing. The clinician should seek expert assistance if drug resistance is newly found, if the patient remains symptomatic, or if smears or cultures remain positive.

Patients with only a clinical diagnosis of pulmonary tuberculosis (smears and cultures negative for *M tuberculosis*) whose symptoms and radiographic abnormalities are unchanged after 3 months of treatment usually either have another process or have had tuberculosis in the past.

H. Treatment of Latent Tuberculosis

Treatment of latent tuberculous infection is essential to controlling and eliminating tuberculosis in the United States. Treatment of latent tuberculous infection substantially reduces the risk that infection will progress to active disease. Targeted testing is used to identify persons who are at high risk for tuberculosis and who stand to benefit from treatment of latent infection. [Table 9-12](#) defines high-risk groups and gives the tuberculin skin test criteria for treatment of latent tuberculous infection. It is essential that each person who meets the criteria for treatment of latent tuberculous infection undergo a careful assessment to exclude active disease. A history of past treatment for tuberculosis and contraindications to treatment should be sought. All patients at risk for HIV infection should be tested for HIV. Patients suspected of having tuberculosis should receive one of the recommended multidrug regimens for active disease until the diagnosis is confirmed or excluded.

Some close contacts of persons with active tuberculosis should be evaluated for treatment of latent tuberculous infection despite a negative tuberculin skin test reaction (< 5 mm induration). These include immunosuppressed persons and those who may develop disease quickly after tuberculous infection. Close contacts who have a negative tuberculin skin test reaction on initial testing should be retested 10-12 weeks later.

Several treatment regimens for both HIV-negative and HIV-positive persons are available for the treatment of latent tuberculous infection: (1) **Isoniazid**: A 9-month regimen (minimum of 270 doses administered within 12 months) is considered optimal. Dosing options include a daily dose of 300 mg or twice-weekly doses of 15 mg/kg. Persons at risk of developing isoniazid-associated peripheral neuropathy (diabetes mellitus, uremia, malnutrition, alcoholism, HIV infection, pregnancy, seizure disorder) may be given supplemental pyridoxine (vitamin B₆), 10-50 mg/d. (2) **Rifampin and pyrazinamide**: A 2-month regimen (60 doses administered within 3 months) of daily rifampin (10 mg/kg up to a maximum dose of 600 mg) and pyrazinamide (15-20 mg/kg up to a maximum dose of 2 g) is recommended. (3) **Rifampin**: Patients who cannot tolerate isoniazid or pyrazinamide can be considered for a 4-month regimen (minimum of 120 doses administered within 6 months) of rifampin. HIV-positive patients given rifampin who are receiving protease inhibitors or nonnucleoside reverse transcriptase inhibitors require management by experts in both tuberculosis and HIV disease (see Treatment of Tuberculosis for HIV-Positive Persons, above).

Contacts of persons with isoniazid-resistant, rifampin-sensitive tuberculosis should receive a 2-month regimen of rifampin and pyrazinamide or a 4-month regimen of daily rifampin alone. Contacts of persons with MDRTB should receive two drugs to which the infecting organism has demonstrated susceptibility. Tuberculin skin test-negative and HIV-negative contacts may be observed without treatment or treated for 6 months. HIV-positive contacts should be treated for 12 months. All contacts of persons with MDRTB should have 2 years of follow up regardless of treatment.

Persons with a positive tuberculin skin test (= 5 mm of induration) and fibrotic lesions suggestive of old tuberculosis on chest radiographs who have no evidence of active disease and no history of treatment for tuberculosis should receive 9 months of isoniazid, or 2 months of rifampin and pyrazinamide, or 4 months of rifampin (with or without isoniazid). Pregnant or breast feeding women with latent tuberculosis should receive either daily or twice-weekly isoniazid with pyridoxine (vitamin B₆).

Baseline laboratory testing is indicated for patients at risk for liver disease, patients with HIV infection, women who are pregnant or within 3 months of delivery, and persons who use alcohol regularly. Patients receiving treatment for latent tuberculous infection should be evaluated once a month to assess for signs and symptoms of active tuberculosis and hepatitis and for adherence to their treatment regimen. Routine laboratory testing during treatment is indicated for those with abnormal baseline laboratory tests and for those at risk for developing liver disease.

Vaccine bacillus Calmette-Guerin (BCG) is an antimycobacterial vaccine developed from an attenuated strain of *Mycobacterium bovis*. Millions of individuals worldwide have been vaccinated with BCG. However, it is not generally recommended in the United States because of the low prevalence of tuberculous infection, the vaccine's interference with the ability to determine latent tuberculous infection using tuberculin skin test reactivity, and its variable effectiveness against pulmonary tuberculosis.

BCG vaccination in the United States should only be undertaken after consultation with local health officials and experts in the management of tuberculosis. Vaccination of health care workers should be considered on an individual basis in settings in which a high percentage of tuberculosis patients are infected with strains resistant to both isoniazid and rifampin; in which transmission of such drug-resistant *M tuberculosis* and subsequent infection are likely; and in which comprehensive tuberculous infection-control precautions have been implemented but have not been successful. The BCG vaccine is contraindicated in persons with impaired immune responses due to disease or medications.

Prognosis

Almost all properly treated patients with tuberculosis can be cured. Relapse rates are less than 5% with current regimens. The main cause of treatment failure is nonadherence to therapy.

PULMONARY DISEASE CAUSED BY NONTUBERCULOUS MYCOBACTERIA

Essentials of Diagnosis

- Chronic cough, sputum production, and fatigue; less commonly: malaise, dyspnea, fever, hemoptysis, and weight loss.
- Parenchymal infiltrates on chest radiograph, often with thin-walled cavities, that spread contiguously and often involve overlying pleura.
- Isolation of nontuberculous mycobacteria in a sputum culture.

General Considerations

Mycobacteria other than *M tuberculosis*—nontuberculous mycobacteria (NTM), sometimes referred to as "atypical" mycobacteria—are ubiquitous in water and soil and have been isolated from tap water. There appears to be a continuing increase in the number and prevalence of NTM species. Marked geographic variability exists, both in the NTM species responsible for disease and in the prevalence of disease. These organisms are not considered communicable from person to person, have distinct laboratory characteristics, and are often resistant to most antituberculous drugs. See [Chapter 33](#) for further information.

Definition & Pathogenesis

The diagnosis of lung disease caused by NTM is based on a combination of clinical, radiographic, and bacteriologic criteria and the exclusion of other diseases that can resemble the condition. Specific diagnostic criteria are discussed below. Complementary data are important for diagnosis because NTM organisms can reside in or colonize the airways without causing clinical disease, especially in patients with AIDS, and many patients have preexisting lung disease that may make their chest radiographs abnormal.

Mycobacterium avium complex (MAC) is the most frequent cause of NTM pulmonary disease in humans in the United States. *M kansasii* is the next most frequent pulmonary pathogen. Other NTM causes of pulmonary disease include *M abscessus*, *M xenopi*, and *M malmoense*; the list of more unusual etiologic NTM species is long. Most NTM cause a chronic, slowly progressive pulmonary infection that resembles tuberculosis but tends to progress more slowly. Disseminated disease is rare in immunocompetent hosts; however, disseminated MAC disease is common in patients with AIDS.

Clinical Findings

A. Symptoms and Signs

Most patients with NTM infection experience a chronic cough, sputum production, and fatigue. Less common symptoms include malaise, dyspnea, fever, hemoptysis, and weight loss. Symptoms from coexisting lung disease (commonly COPD, bronchiectasis, previous mycobacterial disease, cystic fibrosis, and pneumoconiosis) may confound the evaluation.

Common physical findings include fever and altered breath sounds, including rales or rhonchi.

B. Laboratory Findings

The diagnosis of NTM infection rests on recovery of the pathogen from cultures. Sputum cultures positive for atypical mycobacteria do not in themselves prove infection because NTM may exist as saprophytes colonizing the airways or may be environmental contaminants. Bronchial washings are considered to be more sensitive than expectorated sputum samples; however, their specificity for clinical disease is not known.

Bacteriologic criteria have been proposed based on studies of patients with cavitary disease with MAC or *M kansasii*. Diagnostic criteria in HIV-seronegative or immunocompetent hosts include the following: (1) at least three sputum or bronchial wash samples within a 1-year period with the following findings: three positive cultures with negative AFB smears or two positive cultures and one positive AFB smear; (2) if expectorated sputum samples are not available, a single bronchial wash culture with 2+ to 4+ growth or any positive culture plus a 2+ to 4+ AFB smear. The diagnosis can also be established by demonstrating NTM in a lung biopsy or bronchial wash plus histopathologic changes such as granulomatous inflammation in a lung biopsy. Rapid species identification of some NTM is possible using DNA probes or high-pressure liquid chromatography. Criteria are less stringent for patients with severe immune suppression. HIV-infected patients may show significant MAC growth on culture of bronchial washings without clinical infection, and, therefore, HIV patients being evaluated for MAC infection must be considered individually.

In general, drug susceptibility testing on cultures of NTM is not recommended except for the following NTM: (1) *M kansasii* and rifampin; (2) rapid growers (such as *M fortuitum*, *M chelonae*, *M abscessus*) and amikacin, doxycycline, imipenem, fluoroquinolones, clarithromycin, cefoxitin, and a sulfonamide.

C. Imaging

Chest radiographic findings include infiltrates that are progressive or persist for at least 2 months, cavitary lesions, and multiple nodular densities. The cavities are often thin-walled and have less surrounding parenchymal infiltrate than is commonly seen with MTB infections. Evidence of contiguous spread and pleural involvement is often present. High-resolution computed tomography of the chest may show multiple small nodules with or without multifocal bronchiectasis. Progression of pulmonary infiltrates during therapy or lack of radiographic improvement over time are poor prognostic signs and also raise concerns about secondary or alternative pulmonary processes. Clearing of pulmonary infiltrates due to NTM is slow.

Treatment

Treatment regimens and responses vary with the species of NTM. Disease caused by *M kansasii* responds well to drug therapy. A daily regimen of rifampin, isoniazid, and ethambutol for at least 18 months with a minimum of 12 months of negative cultures is usually successful.

The treatment of the immunocompetent patient with MAC infection is controversial and largely empirical. Traditional chemotherapeutic regimens have taken an aggressive approach using a combination of agents, but these have been associated with a high incidence of drug-induced side effects. Adherence to such regimens is also difficult. Non-HIV-infected patients with MAC pulmonary disease usually receive a combination of daily clarithromycin or azithromycin, rifampin or rifabutin, and ethambutol. Streptomycin is considered for the first 2 months as tolerated. The optimal duration of treatment is unknown, but therapy should be continued for 12 months after sputum conversion. Medical treatment is initially successful in about two-thirds of cases, but relapses after treatment are common; long-term benefit is demonstrated in about half of all patients. Those who do not respond favorably generally have active but stable disease. Surgical resection is an alternative for the patient with progressive disease that responds poorly to chemotherapy; the success rate with surgical therapy is good.

Diagnosis and treatment of disease caused by nontuberculous mycobacteria. Am J Respir Crit Care Med 1997;156(2 Part 2):S1. [PMID: 9279284]

COMMON MANIFESTATIONS OF LUNG DISEASE
 -
-

■ PULMONARY NEOPLASMS

SCREENING FOR LUNG CANCER

Periodic evaluation of asymptomatic people at high risk for lung cancer is an attractive strategy without demonstrated benefit. Available evidence from the Mayo Lung Project suggests that serial chest radiographs can identify a significant number of early stage malignancies and that screened patients have an improved 5-year survival from their lung cancers. However, neither disease-specific mortality from lung cancer nor all-cause mortality is affected by screening. Three large randomized clinical trials published between 1984 and 1986 came to similar conclusions. Since then, screening for lung cancer has not been recommended by any major advisory group. The illusory benefits of screening have been attributed to lead time, length time, and overdiagnosis biases.

The availability of rapid-acquisition, low-dose helical computed tomography (LDCT) has rekindled enthusiasm for lung cancer screening. LDCT is a very sensitive test. Compared with chest radiography, LDCT identifies between four and ten times the number of asymptomatic lung malignancies. LDCT may also increase the number of false-positive tests, unnecessary diagnostic procedures, and overdiagnosis. A mortality benefit remains to be proved. The National Lung Cancer Screening Trial is an ongoing NCI-funded multicenter trial to determine whether using LDCT to screen current or former heavy smokers for lung cancer will improve mortality in this population. Information is available at <http://www.cancer.gov/NLST/>

Bach PB et al: Screening for lung cancer: a review of the current literature. Chest 2003;123(1 Suppl):72S. [PMID: 12527566]

SOLITARY PULMONARY NODULE

A solitary pulmonary nodule, sometimes referred to as a "coin lesion," is a < 3 cm isolated, rounded opacity on the chest radiograph outlined by normal lung and not associated with infiltrate, atelectasis, or adenopathy. Most are asymptomatic and represent an unexpected finding on chest radiography. The finding is important because it carries a significant risk of malignancy. The frequency of malignancy in surgical series ranges from 10% to 68% depending on patient population. Most benign nodules are infectious granulomas. **Benign neoplasms** such as hamartomas account for less than 5% of solitary nodules.

The goals of evaluation are to identify and resect malignant tumors in patients who stand to benefit from resection while avoiding invasive procedures in benign disease. The task is to identify nodules with a sufficiently high probability of malignancy to warrant biopsy or resection or a sufficiently low probability of malignancy to justify observation.

Symptoms alone rarely establish the cause, but clinical and radiographic data can be used to assess the probability of malignancy. The patient's age is important. Malignant nodules are rare in persons under age 30. Above age 30, the likelihood of malignancy increases with age. Smokers are at increased risk, and the likelihood of malignancy increases with the number of cigarettes smoked daily. Patients with a prior malignancy have a higher likelihood of having a malignant solitary nodule.

The first and most important step in the radiographic evaluation is to review old radiographs. Comparison with prior studies allows estimation of doubling time, which is an important marker for malignancy. Rapid progression (doubling time less than 30 days) suggests infection; long-term stability (doubling time over 465 days) suggests benignity. Certain radiographic features help in estimating the probability of malignancy. Increasing size is correlated with malignancy. A recent study of solitary nodules identified by CT scan showed a 1% malignancy rate in those measuring 2-5 mm, 24% in 6-10 mm, 33% in 11-20 mm, and 80% in 21-45 mm. The appearance of a smooth, well-defined edge is characteristic of a benign process. Ill-defined margins or a lobular appearance suggest malignancy. A high-resolution computed tomographic (HRCT) finding of spiculated margins and a peripheral halo are both highly associated with malignancy. Calcification and its pattern are also helpful clues. Benign lesions tend to have dense calcification in a central or laminated pattern. Malignant lesions are associated with sparser calcification that is typically stippled or eccentric. Cavitary lesions with thick (> 16 mm) walls are much more likely to be malignant. HRCT offers better resolution of these characteristics than chest radiography and is more likely to detect lymphadenopathy or the presence of multiple lesions. HRCT is indicated in any suspicious solitary pulmonary nodule.

Treatment

Based on clinical and radiologic data, the clinician should assign a specific probability of malignancy to the lesion. The decision whether and how to obtain a diagnostic biopsy depends on the interpretation of this probability in light of the patient's unique clinical situation. The probabilities in parentheses below represent guidelines only and should not be interpreted as prescriptive.

In the case of solitary pulmonary nodules, a continuous probability function may be grouped into three categories. In patients with a low probability (< 8%) of malignancy (eg, age under 30, lesions stable for more than 2 years, characteristic pattern of benign calcification), watchful waiting is appropriate. Management consists of serial radiographs every 3 months for 1 year and then every 6 months for a second year. Three-dimensional reconstruction of HRCT images may provide a more sensitive test for growth. These techniques are in research trials.

Patients with a high probability (> 70%) of malignancy should proceed directly to resection provided there are no contraindications to surgery. Biopsies rarely yield a specific benign diagnosis and are not indicated.

Optimal management of patients with an intermediate probability of malignancy (8-70%) remains controversial. The traditional approach is to obtain a diagnostic biopsy either through transthoracic needle aspiration (TTNA) or bronchoscopy. Bronchoscopy yields a diagnosis in 10-80% of procedures depending on the size of the nodule and its location. Complications are generally rare. TTNA has a higher diagnostic yield, reported to be between 50% and 97%. The yield is strongly operator-dependent, however, and is affected by the location and size of the lesion. Complications are higher than bronchoscopy, with pneumothorax occurring in up to 30% of patients.

Disappointing diagnostic yields and a high false-negative rate (up to 25-30% in TTNA) have prompted alternative approaches. Several new imaging techniques may help to improve the specificity of HRCT in excluding malignancy. Malignant nodules tend to be more highly vascularized and therefore show increased enhancement on HRCT following the intravenous infusion of iodine-containing contrast media. Sensitivity and specificity appear promising but await validation. Positron emission tomography (PET) detects increased glucose metabolism within malignant lesions with high sensitivity (85-97%) and specificity (70-85%). Many diagnostic algorithms have incorporated PET into the assessment of patients with inconclusive HRCT findings. PET has several drawbacks, however: resolution below 1 cm is poor, the test is expensive, and availability remains limited. Sputum cytology is highly specific but lacks sensitivity. It is used in central lesions and in patients who are poor candidates for invasive diagnostic procedures. Researchers have attempted to improve the sensitivity of sputum cytology through the use of monoclonal antibodies to proteins that are up-regulated in pulmonary malignancies. Such tests offer promise but remain research tools at this time.

Video-assisted thoracoscopic surgery (VATS) offers a more aggressive approach to diagnosis. VATS is more invasive than bronchoscopy or TTNA but is associated with less postoperative pain, shorter hospital stays, and more rapid return to function than traditional thoracotomy. These advantages have led some centers to recommend VATS resection of all solitary pulmonary nodules with intermediate probability of malignancy. In some cases, surgeons will remove the nodule and evaluate it in the operating room with frozen section. If the nodule is malignant, they will proceed to lobectomy and lymph node sampling, either thoracoscopically or through conversion to standard thoracotomy.

BRONCHOGENIC CARCINOMA

Essentials of Diagnosis

- New cough, or change in chronic cough.
- Dyspnea, hemoptysis, anorexia, weight loss.
- Enlarging nodule or mass; persistent infiltrate, atelectasis, or pleural effusion on chest radiograph or CT scan.
- Cytologic or histologic findings of lung cancer in sputum, pleural fluid, or biopsy specimen.

General Considerations

Lung cancer is the leading cause of cancer deaths in both men and women. The American Cancer Society estimates 171,900 new diagnoses and 157,200 deaths from lung cancer in the USA in 2003, accounting for 13% of new cancer diagnoses and 28% of all cancer deaths. More Americans now die of lung cancer than of colorectal, breast, and prostate cancers combined. This dramatic increase in a previously reportable disease is causally related to exposure to carcinogens through inhalation of tobacco smoke. The causal connection between cigarettes and lung cancer is now established not only epidemiologically but also through identification of carcinogens in tobacco smoke and analysis of the effect of these carcinogens on specific oncogenes expressed in lung cancer. Even cigarette manufacturers no longer dispute the role of tobacco in this epidemic.

Ninety percent of cases of lung cancer in men and 79% in women are directly attributable to cigarette smoking. Through the 1990s, mortality from lung cancer fell among men while it increased among women, reflecting changing patterns of tobacco use over the past 30 years (see [Chapter 1](#)). Other environmental risk factors for the development of lung cancer include exposure to environmental tobacco smoke, radon gas (among uranium miners and in areas where radium in the soil causes significant indoor air contamination), asbestos (60- to 100-fold increased risk in smokers with asbestos exposure), metals (arsenic, chromium, nickel, iron oxide), and industrial carcinogens (bis-chloromethyl ether). A familial predisposition to lung cancer is recognized. Certain diseases are associated with an increased risk of lung cancer, including pulmonary fibrosis, COPD, and sarcoidosis. Second primary lung cancers are more frequent in patients who survive their initial lung cancer.

The mean age at diagnosis of lung cancer is 60; it is unusual under the age of 40. Forty-one percent of patients diagnosed with lung cancer in 1997 survived for 1 year, compared with 34% in 1975. The combined 5-year survival rate for all stages of lung cancer was 15% in 1997, compared with 12% in 1974-76.

Four histologic types of bronchogenic carcinoma account for more than 90% of cases of primary lung cancer. **Squamous cell carcinoma** (25-35% of cases) arises from the bronchial epithelium, typically as a centrally located, intraluminal sessile or polypoid mass. Squamous cell tumors are more likely to present with hemoptysis and more frequently are diagnosed by sputum cytology. They spread locally and may be associated with hilar adenopathy and mediastinal widening on chest radiography. **Adenocarcinoma** (35-40% of cases) arises from mucous glands or, in the case of the **bronchioloalveolar cell carcinoma** (2% of cases), from any epithelial cell within or distal to the terminal bronchioles. Adenocarcinomas usually present as peripheral nodules or masses. Bronchioloalveolar cell carcinoma spreads intra-alveolarly and may present as an infiltrate or as single or multiple pulmonary nodules. **Large cell carcinoma** (5-10% of cases) is a heterogeneous group of relatively undifferentiated tumors that share large cells and do not fit into other categories. Large cell carcinomas typically have rapid doubling times and an aggressive clinical course. They present as central or peripheral masses. **Small cell carcinoma** (15-20% of cases) is a tumor of bronchial origin that typically begins centrally, infiltrating submucosally to cause narrowing or obstruction of the bronchus without a discrete luminal mass. Hilar and mediastinal abnormalities are common on chest radiography.

For purposes of staging and treatment, bronchogenic carcinoma is divided into small cell lung cancer (SCLC) and the other three types, conveniently labeled non-small cell lung cancer (NSCLC). This practical classification reflects different natural histories and different treatment. SCLC is prone to early hematogenous spread. It is rarely amenable to surgical resection and has a very aggressive course with a median survival (untreated) of 6-18 weeks. The three histologic categories comprising NSCLC spread more slowly. They may be cured in the early stages following resection, and they respond similarly to chemotherapy.

Clinical Findings

Lung cancer is symptomatic at diagnosis in 75-90% of patients. The clinical presentation depends on the type and location of the primary tumor, the extent of local spread, and the presence of distant metastases and any paraneoplastic syndromes.

A. Symptoms and Signs

Anorexia, weight loss, or asthenia occurs in 55-88% of patients presenting with a new diagnosis of lung cancer. Up to 60% of patients have a new cough or a change in a chronic cough; 6-31% have hemoptysis; and 25-40% complain of pain, sometimes nonspecific chest pain but often referable to bony metastases to the vertebrae, ribs, or pelvis. Local spread may cause endobronchial obstruction with atelectasis and postobstructive pneumonia, pleural effusion (12-33%), change in voice (compromise of the recurrent laryngeal nerve), superior vena cava syndrome (obstruction of the SVC with supraclavicular venous engorgement), and Horner's syndrome (ipsilateral ptosis, miosis, and anhidrosis from involvement of the inferior cervical ganglion and the paravertebral sympathetic chain). Distant metastases to the liver are associated with asthenia and weight loss. Brain metastases (10%; more common in adenocarcinoma) may present with headache, nausea, vomiting, seizures, or altered mental status.

Paraneoplastic syndromes are incompletely understood patterns of organ dysfunction related to immune-mediated or secretory effects of neoplasms (see [Chapter 40](#)). These syndromes occur in 10-20% of lung cancer patients. They may precede, accompany, or follow the diagnosis of lung cancer. They do not necessarily indicate metastatic disease. Digital clubbing is seen in up to 20% of patients at diagnosis. Fifteen percent of patients with small cell carcinoma will develop SIADH; 10% of patients with squamous cell carcinoma will develop hypercalcemia. Other common paraneoplastic syndromes include increased ACTH production, anemia, hypercoagulability, peripheral neuropathy, and the Eaton-Lambert myasthenia syndrome. Their recognition is important because treatment of the primary tumor may improve or resolve symptoms even when the cancer is not curable.

B. Laboratory Findings

The diagnosis of lung cancer rests on examination of a tissue or cytology specimen. Sputum cytology is highly specific but insensitive; the yield is highest when there are lesions in the central airways. Thoracentesis (sensitivity 50-65%) can be used to establish a diagnosis of lung cancer in patients with malignant pleural effusions. If cytologic examination of an adequate sample (50-100 mL) of pleural fluid is nondiagnostic, the procedure should be repeated once. If results remain negative, thoracoscopy is preferred to blind pleural biopsy. Fine needle aspiration of palpable supraclavicular or cervical lymph nodes is frequently diagnostic. Serum tumor markers are neither sensitive nor specific enough to aid in diagnosis.

Fiberoptic bronchoscopy allows visualization of the major airways, cytology brushing of visible lesions or lavage of lung segments with cytologic evaluation of specimens, direct biopsy of endobronchial abnormalities, blind transbronchial biopsy of the pulmonary parenchyma or peripheral nodules, and fine needle aspiration biopsy of mediastinal lymph nodes. Diagnostic yield varies widely (10-90%) depending on the size of the lesion and its location. Recent advances include fluorescence bronchoscopy, which improves the ability to identify early endobronchial lesions; and endoscopic ultrasound, which permits more accurate direction of fine needle aspiration. Transthoracic needle aspiration (TTNB) has a sensitivity between 50% and 97%. Mediastinoscopy, video-assisted thoracoscopic surgery (VATS), and thoracotomy are necessary in cases where less invasive techniques fail to yield a diagnosis.

C. Imaging

Nearly all patients with lung cancer have abnormal findings on chest radiography or CT scan. These findings are rarely specific for a particular diagnosis. Interpretation of characteristic findings in isolated nodules is described above (see Solitary Pulmonary Nodule).

D. Special Examinations

1. Staging—Accurate staging ([Table 9-15](#)) is crucial (1) to provide the clinician with information to guide treatment, (2) to provide the patient with accurate information regarding prognosis, and (3) to standardize entry criteria for clinical trials to allow interpretation of results.

There are two essential principles of staging NSCLC. First, the more extensive the disease, the worse the prognosis; and second, surgical resection offers the best and perhaps the only realistic hope for cure. Staging of NSCLC uses two integrated systems. The **TNM international staging system** attempts a physical description of the neoplasm: T describes the size and location of the primary tumor; N describes the presence and location of nodal metastases; and M refers to the presence or absence of distant metastases. These TNM stages are grouped into prognostic categories (stages I-IV) using the results of clinical trials. This classification is used to guide therapy. Many patients with stage I and stage II disease are cured through surgery. Patients with stage IIIB and stage IV disease do not benefit from surgery. Patients with stage IIIA disease have locally invasive disease that may benefit from surgery in certain circumstances.

Small cell lung cancer is not staged using the TNM system because micrometastases are assumed to be present on diagnosis. SCLC is divided into two categories: **limited disease** (30%), when the tumor is limited to the unilateral hemithorax (including contralateral mediastinal nodes); or **extensive disease** (70%), when the tumor extends beyond the hemithorax (including pleural effusion). This scheme also guides therapy. Patients with limited SCLC benefit from thoracic radiation therapy in addition to chemotherapy and may benefit from prophylactic cranial radiation therapy.

For both SCLC and NSCLC, staging begins with a thorough history and physical examination. A complete examination is essential to exclude obvious metastatic disease to lymph nodes, skin, and bone. A detailed history is essential because the patient's performance status is a powerful predictor of disease course. All patients should have measurement of a complete blood count, electrolytes including calcium, creatinine, liver tests including LDH and alkaline phosphatase, and a chest radiograph. Further evaluation will follow the results of these tests. In general, screening asymptomatic lung cancer patients with CT and MRI imaging of the brain, radionuclide bone imaging, and abdominal CT imaging does not change patient outcomes. These tests should be targeted to specific symptoms and signs (see [Table 9-16](#)).

NSCLC patients being considered for surgery require meticulous evaluation to identify those with resectable disease. CT imaging is the most important modality for staging candidates for resection. A chest CT scan precisely defines the size of parenchymal lesions and identifies atelectatic lung or pleural effusions. However, CT

imaging is less accurate at determining invasion of the chest wall (sensitivity 62%) or mediastinum (sensitivity 60-75%). The sensitivity and specificity of CT imaging for identifying lung cancer metastatic to the mediastinal lymph nodes are 57% (49-66%) and 82% (77-86%), respectively. Therefore, chest CT imaging does not provide definitive information on staging. CT imaging does inform the decision about whether to proceed to resection of the primary tumor and sample the mediastinum at thoracotomy (common if there are no lymph nodes > 1 cm), or to employ TTNA, mediastinoscopy, esophageal ultrasound with transesophageal needle aspiration, or limited thoracotomy to biopsy-suspected metastatic disease (common where there are lymph nodes > 1-2 cm).

Positron emission tomography (PET) using 2-[¹⁸F]fluoro-2-deoxyglucose (FDG) is a noninvasive alternative for identifying metastatic foci in the mediastinum or distant sites. The sensitivity and specificity of PET for detecting mediastinal spread of primary lung cancer depend on the size of mediastinal nodes or masses. When only normal-sized (< 1 cm) mediastinal lymph nodes are present, the sensitivity and specificity of PET for tumor involvement of nodes are 74% and 96%, respectively. When CT shows enlarged (> 1 cm) lymph nodes, the sensitivity and specificity are 95% and 76%, respectively.

PET imaging is being incorporated into diagnostic algorithms that take advantage of both its positive and negative predictive values. Many lung cancer specialists find PET most useful to confirm lack of metastatic disease in NSCLC patients who are candidates for surgical resection. There is also evidence that PET imaging reduces futile thoracotomies by identifying mediastinal and distant metastases in patients with NSCLC. Disadvantages of PET imaging include limited resolution below 1 cm, the expense of FDG, limited availability, and false-positive scans due to sarcoidosis, tuberculosis, or fungal infections.

2. Preoperative assessment—See [Chapter 2](#).

3. Pulmonary function testing—Many patients with NSCLC have moderate to severe chronic lung disease that increases the risk of perioperative complications as well as long-term pulmonary insufficiency following lung resection. All patients considered for surgery require spirometry. In the absence of other comorbidities, patients with good lung function (preoperative FEV₁ > 2 L) are at low risk for complications from lobectomy or pneumonectomy. If the FEV₁ is less than 2 L, then an estimated postoperative FEV₁ should be calculated. The postresection FEV₁ may be estimated from considering preoperative spirometry and the amount of lung to be resected; in severe obstructive disease, a quantitative lung perfusion scan may improve the estimate. A predicted post-lung resection FEV₁ > 800 mL (or > 40% of predicted FEV₁) is associated with a low incidence of perioperative complications. High-risk patients include those with a predicted postoperative FEV₁ < 700 mL (or < 40% of predicted FEV₁). In these patients—and in those with borderline spirometry—cardiopulmonary exercise testing may be helpful. A maximal oxygen uptake (MVO₂) of > 15 mL/kg/min identifies patients with an acceptable incidence of complications and mortality. Patients with an MVO₂ of < 10 mL/kg/min have a very high mortality rate at thoracotomy. Hypoxemia and hypercapnia are not independent predictors of outcome.

Treatment.

A. Non-Small Cell Carcinoma

In NSCLC, cure is unlikely without resection. Therefore, the initial approach to the patient is determined by the answers to two questions: (1) Is complete surgical resection technically feasible? (2) If yes, is the patient able to tolerate the surgery with acceptable morbidity and mortality? Clinical features that preclude complete resection include extrathoracic metastases or a malignant pleural effusion; or tumor involving the heart, pericardium, great vessels, esophagus, recurrent laryngeal or phrenic nerves, trachea, main carina, or contralateral mediastinal lymph nodes. Accordingly, stage I and stage II patients are treated with surgical resection where possible. Stage IIIA patients have poor outcomes when treated with resection alone. They should be referred to multimodality protocols, including chemotherapy and radiotherapy. Stage IIIB patients treated with combined chemotherapy and radiation therapy have improved survival. Selected stage IIIB patients taken to resection following multimodality therapy have shown long-term survival and may be cured. Stage IV patients are treated with symptom-based palliative therapy, which may include outpatient chemotherapy (see below).

The surgical approach affects the outcome. In a prospective trial of stage I patients randomized to lobectomy versus limited resection, there was a threefold increased rate of local recurrence in the limited resection group and a trend toward mortality benefit at 5 years in the lobectomy patients (56% versus 73% mortality, *P* = .09). There are inadequate outcome data on which to base a comparison of VATS with standard thoracotomy. Radiation therapy following surgery improves local control but does not improve survival.

Neoadjuvant chemotherapy consists of giving antineoplastic drugs in advance of surgery or radiation therapy. There is no consensus on the impact of neoadjuvant therapy on survival in stage I and stage II NSCLC. Such therapy is not recommended outside of ongoing clinical trials. Neoadjuvant therapy is more widely used in selected patients with stage IIIA or stage IIIB disease. Some studies suggest a survival advantage. This remains an area of active research.

Adjuvant chemotherapy consists of administering antineoplastic drugs following surgery or radiation therapy. Adjuvant chemotherapy with alkylating agents such as cyclophosphamide increases mortality. In stage I and N0 stage II disease, patients treated with multidrug platinum-based chemotherapy show a trend toward improved survival—on the order of 3 months (5%) at 5 years. Toxicity may be significant, however, and such therapy is not recommended. Newer antineoplastic agents with less toxicity are in clinical trials in these patients. In patients with stage IIIA disease and node positive stage II disease, the data are conflicting whether chemotherapy following surgery improves survival. Patients with locally advanced disease (stages IIIA and IIIB) who are not surgical candidates have improved survival when treated with combination chemotherapy and radiation therapy compared with no therapy or radiation alone.

In patients with advanced disease (stage IIIB and stage IV) but good performance status (WHO performance status 0-1, < 5% weight loss in the past 6 months; see [Chapter 40](#)), multidrug platinum-based chemotherapy is associated with an increase in survival equivalent to a mean gain of 6 weeks at 1 year. There is no evidence of a survival benefit in patients with poor performance status.

Multiple clinical trials evaluating quality of life suggest that there is better overall performance status and symptom control in patients with stage IIIB and stage IV NSCLC receiving chemotherapy plus good supportive care versus supportive care alone. Several trials suggest an increase in median survival of from 5 months to 7 months. These trials compare small numbers of patients; they are unblinded; and they are supported by the pharmaceutical companies that make the drugs used—all of which suggests caution in interpreting the results. Nonetheless, the reported findings are consistent. Furthermore, newer antineoplastic agents such as paclitaxel, vinorelbine, and navelbine show increased effectiveness in advanced NSCLC along with favorable side effect profiles. It remains to be seen which patients stand to benefit most from what combination of agents. At this time, outpatient chemotherapy for advanced NSCLC should be offered on protocol to patients with good performance status.

B. Small Cell Carcinoma

In SCLC, response rates to cisplatin and etoposide are excellent: 80-100% response in limited-stage disease (50-70% complete response), and 60-80% response in extensive stage disease (15-40% complete response). However, remissions tend to be short-lived with a median duration of 6-8 months. Once the disease has recurred, median survival is 3-4 months. Overall 2-year survival is 20% in limited-stage disease and 5% in extensive-stage disease. Thoracic radiation therapy improves survival in patients with limited SCLC but not those with extensive disease. Whole brain radiation therapy decreases the incidence of central nervous system disease but does not affect survival. Its effect on symptoms is controversial.

Occasionally, a patient may have a peripheral nodule resected that turns out to be SCLC. Five-year survival following resection of the equivalent of stage I and stage II SCLC is higher than in patients treated with chemotherapy.

C. Palliative therapy

Photoresection with the Nd:YAG laser is sometimes performed on central tumors to relieve endobronchial obstruction, improve dyspnea, and control hemoptysis. External beam radiation therapy is also used to control dyspnea and hemoptysis in addition to pain from bony metastases, obstruction from superior vena cava syndrome, and symptomatic brain metastases. Resection of *solitary* brain metastases does not affect survival but may improve quality of life when combined with radiation therapy. Intraluminal radiation (brachytherapy) is an alternative approach to endobronchial disease. Pain syndromes are very common in advanced disease. As patients approach the end of life, meticulous efforts at pain control are essential (see [Chapter 5](#)). Consultation with or referral to a palliative care specialist is recommended in advanced disease to aid in symptom management and to facilitate referrals to hospice programs.

Prognosis

The overall 5-year survival rate for lung cancer is 15%. Predictors of survival are the type of tumor (SCLC versus NSCLC), the stage of the tumor, and the patient's performance status, including weight loss in the past 6 months. These are independent predictors in both early and late stage disease. Most data suggest that there is no difference among non-small cell carcinomas when adjusted for stage and performance status. However, squamous cell carcinoma may have a better prognosis than adenocarcinoma or large cell carcinoma at the same TNM stage. (See [Table 9-17](#).)

BRONCHIAL CARCINOID TUMORS

Carcinoid and bronchial gland tumors are sometimes termed bronchial adenomas. This term should be avoided because it implies that the lesions are benign, when in fact carcinoid tumors and bronchial gland carcinomas are low-grade malignant neoplasms.

Carcinoid tumors are about six times more common than bronchial gland carcinomas, and most of them occur as pedunculated or sessile growths in central bronchi. Men and women are equally affected. Most patients are under 60 years of age. Common symptoms of bronchial carcinoid tumors are hemoptysis, cough, focal wheezing, and recurrent pneumonia. Peripherally located bronchial carcinoid tumors are rare and present as asymptomatic solitary pulmonary nodules. Carcinoid syndrome (flushing, diarrhea, wheezing, hypotension) is rare. Fiberoptic bronchoscopy may reveal a pink or purple tumor in a central airway. These lesions have a well-vascularized stroma, and biopsy may be complicated by significant bleeding. CT scanning is helpful to localize the lesion and to follow its growth over time. Octreotide scintigraphy is also available for localization of these tumors.

Bronchial carcinoid tumors grow slowly and rarely metastasize. Complications involve bleeding and airway obstruction rather than invasion by tumor and metastases. Surgical excision is necessary in some cases, and the prognosis is generally favorable. Most bronchial carcinoid tumors are resistant to radiation and chemotherapy.

SECONDARY LUNG CANCER

Secondary lung cancers represent metastases from extrapulmonary malignant neoplasms that spread to the lungs through vascular or lymphatic channels or by direct extension. Almost any cancer can metastasize to the lung. Metastases usually occur via the pulmonary artery and typically present as multiple nodules or masses on chest radiography. The radiographic differential diagnosis of multiple pulmonary nodules also includes pulmonary arteriovenous malformation, pulmonary abscesses, granulomatous infection, sarcoidosis, rheumatoid nodules, and Wegener's granulomatosis. Metastases to the lungs are found in 20-55% of patients dying of various malignancies. Most are intraparenchymal. Endobronchial metastases occur in fewer than 5% of patients dying of nonpulmonary cancer; carcinoma of the kidney, breast, colon, and cervix and malignant melanoma are the most likely primary tumors.

Lymphangitic carcinoma denotes diffuse involvement of the pulmonary lymphatic network by primary or secondary lung cancer, probably a result of extension of tumor from lung capillaries to the lymphatics. **Tumor embolization** from extrapulmonary cancer (renal cell carcinoma, hepatocellular carcinoma, choriocarcinoma) is an uncommon route for tumor spread to the lungs. Secondary lung cancer may also present as malignant pleural effusion (see below).

Clinical Findings

A. Symptoms and Signs

Symptoms are uncommon but include cough, hemoptysis, and, in advanced cases, dyspnea. Symptoms are more often referable to the site of the primary tumor.

B. Laboratory Findings

The diagnosis of secondary lung cancer is usually established by identifying a primary tumor. Appropriate studies should be ordered if there is a suspicion of any primary cancer, such as breast, thyroid, testis, or prostate, for which specific treatment is available. Mammography should be considered unless one has been performed recently. If the history and physical examination fail to reveal the site of the primary tumor, attention is better focused on the lung, where tissue samples obtained by bronchoscopy, percutaneous needle biopsy, or thoracotomy may establish the histologic diagnosis and suggest the most likely primary. Occasionally, cytologic studies of pleural fluid or pleural biopsy reveal the diagnosis. Sputum cytology is rarely helpful.

C. Imaging

Chest radiographs usually show multiple spherical densities with sharp margins. The size of metastatic lesions varies from a few millimeters (miliary densities) to large masses. Nearly all are less than 5 cm in diameter. The lesions are usually bilateral, pleural or subpleural in location, and more common in lower lung zones. Cavitation suggests primary squamous cell tumor; calcification suggests osteosarcoma. Lymphangitic spread and solitary pulmonary nodule are less common radiographic presentations of secondary lung cancer. Conventional chest radiography is less sensitive than CT scan in detecting pulmonary metastases.

Treatment

Once the diagnosis has been established, management consists of treatment of the primary neoplasm and any pulmonary complications. Surgical resection of a *solitary* pulmonary nodule is often prudent in the patient with known current or previous extrapulmonary cancer. Local resection of one or more pulmonary metastases is feasible in a few carefully selected patients with various sarcomas and carcinomas (breast, testis, colon, kidney, and head and neck). Surgical resection should be considered only if the primary tumor is under control, if the patient is a good surgical risk, if all of the metastatic tumor can be resected, if nonsurgical approaches are not available, and if there are no metastases elsewhere in the body. Relative contraindications to resection of pulmonary metastases include (1) malignant melanoma primary, (2) requirement for pneumonectomy, (3) pleural involvement, and (4) simultaneous appearance of two or more metastases. The overall 5-year survival rate in secondary lung cancer treated surgically is 20-35%. For patients with progressive disease, diligent attention to palliative care is essential (see [Chapter 5](#)).

Greulich JP et al: Secondary pulmonary malignancy. Surg Clin North Am 2000;80:633. [\[PMID: 10836010\]](#)

MESOTHELIOMA

Mesotheliomas are primary tumors arising from the surface lining of the pleura (80% of cases) or peritoneum (20% of cases). About three-fourths of pleural mesotheliomas are diffuse (usually malignant) tumors, and the remaining one-fourth are localized (usually benign). Men outnumber women by a 3:1 ratio. Numerous studies have confirmed the association of **malignant pleural mesothelioma** with exposure to asbestos (particularly the crocidolite form). The lifetime risk to asbestos workers of developing malignant pleural mesothelioma is about 8%. The clinician should inquire about asbestos exposure through mining, milling, manufacturing, shipyard work, insulation, brake linings, building construction and demolition, roofing materials, and a variety of asbestos products (pipe, textiles, paint, tile, gaskets, panels). Sixty to 80 percent of patients with malignant mesothelioma report a history of asbestos exposure. Although cigarette smoking significantly increases the risk of bronchogenic carcinoma in asbestos workers and aggravates asbestosis, there is no association between smoking and mesothelioma.

The mean age at onset of symptoms of malignant pleural mesothelioma is about 60 years. The latent period between exposure and onset of symptoms ranges from 20 to 40 years. Symptoms include the insidious onset of shortness of breath, nonpleuritic chest pain, and weight loss. Physical findings include dullness to percussion, diminished breath sounds, and, in some cases, finger clubbing. Radiographic abnormalities consist of nodular, irregular, unilateral pleural thickening and varying degrees of unilateral pleural effusion. CT scan helps demonstrate the extent of pleural involvement.

Pleural fluid is exudative and often hemorrhagic. Open pleural biopsy is usually necessary to obtain an adequate specimen for histologic diagnosis; even then, distinction from benign inflammatory conditions and from metastatic adenocarcinoma may be difficult. The histologic variants of malignant pleural mesothelioma are epithelial and fibrous (sarcomatous). Special stains and electron microscopy may be needed to confirm the diagnosis.

Malignant pleural mesothelioma progresses rapidly as the tumor spreads quickly along the pleural surface to involve the pericardium, mediastinum, and contralateral pleura. The tumor may eventually extend beyond the thorax to involve abdominal lymph nodes and organs. Progressive pain and dyspnea are characteristic. Median survival time from onset of symptoms ranges from 5 months in extensive disease to 16 months in localized disease, and about 75% of patients are dead within 1 year after diagnosis. Treatment with surgery, radiotherapy, chemotherapy, and a combination of methods has been attempted but is generally unsuccessful. Some surgeons believe that extrapleural pneumonectomy is the preferred surgical approach for patients with early stage disease. Drainage of pleural effusions, pleurodesis, radiation therapy, and even surgical resection may offer palliative benefit in some patients.

MEDIASTINAL MASSES

Various developmental, neoplastic, infectious, traumatic, and cardiovascular disorders may cause masses that appear in the mediastinum on chest radiograph. A useful convention arbitrarily divides the mediastinum into three compartments—anterior, middle, and posterior—in order to classify mediastinal masses and assist in differential diagnosis. Specific mediastinal masses have a predilection for one or more of these compartments; most are located in the anterior or middle compartment. The differential diagnosis of an anterior mediastinal mass includes thymoma, teratoma, thyroid lesions, lymphoma, and mesenchymal tumors (lipoma, fibroma). The differential diagnosis of a middle mediastinal mass includes lymphadenopathy, pulmonary artery enlargement, aneurysm of the aorta or innominate artery, developmental cyst (bronchogenic, enteric, pleuropericardial), dilated azygous or hemiazygous vein, and foramen of Morgagni hernia. The differential diagnosis of a posterior mediastinal mass includes hiatus hernia, neurogenic tumor, meningocele, esophageal tumor, foramen of Bochdalek hernia, thoracic spine disease, and extramedullary hematopoiesis. The neurogenic tumor group includes neurilemmoma, neurofibroma, neurosarcoma, ganglioneuroma, and pheochromocytoma.

Symptoms and signs of mediastinal masses are nonspecific and are usually caused by the effects of the mass on surrounding structures. Insidious onset of retrosternal chest pain, dysphagia, or dyspnea is often an important clue to the presence of a mediastinal mass. In about half of cases, symptoms are absent, and the mass is detected on routine chest radiograph. Physical findings vary depending upon the nature and location of the mass.

CT scanning is helpful in management; additional radiographic studies of benefit include barium swallow if esophageal disease is suspected, Doppler sonography or venography of brachiocephalic veins and the superior vena cava, and arteriography. MRI is useful; its advantages include distinction between vessels and masses, no need for contrast media, and better delineation of hilar structures. MRI also allows imaging in multiple planes, whereas CT permits only axial imaging. Tissue diagnosis is necessary if a neoplastic disorder is suspected. Treatment and prognosis depend on the underlying cause of the mediastinal mass.

■ INTERSTITIAL LUNG DISEASE (DIFFUSE PARENCHYMAL LUNG DISEASE)

Interstitial lung disease, or diffuse parenchymal lung disease, comprises a heterogeneous group of disorders that share a common response of the lung to injury: alveolitis, or inflammation, and fibrosis of the interalveolar septum. The term "interstitial" is misleading since the pathologic process usually begins with injury to the alveolar epithelial or capillary endothelial cells. Persistent alveolitis may lead to obliteration of alveolar capillaries and reorganization of the lung parenchyma, accompanied by irreversible fibrosis. The process does not affect the airways proximal to the respiratory bronchioles. At least 180 disease entities may present as interstitial lung disease ([Table 9-18](#)). In the majority of patients, no specific cause can be identified. In the remainder, drugs and a variety of organic and inorganic dusts are the principal causes.

The clinical consequence of widespread lung fibrosis is diminished lung compliance, which presents as restrictive lung disease. Patients usually describe an insidious onset of exertional dyspnea and cough. Sputum production is minimal. Chest examination reveals fine, late inspiratory crackles at the lung bases. Digital clubbing is seen in 25-50% of patients at diagnosis. Pulmonary function testing shows a loss of lung volume with normal to increased airflow rates. The diffusing capacity for carbon monoxide is decreased, and hypoxemia with exercise is common. In advanced cases, resting hypoxemia may be present. The chest radiograph is normal on presentation in up to 10% of patients. More typically, it shows patchy distribution of ground-glass, reticular, or reticulonodular infiltrates. In advanced disease there are multiple small, thick-walled cystic spaces in the lung periphery ("honeycomb lung"). Honeycombing indicates the presence of locally advanced fibrosis with destruction of normal lung architecture. Conventional and high-resolution CT imaging (HRCT) reveal in greater detail the findings described on chest radiograph. In some cases, HRCT may be strongly suggestive of a specific pathologic process.

The history—particularly the occupational and medication history—may provide evidence of a specific cause. Serologic tests for antinuclear antibodies and rheumatoid factor are positive in 20-40% of patients but are rarely diagnostic. Antineutrophil cytoplasmic antibodies (ANCAs) may be diagnostic in some clinical settings. Invasive diagnostic testing is frequently necessary to make a specific diagnosis. Three diagnostic techniques are in common use: bronchoalveolar lavage, transbronchial biopsy, and surgical lung biopsy, either through an open procedure or using video-assisted thoracoscopic surgery.

Bronchoalveolar lavage may provide a specific diagnosis in cases of infection, particularly with *Pneumocystis jiroveci* or mycobacteria, or when cytologic examination reveals the presence of malignant cells. The findings may be suggestive if not diagnostic of eosinophilic pneumonia, Langerhans cell histiocytosis, and alveolar proteinosis. Analysis of the cellular constituents of lavage fluid may suggest a specific disease, but these findings are not diagnostic.

Transbronchial biopsy through the flexible bronchoscope is easily performed in most patients. The risks of pneumothorax (5%) and hemorrhage (1-10%) are low. However, the tissue specimens recovered are small, sampling error is common, and crush artifact may complicate diagnosis. Transbronchial biopsy can make a definitive diagnosis of sarcoidosis, lymphangitic spread of carcinoma, pulmonary alveolar proteinosis, miliary tuberculosis, and Langerhans cell histiocytosis. Transbronchial biopsy cannot establish a specific diagnosis of idiopathic interstitial pneumonia. These patients generally require surgical lung biopsy.

Surgical lung biopsy is the standard for diagnosis of interstitial lung disease. Two or three biopsies taken from multiple sites in the same lung, including apparently normal tissue, may yield a specific diagnosis as well as prognostic information regarding the extent of fibrosis versus active inflammation. Patients under age 60 without a specific diagnosis generally should undergo surgical lung biopsy. In older and sicker patients, the risks and benefits must be weighed carefully for three reasons: (1) the morbidity of the procedure can be significant; (2) a definitive diagnosis may not be possible even with surgical lung biopsy; and (3) when a specific diagnosis is made, there may be no effective treatment. Empirical therapy or no treatment may be preferable to surgical lung biopsy in some patients.

Known causes of interstitial lung disease are dealt with in their specific sections. The important idiopathic forms are discussed below.

IDIOPATHIC FIBROSING INTERSTITIAL PNEUMONIA (FORMERLY: IDIOPATHIC PULMONARY FIBROSIS)

The most common diagnosis among patients presenting with interstitial lung disease is idiopathic pulmonary fibrosis, known in Britain as cryptogenic fibrosing alveolitis. Historically, this diagnosis was based on clinical and radiographic criteria with only a minority of patients undergoing surgical lung biopsy. When biopsies were obtained, several histologic patterns were grouped together under the category idiopathic pulmonary fibrosis because of the common element of fibrosis. We now recognize that these distinct histopathologic features are associated with different natural histories and responses to therapy (see [Table 9-19](#)). Therefore, in the evaluation of patients with idiopathic interstitial lung disease, one should attempt to identify specific disorders and use the terms idiopathic pulmonary fibrosis or cryptogenic fibrosing alveolitis to denote only the histologic pattern of usual interstitial pneumonitis (UIP).

Patients with idiopathic fibrosing interstitial pneumonia may present with any of the histologic patterns described in [Table 9-19](#). The first step in evaluation is to identify patients whose disease is truly idiopathic. As indicated in [Table 9-18](#), most identifiable causes of interstitial lung disease are either infectious, drug- related, or environmental or occupational agents. Interstitial lung diseases associated with other medical conditions (pulmonary-renal syndromes, collagen-vascular disease) may be identified through a careful medical history. Apart from acute interstitial pneumonia, the clinical presentations of the idiopathic interstitial pneumonias are sufficiently similar to preclude a specific diagnosis. Chest radiographs and HRCT scans are occasionally diagnostic. Ultimately, many patients with apparently idiopathic disease require surgical lung biopsy to make a definitive diagnosis. The importance of accurate diagnosis is twofold. First, it allows the clinician to provide accurate information about the cause and natural history of the illness. Second, accurate diagnosis helps to distinguish patients most likely to benefit from therapy. Surgical lung biopsy may spare patients with usual interstitial pneumonia treatment with potentially morbid therapies.

The diagnosis of usual interstitial pneumonia can be made on clinical grounds alone in selected patients. A diagnosis of UIP can be made with 90% confidence in patients over 65 who present with idiopathic disease by history, demonstrate inspiratory crackles on physical examination and restrictive physiology on pulmonary function testing, characteristic radiographic evidence of progressive fibrosis over several years, and diffuse, patchy fibrosis with pleural-based honeycombing on high-resolution CT scan. Such patients do not need surgical lung biopsy. Note that the diagnosis of UIP cannot be confirmed on transbronchial lung biopsy since the histologic diagnosis requires a pattern of changes rather than a single pathognomonic finding. Transbronchial biopsy may exclude UIP by confirming a specific alternative diagnosis.

Treatment of idiopathic fibrosing interstitial pneumonia is controversial. No randomized study has demonstrated that any treatment improves survival or quality of life compared with no treatment. Clinical experience suggests that patients with desquamative interstitial pneumonia (DIP; or respiratory bronchiolitis-associated interstitial lung disease, RB-ILD), nonspecific interstitial pneumonia (NSIP), or bronchiolitis obliterans-organizing pneumonia (BOOP) (see [Table 9-19](#)) frequently respond to corticosteroids and should be given a trial of therapy—typically prednisone, 1-2 mg/kg/d for a minimum of 2 months. The same therapy is almost uniformly ineffective in patients with UIP. Since this therapy carries significant morbidity, the pulmonary community no longer recommends routine use of corticosteroids in patients with UIP. A recent phase III clinical trial of interferon gamma-1b in UIP did not demonstrate statistically significant improvement in any of the primary end points: (1) a decrease in forced vital capacity (FVC) of > 10%, (2) an increase in A-a DO₂ of 5 mm Hg, or (3) death. Subgroup analysis showed improved survival in patients with mild to moderate disease. Antifibrotic therapy remains an area of intense research.

SARCOIDOSIS

Sarcoidosis is a systemic disease of unknown cause characterized in about 90% of patients by granulomatous inflammation of the lung. The incidence is highest in North American blacks and northern European whites; among blacks, women are more frequently affected than men. Onset of disease is usually in the third or fourth decade.

Patients may present with malaise, fever, and dyspnea of insidious onset. Symptoms referable to the skin, eyes, peripheral nerves, liver, kidney, or heart may also cause the patient to seek care. Some individuals are asymptomatic and come to medical attention after abnormal findings (typically bilateral hilar and right paratracheal lymphadenopathy) on chest radiographs. Physical findings are atypical of interstitial lung disease: crackles are uncommon on chest examination. Other findings may include erythema nodosum, parotid gland enlargement, hepatosplenomegaly, and lymphadenopathy. Laboratory tests may show leukopenia, an elevated erythrocyte sedimentation rate, and hypercalcemia (about 5% of patients) or hypercalciuria (20%). Angiotensin-converting enzyme (ACE) levels are elevated in 40-80% of patients with active disease. This finding is neither sensitive nor specific enough to have diagnostic significance. Physiologic testing may reveal evidence of airflow obstruction, but restrictive changes with decreased lung volumes and diffusing capacity are more common. Skin test anergy is present in 70%.

Radiographic findings are variable and include bilateral hilar adenopathy alone (stage I), hilar adenopathy and parenchymal involvement (stage II), or parenchymal involvement alone (stage III). Parenchymal involvement is usually manifested radiographically by diffuse reticular infiltrates, but focal infiltrates, acinar shadows, nodules, and, rarely, cavitation may be seen. Pleural effusion is noted in fewer than 10% of patients.

The diagnosis of sarcoidosis generally requires histologic demonstration of noncaseating granulomas in biopsies from a patient with other typical associated manifestations. Other granulomatous diseases (eg, berylliosis, tuberculosis) must be excluded. Biopsy of easily accessible sites (eg, palpable lymph nodes, skin lesions, or salivary glands) is likely to be positive. Transbronchial lung biopsy has a high yield (75-90%) as well, especially in patients with radiographic evidence of parenchymal involvement. Some clinicians believe that tissue biopsy is not necessary when stage I radiographic findings are detected in a clinical situation that strongly favors the diagnosis of sarcoidosis (eg, a young black woman with erythema nodosum). Biopsy is essential whenever clinical and radiographic findings suggest the possibility of an alternative diagnosis such as lymphoma. Bronchoalveolar lavage fluid in sarcoidosis is usually characterized by an increase in lymphocytes and a high CD4/CD8 cell ratio. Bronchoalveolar lavage is useful in following the activity of sarcoidosis in selected patients but does not establish a diagnosis.

Indications for treatment with oral corticosteroids include constitutional symptoms, hypercalcemia, iritis, arthritis, central nervous system involvement, cardiac involvement, granulomatous hepatitis, cutaneous lesions other than erythema nodosum, and symptomatic pulmonary lesions. Long-term therapy is usually required over months to years. Serum ACE levels usually fall with clinical improvement. Immunosuppressive drugs and cyclosporine have been tried, primarily when corticosteroid therapy has been exhausted, but experience with these drugs is limited.

About 20% of patients with lung involvement suffer irreversible lung impairment, characterized by progressive fibrosis, bronchiectasis, and cavitation. Pneumothorax, hemoptysis, mycetoma formation in lung cavities, and respiratory failure often complicate this advanced stage. Myocardial sarcoidosis occurs in about 5% of patients, sometimes leading to restrictive cardiomyopathy, cardiac arrhythmias and conduction disturbances. The outlook is best for patients with hilar adenopathy alone; radiographic involvement of the lung parenchyma is associated with a worse prognosis. Erythema nodosum portends a good outcome. Death due to pulmonary insufficiency occurs in about 5% of patients.

PULMONARY ALVEOLAR PROTEINOSIS

Pulmonary alveolar proteinosis is a disease in which phospholipids accumulate within alveolar spaces. The condition may be primary (idiopathic) or secondary (occurring in immune deficiency, hematologic malignancies, inhalation of mineral dusts, or following lung infections, including tuberculosis and viral infections). Progressive dyspnea is the usual presenting symptom, and chest radiograph shows bilateral alveolar infiltrates suggestive of pulmonary edema. The diagnosis is based on demonstration of characteristic findings on bronchoalveolar lavage (milky appearance and PAS-positive lipoproteinaceous material) in association with typical clinical and radiographic features. In some cases, transbronchial or open lung biopsy (revealing amorphous intra-alveolar phospholipid) is necessary.

The course of the disease varies. Some patients experience spontaneous remission; others develop progressive respiratory insufficiency. Pulmonary infection with nocardia or fungi may occur. Therapy for alveolar proteinosis consists of periodic whole lung lavage.

Shah PL et al: Pulmonary alveolar proteinosis: clinical aspects and current concepts on pathogenesis. Thorax 2000;55:67. [\[PMID: 10607805\]](#)

EOSINOPHILIC PULMONARY SYNDROMES

Eosinophilic pulmonary syndromes are a diverse group of disorders typically characterized by eosinophilic pulmonary infiltrates, peripheral blood eosinophilia, and pulmonary symptoms such as dyspnea and cough. Many patients have constitutional symptoms, including fever. **Chronic eosinophilic pneumonia** is predominantly a disorder of women characterized by fever, night sweats, weight loss, and dyspnea. Pulmonary infiltrates on chest radiography are invariably peripheral. Therapy with oral prednisone (1 mg/kg daily for 1-2 weeks followed by a gradual taper over many months) usually results in dramatic improvement; however, most patients require at least 10-15 mg of prednisone every other day for a year or more (sometimes indefinitely) to prevent relapses.

Other eosinophilic pulmonary syndromes demonstrate a variety of patterns of pulmonary infiltrates associated with exposure to various drugs (common drugs include nitrofurantoin, phenytoin, ampicillin, acetaminophen, and ranitidine) or infection with helminths (eg, ascaris, hookworms, strongyloides) or filariae (eg, *Wuchereria bancrofti*, *Brugia malayi*, tropical pulmonary eosinophilia). Löffler's syndrome is acute eosinophilic pneumonia with transient pulmonary infiltrates. Pulmonary eosinophilia can also be a feature of many other processes, including allergic bronchopulmonary aspergillosis, Churg-Strauss syndrome, systemic hypereosinophilic syndromes, eosinophilic granuloma of the lung (properly referred to as pulmonary Langerhans cell histiocytosis), neoplasms, and numerous interstitial lung diseases. No precipitating cause may be apparent in as many as one-third of cases. If an extrinsic cause is identified, therapy consists of removal of the offending drug or treatment of the underlying parasitic infection. Corticosteroid treatment (prednisone, 1 mg/kg body weight orally per day) should be instituted if no treatable extrinsic cause is discovered. The response to corticosteroids is usually dramatic. Recurrences are common.

■ DISORDERS OF THE PULMONARY CIRCULATION

PULMONARY THROMBOEMBOLISM

- Predisposition to venous thrombosis, usually of the lower extremities.
- One or more of the following: dyspnea, chest pain, hemoptysis, syncope.
- Tachypnea and a widened alveolar-arterial PO₂ difference.
- Characteristic defects on ventilation-perfusion lung scan, helical CT scan of the chest, or pulmonary arteriogram.

General Considerations

Pulmonary thromboembolism, often referred to as pulmonary embolism, is a common, serious and potentially fatal complication of thrombus formation within the deep venous circulation. Pulmonary thromboembolism is estimated to cause 50,000 deaths each year in the United States and is the third leading cause of death among hospitalized patients. Despite this prevalence, the majority of cases are not recognized antemortem, and fewer than 10% of patients with fatal emboli have received specific treatment for the condition. Management demands a vigilant systematic approach to diagnosis and an understanding of risk factors so that appropriate preventive therapy can be given.

Many substances can embolize to the pulmonary circulation, including air (during neurosurgery, as a complication of central venous catheters), amniotic fluid (during active labor), fat (as a complication of long bone fractures), foreign bodies (talc in intravenous drug users), parasite eggs (schistosomiasis), septic emboli (as a complication of acute infectious endocarditis), and tumor cells (renal cell carcinoma). The most common embolus is thrombus, which may arise anywhere in the venous circulation or heart but most often originates in the deep veins of the major calf muscles. Thrombi confined to the calf rarely embolize to the pulmonary circulation. However, about 20% of calf vein thrombi propagate proximally to the popliteal and iliofemoral veins, at which point they may break off and embolize to the pulmonary circulation. Fifty to 60 percent of patients with proximal deep venous thrombosis (DVT) will develop pulmonary emboli; half of these embolic events will be asymptomatic. Nearly 70% of patients who present with symptomatic pulmonary emboli will have lower extremity DVT when evaluated.

Pulmonary embolism and deep venous thrombosis are two manifestations of the same disease. The risk factors for pulmonary emboli are the risk factors for thrombus formation within the venous circulation: venous stasis, injury to the vessel wall, and hypercoagulability. Venous stasis increases with immobility (bed rest—especially postoperative—obesity, stroke), hyperviscosity (polycythemia), and increased central venous pressures (low cardiac output states, pregnancy). Vessels may be damaged by prior episodes of thrombosis, orthopedic surgery, or trauma. Hypercoagulability can be caused by medications (oral contraceptives, hormonal replacement therapy) or disease (malignancy, extensive surgery) or may be the result of inherited gene defects. The most common inherited cause in Caucasian populations is resistance to activated protein C, also known as factor V Leiden. The trait is present in approximately 3% of healthy American men and in 20-40% of patients with idiopathic venous thrombosis. Other major risks for hypercoagulability include the following: deficiencies or dysfunction of protein C, protein S, and antithrombin III; prothrombin gene mutation; and the presence of antiphospholipid antibodies (lupus anticoagulant and anticardiolipin antibody).

Pulmonary thromboembolism has multiple physiologic effects. Physical obstruction of the vascular bed and vasoconstriction from neurohumoral reflexes both increase pulmonary vascular resistance. Massive thrombus may cause right ventricular failure. Vascular obstruction increases physiologic dead space (wasted ventilation) and leads to hypoxemia through right-to-left shunting, decreased cardiac output, and surfactant depletion causing atelectasis. Reflex bronchoconstriction promotes wheezing and increased work of breathing.

Clinical Findings

A. Symptoms and Signs

The clinical diagnosis of pulmonary thromboembolism is notoriously difficult for two reasons. First, the clinical findings depend on both the size of the embolus and the patient's preexisting cardiopulmonary status. Second, common symptoms and signs of pulmonary emboli are not specific to this disorder ([Table 9-20](#)).

Indeed, no single symptom or sign or combination of clinical findings is specific to pulmonary thromboembolism. Some findings are fairly sensitive: dyspnea and pain on inspiration occur in 75-85% and 65-75% of patients, respectively. Tachypnea is the only sign reliably found in more than half of patients. A common clinical strategy is to use combinations of clinical findings to identify patients at low risk for pulmonary thromboembolism. For example, 97% of patients in the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study with angiographically proved pulmonary emboli had one or more of three findings: dyspnea, chest pain with breathing, or tachypnea. Such a sensitive screen allows exclusion of the diagnosis on clinical grounds in a small number of patients. To establish the diagnosis or to exclude it definitively, further testing is required in the majority of patients.

B. Laboratory Findings

The ECG is abnormal in 70% of patients with pulmonary thromboembolism. However, the most common abnormalities are sinus tachycardia and nonspecific ST and T wave changes, each seen in approximately 40% of patients. Five percent or less of patients in the PIOPED study had P pulmonale, right ventricular hypertrophy, right axis deviation, and right bundle branch block.

Arterial blood gases usually reveal acute respiratory alkalosis due to hyperventilation. The arterial PO₂ and the alveolar-arterial oxygen difference (A-a DO₂) are most often abnormal in patients with pulmonary thromboembolism compared with healthy, age-matched controls. However, arterial blood gases are not diagnostic: among patients who presented for evaluation in the PIOPED study, neither the PO₂ nor the A-a DO₂ differentiated between those with and those without pulmonary emboli. Profound hypoxia with a normal chest radiograph in the absence of preexisting lung disease is highly suspicious for pulmonary thromboembolism.

Plasma levels of D-dimer, a degradation product of cross-linked fibrin, are elevated in the presence of thrombus. Using a D-dimer threshold between 300 and 500 ng/mL, the quantitative enzyme-linked immunosorbent assay (ELISA) has shown a sensitivity for venous thromboembolism of 95-97% and a specificity of 45%. Therefore, a D-dimer < 500 ng/mL using the ELISA assay provides strong evidence against venous thromboembolism, with a likelihood ratio of 0.11-0.13. Two considerations have delayed widespread inclusion of plasma D-dimer assays into diagnostic algorithms. First, the accurate quantitative ELISA assay used in clinical research takes several hours to perform and is not widely available. Commonly used latex agglutination assays are much less sensitive and are difficult to standardize. Second, the D-dimer is elevated in most hospitalized patients, particularly those with malignancies or following surgery. Appropriate diagnostic thresholds are not yet established for inpatients.

C. Imaging and Special Examinations

1. Chest radiography—The chest radiograph is necessary to exclude other common lung diseases and to permit interpretation of the ventilation-perfusion scan, but it does not establish the diagnosis by itself. The chest radiograph was normal in only 12% of patients with confirmed pulmonary thromboembolism in the PIOPED study. The most frequent findings were atelectasis, parenchymal infiltrates, and pleural effusions. However, the prevalence of these findings was the same in hospitalized patients without pulmonary thromboembolism. A prominent central pulmonary artery with local oligemia (Westermarck's sign) or pleural-based areas of increased opacity that represent intraparenchymal hemorrhage (Hampton's hump) are uncommon. Paradoxically, the chest radiograph may be most helpful when normal in the setting of hypoxemia.

2. Lung scanning—A perfusion scan is performed by injecting radiolabeled microaggregated albumin into the venous system, allowing the particles to embolize to the pulmonary capillary bed. To perform a ventilation scan, the patient breathes a radioactive gas or aerosol while the distribution of radioactivity in the lungs is recorded.

A defect on perfusion scanning represents diminished blood flow to that region of the lung. This finding is not specific for pulmonary embolism. Defects in the perfusion scan are interpreted in conjunction with the ventilation scan to give a high, low, or intermediate (indeterminate) probability that pulmonary thromboembolism is the cause of the abnormalities. Criteria for the combined interpretation of ventilation and perfusion scans (commonly referred to as a single test, the V/Q scan) are complex, confusing, and not completely standardized. A normal perfusion scan excludes the diagnosis of clinically significant pulmonary thromboembolism (negative predictive value of 91% in the PIOPED study). A high-probability V/Q scan is most often defined as having two or more segmental perfusion defects in the presence of normal ventilation and is sufficient to make the diagnosis of pulmonary thromboembolism in most instances (positive predictive value of 88% among PIOPED patients). In the presence of abnormal pulmonary vasculature, as commonly happens in prior pulmonary thromboembolism, or if the clinical pretest probability for embolism is low, angiography may be indicated even in the presence of a high-probability V/Q scan.

Ventilation-perfusion scans are most helpful when they are either normal or indicate a high probability of pulmonary thromboembolism. Such readings are reliable—interobserver agreement is best for normal and high-probability scans, and they carry predictive power. The likelihood ratios associated with normal and high-probability scans are 0.10 and 18, respectively, indicating significant and frequently conclusive changes from pretest to posttest probability.

However, 75% of PIOPED V/Q scans were nondiagnostic, ie, of low or intermediate probability. At angiography, these patients had an overall incidence of pulmonary thromboembolism of 14% and 30%, respectively. The likelihood ratios associated with low-probability and intermediate scans are 0.36 and 1.2, respectively, confirming the clinical impression that these studies add little diagnostic information. One of the most important findings of PIOPED was that the clinical assessment of pretest probability could be used to aid the interpretation of the V/Q scan. For those patients with low-probability V/Q scans and a low (20% or less) clinical pretest probability of pulmonary thromboembolism, the diagnosis was confirmed in only 4%. Such patients may reasonably be observed without angiography. All other patients with

nondiagnostic V/Q scans require further testing to determine the presence of venous thromboembolism.

3. CT—Helical CT arteriography is rapidly supplanting V/Q scanning as the initial diagnostic study for suspected pulmonary thromboembolism. Helical CT arteriography requires administration of intravenous radiocontrast dye but is otherwise noninvasive. It is very sensitive for the detection of thrombus in the proximal pulmonary arteries but less so in the segmental and subsegmental arteries. Test results vary widely by study and facility. Factors influencing results include patient size and cooperation, the type and quality of the scanner, the imaging protocol, and the experience of the radiologist. One report comparing helical CT with standard arteriography reported sensitivity of 53-60% and specificity of 81-97%. Comparing helical CT to the V/Q scan as the initial test for pulmonary thromboembolism, detection of thrombi is comparable, but more nonthromboembolism pulmonary diagnoses are made with CT scanning. Independent of cost and availability, helical CT may offer advantages as a screening examination, especially in hospitalized patients and in patients with significant comorbidities. A contentious issue is whether a negative helical CT requires any further evaluation. False-negative results may occur in up to 20% of helical CTs. Advocates contend that these false-negatives represent small peripheral thromboemboli and that such patients can be followed off anticoagulation without undue risk. A recent study reported a venous thromboembolism rate of 0.8% in 3-month follow-up of 376 patients with negative helical CT scans, but the mortality rate at 3 months was 10.1%. Further study is required to clarify the role of this diagnostic modality, especially in view of ongoing advances in CT technology and the increasing availability of multi-detector-row scanners.

4. Venous thrombosis studies—Seventy percent of patients with pulmonary thromboembolism will have deep venous thrombosis on evaluation, and approximately half of patients with DVT will have pulmonary thromboembolism on angiography. Since the history and physical examination are neither sensitive nor specific for pulmonary thromboembolism and since the results of V/Q scanning are frequently equivocal, documentation of DVT in a patient with suspected pulmonary thromboembolism establishes the need for treatment and may preclude pulmonary arteriography.

Commonly available diagnostic techniques include venous ultrasonography, impedance plethysmography, and contrast venography. In most centers, venous ultrasonography is the test of choice to detect proximal DVT. Inability to compress the common femoral or popliteal veins in symptomatic patients is diagnostic of first-episode DVT (positive predictive value of 97%); full compressibility of both sites excludes proximal DVT (negative predictive value of 98%). The test is less accurate in distal thrombi, recurrent thrombi, or in asymptomatic patients. Impedance plethysmography relies on changes in electrical impedance between patent and obstructed veins to determine the presence of thrombus. Accuracy is comparable though not quite as high as ultrasonography. Both ultrasonography and impedance plethysmography are useful in the serial examination of patients with high clinical suspicion of venous thromboembolism but negative leg studies. In patients with suspected first-episode DVT and a negative ultrasound or impedance plethysmography examination, multiple studies have confirmed the safety of withholding anticoagulation while conducting two sequential studies on days 1-3 and 7-10. Similarly, patients with nondiagnostic V/Q scans and an initial negative venous ultrasound or impedance plethysmography examination may be followed off therapy with serial leg studies over 2 weeks. When serial examinations are negative for proximal DVT, the risk of subsequent venous thromboembolism over the following 6 months is less than 2%.

Contrast venography remains the reference standard for the diagnosis of DVT. An intraluminal filling defect is diagnostic of venous thrombosis. However, venography has significant shortcomings and has been replaced by venous ultrasound as the diagnostic procedure of choice. Difficulties include patient discomfort, expense, allergic reactions to radiocontrast media, contrast-induced phlebitis, and technical difficulties in cannulation of dorsal foot veins and in the interpretation of studies. There is a significant (2-4%) risk of developing venous thrombosis from the procedure—a risk that may be higher than the false-negative rate of noninvasive studies. Venography is used principally in complex situations where there is discrepancy between clinical suspicion and noninvasive testing.

5. Pulmonary arteriography—Pulmonary arteriography remains the reference standard for the diagnosis of pulmonary thromboembolism. An intraluminal filling defect in more than one projection establishes a definitive diagnosis. Secondary findings highly suggestive of pulmonary thromboembolism include abrupt arterial cutoff, asymmetry of blood flow—especially segmental oligemia—or a prolonged arterial phase with slow filling. Pulmonary arteriography was performed in 755 patients in the PIOPED study. A definitive diagnosis was established in 97%; in 3% the studies were nondiagnostic; and four patients (0.8%) with negative arteriograms subsequently had pulmonary thromboemboli at autopsy. Serial arteriography has demonstrated minimal resolution of thrombus prior to day 7. Thus, negative arteriography prior to day 7 for practical purposes excludes the diagnosis.

Pulmonary arteriography is a safe but invasive procedure with well-defined morbidity and mortality data. Minor complications occur in approximately 5% of patients. Most are allergic contrast reactions, transient renal dysfunction, or related to percutaneous catheter insertion; cardiac perforation and arrhythmias are reported but rare. Among the PIOPED patients who underwent arteriography, there were five deaths (0.7%) directly related to the procedure. Pulmonary hypertension is thought to increase the risk of serious complications, though a study of patients with average pulmonary arterial pressures of 74/34 mm Hg developed no major complications or deaths associated with pulmonary arteriography.

The appropriate role of pulmonary arteriography in the diagnosis of pulmonary thromboembolism remains a subject of active debate. There is wide agreement that arteriography is indicated in several specific situations: in patients with intermediate or high clinical pretest probability of pulmonary thromboembolism, nondiagnostic V/Q scans, and negative noninvasive leg studies; in any patient in whom the diagnosis is in doubt when there is a high clinical pretest probability of pulmonary thromboembolism; and when the diagnosis of pulmonary thromboembolism must be established with certainty, as when anticoagulation is contraindicated or placement of an inferior vena cava filter is contemplated.

6. MRI—MRI has sensitivity and specificity equivalent to contrast venography in the diagnosis of deep venous thrombosis. It has improved sensitivity when compared with venous ultrasound in the diagnosis of DVT, without loss of specificity. The test is noninvasive and avoids the use of potentially nephrotoxic radiocontrast dye. However, it remains expensive and not widely available. Artifacts introduced by respiratory and cardiac motion have limited the use of MRI in the diagnosis of pulmonary thromboembolism. New techniques have improved sensitivity and specificity to levels comparable with helical CT, but MRI remains primarily a research tool for pulmonary thromboembolism.

7. Integrated approach—The integrated approach uses the clinical likelihood of venous thromboembolism along with the overlapping results of noninvasive testing to come to one of three decision points: to establish venous thromboembolism (pulmonary thromboembolism or DVT) as the diagnosis; to exclude venous thromboembolism with sufficient confidence to follow the patient without therapy; or to refer the patient for pulmonary arteriography. An ideal diagnostic algorithm would proceed in a stepwise fashion to come to these decision points in a cost-effective way at minimal risk to the patient. We present two such algorithms in [Figure 9-3](#).

Prevention

Venous thromboembolism is often clinically silent until it presents with significant morbidity or mortality. It is a prevalent disease, clearly associated with identifiable risk factors. For example, the incidence of proximal DVT, pulmonary thromboembolism, and fatal pulmonary thromboembolism in untreated patients undergoing hip fracture surgery is reported to be 10-20%, 4-10%, and 0.2-5%, respectively. There is unambiguous evidence of the efficacy of prophylactic therapy in this and other clinical situations, yet it remains underused. Only about 50% of surgical deaths from pulmonary thromboembolism had received any form of preventive therapy. [Tables 9-21](#) and [9-22](#) provide overviews of strategies for the prevention of venous thromboembolism.

Options for therapy begin with mechanical devices such as graduated-compression stockings and intermittent pneumatic compression. The latter improves venous return and may increase endogenous fibrinolysis by stimulating the vascular endothelium. Standard pharmacologic therapy in medical patients is low-dose unfractionated heparin, 5000 units subcutaneously every 8-12 hours. Low-molecular-weight heparins are more expensive but have several advantages compared with unfractionated heparin: better bioavailability, once- or twice-daily dosing, and a lower incidence of heparin-associated thrombocytopenia. In high-risk surgical patients, low-molecular-weight heparins can be administered without the need for coagulation monitoring and dose adjustments, as would be the case with unfractionated heparin.

Treatment

A. Anticoagulation

Anticoagulation is not definitive therapy but a form of secondary prevention. Heparin binds to and accelerates the ability of antithrombin III to inactivate thrombin, factor Xa, and factor IXa. It thus retards additional thrombus formation, allowing endogenous fibrinolytic mechanisms to lyse existing clot. The standard regimen of heparin followed by 6 months of oral warfarin results in an 80-90% reduction in the risk of both recurrent venous thrombosis and death from pulmonary thromboembolism.

Heparin has troublesome pharmacokinetics. Its clearance is dose-dependent; it is highly protein-bound; and a minimum or threshold level is necessary to achieve an antithrombotic effect. It is necessary to monitor the activated partial thromboplastin time (aPTT) and adjust dosing to maintain the aPTT 1.5-2.5 times control. In patients with a moderate to high clinical likelihood of pulmonary thromboembolism and no contraindications, full anticoagulation with heparin should begin with the diagnostic evaluation. Once the diagnosis of proximal DVT or pulmonary thromboembolism is established, it is critical to ensure adequate therapy. Failure to achieve therapeutic heparin levels within 24 hours is associated with a fivefold-increased risk of clot propagation. The weight-based regimen in [Table 9-23](#) is superior to standard dosing. Heparin causes immune-mediated thrombocytopenia in 3% of patients; therefore, the platelet count should be determined frequently for the first 14 days of therapy.

Low-molecular-weight heparins are depolymerized preparations of heparin with multiple advantages over unfractionated heparin. They exhibit less binding to cells and proteins and have superior bioavailability, a longer plasma half-life, and more predictable dose-response characteristics. They appear to carry an equivalent or lower risk of hemorrhage, and immune-mediated thrombocytopenia is less common. LMW heparins appear to be at least as effective as unfractionated heparin in the

treatment of venous thromboembolism. They are administered in dosages determined by body weight once or twice daily without the need for coagulation monitoring, and subcutaneous administration appears to be as effective as the intravenous route. This profile makes LMW heparins ideal for home-based therapy of venous thromboembolism. Home-based therapy appears safe and efficacious in a small number of selected patients. [Table 9-24](#) sets forth selected LMW heparin anticoagulation regimens.

Anticoagulation therapy for venous thromboembolism is continued for a minimum of 3 months, so oral anticoagulant therapy with warfarin is usually initiated concurrently with heparin. Warfarin affects hepatic synthesis of vitamin K-dependent coagulant proteins. It usually requires 5-7 days to become therapeutic; therefore, heparin is generally continued for 5 days. Warfarin is safe if begun concurrently with heparin, initially at a dose of 2.5-10 mg/d. The lower dose is preferred in elderly patients. Maintenance therapy usually requires 2-15 mg/d. Adequacy of therapy must be monitored by following the prothrombin time, most often adjusted for differences in reagents and reported as the international normalized ratio, or INR. The target INR is 2.5, with the acceptable range from 2.0 to 3.0; below 2.0, there is an increased risk of thrombosis; above 4.0, there is an increased risk of hemorrhage. Warfarin has interactions with many drugs. Meticulous attention to medications is part of the routine management of every patient receiving warfarin. Warfarin is a pregnancy category X medication, indicating known fetopathic and teratogenic effects. When oral anticoagulation with warfarin is contraindicated, LMW heparin is a convenient alternative.

The optimal duration of anticoagulation therapy for venous thromboembolism is unknown. There appears to be a protective benefit to continued anticoagulation in first-episode venous thromboembolism (twice the rate of recurrence in 6 weeks compared with 6 months of therapy) and recurrent disease (eightfold risk of recurrence in 6 months compared with 4 years of therapy). These studies do not distinguish patients with reversible risk factors, such as surgery or transient immobility, from patients who have a nonreversible hypercoagulable state such as factor V Leiden, inhibitor deficiency, antiphospholipid syndrome, or malignancy. A recent randomized controlled trial of low-dose warfarin (INR 1.5-2.0) versus no therapy following 6 months of standard therapy in patients with idiopathic DVT was stopped early. The protective benefits of continued anticoagulation include fewer DVTs in addition to a trend toward lower mortality despite more hemorrhage in the warfarin group. Risk reductions were consistent across groups with and without inherited thrombophilia.

For many patients, venous thrombosis is a recurrent disease, and continued therapy will result in a lower rate of recurrence at the cost of an increased risk of hemorrhage. Therefore, the appropriate duration of therapy will need to take into consideration potentially reversible risk factors, the individual's age, the likelihood and potential consequences of hemorrhage, and patient preferences for continued therapy. It is reasonable to continue therapy for 6 months after a first episode when there is a reversible risk factor, 12 months after a first-episode idiopathic thrombus, and 6-12 months to indefinitely in patients with nonreversible risk factors or recurrent disease. If confirmed, these new data may lead to lifelong low-dose anticoagulation.

The major complication of anticoagulation is hemorrhage. Risk factors for hemorrhage include the intensity of the anticoagulant effect; the duration of therapy; concomitant administration of drugs such as aspirin that interfere with platelet function; and patient characteristics, particularly increased age, previous gastrointestinal hemorrhage, and coexistent renal insufficiency.

The reported incidence of major hemorrhage following intravenous administration of unfractionated heparin is nil to 7%; that of fatal hemorrhage is nil to 2%. The incidence with LMW heparins is not statistically different. There is no information comparing hemorrhage rates at different doses of heparin. The risk of subtherapeutic heparin administration in the first 24-48 hours after diagnosis is significant; it appears to outweigh the risk of short-term supratherapeutic heparin levels. The incidence of hemorrhage during therapy with warfarin is reported to be between 3% and 4% per patient year. The frequency varies with the target INR and is consistently higher when the INR exceeds 4.0. There is no apparent additional antithrombotic benefit in venous thromboembolism with a target INR above 2.0-3.0.

B. Thrombolytic Therapy

Streptokinase, urokinase, and recombinant tissue plasminogen activator (rt-PA; alteplase) increase plasmin levels and thereby directly lyse intravascular thrombi. In patients with established pulmonary thromboembolism, thrombolytic therapy accelerates resolution of emboli within the first 24 hours compared with standard heparin therapy. This is a consistent finding using angiography, V/Q scanning, echocardiography, and direct measurement of pulmonary artery pressures. However, at 1 week and 1 month after diagnosis, these agents show no difference in outcome compared with heparin and warfarin. There is no evidence that thrombolytic therapy improves mortality. Subtle improvements in pulmonary function, including improved single-breath diffusing capacity and a lower incidence of exercise-induced pulmonary hypertension, have been observed. The reliability and clinical importance of these findings is unclear. The major disadvantages of thrombolytic therapy compared with heparin are its greater cost and a significant increase in major hemorrhagic complications. The incidence of intracranial hemorrhage in patients with pulmonary thromboemboli treated with alteplase is 2.1% compared with 0.2% in patients treated with heparin.

Current evidence supports thrombolytic therapy for pulmonary thromboembolism in patients at high risk for death in whom the more rapid resolution of thrombus may be lifesaving. Such patients are usually hemodynamically unstable despite heparin therapy. Absolute contraindications to thrombolytic therapy include active internal bleeding and stroke within the past 2 months. Major contraindications include uncontrolled hypertension and surgery or trauma within the past 6 weeks.

C. Additional Measures

Interruption of the inferior vena cava may be indicated in patients with a major contraindication to anticoagulation who have or are at high risk for development of proximal deep vein thrombosis or pulmonary embolus. Placement of an inferior vena cava filter is also recommended for recurrent thromboembolism despite adequate anticoagulation, for chronic recurrent embolism with pulmonary hypertension, and with the concurrent performance of surgical pulmonary embolectomy or pulmonary thromboendarterectomy. Percutaneous transjugular placement of a mechanical filter is the preferred mode of inferior vena cava interruption. These devices reduce the short-term incidence of pulmonary thromboemboli in patients presenting with proximal lower extremity deep venous thrombosis. However, they are associated with a two-fold increased risk of recurrent deep venous thrombosis in the first 2 years following placement.

In rare critically ill patients for whom thrombolytic therapy is contraindicated or unsuccessful, mechanical or surgical extraction of thrombus may be indicated. Pulmonary embolectomy is an emergency procedure of last resort with a very high mortality rate. It is now performed only in a few specialized centers. Several catheter devices to fragment and extract thrombus through a transvenous approach have been reported in small numbers of patients. Comparative outcomes with surgery, thrombolytic therapy, or heparin have not been studied.

Prognosis

Pulmonary thromboembolism is estimated to cause more than 50,000 deaths annually. In the majority of deaths, pulmonary thromboembolism is not recognized antemortem or death occurs before specific treatment can be initiated. These statistics highlight the importance of preventive therapy in high-risk patients. The outlook for patients with diagnosed and appropriately treated pulmonary thromboembolism is generally good. Overall prognosis depends on the underlying disease rather than the pulmonary thromboembolism itself. Death from recurrent thromboemboli is uncommon, occurring in less than 3% of cases. Perfusion defects resolve in most survivors. Approximately 1% of patients develop chronic thromboembolic pulmonary hypertension. Selected patients may benefit from pulmonary endarterectomy.

PULMONARY HYPERTENSION

Essentials of Diagnosis

- Dyspnea, fatigue, chest pain, and syncope on exertion.

- Narrow splitting of second heart sound with loud pulmonary component; findings of right ventricular hypertrophy and cardiac failure in advanced disease.
- Hypoxemia and increased wasted ventilation on pulmonary function tests.
- Electrocardiographic evidence of right ventricular strain or hypertrophy and right atrial enlargement.
- Enlarged central pulmonary arteries on chest radiograph.

General Considerations

The pulmonary circulation is unique because of its high blood flow, low pressure (normally 25/8 mm Hg, mean 12), and low resistance (normally 200-250 dynes/sec/cm⁵). It can accommodate large increases in blood flow during exercise with only modest increases in pressure because of its ability to recruit and distend lung blood vessels. The normal pulmonary circulation is largely passive, since its pressures are determined mainly by the function of the right and left ventricles. Contraction of smooth muscle in the walls of pulmonary arteriolar resistance vessels becomes an important factor in numerous pathologic states. Pulmonary hypertension is present when pulmonary artery pressure rises to a level inappropriate for a given cardiac output. Once present, pulmonary hypertension is self-perpetuating. It induces secondary structural abnormalities in pulmonary vessels, including smooth muscle hypertrophy and intimal proliferation, and these may eventually stimulate atheromatous changes and in situ thrombosis, leading to further narrowing of the arterial bed.

Primary (idiopathic) pulmonary hypertension (see [Chapter 10](#)) is a rare disorder of the pulmonary circulation occurring mostly in young and middle-aged women. It is characterized by progressive dyspnea, a rapid downhill course, and an invariably fatal outcome. This condition is also called plexogenic pulmonary arteriopathy, in reference to the characteristic histopathologic plexiform lesion found in muscular pulmonary arteries. It has been observed in occasional patients with HIV infection.

Selected mechanisms responsible for **secondary pulmonary hypertension** and examples of corresponding clinical conditions are set forth in [Table 9-25](#). Pulmonary arteriolar vasoconstriction due to chronic hypoxemia may complicate any chronic lung disease and compound the effects of loss of pulmonary blood vessels (as seen with disorders such as emphysema and pulmonary fibrosis) and obstruction of the pulmonary vascular bed (as seen with disorders such as chronic pulmonary thromboembolic disease). Sustained increases in pulmonary venous pressure from disorders such as left ventricular failure (systolic, diastolic, or both), mitral stenosis, and pulmonary veno-occlusive disease may cause "postcapillary" pulmonary hypertension. Increased pulmonary blood flow due to intracardiac shunts and increased blood viscosity due to polycythemia can also cause pulmonary hypertension. Pulmonary hypertension has also been associated with hepatic cirrhosis and portal hypertension.

Pulmonary veno-occlusive disease is a rare cause of postcapillary pulmonary hypertension occurring in children and young adults. The cause is unknown, but associations with various conditions such as viral infection, bone marrow transplantation, chemotherapy, and malignancy have been described. The disease is characterized by progressive fibrotic occlusion of pulmonary veins and venules, along with secondary hypertensive changes in the pulmonary arterioles and muscular pulmonary arteries. Nodular areas of pulmonary congestion, edema, hemorrhage, and hemosiderosis are found. Chest radiography reveals prominent, symmetric interstitial markings, Kerley B lines, pulmonary artery dilation, and normally sized left atrium and left ventricle. Antemortem diagnosis is often difficult but is occasionally established by open lung biopsy. There is no effective therapy, and most patients die within 2 years as a result of progressive pulmonary hypertension.

Clinical Findings

A. Symptoms and Signs

Secondary pulmonary hypertension is difficult to recognize clinically in the early stages, when symptoms and signs are primarily those of the underlying disease. Pulmonary hypertension may cause or contribute to dyspnea, present initially on exertion and later at rest. Dull, retrosternal chest pain resembling angina pectoris may be present. Fatigue and syncope on exertion also occur, presumably a result of reduced cardiac output related to elevated pulmonary artery pressures or bradycardia.

The signs of pulmonary hypertension include narrow splitting of the second heart sound, accentuation of the pulmonary component of the second heart sound, and a systolic ejection click. In advanced cases, tricuspid and pulmonary valve insufficiency and signs of right ventricular failure and cor pulmonale are found.

B. Laboratory Findings

Polycythemia is found in many cases of pulmonary hypertension that are associated with chronic hypoxemia. Electrocardiographic changes are those of right axis deviation, right ventricular hypertrophy, right ventricular strain, or right atrial enlargement.

C. Imaging and Special Examinations

Chest radiographs (plain films as well as high-resolution CT scans) can assist in the diagnosis of pulmonary hypertension as well as determination of the cause. Radiographic findings depend on the cause of pulmonary hypertension. In chronic disease, dilation of the right and left main and lobar pulmonary arteries and enlargement of the pulmonary outflow tract are seen; in advanced disease, right ventricular and right atrial enlargement are seen. Peripheral "pruning" of large pulmonary arteries is characteristic of pulmonary hypertension in severe emphysema.

Echocardiography is helpful in evaluating patients thought to have mitral stenosis, left atrial myxoma, and pulmonary valvular disease and may also reveal right ventricular enlargement and paradoxical motion of the interventricular septum. Doppler ultrasonography is a reliable noninvasive means of estimating pulmonary artery systolic pressure. However, precise hemodynamic measurements can only be obtained with right heart catheterization, which is helpful when postcapillary pulmonary hypertension, intracardiac shunting, or thromboembolic disease is considered as part of the differential diagnosis.

Routine pulmonary function tests reveal no findings diagnostic of pulmonary hypertension. However, they may help identify the cause. Diminution of the pulmonary capillary bed may cause reduction in the single breath diffusing capacity.

The following studies may be useful to exclude causes of secondary pulmonary hypertension: liver function tests, HIV test, collagen-vascular serologic studies, polysomnography, ventilation-perfusion lung scanning, pulmonary angiography, and surgical lung biopsy. Ventilation-perfusion lung scanning is very helpful in identifying patients with pulmonary hypertension caused by recurrent pulmonary thromboemboli, a condition that is often very difficult to recognize clinically.

Treatment

Treatment of primary pulmonary hypertension is discussed in [Chapter 10](#). Treatment of secondary pulmonary hypertension consists mainly of treating the underlying disorder. Early recognition of pulmonary hypertension is crucial to interrupt the self-perpetuating cycle responsible for rapid clinical progression. By the time most patients present with symptoms and signs of pulmonary hypertension, however, the condition is far advanced. If hypoxemia or acidosis is detected, corrective measures should be started immediately. Inhaled nitric oxide has been found to be effective in lowering the pulmonary artery pressure in critically ill patients with pulmonary hypertension, asthma, and acute respiratory distress syndrome. This benefit is only temporary, however. Supplemental oxygen administered for at least 15 hours per day has been demonstrated to slow the progression of pulmonary hypertension in patients with hypoxemic COPD.

Some clinicians employ permanent anticoagulation therapy in pulmonary hypertension of unknown cause, since multiple small pulmonary emboli or in situ thrombosis may produce this picture and be difficult to recognize clinically. Vasodilator therapy using various pharmacologic agents (eg, calcium antagonists, hydralazine, isoproterenol, diazoxide, nitroglycerin) has been tried in primary pulmonary hypertension and a few patients with secondary pulmonary hypertension with disappointing results. Patients most likely to benefit from long-term pulmonary vasodilator therapy are those who respond favorably to a vasodilator challenge at right heart catheterization. It is clear that long-term oral vasodilator therapy should be employed only if hemodynamic benefit is documented. Complications of pulmonary vasodilator therapy include systemic hypotension, hypoxemia, and even death.

Continuous long-term intravenous infusion (using a portable pump) of prostacyclin (PGI₂; epoprostenol), a potent pulmonary vasodilator, has been shown to confer hemodynamic and symptomatic benefits in selected patients with primary or secondary pulmonary hypertension. Continuous infusion prostacyclin is the first therapy to demonstrate improved survival of patients with primary pulmonary hypertension. Drawbacks of therapy are difficulties in titration, technical problems with portable delivery systems, and the high cost of the drug.

Patients with marked polycythemia (hematocrit > 60%) should undergo repeated phlebotomy in an attempt to reduce blood viscosity. Cor pulmonale complicating pulmonary hypertension is treated by managing the underlying pulmonary disease and by using diuretics, salt restriction, and, in appropriate patients, supplemental oxygen. The use of digitalis in cor pulmonale remains controversial. Pulmonary thromboendarterectomy may benefit selected patients with pulmonary hypertension secondary to chronic thrombotic obstructions of major pulmonary arteries.

Single or double lung transplantation may be performed on patients with end-stage primary pulmonary hypertension. The two-year survival rate is 50%. Bronchiolitis obliterans is common in those who survive the operation.

Prognosis

The prognosis in secondary pulmonary hypertension depends on the course of the underlying disease. Patients with pulmonary hypertension due to fixed obliteration of the pulmonary vascular bed generally respond poorly to therapy; development of cor pulmonale in these cases implies a poor prognosis. The prognosis is favorable

when pulmonary hypertension is detected early and the conditions leading to it are readily reversed.

PULMONARY VASCULITIS

Wegener's granulomatosis is an idiopathic disease manifested by a combination of glomerulonephritis, necrotizing granulomatous vasculitis of the upper and lower respiratory tracts, and varying degrees of small vessel vasculitis (see [Chapter 20](#)). Chronic sinusitis, arthralgias, fever, skin rash, and weight loss are frequent presenting symptoms. Pulmonary complaints occur less often. The most common sign of lung disease is nodular pulmonary infiltrates, often with cavitation, seen on chest radiography. Tracheal stenosis and endobronchial disease are sometimes seen.

Normochromic anemia, normocytic anemia, mild leukocytosis, and thrombocytosis are common, and virtually all patients have an elevated erythrocyte sedimentation rate. Serum anti-neutrophil cytoplasmic antibodies (ANCAs) that display a cytoplasmic immunofluorescent staining pattern (c-ANCAs) are elevated in 90% of patients with active Wegener's granulomatosis and in 40% of patients in remission. The specificity of c-ANCA is about 90% for the diagnosis of Wegener's granulomatosis. ANCAs that display a perinuclear immunofluorescent staining pattern (p-ANCAs) are not specific for Wegener's granulomatosis but may be seen in Wegener's variants such as microscopic polyangiitis and other types of vasculitis, rheumatoid arthritis, liver disease, and inflammatory bowel disease. The diagnosis is most often based on biopsy of lung, sinus tissue, or kidney with demonstration of necrotizing granulomatous vasculitis.

Allergic angiitis and granulomatosis (Churg-Strauss syndrome) is an idiopathic multisystem vasculitis of small and medium-sized arteries that occurs in patients with asthma. Histologic features include fibrinoid necrotizing epithelioid and eosinophilic granulomas. The skin and lungs are most often involved, but other organs, including the heart, gastrointestinal tract, liver, and peripheral nerves, may also be affected. Marked peripheral eosinophilia is the rule. Abnormalities on chest radiographs range from transient infiltrates to multiple nodules. This illness may be part of a spectrum that includes polyarteritis nodosa.

Treatment of pulmonary vasculitis consists of combination therapy with corticosteroids and cyclophosphamide. Oral prednisone (1 mg/kg ideal body weight per day initially, tapering slowly to alternate-day therapy over 3-6 months) is the corticosteroid of choice; in Wegener's granulomatosis, some clinicians may omit the use of steroids. For fulminant vasculitis, therapy may be initiated with intravenous methylprednisolone (up to 1 g intravenously per day) for several days. Cyclophosphamide (1-2 mg/kg ideal body weight per day initially, with dosage adjustments to avoid neutropenia) is given daily by mouth for at least 1 year after complete remission is obtained and then is slowly tapered.

Five-year survival rates in patients with these vasculitis syndromes have been improved by the combination therapy. Complete remissions can be achieved in over 90% of patients with Wegener's granulomatosis. The addition of trimethoprim-sulfamethoxazole (one double-strength tablet by mouth twice daily) to standard therapy may help prevent relapses, but its role as sole therapy or as part of combination therapy in patients with active disease remains uncertain.

ALVEOLAR HEMORRHAGE SYNDROMES

Diffuse alveolar hemorrhage may occur in a variety of immune and nonimmune disorders. Hemoptysis, alveolar infiltrates on chest radiograph, anemia, dyspnea, and occasionally fever are characteristic. Rapid clearing of diffuse lung infiltrates within 2 days is a clue to the diagnosis of diffuse alveolar hemorrhage. Pulmonary hemorrhage can be associated with an increased D_LCO .

Causes of **immune alveolar hemorrhage** have been classified as anti-basement membrane antibody disease (Goodpasture's syndrome), vasculitis and collagen vascular disease (systemic lupus erythematosus, Wegener's granulomatosis, systemic necrotizing vasculitis, and others), and pulmonary capillaritis associated with idiopathic rapidly progressive glomerulonephritis. **Nonimmune causes** of diffuse hemorrhage include coagulopathy, mitral stenosis, necrotizing pulmonary infection, drugs (penicillamine), toxins (trimellitic anhydride), and idiopathic pulmonary hemosiderosis.

Goodpasture's syndrome is idiopathic recurrent alveolar hemorrhage and rapidly progressive glomerulonephritis. The disease is mediated by anti-glomerular basement membrane antibodies. Goodpasture's syndrome occurs mainly in men who are in their 30s and 40s. Hemoptysis is the usual presenting symptom, but pulmonary hemorrhage may be occult. Dyspnea, cough, hypoxemia, and diffuse bilateral alveolar infiltrates are typical features. Iron deficiency anemia and microscopic hematuria are usually present. The diagnosis is based on characteristic linear IgG deposits in glomeruli or alveoli by immunofluorescence and on the presence of anti-glomerular basement membrane antibody in serum. Combinations of immunosuppressive drugs (initially methylprednisolone, 30 mg/kg intravenously over 20 minutes every other day for three doses, followed by daily oral prednisone, 1 mg/kg/d; with cyclophosphamide, 2 mg/kg by mouth per day) and plasmapheresis have yielded excellent results.

Idiopathic pulmonary hemosiderosis is a disease of children or young adults characterized by recurrent pulmonary hemorrhage; in contrast to Goodpasture's syndrome, renal involvement and anti-glomerular basement membrane antibodies are absent, but iron deficiency is typical. Treatment of acute episodes of hemorrhage with corticosteroids may be useful. Recurrent episodes of pulmonary hemorrhage may result in interstitial fibrosis and pulmonary failure.

■ ENVIRONMENTAL & OCCUPATIONAL LUNG DISORDERS

SMOKE INHALATION

The inhalation of products of combustion may cause serious respiratory complications. As many as one-third of patients admitted to burn treatment units have pulmonary injury from smoke inhalation. Morbidity and mortality due to smoke inhalation exceed those attributed to the burns themselves. The death rate of patients with both severe burns and smoke inhalation exceeds 50%.

All patients suspected of having significant smoke inhalation must be assessed for three consequences of smoke inhalation: impaired tissue oxygenation, thermal injury to the upper airway, and chemical injury to the lung. Impaired tissue oxygenation results from inhalation of carbon monoxide or cyanide and is an immediate threat to life. The management of patients with carbon monoxide and cyanide poisoning is discussed in [Chapter 39](#). The clinician must recognize that patients with carbon monoxide poisoning display a normal partial pressure of oxygen in arterial blood (PaO_2) but have a low *measured* (ie, not oximetric) hemoglobin saturation (SaO_2). Immediate treatment with 100% oxygen is essential and should be continued until the measured carboxyhemoglobin level falls to less than 10% and concomitant metabolic acidosis has resolved.

Thermal injury to the mucosal surfaces of the upper airway occurs from inhalation of hot gases. Complications become evident by 18-24 hours. These include edema, impaired ability to clear oral secretions, and upper airway obstruction, producing inspiratory stridor. Respiratory failure occurs in severe cases. Early management (see also [Chapter 38](#)) includes the use of a high-humidity face mask with supplemental oxygen, gentle suctioning to evacuate oral secretions, elevation of the head 30 degrees to promote clearing of secretions, and topical epinephrine to reduce edema of the oropharyngeal mucous membrane. Helium-oxygen gas mixtures (Heliox) may reduce labored breathing due to upper airway narrowing. Close monitoring with arterial blood gases and later with oximetry is important. Examination of the upper airway with a fiberoptic laryngoscope or bronchoscope is superior to routine physical examination. Endotracheal intubation is often necessary to establish airway patency and is likely to be necessary in patients with deep facial burns or oropharyngeal or laryngeal edema. Tracheotomy should be avoided if possible because of an increased risk of pneumonia and death from sepsis.

Chemical injury to the lung results from inhalation of toxic gases and products of combustion, including aldehydes and organic acids. The site of lung injury depends upon the solubility of the gases inhaled, the duration of exposure, and the size of inhaled particles that transport noxious gases to distal lung units. Bronchorrhea and bronchospasm are seen early after exposure along with dyspnea, tachypnea, and tachycardia. Labored breathing and cyanosis may follow. Physical examination at this stage reveals diffuse wheezing and rhonchi. Bronchiolar edema and high-permeability pulmonary edema (ARDS) may develop within 1-2 days after exposure. Sloughing of the bronchiolar mucosa may occur within 2-3 days, leading to airway obstruction, atelectasis, and worsening hypoxemia. Bacterial colonization and pneumonia are common by 5-7 days after the exposure.

Treatment of smoke inhalation consists of supplemental oxygen, bronchodilators, suctioning of mucosal debris and mucopurulent secretions via an indwelling endotracheal tube, chest physical therapy to aid clearance of secretions, and adequate humidification of inspired gases. Positive end-expiratory pressure (PEEP) has been advocated to treat bronchiolar edema. Judicious fluid management and close monitoring for secondary bacterial infection with daily sputum Gram stains round out the management protocol.

The routine use of corticosteroids for chemical lung injury from smoke inhalation has been shown to be ineffective and may even be harmful. Routine or prophylactic use of antibiotics is not recommended.

Those patients who survive should be watched for the development of late bronchiolitis obliterans.

PULMONARY ASPIRATION SYNDROMES

Aspiration of foreign material into the tracheobronchial tree results from various disorders that impair normal deglutition, especially disturbances of consciousness and esophageal dysfunction.

Aspiration of Inert Material

Aspiration of inert material may cause asphyxia if the amount aspirated is massive and if cough is impaired, in which case immediate tracheobronchial suctioning is necessary. Most patients suffer no serious sequelae from aspiration of inert material.

Aspiration of Toxic Material

Aspiration of toxic material into the lung usually results in clinically evident pneumonia. **Hydrocarbon pneumonitis** is caused by aspiration of ingested petroleum distillates, eg, gasoline, kerosene, furniture polish, and other household petroleum products. Lung injury results mainly from vomiting and secondary aspiration. Therapy is supportive. The lung should be protected from repeated aspiration with a cuffed endotracheal tube if necessary. **Lipoid pneumonia** is a chronic syndrome related to the repeated aspiration of oily materials, eg, mineral oil, cod liver oil, and oily nose drops; it often occurs in elderly patients with impaired swallowing. Patchy infiltrates in dependent lung zones and lipid-laden macrophages in expectorated sputum are characteristic findings.

"Cafe Coronary"

Acute obstruction of the upper airway by food is associated with difficulty in swallowing, old age, dental problems that impair chewing, and use of alcohol and sedative drugs. The Heimlich procedure is lifesaving in many cases.

Retention of an Aspirated Foreign Body

Retention of an aspirated foreign body in the tracheobronchial tree may produce both acute and chronic conditions, including recurrent pneumonia, bronchiectasis, lung abscess, atelectasis, and postobstructive hyperinflation. Occasionally, a misdiagnosis of asthma, COPD, or lung cancer is made in adult patients who have aspirated a foreign body. The plain chest radiograph usually suggests the site of the foreign body. In some cases, an expiratory film, demonstrating regional hyperinflation due to a check-valve effect, is helpful. Bronchoscopy is usually necessary to establish the diagnosis and attempt removal of the foreign body.

Baharloo F et al: Tracheobronchial foreign bodies: presentation and management in children and adults. Chest 1999;115: 1357. [PMID: 10334153]

Chronic Aspiration of Gastric Contents

Chronic aspiration of gastric contents may result from primary disorders of the larynx or the esophagus, such as achalasia, esophageal stricture, systemic sclerosis (scleroderma), esophageal carcinoma, esophagitis, and gastroesophageal reflux. In the last condition, relaxation of the tone of the lower esophageal sphincter allows reflux of gastric contents into the esophagus and predisposes to chronic pulmonary aspiration, especially at night. Cigarette smoking, consumption of alcohol, and use of theophylline are known to relax the lower esophageal sphincter. Pulmonary disorders linked to gastroesophageal reflux and chronic aspiration include bronchial asthma, pulmonary fibrosis, and bronchiectasis. Even in the absence of aspiration, acid in the esophagus may trigger bronchospasm through reflex mechanisms.

The diagnosis of chronic aspiration is difficult. Ambulatory monitoring of esophageal pH for 24 hours detects esophageal reflux. Esophagogastroscope and barium swallow are sometimes necessary to rule out esophageal disease. Management consists of elevation of the head of the bed, cessation of smoking, weight reduction, and antacids, H₂ receptor antagonists (eg, cimetidine, 300-400 mg), or proton pump inhibitors (eg, omeprazole, 20 mg) at night. Metoclopramide (10-15 mg orally four times daily or 20 mg at bedtime), or bethanechol (10-25 mg at bedtime) may also be helpful in some patients with gastroesophageal reflux.

Acute Aspiration of Gastric Contents (Mendelson's Syndrome)

Acute aspiration of gastric contents is often catastrophic. The pulmonary response depends on the characteristics and amount of the gastric contents aspirated. The more acidic the material, the greater the degree of chemical pneumonitis. Aspiration of pure gastric acid (pH < 2.5) causes extensive desquamation of the bronchial epithelium, bronchiolitis, hemorrhage, and pulmonary edema. Acute gastric aspiration is one of the commonest causes of adult respiratory distress syndrome. The clinical picture is one of abrupt onset of respiratory distress, with cough, wheezing, fever, and tachypnea. Crackles are audible at the bases of the lungs. Hypoxemia may be noted immediately after aspiration occurs. Radiographic abnormalities, consisting of patchy alveolar infiltrates in dependent lung zones, appear within a few hours. If particulate food matter has been aspirated along with gastric acid, radiographic features of bronchial obstruction may be observed. Fever and leukocytosis are common even in the absence of superinfection.

Treatment of acute aspiration of gastric contents consists of supplemental oxygen, measures to maintain the airway, and the usual measures for treatment of acute respiratory failure. There is no evidence to support the routine use of corticosteroids or prophylactic antibiotics after gastric aspiration has occurred. Secondary pulmonary infection, which occurs in about one-fourth of patients, typically appears 2-3 days after aspiration. Management of this complication depends upon the observed flora of the tracheobronchial tree. Hypotension secondary to alveolocapillary membrane injury and intravascular volume depletion is common and is managed with the judicious administration of intravenous fluids.

OCCUPATIONAL PULMONARY DISEASES

Many acute and chronic pulmonary diseases are directly related to inhalation of noxious substances encountered in the workplace. Disorders that are due to chemical agents may be classified as follows: (1) pneumoconioses, (2) hypersensitivity pneumonitis, (3) obstructive airway disorders, (4) toxic lung injury, (5) lung cancer, (6) pleural diseases, and (7) miscellaneous disorders.

Pneumoconioses

Pneumoconioses are chronic fibrotic lung diseases caused by the inhalation of coal dust and various other inert, inorganic, or silicate dusts (Table 9-26). Pneumoconioses due to inhalation of inert dusts may be asymptomatic disorders with diffuse nodular infiltrates on chest radiograph. Clinically important pneumoconioses include coal workers' pneumoconiosis, silicosis, and asbestosis. Treatment for each is supportive.

A. Coal Worker's Pneumoconiosis

In coal worker's pneumoconiosis, ingestion of inhaled coal dust by alveolar macrophages leads to the formation of coal macules, usually 2-5 mm in diameter, which appear on chest radiograph as diffuse small opacities that are especially prominent in the upper lung. Simple coal worker's pneumoconiosis is usually asymptomatic; pulmonary function abnormalities are unimpressive. Cigarette smoking does not increase the prevalence of coal worker's pneumoconiosis but may have an additive detrimental effect on ventilatory function. In complicated coal worker's pneumoconiosis ("progressive massive fibrosis"), conglomeration and contraction in the upper lung zones occur, with radiographic features resembling complicated silicosis. **Caplan's syndrome** is a rare condition characterized by the presence of necrobiotic rheumatoid nodules (1-5 cm in diameter) in the periphery of the lung in coal workers with rheumatoid arthritis.

B. Silicosis

In silicosis, extensive or prolonged inhalation of free silica (silicon dioxide) particles in the respirable range (0.3-5 μ m) causes the formation of small rounded opacities (silicotic nodules) throughout the lung. Calcification of the periphery of hilar lymph nodes ("eggshell" calcification) is an unusual finding that strongly suggests silicosis. Simple silicosis is usually asymptomatic and has no effect on routine pulmonary function tests; in complicated silicosis, large conglomerate densities appear in the upper lung and are accompanied by dyspnea and obstructive and restrictive pulmonary dysfunction. The incidence of pulmonary tuberculosis is increased in patients with chronic silicosis. All patients with silicosis should have a tuberculin skin test and a current chest radiograph. If old, healed pulmonary tuberculosis is suspected, multidrug treatment for tuberculosis (not single-agent preventive therapy) should be instituted.

C. Asbestosis

Asbestosis is a nodular interstitial fibrosis occurring in asbestos workers and miners is characterized by inexorably progressive dyspnea, inspiratory crackles, and in some cases, clubbing and cyanosis. The radiographic features include interstitial fibrosis, thickened pleura, and calcified plaques (pleural) on the diaphragms or lateral chest wall. The lower lungs are more often involved than the upper. High-resolution CT scanning is the best imaging method in asbestosis because of its ability to detect parenchymal fibrosis and define the presence of coexisting pleural plaques. Cigarette smoking in asbestos workers increases the prevalence of radiographic pleural and parenchymal changes and markedly increases the incidence of lung carcinoma. It may also interfere with the clearance of short asbestos fibers from the lung. Pulmonary function studies show restrictive dysfunction and reduced diffusing capacity. There is no specific treatment.

Scarlsbrick D: Silicosis and coal workers' pneumoconiosis. Practitioner 2002;246:114. [\[PMID: 11852619\]](#)

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis (extrinsic allergic alveolitis) is a nonatopic, nonasthmatic allergic pulmonary disease. It is manifested mainly as occupational disease ([Table 9-27](#)), in which exposure to inhaled organic agents leads to acute and eventually chronic pulmonary disease. Acute illness is characterized by sudden onset of malaise, chills, fever, cough, dyspnea, and nausea 4-8 hours after exposure to the offending agent. This may occur after the patient has left work or even at night and thus may mimic paroxysmal nocturnal dyspnea. Bibasilar crackles, tachypnea, tachycardia, and (occasionally) cyanosis are noted. Small nodular densities sparing the apices and bases of the lungs are noted on chest radiograph. Pulmonary function studies reveal restrictive dysfunction and reduced diffusing capacity. Laboratory studies reveal an increase in the white blood cell count with a shift to the left, hypoxemia, and the presence of precipitating antibodies to the offending agent in serum. Hypersensitivity pneumonitis antibody panels against common offending antigens are available.

Acute hypersensitivity pneumonitis is characterized by interstitial infiltrates of lymphocytes and plasma cells, with noncaseating granulomas in the interstitium and air spaces. A subacute hypersensitivity pneumonitis syndrome (15% of cases) has been described that is characterized by the insidious onset of chronic cough and slowly progressive dyspnea, anorexia, and weight loss. Chronic respiratory insufficiency and the appearance of pulmonary fibrosis on radiographs may occur after repeated exposure to the offending agent. Surgical lung biopsy is occasionally necessary for diagnosis. Diffuse fibrosis is the hallmark of the subacute and chronic phases.

Treatment of hypersensitivity pneumonitis consists of identification of the offending agent, avoidance of further exposure, and, in severe acute or protracted cases, oral corticosteroids (prednisone, 0.5 mg/kg daily as a single morning dose, tapered to nil over 4-6 weeks). Change in occupation is often unavoidable.

Hayakawa H et al: Clinicopathological features of chronic hypersensitivity pneumonitis. Respirology. 2002;7:359. [\[PMID: 12421245\]](#)

Obstructive Airway Disorders

Occupational pulmonary diseases manifested as obstructive airway disorders include occupational asthma, industrial bronchitis, and byssinosis.

A. Occupational Asthma

It has been estimated that from 2% to 5% of all cases of asthma are related to occupation. Offending agents in the workplace are numerous; they include grain dust, wood dust, tobacco, pollens, enzymes, gum arabic, synthetic dyes, isocyanates (particularly toluene diisocyanate), rosin (soldering flux), inorganic chemicals (salts of nickel, platinum, and chromium), trimellitic anhydride, phthalic anhydride, formaldehyde, and various pharmaceutical agents. Diagnosis of occupational asthma depends on a high index of suspicion, an appropriate history, spirometric studies before and after exposure to the offending substance, and peak flow rate measurements in the workplace. Bronchial provocation testing may be helpful in some cases. Treatment consists of avoidance of further exposure to the offending agent and bronchodilators, but symptoms may persist for years after workplace exposure has been terminated.

B. Industrial Bronchitis

Industrial bronchitis is chronic bronchitis found in coal miners and others exposed to cotton, flax, or hemp dust. Chronic disability from industrial bronchitis is infrequent.

C. Byssinosis

Byssinosis is an asthma-like disorder in textile workers caused by inhalation of cotton dust. The pathogenesis is obscure. Chest tightness, cough, and dyspnea are characteristically worse on Mondays or the first day back at work, with symptoms subsiding later in the week. Repeated exposure leads to chronic bronchitis.

Toxic Lung Injury

Toxic lung injury from inhalation of irritant gases is discussed in the section on smoke inhalation. **Silo-filler's disease** is acute toxic high-permeability pulmonary edema caused by inhalation of nitrogen dioxide encountered in recently filled silos. Bronchiolitis obliterans is a common late complication, which may be prevented by early treatment of the acute reaction with corticosteroids. Extensive exposure to silage gas may be fatal.

Lung Cancer

Many industrial pulmonary carcinogens have been identified, including asbestos, radon gas, arsenic, iron, chromium, nickel, coal tar fumes, petroleum oil mists, isopropyl oil, mustard gas, and printing ink. Cigarette smoking acts as a cocarcinogen with asbestos and radon gas to cause bronchogenic carcinoma. Asbestos alone causes malignant mesothelioma. Almost all histologic types of lung cancer have been associated with these carcinogens. Chloromethyl methyl ether specifically causes small cell carcinoma of the lung.

Pleural Diseases

Occupational diseases of the pleura may result from exposure to asbestos (see above) or talc. Inhalation of talc causes pleural plaques that are similar to those caused by asbestos. Benign asbestos pleural effusion occurs in some asbestos workers and may cause chronic blunting of the costophrenic angle on chest radiograph.

Other Occupational Pulmonary Diseases

Occupational agents are also responsible for other pulmonary disorders. These include **berylliosis**, an acute or chronic pulmonary disorder related to exposure to beryllium, which is absorbed through the lungs or skin and widely disseminated throughout the body. Acute berylliosis is a toxic, ulcerative tracheobronchitis and chemical pneumonitis following intense and severe exposure to beryllium. Chronic berylliosis, a systemic disease closely resembling sarcoidosis, is more common. Chronic pulmonary beryllium disease is thought to be an alveolitis mediated by the proliferation of beryllium-specific helper-inducer T cells in the lung. Exposure to beryllium now occurs in machining and handling of beryllium products and alloys. Beryllium miners are not at risk for berylliosis. Beryllium is no longer used in fluorescent lamp production, which was a source of exposure before 1950.

DRUG-INDUCED LUNG DISEASE

Typical patterns of pulmonary response to drugs implicated in drug-induced respiratory disease are summarized in [Table 9-28](#). Pulmonary injury due to drugs occurs as a result of allergic reactions, idiosyncratic reactions, overdose, or undesirable side effects. In most patients, the mechanism of pulmonary injury is unknown.

Precise diagnosis of drug-induced pulmonary disease is often difficult, because results of routine laboratory studies are not helpful and radiographic findings are not specific. A high index of suspicion and a thorough medical history of drug usage are critical to establishing the diagnosis of drug-induced lung disease. The clinical response to cessation of the suspected offending agent is also helpful. Acute episodes of drug-induced pulmonary disease usually disappear 24-48 hours after the drug has been discontinued, but chronic syndromes may take longer to resolve. Challenge tests to confirm the diagnosis are risky and rarely performed.

Treatment of drug-induced lung disease consists of discontinuing the offending agent immediately and managing the pulmonary symptoms appropriately.

Inhalation of crack cocaine may cause a spectrum of acute pulmonary syndromes, including pulmonary infiltration with eosinophilia, pneumothorax and pneumomediastinum, bronchiolitis obliterans, and acute respiratory failure associated with diffuse alveolar damage and alveolar hemorrhage. Corticosteroids have been used with variable success to treat alveolar hemorrhage.

RADIATION LUNG INJURY

The lung is an exquisitely radiosensitive organ that can be affected by external beam radiation therapy. The degree of pulmonary injury is determined by the volume of lung irradiated, the dose and rate of exposure, and potentiating factors (eg, concurrent chemotherapy, previous radiation therapy in the same area, and simultaneous withdrawal of corticosteroid therapy). Symptomatic radiation lung injury occurs in about 10% of patients treated for carcinoma of the breast, 5-15% of patients treated for carcinoma of the lung, and 5-35% of patients treated for lymphoma. Two phases of the pulmonary response to radiation are apparent: an acute phase (radiation pneumonitis) and a chronic phase (radiation fibrosis).

Radiation Pneumonitis

Radiation pneumonitis usually occurs 2-3 months (range 1-6 months) after completion of radiotherapy and is characterized by insidious onset of dyspnea, intractable dry cough, chest fullness or pain, weakness, and fever. The pathogenesis of acute radiation pneumonitis is unknown, but there is speculation that hypersensitivity mechanisms are involved. The dominant histopathologic findings are a lymphocytic interstitial pneumonitis progressing to an exudative alveolitis. Inspiratory crackles may be heard in the involved area. In severe disease, respiratory distress and cyanosis occur that are characteristic of acute respiratory distress syndrome (ARDS). An increased white blood cell count and elevated sedimentation rate are common. Pulmonary function studies reveal reduced lung volumes, reduced lung compliance, hypoxemia, reduced diffusing capacity, and reduced maximum voluntary ventilation. Chest radiography, which correlates poorly with the presence of symptoms, usually demonstrates an alveolar or nodular infiltrate limited to the irradiated area. Air bronchograms are often observed. Sharp borders of the infiltrate may help distinguish radiation pneumonitis from other conditions such as infectious pneumonia, lymphangitic spread of carcinoma, and recurrent tumor. No specific therapy is proved to be effective in radiation pneumonitis, but prednisone (1 mg/kg/d orally) is commonly given immediately for about 1 week. The dose is then reduced and maintained at 20-40 mg/d for several weeks, then slowly tapered. Radiation pneumonitis may improve in 2-3 weeks following onset of symptoms as the exudative phase resolves. Acute respiratory failure, if present, is treated supportively. Death from ARDS is unusual.

Pulmonary Radiation Fibrosis

Pulmonary radiation fibrosis occurs in nearly all patients who receive a full course of radiation therapy for cancer of the lung and breast. Patients who experience radiation pneumonitis develop pulmonary fibrosis after an intervening period (6-12 months) of well-being. Most patients are asymptomatic, though slowly progressive dyspnea may occur. Radiation fibrosis may occur with or without antecedent radiation pneumonitis. Cor pulmonale and chronic respiratory failure are rare. Radiographic findings include obliteration of normal lung markings, dense interstitial and pleural fibrosis, reduced lung volumes, tenting of the diaphragm, and sharp delineation of the irradiated area. No specific therapy is proved effective, and corticosteroids have no value.

Other Complications of Radiation Therapy

Other complications of radiation therapy directed to the thorax include pericardial effusion, constrictive pericarditis, tracheoesophageal fistula, esophageal candidiasis, radiation dermatitis, and rib fractures. Small pleural effusions, radiation pneumonitis outside the irradiated area, spontaneous pneumothorax, and complete obstruction of central airways are unusual occurrences.

■ PLEURAL DISEASES

PLEURITIS

Pain due to acute pleural inflammation is caused by irritation of the parietal pleura. Such pain is localized, sharp, and fleeting, and is made worse by cough, sneezing, deep breathing, or movement. When the central portion of the diaphragmatic parietal pleura is irritated, pain may be referred to the ipsilateral shoulder. There are numerous causes of pleuritis. The setting in which pleuritic pain develops helps to narrow the differential diagnosis. In young, otherwise healthy individuals, pleuritis is usually caused by viral respiratory infections or pneumonia. The presence of pleural effusion, pleural thickening, or air in the pleural space requires further diagnostic and therapeutic measures. Simple rib fracture may cause severe pleurisy.

Treatment of pleuritis consists of treating the underlying disease. Analgesics and anti-inflammatory drugs (eg, indomethacin, 25 mg orally two or three times daily) are often helpful for pain relief. Codeine (30-60 mg orally every 8 hours) may be used to control cough associated with pleuritic chest pain if retention of airway secretions is not a likely complication. Intercostal nerve blocks are sometimes helpful but the benefit is usually transient.

PLEURAL EFFUSION

Essentials of Diagnosis

- May be asymptomatic; chest pain frequently seen in the setting of pleuritis, trauma, or infection; dyspnea is common with large effusions.
- Dullness to percussion and decreased breath sounds over the effusion.
- Radiographic evidence of pleural effusion.
- Diagnostic findings on thoracentesis.

General Considerations

There is constant movement of fluid from parietal pleural capillaries into the pleural space at a rate of 0.01 mL/kg body weight/h. Absorption of pleural fluid occurs through parietal pleural lymphatics. The resultant homeostasis leaves 5-15 mL of fluid in the normal pleural space. A pleural effusion is an abnormal accumulation of fluid in the pleural space. Pleural effusions may be classified by differential diagnosis ([Table 9-29](#)) or by underlying pathophysiology. Five pathophysiologic processes account for most pleural effusions: increased production of fluid in the setting of normal capillaries due to increased hydrostatic or decreased oncotic pressures (transudates); increased production of fluid due to abnormal capillary permeability (exudates); decreased lymphatic clearance of fluid from the pleural space (exudates); infection in the pleural space (empyema); and bleeding into the pleural space (hemothorax).

Diagnostic thoracentesis should be performed whenever there is a new pleural effusion and no clinically apparent cause. Observation is appropriate in some situations (eg, symmetric bilateral pleural effusions in the setting of congestive heart failure), but an atypical presentation or failure of an effusion to resolve as expected warrants thoracentesis. Sampling allows visualization of the fluid in addition to chemical and microbiologic analyses to identify the pathophysiologic processes listed above. A definitive diagnosis is made through positive cytology or identification of a specific causative organism in approximately 25% of cases. In another 50-60% of patients, identification of relevant pathophysiology in the appropriate clinical setting greatly narrows the differential diagnosis and leads to a presumptive diagnosis.

Clinical Findings

A. Symptoms and Signs

Patients with pleural effusions most often report dyspnea, cough, or respirophasic chest pain. Symptoms are more common in patients with existing cardiopulmonary disease. Small pleural effusions are less likely to be symptomatic than larger effusions. Physical findings are usually absent in small effusions. Larger effusions may present with dullness to percussion and diminished or absent breath sounds over the effusion. Compressive atelectasis may cause bronchial breath sounds and egophony just above the effusion. A massive effusion with increased intrapleural pressure may cause contralateral shift of the trachea and bulging of the intercostal spaces. A pleural friction rub indicates infarction or pleuritis.

B. Laboratory Findings

The gross appearance of pleural fluid helps to identify several types of pleural effusion. Grossly purulent fluid signifies empyema, an infection of the pleural space. Milky white pleural fluid should be centrifuged. A clear supernatant above a pellet of white cells indicates empyema, whereas a persistently turbid supernatant suggests a chylous effusion. Analysis of this supernatant reveals chylomicrons and a high triglyceride level (> 100 mg/dL), often from traumatic disruption of the thoracic duct.

Hemorrhagic pleural effusion is a mixture of blood and pleural fluid. Ten thousand red cells per milliliter create blood-tinged pleural fluid; 100,000/mL create grossly bloody pleural fluid. Hemothorax is the presence of gross blood in the pleural space, usually following chest trauma or instrumentation. It is defined as a ratio of pleural fluid hematocrit to peripheral blood hematocrit > 0.5.

Pleural fluid samples should be sent for measurement of protein, glucose, and LDH in addition to total and differential white blood cell counts. Chemistry determinations are used to classify effusions as transudates or exudates. This classification is important because the differential diagnosis for each entity is vastly different ([Table 9-29](#)). A pleural exudate is an effusion that has *one or more* of the following laboratory features: (1) ratio of pleural fluid protein to serum protein > 0.5; (2) ratio of pleural fluid LDH to serum LDH > 0.6; (3) pleural fluid LDH greater than two-thirds the upper limit of normal serum LDH.

Transudates have none of these features. Transudates occur in the setting of normal capillary integrity and suggest the *absence* of local pleural disease. Distinguishing laboratory findings include a glucose equal to serum glucose, pH between 7.40 and 7.55, and fewer than 1000 WBC/uL with a predominance of mononuclear cells. Causes include increased hydrostatic pressure (congestive heart failure accounts for 90% of transudates), decreased oncotic pressure (hypoalbuminemia, cirrhosis), and greater negative pleural pressure (acute atelectasis). Exudates form as a result of pleural disease associated with increased capillary permeability or reduced lymphatic drainage. Bacterial pneumonia and cancer are the most common causes of exudative effusion, but there are many other causes with characteristic laboratory findings. These findings are summarized in [Table 9-30](#).

Pleural fluid pH is useful in the assessment of parapneumonic effusions. A pH below 7.30 suggests the need for drainage of the pleural space. An elevated amylase level in pleural fluid suggests pancreatitis, pancreatic pseudocyst, adenocarcinoma of the lung or pancreas, or esophageal rupture.

Thoracentesis with culture and pleural biopsy is indicated in suspected tuberculous pleural effusion. Pleural fluid culture is 44% sensitive, and the combination of closed pleural biopsy with culture and histologic examination for granulomas is 70-90% sensitive for the diagnosis of pleural tuberculosis.

Pleural fluid specimens should be sent for cytologic examination in all cases of exudative effusions in patients suspected of harboring an underlying malignancy. The diagnostic yield depends on the nature and extent of the underlying malignancy. Sensitivity is between 50% and 65%. A negative cytologic examination in a patient with a high prior probability of malignancy should be followed by one repeat thoracentesis. If that examination is negative, thoracoscopy (by a pulmonologist or by video-assisted thoracoscopic surgery) is preferred to closed pleural biopsy. The sensitivity of thoracoscopy is 92-96%.

C. Imaging

The lung is less dense than water and floats on pleural fluid that accumulates in dependent regions. Subpulmonary fluid may appear as lateral displacement of the apex of the diaphragm with an abrupt slope to the costophrenic sulcus or a greater than 2 cm separation between the gastric air bubble and the lung. On a standard upright chest radiograph, approximately 75-100 mL of pleural fluid must accumulate in the posterior costophrenic sulcus to be visible on the lateral view, and 175-200 mL must be present in the lateral costophrenic sulcus to be visible on the frontal view. Chest CT scans may identify as little as 10 mL of fluid. At least 1 cm of fluid on the decubitus view is necessary to permit blind thoracentesis. Ultrasonography is useful to guide thoracentesis in the setting of smaller effusions.

Pleural fluid may become trapped (loculated) by pleural adhesions, thereby forming unusual collections along the lateral chest wall or within lung fissures. Round or oval fluid collections in fissures that resemble intraparenchymal masses are called pseudotumors. Massive pleural effusion causing opacification of an entire hemithorax is most commonly caused by cancer but may be seen in tuberculosis and other diseases.

Treatment

A. Transudative Pleural Effusion

Transudative pleural effusions characteristically occur in the absence of pleural disease. Treatment is directed at the underlying condition. Therapeutic thoracentesis for severe dyspnea typically offers only transient benefit. Pleurodesis and tube thoracostomy are rarely indicated.

B. Malignant Pleural Effusion

Approximately 15% of patients dying of cancer are reported to have malignant pleural effusions. Almost any form of cancer may cause effusions, but the most common causes are lung cancer (one-third of cases) and breast cancer. In 5-10% of malignant pleural effusions, no primary tumor is identified.

Between 40% and 80% of exudative pleural effusions are malignant, while over 90% of malignant pleural effusions are exudative. The most common mechanisms contributing to the formation of malignant effusions include direct tumor involvement of the pleura, local inflammation in response to tumor spread, and impairment or disruption of lymphatics. The term "paramalignant pleural effusion" attaches to an effusion in a patient with cancer when repeated attempts to identify tumor cells in the pleura or pleural fluid are nondiagnostic but when there is a presumptive relation to the underlying malignancy. For example, superior vena caval syndrome with elevated systemic venous pressures causing a transudative effusion would be "paramalignant."

Most patients with malignant effusions have advanced disease and multiple symptoms. Dyspnea occurs in over half of patients with malignant pleural effusions. The cause of dyspnea is probably related to mechanical distortion of the lung and chest wall. Hypoxemia from intrapulmonary shunting and ventilation-perfusion mismatching is common and may be severe. Treatment may be systemic, with therapy for the underlying malignancy; or local, to address specific symptoms related to the effusion itself. Local treatment usually involves drainage through repeated thoracentesis or placement of a chest tube. Pleurodesis is a procedure by which an irritant is placed into the pleural space following chest tube drainage and lung reexpansion. The goal is to form fibrous adhesions between the visceral and parietal pleura, resulting in obliteration of the pleural space to prevent or significantly reduce reaccumulation of pleural fluid. Multiple agents have been used for pleurodesis, but the two in most common use are doxycycline (500 mg in 50-100 mL saline) and sterile, asbestos-free talc (by poudrage at thoracoscopy using 5 g or instillation of talc slurry through a chest tube using 4-5 g in 50 mL). Doxycycline and talc are associated with a 70-75% and a 90% success rate, respectively. Major side effects are pain and fever, which appear to be less common with talc. Pain associated with pleurodesis can be extreme. Patients should be premedicated with an anxiolytic-amnestic agent in addition to opioid analgesics.

C. Parapneumonic Pleural Effusion

Parapneumonic pleural effusions are exudates that accompany approximately 40% of bacterial pneumonias. They are divided into three categories: simple or uncomplicated, complicated, and empyema. Uncomplicated parapneumonic effusions are free-flowing sterile exudates of modest size that resolve quickly with antibiotic treatment of pneumonia. They do not need drainage. Empyema is gross infection of the pleural space indicated by positive Gram stain or culture. Empyema should always be drained by tube thoracostomy to facilitate clearance of infection and to reduce the probability of fibrous encasement of the lung, causing permanent pulmonary impairment.

Complicated parapneumonic effusions present the most difficult management decisions. They tend to be larger than simple parapneumonic effusions and to show more evidence of inflammatory stimuli such as low glucose level, low pH, or evidence of loculation. Inflammation probably reflects ongoing bacterial invasion of the pleural space despite rare positive bacterial cultures. The morbidity associated with complicated effusions is due to their tendency to form a fibropurulent pleural "peel," trapping otherwise functional lung and leading to permanent impairment. Tube thoracostomy is indicated when pleural fluid glucose is < 60 mg/dL or the pH is < 7.2. These thresholds have not been prospectively validated and should not be interpreted strictly. The clinician should consider drainage of a complicated effusion if the pleural fluid pH is between 7.2 and 7.3 or the LDH is > 1000 units/mL. Pleural fluid cell count and protein have little diagnostic value in this setting.

Tube thoracostomy drainage of empyema or parapneumonic effusions is frequently complicated by loculation that prevents adequate drainage. Intrapleural injection of fibrinolytic agents (streptokinase, 250,000 units, or urokinase, 100,000 units, in 100 mL of normal saline once or twice daily) has been reported to improve drainage, shorten hospitalization, and reduce the need for surgery. Reported success rates in small studies are between 70% and 90%.

D. Hemothorax

A small-volume hemothorax that is stable or improving on chest radiographs may be managed by close observation. In all other cases, hemothorax is treated by immediate insertion of a large-bore thoracostomy tube to (1) drain existing blood and clot, (2) quantify the amount of bleeding, (3) reduce the risk of fibrothorax, and (4) permit apposition of the pleural surfaces in an attempt to reduce hemorrhage. Thoracotomy may be indicated to control hemorrhage, remove clot, and treat complications such as bronchopleural fistula formation.

Light RW: Clinical practice. Pleural effusion. N Engl J Med. 2002;346:1971. [\[PMID: 12075059\]](#)

SPONTANEOUS PNEUMOTHORAX

- Acute onset of unilateral chest pain and dyspnea.
- Minimal physical findings in mild cases; unilateral chest expansion, decreased tactile fremitus, hyperresonance, diminished breath sounds, mediastinal shift, cyanosis and hypotension in tension pneumothorax.
- Presence of pleural air on chest radiograph.

General Considerations

Pneumothorax, or accumulation of air in the pleural space, is classified as spontaneous (primary or secondary) or traumatic. Primary spontaneous pneumothorax occurs in the absence of an underlying lung disease, whereas secondary spontaneous pneumothorax is a complication of preexisting pulmonary disease. Traumatic pneumothorax results from penetrating or blunt trauma. Iatrogenic pneumothorax may follow procedures such as thoracentesis, pleural biopsy, subclavian or internal jugular vein catheter placement, percutaneous lung biopsy, bronchoscopy with transbronchial biopsy, and positive-pressure mechanical ventilation. Tension pneumothorax usually occurs in the setting of penetrating trauma, lung infection, cardiopulmonary resuscitation, or positive-pressure mechanical ventilation. In tension pneumothorax, the pressure of air in the pleural space exceeds ambient pressure throughout the respiratory cycle. A check-valve mechanism allows air to enter the pleural space on inspiration and prevents egress of air on expiration.

Primary pneumothorax affects mainly tall, thin boys and men between the ages of 10 and 30 years. It is thought to occur from rupture of subpleural apical blebs in response to high negative intrapleural pressures. Family history and cigarette smoking may also be important factors.

Secondary pneumothorax occurs as a complication of COPD, asthma, cystic fibrosis, tuberculosis, pneumocystis pneumonia, menstruation (catamenial pneumothorax), and a wide variety of interstitial lung diseases including sarcoidosis, lymphangioleiomyomatosis, Langerhans cell histiocytosis, and tuberous sclerosis. Aerosolized pentamidine and a prior history of pneumocystis pneumonia are considered risk factors for the development of pneumothorax. One-half of patients with pneumothorax in the setting of recurrent pneumocystis pneumonia will develop pneumothorax on the contralateral side. The mortality rate of pneumothorax in pneumocystis pneumonia is high.

Clinical Findings

A. Symptoms and Signs

Chest pain ranging from minimal to severe on the affected side and dyspnea occur in nearly all patients. Symptoms usually begin during rest and usually resolve within 24 hours even if the pneumothorax persists. Alternatively, pneumothorax may present with life-threatening respiratory failure if underlying COPD or asthma is present.

If pneumothorax is small (less than 15% of a hemithorax), physical findings, other than mild tachycardia, are unimpressive. If pneumothorax is large, diminished breath sounds, decreased tactile fremitus, and decreased movement of the chest are often noted. Tension pneumothorax should be suspected in the presence of marked tachycardia, hypotension, and mediastinal or tracheal shift.

B. Laboratory Findings

Arterial blood gas analysis is often unnecessary but reveals hypoxemia and acute respiratory alkalosis in most patients. Left-sided primary pneumothorax may produce QRS axis and precordial T wave changes on the ECG that may be misinterpreted as acute myocardial infarction.

C. Imaging

Demonstration of a visceral pleural line on chest radiograph is diagnostic and may only be seen on an expiratory film. A few patients have secondary pleural effusion that demonstrates a characteristic air-fluid level on chest radiography. In supine patients, pneumothorax on a conventional chest radiograph may appear as an abnormally radiolucent costophrenic sulcus (the "deep sulcus" sign). In patients with tension pneumothorax, chest radiographs show a large amount of air in the affected hemithorax and contralateral shift of the mediastinum.

Differential Diagnosis

If the patient is a young, tall, thin, cigarette-smoking man, the diagnosis of primary spontaneous pneumothorax is usually obvious and can be confirmed by chest radiograph. In secondary pneumothorax, it is sometimes difficult to distinguish loculated pneumothorax from an emphysematous bleb. Occasionally, pneumothorax may mimic myocardial infarction, pulmonary embolization, or pneumonia.

Complications

Tension pneumothorax may be life-threatening. Pneumomediastinum and subcutaneous emphysema may occur as complications of spontaneous pneumothorax. If pneumomediastinum is detected, rupture of the esophagus or a bronchus should be considered.

Treatment

Treatment depends upon the severity of pneumothorax and the nature of the underlying disease. In a reliable patient with a small (< 15% of a hemithorax), stable spontaneous primary pneumothorax, observation alone may be appropriate. Many small pneumothoraces resolve spontaneously as air is absorbed from the pleural space; supplemental oxygen therapy may increase the rate of reabsorption. Simple aspiration drainage of pleural air with a small-bore catheter (eg, 16 gauge angiocatheter or larger drainage catheter) can be performed for spontaneous primary pneumothoraces that are large or progressive. Placement of a small-bore chest tube (7F to 14F) attached to a one-way Heimlich valve provides protection against development of tension pneumothorax and may permit observation from home. The patient should be treated symptomatically for cough and chest pain, and followed with serial chest radiographs every 24 hours.

Patients with secondary pneumothorax, large pneumothorax, tension pneumothorax, or severe symptoms or those who have a pneumothorax on mechanical ventilation should undergo chest tube placement (tube thoracostomy). The chest tube is placed under water-seal drainage, and suction is applied until the lung expands. The chest tube can be removed after the air leak subsides.

All patients who smoke should be advised to discontinue smoking and warned that the risk of recurrence is 50%. Future exposure to high altitudes, flying in unpressurized aircraft, and scuba diving should be avoided.

Indications for thoracoscopy or open thoracotomy include recurrences of spontaneous pneumothorax, any occurrence of bilateral pneumothorax, and failure of tube thoracostomy for the first episode (failure of lung to reexpand or persistent air leak). Surgery permits resection of blebs responsible for the pneumothorax and pleurodesis by mechanical abrasion and insufflation of talc.

Management of pneumothorax in patients with pneumocystis pneumonia is challenging because of a tendency toward recurrence, and there is no consensus on the best approach. Use of a small chest tube attached to a Heimlich valve has been proposed to allow the patient to leave the hospital. Some clinicians favor its insertion early in the course.

Prognosis

An average of 30% of patients with spontaneous pneumothorax experience recurrence of the disorder after either observation or tube thoracostomy for the first episode. Recurrence after surgical therapy is less frequent. Following successful therapy, there are no long-term complications.

■ DISORDERS OF CONTROL OF VENTILATION

The principal influences on ventilatory control are arterial PCO₂, pH, PO₂, and brainstem tissue pH. These variables are monitored by peripheral and central chemoreceptors. Under normal conditions, the ventilatory control system maintains arterial pH and PCO₂ within narrow limits; arterial PO₂ is more loosely controlled.

Abnormal control of ventilation can be seen with a variety of conditions ranging from rare disorders such as Ondine's curse, neuromuscular disorders, myxedema, starvation, and carotid body resection to more common disorders such as asthma, COPD, obesity, congestive heart failure, and sleep-related breathing disorders. A few of these disorders will be discussed in this section.

Caruana-Montaldo B et al: The control of breathing in clinical practice. Chest 2000;117:205. [\[PMID: 10631221\]](#)

PRIMARY ALVEOLAR HYPOVENTILATION

Primary alveolar hypoventilation ("Ondine's curse") is a rare syndrome of unknown cause characterized by inadequate alveolar ventilation despite normal neurologic function and normal airways, lungs, chest wall, and ventilatory muscles. Hypoventilation is even more marked during sleep. Individuals with this disorder are usually nonobese males in their third or fourth decades who present with lethargy, headache, and somnolence. Dyspnea is absent. Physical examination may reveal cyanosis and evidence of pulmonary hypertension and cor pulmonale. Hypoxemia and hypercapnia are present and improve with voluntary hyperventilation. Erythrocytosis is common. Treatment with ventilatory stimulants is usually unrewarding. Augmentation of ventilation by mechanical methods (phrenic nerve stimulation, rocking bed, mechanical ventilators) has been helpful to some patients. Adequate oxygenation should be maintained with supplemental oxygen, but nocturnal oxygen therapy should be prescribed only if diagnostic nocturnal polysomnography has demonstrated its efficacy and safety. Primary alveolar hypoventilation resembles—but should be distinguished from—**central alveolar hypoventilation**, in which impaired ventilatory drive with chronic respiratory acidemia and hypoxemia follows an insult to the brain stem (eg, bulbar poliomyelitis, infarction, meningitis, encephalitis, trauma).

OBESITY-HYPOVENTILATION SYNDROME (PICKWICKIAN SYNDROME)

Some obese individuals display symptoms and findings of alveolar hypoventilation. In obesity-hypoventilation syndrome, hypoventilation appears to result from a combination of blunted ventilatory drive and increased mechanical load imposed upon the chest by obesity. Voluntary hyperventilation returns the PCO₂ and the PO₂ toward normal values, a correction not seen in lung diseases causing chronic respiratory failure such as COPD. Most patients with obesity-hypoventilation syndrome also suffer from obstructive sleep apnea (see below), which must be treated aggressively if identified as a comorbid disorder. Therapy of obesity-hypoventilation syndrome consists mainly of weight loss, which improves hypercapnia and hypoxemia as well as the ventilatory responses to hypoxia and hypercapnia. Noninvasive positive-pressure ventilation is helpful in some patients. Respiratory stimulants may be helpful and include theophylline, acetazolamide, and medroxyprogesterone acetate, 10-20 mg every 8 hours orally. Improvement in hypoxemia, hypercapnia, erythrocytosis, and cor pulmonale are goals of therapy.

Teichtahl H: The obesity-hypoventilation syndrome revisited. Chest 2001;120:336. [\[PMID: 11502624\]](#)

SLEEP-RELATED BREATHING DISORDERS

Abnormal ventilation during sleep is manifested by apnea (breath cessation for at least 10 seconds) or hypopnea (decrement in airflow with drop in hemoglobin saturation of at least 4%). Episodes of apnea are **central** if ventilatory effort is absent for the duration of the apneic episode, **obstructive** if ventilatory effort persists throughout the apneic episode but no airflow occurs because of transient obstruction of the upper airway, and **mixed** if absent ventilatory effort precedes upper airway obstruction during the apneic episode. Pure central sleep apnea is uncommon; it may be an isolated finding or may occur in patients with primary alveolar hypoventilation or with lesions of the brain stem. Obstructive and mixed sleep apneas are more common and may be associated with life-threatening cardiac arrhythmias, severe hypoxemia during sleep, daytime somnolence, pulmonary hypertension, cor pulmonale, systemic hypertension, and secondary erythrocytosis.

Definitive diagnostic evaluation for suspected sleep apnea should include otolaryngologic examination and overnight polysomnography (the monitoring of multiple physiologic factors during sleep). Electroencephalography, electro-oculography, electromyography, electrocardiography, pulse oximetry, and measurement of respiratory effort and airflow are performed in a complete evaluation. Screening may be performed using home nocturnal pulse oximetry, which when normal has a high negative predictive value in ruling out significant sleep apnea.

Obstructive Sleep Apnea

Upper airway obstruction during sleep occurs when loss of normal pharyngeal muscle tone allows the pharynx to collapse passively during inspiration. Patients with anatomically narrowed upper airways (eg, micrognathia, macroglossia, obesity, tonsillar hypertrophy) are predisposed to the development of obstructive sleep apnea. Ingestion of alcohol or sedatives before sleeping or nasal obstruction of any type, including the common cold, may precipitate or worsen the condition. Hypothyroidism and cigarette smoking are additional risk factors for obstructive sleep apnea. Before making the diagnosis of obstructive sleep apnea, a drug history should be obtained and a seizure disorder, narcolepsy, or psychiatric depression excluded.

Most patients with obstructive or mixed sleep apnea are obese middle-aged men. Systemic hypertension is common. Patients may complain of excessive daytime somnolence, morning sluggishness and headaches, daytime fatigue, cognitive impairment, recent weight gain, and impotence. Bed partners usually report loud cyclical snoring, breath cessation, witnessed apneas, restlessness, and thrashing movements of the extremities during sleep. Personality changes, poor judgment, work-related problems, depression, and intellectual deterioration (memory impairment, inability to concentrate) may also be observed.

Physical examination may be normal or may reveal systemic and pulmonary hypertension with cor pulmonale. The patient may appear sleepy or even fall asleep during the evaluation. The oropharynx is frequently found to be narrowed by excessive soft tissue folds, large tonsils, pendulous uvula, or prominent tongue. Nasal obstruction by a deviated nasal septum, poor nasal air flow, and a nasal twang to the speech may be observed. A "bull neck" appearance is common.

Erythrocytosis is common. A hemoglobin level and thyroid function tests should be obtained. Observation of the sleeping patient reveals loud snoring interrupted by episodes of increasingly strong ventilatory effort that fail to produce airflow. A loud snort often accompanies the first breath following an apneic episode. Polysomnography reveals apneic episodes lasting as long as 60 seconds. Oxygen saturation falls, often to very low levels. Bradyarrhythmias such as sinus bradycardia, sinus arrest, or atrioventricular block may occur. Tachyarrhythmias, including paroxysmal supraventricular tachycardia, atrial fibrillation, and ventricular tachycardia, may be seen once airflow is reestablished.

Weight loss and strict avoidance of alcohol and hypnotic medications are the first steps in management. Weight loss may be curative, but most patients are unable to lose the 10-20% of body weight required. Nasal continuous positive airway pressure (nasal CPAP) at night is curative in many patients. Polysomnography is frequently necessary to determine the level of CPAP (usually 5-15 cm H₂O) necessary to abolish obstructive apneas. Unfortunately, only about 75% of patients continue to use nasal CPAP after 1 year. Pharmacologic therapy for obstructive sleep apnea is disappointing. Supplemental oxygen may lessen the severity of nocturnal desaturation but may also lengthen apneas. Polysomnography is necessary to assess the effects of oxygen therapy; it should not be routinely prescribed. Mechanical devices inserted into the mouth at bedtime to hold the jaw forward and prevent pharyngeal occlusion have modest effectiveness in relieving apnea; however, patient compliance is not optimal.

Uvulopalatopharyngoplasty (UPPP), a procedure consisting of resection of pharyngeal soft tissue and amputation of approximately 15 mm of the free edge of the soft palate and uvula, is helpful in approximately 50% of selected patients. It is more effective in eliminating snoring than apneic episodes. UPPP may now be performed on an outpatient basis with a laser. **Nasal septoplasty** is performed if gross anatomic nasal septal deformity is present. **Tracheostomy** relieves upper airway obstruction and its physiologic consequences and represents the definitive treatment for obstructive sleep apnea. However, it has numerous adverse effects, including granuloma formation, difficulty with speech, and stoma and airway infection. Furthermore, the long-term care of the tracheostomy, especially in obese patients, can be difficult. Tracheostomy and other maxillofacial surgery approaches are reserved for patients with life-threatening arrhythmias or severe disability who have failed to respond to conservative therapy.

Some patients with sleep apnea have nocturnal bradycardia. A pilot study in 15 patients with either central or obstructive sleep apnea showed some improvement in oxygen saturation with atrial pacing. This single study must be considered preliminary.

HYPERVENTILATION SYNDROMES

Hyperventilation is an increase in alveolar ventilation that leads to hypocapnia. It may be caused by a variety of conditions, such as pregnancy, hypoxemia, obstructive and infiltrative lung diseases, sepsis, hepatic dysfunction, fever, and pain. The term "central neurogenic hyperventilation" denotes a monotonous, sustained pattern of rapid and deep breathing seen in comatose patients with brain stem injury of multiple causes. Functional hyperventilation may be acute or chronic. Acute hyperventilation presents with hyperpnea, paresthesias, carpopedal spasm, tetany, and anxiety. Chronic hyperventilation may present with various nonspecific

symptoms, including fatigue, dyspnea, anxiety, palpitations, and dizziness. The diagnosis of chronic hyperventilation syndrome is established if symptoms are reproduced during voluntary hyperventilation. Once organic causes of hyperventilation have been excluded, treatment of acute hyperventilation consists of rebreathing expired gas from a paper bag held over the face in order to decrease respiratory alkalemia and its associated symptoms. Anxiolytic drugs may also be useful.

■ ACUTE RESPIRATORY FAILURE

Respiratory failure is defined as respiratory dysfunction resulting in abnormalities of oxygenation or ventilation (CO₂ elimination) severe enough to threaten the function of vital organs. Arterial blood gas criteria for respiratory failure are not absolute but may be arbitrarily established as a PO₂ under 60 mm Hg or a PCO₂ over 50 mm Hg. Acute respiratory failure may occur in a variety of pulmonary and nonpulmonary disorders (Table 9-31). A complete discussion of treatment of acute respiratory failure is beyond the scope of this chapter. Only a few selected general principles of management will be reviewed here.

Clinical Findings

Symptoms and signs of acute respiratory failure are those of the underlying disease combined with those of hypoxemia or hypercapnia. The chief symptom of hypoxemia is dyspnea, though profound hypoxemia may exist in the absence of complaints. Signs of hypoxemia include cyanosis, restlessness, confusion, anxiety, delirium, tachypnea, tachycardia, hypertension, cardiac dysrhythmias, and tremor. Dyspnea and headache are the cardinal symptoms of hypercapnia. Signs of hypercapnia include peripheral and conjunctival hyperemia, hypertension, tachycardia, tachypnea, impaired consciousness, papilledema, and asterixis. The symptoms and signs of acute respiratory failure are both insensitive and nonspecific; therefore, the physician must maintain a high index of suspicion and obtain arterial blood gas analysis if respiratory failure is suspected.

Treatment

Treatment of the patient with acute respiratory failure consists of (1) specific therapy directed toward the underlying disease; (2) respiratory supportive care directed toward the maintenance of adequate gas exchange; and (3) general supportive care. Only the last two aspects are discussed below.

A. Respiratory Support

Respiratory support has both nonventilatory and ventilatory aspects.

1. Nonventilatory aspects—The main therapeutic goal in acute hypoxemic respiratory failure is to ensure adequate oxygenation of vital organs. Inspired oxygen concentration should be the lowest value that results in an arterial oxygen saturation of = 90% (PO₂ = 60 mm Hg). Higher arterial oxygen tensions are of no proven benefit. Restoration of normoxia may cause hypoventilation in patients with chronic hypercapnia; however, *oxygen therapy should not be withheld for fear of causing progressive respiratory acidemia*. Hypoxemia in patients with obstructive airway disease is usually easily corrected by administering low-flow oxygen by nasal cannula (1-3 L/min) or Venturi mask (24-28%). Higher concentrations of oxygen are necessary to correct hypoxemia in patients with acute respiratory distress syndrome (ARDS), pneumonia, and other parenchymal lung diseases.

2. Ventilatory aspects—Ventilatory support consists of maintaining patency of the airway and ensuring adequate alveolar ventilation. Mechanical ventilation may be provided via face mask (noninvasive) or through tracheal intubation.

a. Noninvasive positive-pressure ventilation (NPPV)—NPPV delivered via a full face mask or nasal mask has become first-line therapy in COPD patients with hypercapnic respiratory failure who can protect and maintain the patency of their airway, handle their own secretions, and tolerate the mask apparatus. Several studies have demonstrated the effectiveness of this therapy in reducing intubation rates and ICU stays in patients with ventilatory failure. Patients with acute lung injury or ARDS or those who suffer from severely impaired oxygenation do not benefit and should be intubated if they require mechanical ventilation. A bilevel positive pressure ventilation mode is preferred for most patients.

b. Tracheal intubation—Indications for tracheal intubation include (1) hypoxemia despite supplemental oxygen, (2) upper airway obstruction, (3) impaired airway protection, (4) inability to clear secretions, (5) respiratory acidosis, (6) progressive general fatigue, tachypnea, use of accessory respiratory muscles, or mental status deterioration, and (7) apnea. In general, orotracheal intubation is preferred to nasotracheal intubation in urgent or emergency situations because it is easier, faster, and less traumatic. The position of the tip of the endotracheal tube at the level of the aortic arch should be verified by chest radiograph immediately following intubation, and auscultation should be performed to verify that both lungs are being inflated. Only tracheal tubes with high-volume, low-pressure air-filled cuffs should be used. Cuff inflation pressure should be kept below 20 mm Hg if possible to minimize tracheal mucosal injury.

c. Mechanical ventilation—Indications for mechanical ventilation include (1) apnea, (2) acute hypercapnia that is not quickly reversed by appropriate specific therapy, (3) severe hypoxemia, and (4) progressive patient fatigue despite appropriate treatment.

Several modes of positive-pressure ventilation are available. Controlled mechanical ventilation (CMV; also known as assist-control or A-C) and synchronized intermittent mandatory ventilation (SIMV) are ventilatory modes in which the ventilator delivers a minimum number of breaths of a specified tidal volume each minute. In both CMV and SIMV, the patient may trigger the ventilator to deliver additional breaths. In CMV, the ventilator responds to breaths initiated by the patient above the set rate by delivering additional full tidal volume breaths. In SIMV, additional breaths are not supported by the ventilator unless the pressure support mode is added. Numerous alternative modes of mechanical ventilation now exist, the most popular being pressure support ventilation (PSV), pressure control ventilation (PCV), and continuous positive airway pressure (CPAP).

Positive end-expiratory pressure (PEEP) is useful in improving oxygenation in patients with diffuse parenchymal lung disease such as ARDS. It should be used cautiously in patients with localized parenchymal disease, hyperinflation, or very high airway pressure requirements during mechanical ventilation.

d. Complications of mechanical ventilation—Potential complications of mechanical ventilation are numerous. Migration of the tip of the endotracheal tube into a main bronchus can cause atelectasis of the contralateral lung and overdistention of the intubated lung. **Barotrauma** (alternatively referred to as "volutrauma"), manifested by subcutaneous emphysema, pneumomediastinum, subpleural air cysts, pneumothorax, or systemic gas embolism, may occur in patients whose lungs are overdistended by excessive tidal volumes, especially those with hyperinflation caused by airflow obstruction. Subtle parenchymal lung injury due to overdistention of alveoli is another potential hazard. Strategies to avoid barotrauma include deliberate hypoventilation through the use of low mechanical tidal volumes and respiratory rates, resulting in "permissive hypercapnia."

Acute respiratory alkalosis caused by overventilation is common. Hypotension induced by elevated intrathoracic pressure that results in decreased return of systemic venous blood to the heart may occur in patients treated with PEEP, those with severe airflow obstruction, and those with intravascular volume depletion. Ventilator-associated pneumonia is another serious complication of mechanical ventilation.

B. General Supportive Care

Maintenance of adequate nutrition is vital; parenteral nutrition should be used only when conventional enteral feeding methods are not possible. Overfeeding, especially with carbohydrate-rich formulas, should be avoided, because it can increase CO₂ production and may potentially worsen or induce hypercapnia in patients with limited ventilatory reserve. However, failure to provide adequate nutrition is more common. Hypokalemia and hypophosphatemia may worsen hypoventilation due to respiratory muscle weakness. Sedative-hypnotics and opioid analgesics are frequently used. They should be titrated carefully to avoid oversedation, leading to prolongation of intubation. Temporary paralysis with a nondepolarizing neuromuscular blocking agent is occasionally used to facilitate mechanical ventilation and to lower oxygen consumption. Prolonged muscle weakness due to an acute myopathy is a potential complication of these agents. It is more common in patients with renal dysfunction and in those given concomitant corticosteroids.

Psychologic and emotional support of the patient and family, skin care to avoid decubitus ulcers, and meticulous avoidance of nosocomial infection and complications of tracheal tubes are vital aspects of comprehensive care for patients with acute respiratory failure.

Attention must also be paid to preventing complications associated with serious illness. Stress gastritis and ulcers may be avoided by administering sucralfate, histamine H₂ receptor antagonists, or proton pump inhibitors. There is some concern that the latter two agents, which raise the gastric pH, may permit increased growth of gram-negative bacteria in the stomach, predisposing to pharyngeal colonization and ultimately nosocomial pneumonia; many clinicians therefore prefer sucralfate. The risk of deep venous thrombosis and pulmonary embolism may be reduced by subcutaneous administration of heparin (5000 units every 12 hours), the use of low-molecular-weight heparin or placement of a sequential compression device on an extremity.

Course & Prognosis

The course and prognosis of acute respiratory failure vary and depend on the underlying disease. The prognosis of acute respiratory failure caused by uncomplicated sedative or narcotic drug overdose is excellent. Acute respiratory failure in patients with COPD who do not require intubation and mechanical ventilation has a good immediate prognosis. On the other hand, ARDS associated with sepsis has an extremely poor prognosis, with mortality rates of about 90%. Overall, adults requiring mechanical ventilation for all causes of acute respiratory failure have survival rates of 62% to weaning, 43% to hospital discharge, and 30% to 1 year after hospital discharge.

■ ACUTE RESPIRATORY DISTRESS SYNDROME (ARDS)

Essentials of Diagnosis

- Acute onset of respiratory failure.
- Bilateral radiographic pulmonary infiltrates.
- Absence of elevated left atrial pressure (if measured, pulmonary capillary wedge pressure = 18 mm Hg).
- Ratio of partial pressure of oxygen in arterial blood (PaO_2) to fractional concentration of inspired oxygen (FIO_2) < 200, regardless of the level of positive end-expiratory pressure (PEEP).

General Considerations

Acute respiratory distress syndrome (ARDS; formerly called adult respiratory distress syndrome) denotes acute hypoxemic respiratory failure following a systemic or pulmonary insult without evidence of heart failure. ARDS is the most severe form of acute lung injury and is characterized by bilateral, widespread radiographic pulmonary infiltrates, normal pulmonary capillary wedge pressure (= 18 mm Hg) and a $\text{PaO}_2/\text{FIO}_2$ ratio < 200. ARDS may follow a wide variety of clinical events ([Table 9-32](#)). Common risk factors for ARDS include sepsis, aspiration of gastric contents, shock, infection, lung contusion, nonthoracic trauma, toxic inhalation, near-drowning, and multiple blood transfusions. About one-third of ARDS patients initially have sepsis syndrome. Pro-inflammatory cytokines released from stimulated inflammatory cells appear to be pivotal in lung injury. Although the mechanism of lung injury varies with the cause, damage to capillary endothelial cells and alveolar epithelial cells is common to ARDS regardless of cause. Damage to these cells causes increased vascular permeability and decreased production and activity of surfactant; these abnormalities lead to interstitial and alveolar pulmonary edema, alveolar collapse, and hypoxemia.

Clinical Findings

ARDS is marked by the rapid onset of profound dyspnea that usually occurs 12-48 hours after the initiating event. Labored breathing, tachypnea, intercostal retractions, and crackles are noted on physical examination. Chest radiography shows diffuse or patchy bilateral infiltrates that rapidly become confluent; these characteristically spare the costophrenic angles. Air bronchograms occur in about 80% of cases. Upper lung zone venous engorgement is distinctly uncommon. Heart size is normal, and pleural effusions are small or nonexistent. Marked hypoxemia occurs that is refractory to treatment with supplemental oxygen. Many patients with ARDS demonstrate multiple organ failure, particularly involving the kidneys, liver, gut, central nervous system, and cardiovascular system.

Differential Diagnosis

Since ARDS is a physiologic and radiographic syndrome rather than a specific disease, the concept of differential diagnosis does not strictly apply. Normal-permeability ("cardiogenic" or hydrostatic) pulmonary edema must be excluded, however, because specific therapy is available for that disorder. Measurement of pulmonary capillary wedge pressure by means of a flow-directed pulmonary artery catheter may be required in selected patients with suspected cardiac dysfunction. Routine use of the Swan-Ganz catheter in ARDS is discouraged.

Prevention

No measures that effectively prevent ARDS have been identified; specifically, prophylactic use of PEEP in patients at risk for ARDS has not been shown to be effective. Intravenous methylprednisolone does not prevent ARDS when given early to patients with sepsis syndrome or septic shock.

Treatment

Treatment of ARDS must include identification and specific treatment of the underlying precipitating and secondary conditions (eg, sepsis). Meticulous supportive care must then be provided to compensate for the severe dysfunction of the respiratory system associated with ARDS and to prevent complications (see above).

Treatment of the hypoxemia seen in ARDS usually requires tracheal intubation and positive-pressure mechanical ventilation. The lowest levels of PEEP (used to recruit atelectatic alveoli) and supplemental oxygen required to maintain the PaO_2 above 60 mm Hg or the SaO_2 above 90% should be used. Efforts should be made to decrease FIO_2 to less than 60% as soon as possible in order to avoid oxygen toxicity. PEEP can be increased as needed as long as cardiac output and oxygen delivery do not decrease and airway pressures do not increase excessively. Prone positioning may transiently improve oxygenation in selected patients by helping recruit atelectatic alveoli; however, great care must be taken during the maneuver to avoid dislodging catheters and tubes.

A variety of mechanical ventilation strategies are available. A multicenter study of 800 patients demonstrated that the use of a detailed volume ventilation protocol that employs small tidal volumes (6 mL/kg of ideal body weight) resulted in a 10% absolute mortality reduction over standard therapy; this trial reported the lowest mortality (31%) of any intervention to date for ARDS.

Cardiac output that falls when PEEP is used may be improved by reducing the level of PEEP or by the judicious use of inotropic drugs (eg, dopamine); administering fluids to increase intravascular volume should be done only with great caution, because increases in pulmonary capillary pressure worsen pulmonary edema in the presence of increased capillary permeability. Therefore, the goal of fluid management is to maintain pulmonary capillary wedge pressure at the lowest level compatible with adequate cardiac output. Crystalloid solutions should be used when intravascular volume expansion is necessary. Diuretics should be used to reduce intravascular volume if pulmonary capillary wedge pressure is elevated.

Oxygen delivery can be increased in anemic patients by ensuring that hemoglobin concentrations are at least 7 g/dL; patients are not likely to benefit from higher levels. Increasing oxygen delivery to supranormal levels through the use of inotropes and high hemoglobin concentrations is not clinically useful and may be harmful. Strategies to decrease oxygen consumption include the appropriate use of sedatives, analgesics, and antipyretics.

A large number of innovative therapeutic interventions to improve outcomes in ARDS patients have been or are being investigated. Unfortunately, to date, none have consistently shown benefit in clinical trials. Systemic corticosteroids have been studied extensively with variable and inconsistent results. While recent studies suggest a benefit in late-phase ARDS, confirmatory studies are required before they can be recommended for use on a routine basis.

Course & Prognosis

The mortality rate associated with ARDS is 30-40%. If ARDS is accompanied by sepsis, the mortality rate may reach 90%. The major causes of death are the primary illness and secondary complications such as multiple organ system failure or sepsis. Median survival is about 2 weeks. Many patients who succumb to ARDS and its complications die after withdrawal of support (see Withdrawal of Support in [Chapter 5](#)). Most survivors of ARDS are left with some pulmonary symptoms (cough, dyspnea, sputum production) which tend to improve over time. Mild abnormalities of oxygenation, diffusing capacity, and lung mechanics persist in some individuals.

-

Table 9-4. Stepwise approach for managing asthma^{1,2}

	Long-Term Control	Quick Relief	Education
Step 1: Mild intermittent	No daily medication needed.	Short-acting bronchodilator: inhaled β_2-agonists as needed for symptoms. Intensity of treatment will depend on severity of exacerbation. Use of short-acting inhaled β_2 -agonists > 2 times a week may indicate the need for longterm control therapy.	Teach basic facts about asthma Teach inhaler/inhalation chamber technique Discuss roles of medications Develop self-management & action plans Discuss appropriate environmental control measures
Step 2: Mild persistent	One daily medication: Anti-inflammatory: either inhaled corticosteroid (low doses) or cromolyn or nedocromil Less desirable alternatives: sustained-release theophylline or leukotriene modifier	Short-acting bronchodilator: inhaled β_2-agonists as needed for symptoms. Intensity of treatment will depend on severity of exacerbation. Use of short-acting inhaled β_2 -agonists on a daily basis, or increasing use, indicates the need for additional long-term control therapy.	Step 1 actions plus: Teach self-monitoring Refer to group education if available Review and update self-management plan
Step 3: Moderate persistent	Daily medication: Either Anti-inflammatory: inhaled corticosteroid (medium dose) or Inhaled corticosteroid (low-medium dose) and a long-acting bronchodilator (long-acting inhaled β_2-agonist , sustained-release theophylline or long-acting β_2 -agonist tablets) If needed: Anti-inflammatory: inhaled corticosteroid (medium-high dose) and Long-acting bronchodilator β_2-agonist , sustained-release theophylline or long-acting β_2 -agonist tablets)	Short-acting bronchodilator: inhaled β_2-agonists as needed for symptoms. Intensity of treatment will depend on severity of exacerbation. Use of short-acting inhaled β_2 -agonists on a daily basis, or increasing use, indicates the need for additional long-term control therapy.	Step 1 actions plus: Teach self-monitoring Refer to group education if available Review and update self-management plan
Step 4: Severe persistent	Daily medication: Anti-inflammatory: inhaled corticosteroid (high dose) and Long-acting bronchodilator (long-acting inhaled β_2-agonist , sustained-release theophylline or long-acting β_2 -agonist tablets) and Corticosteroid tablets or syrup (2 mg/kg/d, generally not to exceed 60 mg/d)	Short-acting bronchodilator: inhaled β_2-agonists as needed for symptoms. Intensity of treatment will depend on severity of exacerbation. Use of short-acting inhaled β_2 -agonists on a daily basis, or increasing use, indicates the need for additional long-term control therapy.	Step 2 and 3 actions plus: Refer to individual education, counseling

Step down: Review treatment every 1-6 months; a gradual stepwise reduction in treatment may be possible.

Step up: If asthma control is not maintained, consider step up to next treatment level after reviewing medication technique, adherence, and environmental control.

¹Modified from National Asthma Education and Prevention Program. Expert Panel Report 2: Guidelines for the Diagnosis and Management of Asthma. National Institutes of Health Pub. No. 97-4051. Bethesda, MD, 1997.

²Preferred treatments are incolored text; however, specific medication plans should be tailored to individual patients.

Drug	Important Formulations	Usual Adult Dosage	Cost ²	Comments
Inhaled corticosteroids³				
Beclomethasone dipropionate QVAR	40 µg/puff	Two or three puffs BID	\$41.32/7.30 g	Chlorofluorocarbon-free; hydrofluoralkane propellant
Beclomethasone dipropionate (Vanceril)	80 mg/puff	One to two puffs BID	\$52.04/7.30 g	Chlorofluorocarbon propellant
	MDI: 42 µg/puff; 200 puffs/inhaler	Two or three puffs four times a day, or four to six puffs twice daily	\$46.52/16.80 g	
	84 mg/puff; 120 puffs/inhaler	Two puffs twice a day	\$53.33/12.20 g	
Budesonide (Pulmicort Turbuhaler)	Dry powder delivery system: 200 µg/puff; 200 puffs/inhaler	One inhalation twice a day	\$146.39/inhaler	Dry powder
Flunisolide (AeroBid)	MDI: 250 µg/puff; 100 puffs/inhaler	Two to four puffs twice a day	\$71.03/7 g	Chlorofluorocarbon propellant
Fluticasone (Flovent)	MDI: 44, 110 or 220 µg/puff; 120 puffs/inhaler	Two or three puffs (of 110µg) twice a day	\$74.11/13 g	Chlorofluorocarbon propellant
(Flovent Rotadisk)	Dry powder delivery system: 44, 88, 220 mg/blister; 4 blisters/Rotadisk, 15 Rotadisks per tube	One or two puffs (of 88 µg) twice a day	\$53.30/60 88 µg disks	Dry powder
Triamcinolone acetonide (Azmacort)	MDI: 100 µg/puff; 240 puffs/inhaler	Two or three puffs four times a day, or four to six puffs twice daily	\$72.69/20 g	Chlorofluorocarbon propellant
Systemic corticosteroids				
Methylprednisolone (many)	Tablets: 4 mg	5-60 mg daily to every other day as needed	\$0.54/4 mg	
Prednisolone (many)	Tablets: 5 mg	5-60 mg daily to every other day as needed	\$0.04/5 mg	
Prednisone (many)	Tablets: 1, 2.5, 5, 10, 20, 50 mg	5-60 mg daily to every other day as needed	\$0.04/5 mg	
Combination Inhaled corticosteroid and long-acting β₂ agonist				
Fluticasone and salmeterol (Advair Diskus)	Dry powder delivery system 100, 250, or 500 µg fluticasone per dose and 50 µg salmeterol per dose	One puff twice a day of 250/50; cannot use more than one puff twice a day due to salmeterol component.	\$142.30/60 250/50 disks	Dry powder
Cromolyn (Intal)	MDI: 800 µg per puff; 200 puffs/inhaler	2-4 puffs 4 times a day	\$92.94/14.2 g	Chlorofluorocarbon propellant
	Nebulizer solution, 20 mg/2 mL ampule	20 mg (2 mL) four times a day	\$1.12/2 mL	Administer with powered nebulizer
Nedocromil (Tilade)	MDI: 1.75 mg/puff; 112 puffs/inhaler	Two puffs four times a day	\$46.58/16.2 g	Chlorofluorocarbon propellant
Long-acting β₂-agonists⁴				
Salmeterol (Serevent)	MDI: 21 mg/puff; 120 puffs/inhaler	Two puffs every 12 hours	\$84.01/13 g	Chlorofluorocarbon propellant
(Serevent Diskus)	Dry powder: 46 µg/blister; 60 blisters per pack	One blister every 12 hours	\$84.01/60	Dry powder
Formoterol (Foradil Aerolizer)	Dry powder: 12 µg/capsule; 60 capsules/Aerolizer	One capsule every 12 hours	\$70.08/60	Dry powder
Sustained-release albuterol (Proventil Repetab)	Sustained-release tablet, 4 mg	One tablet every 12 hours	\$0.88/4 mg	Usually reserved for nocturnal symptoms not improved with other therapies
Theophylline (many)	Sustained-release tablets and capsules	Initially 10 mg/kg/d up to 300 mg maximum; then 200-600 mg every 8-24 hours	\$0.33/200 mg	Maintenance dose guided by serum drug level. Absorption and dosing vary with brand
Leukotriene modifiers				
Montelukast (Singulair)	Tablet, 10 mg	One tablet each evening	\$2.93/10 mg \$87.95/mo	
Zafirlukast (Accolate)	Tablet, 20 mg	One tablet twice a day	\$1.26/20 mg \$75.59/mo	Administration with meals decreases bioavailability; take at least 1 hour before or 2 hours after meals
Zileuton (Zyflo)	Tablet, 600 mg	One tablet four times a day	\$0.86/600 mg \$103.19/mo	Monitor hepatic enzymes

Table 9-6. Quick-relief medications for asthma.¹

Drug	Important Formulations	Usual Adult Dosage	Cost ²	Comments
Short-acting Inhaled β_2-agonists Albuterol (Proventil, Ventolin)	MDI: 90 μ g/puff, 200 puffs/canister	Two puffs 5 minutes before exercise Two puffs every 4-6 hours as needed	\$29.79/17 g	Preferred formulation in most cases. Chlorofluorocarbon propellant.
	Nebulizer solutions: 5 mg/mL (0.5%)	1.25-5 mg (0.25-1 mL) in 2-3 mL of normal saline every 4-8 hours as needed	\$16.71/20 mL	Administer with powered nebulizer. More frequent dosing is acceptable for acute or severe exacerbations.
	Unit dose: 0.083%, 3 mL	One dose every 4-8 hours as needed	\$1.24/unit	May mix with cromolyn or ipratropium nebulizer solutions.
	Dry powder (Ventolin Rotocaps): 200 μ g/capsule	One or two capsules every 4-6 hours as needed	\$37.92/100 200- μ g capsules	Rotohaler required for inhalation.
	Tablets: 2 mg, 4 mg	2-4 mg orally every 6-8 hours	\$31.14/100 2-mg tablets	Extended-release 4 mg tablet (Proventil Repetab) available for use every 12 hours.
Albuterol HFA (Proventil HFA)	MDI: 90 μ g/puff, 200 puffs/canister	Two puffs 5 minutes before exercise Two puffs every 4-6 hours as needed	\$39.41/6.7 g	Nonchlorofluorocarbon propellant.
Bitolterol (Tornalate)	Nebulizer solution, 2 mg/mL (0.2%)	0.5-2 mg (0.25-1 mL) in 2-3 mL of normal saline every 4-8 hours as needed	\$16.54/30 mL	Administer with powered nebulizer. May not mix with other nebulizer solutions.
Pirbuterol (Maxair)	MDI: 200 μ g/puff, 300 puffs/canister	Two puffs every 4-6 hours as needed	\$50.52/25 g	Chlorofluorocarbon propellant.
(Maxair Autoinhaler)	MDI 200 μ g/puff, 400 puffs/canister	Two puffs every 4-6 hours as needed	\$76.50/14 g	Breath-activated MDI system. Chlorofluorocarbon propellant.
Terbutaline (Brethine)	Tablets: 2.5 mg, 5 mg	2.5-5 mg orally three times a day	\$49.79/100 5-mg tablets	Tremor, nervousness, palpitations common; therefore not recommended.
	Injection solution, 1 mg/mL	0.25 mg (0.25 mL) subcutaneously; may be repeated once in 30 minutes	\$4.67/1 mg	Onset of action 30 minutes. Not limited to β_2 -agonist effects.
Anticholinergics Ipratropium bromide (Atrovent)	MDI: 18 μ g/puff, 200 puffs/canister	Two to four puffs every 6 hours	\$54.91/14 g	Chlorofluorocarbon propellant.
	Unit dose nebulizer solution, 0.2 mg/ mL (0.02%), 2.5 mL (0.5 mg)	0.25-0.5 mg (1-2 mL) every 6 hours	\$1.76/unit	
Systemic corticosteroids Methylprednisolone (many)	Tablets: 4 mg	40-60 mg/d as single dose or in two divided doses for 3-10 days	\$11.00/4 mg dose-pack	
Methylprednisolone sodium succinate (many)	Intravenous injection solution vials: 40, 125, 500 mg	0.5-1 mg/kg every 6 hours	\$3.41/125 mg vial	
Prednisolone (many)	Tablets: 5 mg Syrup: 15 mg/5 mL	40-60 mg/d as single dose or in two divided doses for 3-10 days	\$0.04/5 mg tablet \$74.50/240 mL syrup	
Prednisone (many)	Tablets: 1, 2.5, 5, 10, 20, 50 mg	40-60 mg/d as single dose or in two divided doses for 3-10 days	\$0.04/5 mg

•

Table 9-7. Patterns of disease in advanced COPD.

	Type A: Pink Puffer (Emphysema Predominant)	Type B: Blue Bloater (Bronchitis Predominant)
History and physical examination	Major complaint is dyspnea, often severe, usually presenting after age 50. Cough is rare, with scant clear, mucoid sputum. Patients are thin, with recent weight loss common. They appear uncomfortable, with evident use of accessory muscles of respiration. Chest is very quiet without adventitious sounds. No peripheral edema.	Major complaint is chronic cough, productive of mucopurulent sputum, with frequent exacerbations due to chest infections. Often presents in late 30s and 40s. Dyspnea usually mild, though patients may note limitations to exercise. Patients frequently overweight and cyanotic but seem comfortable at rest. Peripheral edema is common. Chest is noisy, with rhonchi invariably present; wheezes are common.
Laboratory studies	Hemoglobin usually normal (12-15 g/dL). PaO ₂ normal to slightly reduced (65-75 mm Hg) but Sao ₂ normal at rest. PaCO ₂ normal to slightly reduced (35-40 mm Hg). Chest radiograph shows hyperinflation with flattened diaphragms. Vascular markings are diminished, particularly at the apices.	Hemoglobin usually elevated (15-18 g/dL). PaO ₂ reduced (45-60 mm Hg) and PaCO ₂ slightly to markedly elevated (50-60 mm Hg). Chest radiograph shows increased interstitial markings ("dirty lungs"), especially at bases. Diaphragms are not flattened.
Pulmonary function tests	Airflow obstruction ubiquitous. Total lung capacity increased, sometimes markedly so. D _{Lco} reduced. Static lung compliance increased.	Airflow obstruction ubiquitous. Total lung capacity generally normal but may be slightly increased. D _{Lco} normal. Static lung compliance normal.
Special evaluations		
V/Q matching	Increased ventilation to high V/Q areas, ie, high dead space ventilation.	Increased perfusion to low V/Q areas.
Hemodynamics	Cardiac output normal to slightly low. Pulmonary artery pressures mildly elevated and increase with exercise.	Cardiac output normal. Pulmonary artery pressures elevated, sometimes markedly so, and worsen with exercise.
Nocturnal ventilation	Mild to moderate degree of oxygen desaturation not usually associated with obstructive sleep apnea.	Severe oxygen desaturation, frequently associated with obstructive sleep apnea.
Exercise ventilation	Increased minute ventilation for level of oxygen consumption. PaO ₂ tends to fall, PaCO ₂ rises slightly.	Decreased minute ventilation for level of oxygen consumption. PaO ₂ may rise; PaCO ₂ may rise significantly.

Table 9-8. Home oxygen therapy: requirements for Medicare coverage.¹

Group I (any of the following):

- 1. PaO₂ = 55 mm Hg or SaO₂ = 88% taken at rest breathing room air, while awake.
- 2. During sleep (prescription for nocturnal oxygen use only):
 - a. PaO₂ = 55 mm Hg or SaO₂ = 88% for a patient whose awake, resting, room air PaO₂ is = 56 mm Hg or SaO₂ = 89%,

or

- b. Decrease in PaO₂ > 10 mm Hg or decrease in SaO₂ > 5% associated with symptoms or signs reasonably attributed to hypoxemia (eg, impaired cognitive processes, nocturnal restlessness, insomnia).

3. During exercise (prescription for oxygen use only during exercise):

- a. PaO₂ = 55 mg Hg or SaO₂ = 88% taken during exercise for a patient whose awake, resting, room air PaO₂ is = 56 mm Hg or SaO₂ = 89%.

and

- b. There is evidence that the use of supplemental oxygen during exercise improves the hypoxemia that was demonstrated during exercise while breathing room air.

Group II:²

PaO₂ = 56-59 mm Hg or SaO₂ = 89% if there is evidence of any of the following:

- 1. Dependent edema suggesting congestive heart failure.
- 2. P pulmonale on ECG (P wave > 3 mm in standard leads II, III, or aVF).
- 3. Hematocrit > 56%.

¹Health Care Financing Administration, 1989.

²Patients in this group must have a second oxygen test 3 months after the initial oxygen set-up.

Table 9-9. Characteristics and treatment of selected pneumonias.

Organism; Appearance on Smear of Sputum	Clinical Setting	Complications	Laboratory Studies	Antimicrobial Therapy ^{1,2}
<i>Streptococcus pneumoniae</i> (pneumococcus). Gram-positive diplococci.	Chronic cardiopulmonary disease; follows upper respiratory tract infection.	Bacteremia, meningitis, endocarditis, pericarditis, empyema.	Gram stain and culture of sputum, blood, pleural fluid	Preferred: ³ Penicillin G, amoxicillin. Alternative: Macrolides, cephalosporins, doxycycline, fluoroquinolones, clindamycin, vancomycin.
<i>Haemophilus influenzae</i> . Pleomorphic gram-negative coccobacilli.	Chronic cardiopulmonary disease; follows upper respiratory tract infection.	Empyema, endocarditis.	Gram stain and culture of sputum, blood, pleural fluid.	Preferred: ³ Cefotaxime, ceftriaxone, cefuroxime, doxycycline, azithromycin, TMP-SMZ. ⁴ Alternative: Fluoroquinolones, clarithromycin.
<i>Staphylococcus aureus</i> . Plump gram-positive cocci in clumps.	Residence in chronic care facility, nosocomial, influenza epidemics; cystic fibrosis, bronchiectasis, injection drug use.	Empyema, cavitation.	Gram stain and culture of sputum, blood, pleural fluid.	For methicillin-susceptible strains: Preferred: A penicillinase-resistant penicillin with or without rifampin, or gentamicin. Alternative: A cephalosporin; clindamycin, TMP-SMZ, ⁴ vancomycin. For methicillin-resistant strains: Vancomycin with or without gentamicin or rifampin.
<i>Klebsiella pneumoniae</i> . Plump gramnegative encapsulated rods.	Alcohol abuse, diabetes mellitus; nosocomial.	Cavitation, empyema.	Gram stain and culture of sputum, blood, pleural fluid.	Preferred: Third-generation cephalosporin. For severe infections, add an aminoglycoside. Alternative: Aztreonam, imipenem, beta-lactam/beta-lactamase inhibitor, or a fluoroquinolone.
<i>Escherichia coli</i> . Gram-negative rods.	Nosocomial; rarely, community-acquired.	Empyema.	Gram stain and culture of sputum, blood, pleural fluid.	Same as for <i>Klebsiella pneumoniae</i> .
<i>Pseudomonas aeruginosa</i> . Gram-negative rods.	Nosocomial; cystic fibrosis, bronchiectasis.	Cavitation.	Gram stain and culture of sputum, blood.	Preferred: An antipseudomonal beta-lactam plus an aminoglycoside. Alternative: Ciprofloxacin plus an aminoglycoside or an antipseudomonal beta-lactam.
Anaerobes. Mixed flora.	Aspiration, poor dental hygiene.	Necrotizing pneumonia, abscess, empyema.	Culture of pleural fluid or of material obtained by transtracheal or transthoracic aspiration.	Preferred: Clindamycin, beta-lactam/beta-lactamase inhibitor, imipenem.
<i>Mycoplasma pneumoniae</i> . PMNs and monocytes; no bacteria.	Young adults; summer and fall.	Skin rashes, bullous myringitis; hemolytic anemia.	PCR. Culture. ⁶ Complement fixation titer. ⁵ Cold agglutinin serum titers are not helpful as they lack sensitivity and specificity.	Preferred: Doxycycline or erythromycin. Alternative: Clarithromycin; azithromycin, or a fluoroquinolone.
Legionella species. Few PMNs; no bacteria.	Summer and fall; exposure to contaminated construction site, water source, air conditioner; community-acquired or nosocomial.	Empyema, cavitation, endocarditis, pericarditis,	Direct immunofluorescent examination or PCR of sputum or tissue; culture of sputum or tissue. ⁶ Urinary antigen assay for <i>L pneumophila</i> serogroup 1.	Preferred: A macrolide with or without rifampin; a fluoroquinolone. Alternative: Doxycycline with or without rifampin.
<i>Chlamydia pneumoniae</i> . Nonspecific.	Clinically similar to <i>M pneumoniae</i> , but prodromal symptoms last longer (up to 2 weeks). Sore throat with hoarseness common. Mild pneumonia in teenagers and young adults.	Reinfection in older adults with underlying COPD or heart failure may be severe or even fatal.	Isolation of the organism is very difficult. Serologic studies include microimmunofluorescence with TWAR antigen. PCR at selected laboratories.	Preferred: Doxycycline. Alternative: Erythromycin, clarithromycin, azithromycin, or a fluoroquinolone.
<i>Moraxella catarrhalis</i> . Gram-negative diplococci.	Preexisting lung disease; elderly; corticosteroid or immunosuppressive therapy.	Rarely, pleural effusions and bacteremia.	Gram stain and culture of sputum, blood, pleural fluid.	Preferred: TMP-SMZ, ⁴ a second- or third-generation cephalosporin, amoxicillin-clavulanic acid, or a macrolide. Alternative: A fluoroquinolone.
<i>Pneumocystis carinii</i> . Nonspecific	AIDS, immunosuppressive or cytotoxic drug therapy, cancer.	Pneumothorax, respiratory failure, ARDS, death.	Methenamine silver, Giemsa, or DFA stains of sputum or bronchoalveolar lavage fluid.	Preferred: TMP-SMZ ⁴ or pentamidine isethionate plus prednisone. Alternative: Dapsone plus trimethoprim; clindamycin plus primaquine; trimetrexate plus folinic acid.

¹Antimicrobial sensitivities should guide therapy when available. (Modified from: The choice of antibacterial drugs. Med Lett Drugs Ther 1999;41:95, and from Bartlett JG et al: Practice guidelines for the management of community-acquired pneumonia in adults. Clin Infect Dis 2000;31:347).

²For additional antimicrobial therapy information, see Chapter 37: Tables 37-1 (drugs of choice), 37-5 and 37-7 (doses per day), and 37-4, 37-7, and 37-9 (pharmacology and dosage adjustment for renal dysfunction).

³Consider penicillin resistance when choosing therapy. See text.

⁴Trimethoprim-sulfamethoxazole.

⁵Fourfold rise in titer is diagnostic.

⁶Selective media are required.

Table 9-12. Classification of positive tuberculin skin test reactions.^{1,2}

Reaction Size	Group
= 5 mm	1. HIV-positive persons. 2. Recent contacts of individuals with active tuberculosis. 3. Persons with fibrotic changes on chest x-rays suggestive of prior tuberculosis. 4. Patients with organ transplants and other immunosuppressed patients (receiving the equivalent of > 15 mg/d of prednisone for 1 month or more).
= 10 mm	1. Recent immigrants (< 5 years) from countries with a high prevalence of tuberculosis (eg, Asia, Africa, Latin America). 2. HIV-negative injection drug users. 3. Mycobacteriology laboratory personnel. 4. Residents of and employees³ in the following high-risk congregate settings: correctional institutions; nursing homes and other long-term facilities for the elderly; hospitals and other health care facilities; residential facilities for AIDS patients; and homeless shelters. 5. Persons with the following medical conditions that increase the risk of tuberculosis: gastrectomy, Â± 10% below ideal body weight, jejunioileal bypass, diabetes mellitus, silicosis, chronic renal failure, some hematologic disorders, (eg leukemias, lymphomas), and other specific malignancies (eg, carcinoma of the head or neck and lung). 6. Children < 4 years of age or infants, children, and adolescents exposed to adults at high risk.
= 15 mm	1. Persons with no risk factors for tuberculosis.

¹Adapted from: Screening for tuberculosis and tuberculosis infection in high-risk populations: recommendations of the Advisory Council for the Elimination of Tuberculosis. MMWR Morb Mortal Wkly Rep 1995;44(RR-11):19.

²A tuberculin skin test reaction is considered positive if the transverse diameter of the indurated area reaches the size required for the specific group. All other reactions are considered negative.

³For persons who are otherwise at high risk and are tested at entry into employment, a reaction of > 15 mm induration is considered positive.

Table 9-13. Characteristics of antituberculous drugs.¹

Drug	Most Common Side Effects	Tests for Side Effects	Drug Interactions	Remarks
Isoniazid	Peripheral neuropathy, hepatitis, rash, mild CNS effects.	AST and ALT; neurologic examination.	Phenytoin (synergistic); disulfiram.	Bactericidal to both extracellular and intracellular organisms. Pyridoxine, 10 mg orally daily as prophylaxis for neuritis; 50-100 mg orally daily as treatment.
Rifampin	Hepatitis, fever, rash, flu-like illness, gastrointestinal upset, bleeding problems, renal failure.	CBC, platelets, AST and ALT.	Rifampin inhibits the effect of oral contraceptives, quinidine, corticosteroids, warfarin, methadone, digoxin, oral hypoglycemics; aminosalicyclic acid may interfere with absorption of rifampin. Significant interactions with protease inhibitors and nonnucleoside reverse transcriptase inhibitors.	Bactericidal to all populations of organisms. Colors urine and other body secretions orange. Discoloring of contact lenses.
Pyrazinamide	Hyperuricemia, hepatotoxicity, rash, gastrointestinal upset, joint aches.	Uric acid, AST, ALT.	. . .	Bactericidal to intracellular organisms.
Ethambutol	Optic neuritis (reversible with discontinuance of drug; rare at 15 mg/kg); rash.	Red-green color discrimination and visual acuity (difficult to test in children under 3 years of age).	. . .	Bacteriostatic to both intracellular and extracellular or ganisms. Mainly used to in hibit development of resistant mutants. Use with caution in renal disease or when ophthalmologic testing is not feasible.
Streptomycin	Eighth nerve damage, nephrotoxicity.	Vestibular function (audiograms); BUN and creatinine.	Neuromuscular blocking agents may be potentiated and cause prolonged paralysis.	Bactericidal to extracellular organisms. Use with caution in older patients or those with renal disease.

Table 9-15. TNM staging for lung cancer.¹

Stage	T	N	M	Description
0	Tis			Carcinoma in situ
IA	T1	N0	M0	Limited local disease without nodal or distant metastases
IB	T2	N0	M0	
IIA	T1	N1	M0	Limited local disease with ipsilateral hilar or peribronchial nodal involvement but not distant metastases <i>or</i> Locally invasive disease without nodal or distant metastases
IIB	T2	N1	M0	
	T3	N0	M0	
IIIA	T3	N1	M0	Limited local disease with ipsilateral or peribronchial nodal involvement but not distant metastases <i>or</i>
	T1-3	N2	M0	Limited or locally invasive disease with ipsilateral mediastinal or subcarinal nodal involvement but not distant metastases
IIIB	Any T	N3	M0	Any primary with contralateral mediastinal or hilar nodes, or ipsilateral scalene or supraclavicular nodes <i>or</i>
	T4	Any N	M0	Unresectable local invasion with any degree of adenopathy but no distant metatases
IV	Any T	Any N	M1	Distant metastases
Primary Tumor (T)				
TX	Primary tumor cannot be assessed; or tumor proved by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy.			
T0	No evidence of primary tumor.			
Tis	Carcinoma in situ.			
T1	A tumor = 3 cm in greatest dimension, surrounded by lung or visceral pleura, and without evidence of invasion proximal to a lobar bronchus at bronchoscopy.			
T2	A tumor > 3.0 cm in greatest dimension, or a tumor of any size that either involves a main bronchus (but is = 2 cm distal to the carina), invades the visceral pleura, or has associated atelectasis or obstructive pneumonitis extending to the hilar region. Any associated atelectasis or obstructive pneumonitis must involve less than an entire lung.			
T3	A tumor of any size with direct extension into the chest wall (including superior sulcus tumors), the diaphragm, the mediastinal pleura, or the parietal pericardium; or a tumor in the main bronchus < 2 cm distal to the carina without involving the carina; or associated atelectasis or obstructive pneumonitis of the entire lung.			
T4	A tumor of any size with invasion of the mediastinum, heart, great vessels, trachea, esophagus, vertebral body, or carina; or with a malignant pleural or pericardial effusion; or with satellite tumor nodules within the ipsilateral lobe of the lung containing the primary tumor.			
Regional Lymph Nodes (N)				
NX	Regional lymph nodes cannot be assessed.			
N0	No demonstrable metastasis to regional lymph nodes.			
N1	Metastasis to lymph nodes in the peribronchial or the ipsilateral hilar region, or both, including direct extension.			
N2	Metastasis to ipsilateral mediastinal lymph nodes and/or subcarinal lymph nodes.			
N3	Metastasis to contralateral mediastinal lymph nodes, contralateral hilar lymph nodes, ipsilateral or contralateral scalene or supraclavicular lymph nodes.			
Distant Metastases (M)				
MX	Presence of distant metastasis cannot be assessed.			
M0	No (known) distant metastasis.			
M1	Distant metastasis present.

Table 9-16. Approach to staging of patients with lung cancer.¹

Part A: Recommended tests for all patients

- Complete blood count
- Electrolytes, calcium, alkaline phosphatase, albumin, AST, ALT, total bilirubin, creatinine
- Chest radiograph
- CT of chest through the adrenal glands^{2,3}
- Pathologic confirmation of malignancy⁴

Part B: Recommended tests for selected but not all patients

Test	Indication
CT of liver with contrast or liver ultrasound	Elevated liver function tests; abnormal non-contrast-enhanced CT of liver or abnormal clinical evaluation
CT of brain with contrast or MRI brain	CNS symptoms or abnormal clinical evaluation
Radionuclide bone scan	Elevated alkaline phosphatase (bony fraction), elevated calcium, bone pain, or abnormal clinical evaluation
Pulmonary function tests	If lung resection or thoracic radiotherapy planned
Quantitative radionuclide perfusion lung scan or exercise testing to evaluate maximum oxygen consumption	Patients with borderline resectability due to limited cardiovascular status

¹Modified and reproduced, with permission, from: Pretreatment evaluation of non-small cell lung cancer. Consensus Statement of the American Thoracic Society and the European Respiratory Society. Am J Respir Crit Care Med 1997;156:320.

²May not be necessary if patient has obvious M1 disease on chest x-ray or physical examination.

³Intravenous iodine contrast enhancement is not essential but is recommended in probable mediastinal invasion.

⁴While optimal in most cases, tissue diagnosis may not be necessary in some cases where the lesion is enlarging or the patient will undergo surgical resection regardless of the outcome of a biopsy.

TABLES
Table 9-18. Differential diagnosis of interstitial lung disease.
 -
-

Table 9-19. Idiopathic fibrosing interstitial pneumonias.

Name and Clinical Presentation	Histopathology	Radiographic Pattern	Response to Therapy and Prognosis
Usual interstitial pneumonia (UIP) Age 55-60, slight male predominance. Insidious dry cough and exertional dyspnea of months' to years' duration. Clubbing present at diagnosis in 25-50%. Diffuse fine late inspiratory crackles on lung auscultation. Restrictive ventilatory deficit and reduced diffusing capacity on pulmonary function tests. ESR elevated. ANA and RF positive in 25% in the absence of documented collagen-vascular disease.	Patchy, temporally and gecographically nonuniform distribution of fibrosis, honeycomb change, and normal lung. Type I pneumocytes are lost, and there is hyperproliferation ofalveolar type II cells. There are "fibroblast foci" of actively proliferating fibroblasts and myofibroblasts. Inflammation is generally mild and consists of small lymphocytes. Intra-alveolar macrophage accumulation is present but is not a prominent feature.	Diminished lung volume. Increased linear or reticular bibasilar and subpleural opacities. Unilateral disease is rare. HRCT shows minimal ground-glass and variable honeycomb change. Areas of normal lung may be adjacent to areas of advanced fibrosis. Between 2% and 10% have normal chest radiographs and HRCT scans on diagnosis.	No randomized study has demonstrated improved survival compared with untreated patients. Inexorably progressive. Response to corticosteroids and cytotoxic agents at best 15% and these probably represent misclassification of histopathology. Median survival approximately 3 years, depending on stage at presentation. Current interest in antifibrotic agents.
Respiratory bronchiolitis-associated interstitial lung disease (RB-ILD)¹ Age 40-45. Presentation similar to that of UIP though in younger patients. Similar results on pulmonary function tests, but less severe abnormalities. Patients with respiratory bronchiolitis are invariably heavy smokers.	Increased numbers of macrophages evenly dispersed within the alveolar spaces. Rare fibroblast foci, little fibrosis, minimal honeycomb change. In RB-ILD the accumulation of macrophages is localized within the peribronchiolar airspaces; in DIP, it is diffuse. Alveolar architecture is preserved.	May be indistinguishable from UIP. More often presents with a nodular or reticulonodular pattern. Honeycombing rare. HRCT more likely to reveal diffuse ground glass opacitiesand upper lobe emphysema.	Spontaneous remission occurs in up to 20% of patients, so natural history unclear. Smoking cessation is essential. Prognosis clearly better than that of UIP: median survival greater than 3 years. Corticosteroids thought to be effective, but there are no randomized clinical trials to support this view.
Acute interstitial pneumonitis (AIP) Clinically known as Hamman-Rich syndrome. Wide age range, many young patients. Acute onset of dyspnea followed by rapid development of respiratory failure. Half of patients report a viral syndrome preceding lung disease. Clinical course indistinguishable from that of idiopathic ARDS.	Pathologic changes reflect acute response to injury within days to weeks. Resembles organizing phase of diffuse alveolar damage. Fibrosis and minimal collagen deposition. May appear similar toUIP but more homogeneous and there is no honeycomb change though this may appear if the process persists for more than a month in a patient on mechanical ventilation.	Diffuse bilateral airspace consolidation with areas of ground-glass attenuation onHRCTscan.	Supportive care (mechanical ventilation) critical but effect of specific therapies unclear. High initial mortality: Fifty to 90 percent die within 2 months after diagnosis. Not progressive if patient survives. Lung function may return tonormal or may be permanently impaired.
Nonspecific interstitial pneumonitis (NSIP) Age 45-55. Slight female predominance. Similar to UIP but onset of cough and dyspnea over months, not years.	Nonspecific in that histopathology does not fit into better-established categories. Varying degrees of inflammation and fibrosis, patchy in distribution but uniform in time, suggesting response to single injury. Most have lymphocytic and plasma cell inflammation without fibrosis. Honeycombing present but scant. Some have advocated division into cellular andfibrotic subtypes.	May be indistinguishable from UIP. Most typical picture is bilateral areas of ground-glass attenuation and fibrosis on HRCT. Honeycombing is rare.	Treatment thought to be effective, but no prospective clinical studies have been published. Prognosis overall good but depends on the extent of fibrosis at diagnosis. Median survival greater than 10 years.
Bronchiolitis obliterans organizing pneumonia (BOOP) Typically age 50-60 but wide variation. Abrupt onset, frequently weeks to a few months following a flu-like illness. Dyspnea and dry cough prominent, but constitutional symptoms are common: fatigue, fever, and weight loss.Pulmonary function tests usually show restriction, but up to 25% show concomitant obstruction.	Included in the idiopathic interstitial pneumonias on clinical grounds. Buds of loose connective tissue (Masson bodies) and inflammatory cells fill alveoli and distal bronchioles.	Lung volumes normal. Chest radiograph typically shows interstitial and parenchymal disease with discrete, peripheral alveolar and ground-glass infiltrates. Nodular opacities common. HRCT shows subpleural consolidation and bronchial wall thickening and dilation.	Rapid response to corticosteroids in two-thirds of patients. Long-term prognosis generally good for those who respond. Relapses are common.

¹Includes desquamative interstitial pneumonia (DIP).

-

Table 9-21. Selected methods for the prevention of venous thromboembolism.¹

Risk Group	Recommendations for Prophylaxis
Surgical patients	
General surgery	
Low-risk: Minor procedures, age under 40, and no clinical risk factors	Early ambulation
Moderate risk: Minor procedures with additional thrombosis risk factors; age 40-60, and no other clinical risk factors; or major operations with age under 40 without additional clinical risk factors	ES, or LDUH, or LMWH, or IPC; plus early ambulation if possible
Higher risk: Major operation, over age 40 or with additional risk factors	LDUH, or LMWH, or IPC
Higher risk plus increased risk of bleeding	ES or IPC
Very high risk: Multiple risk factors	LDUH, or higher-dose LMWH, plus ES or IPC
Selected very high risk	Consider ADPW, INR 2.0-3.0, or postdischarge LMWH
Orthopedic surgery	
Elective total hip replacement surgery	Subcutaneous LMWH, or ADPW, or adjusted-dose heparin started preoperatively; plus IPC or ES
Elective total knee replacement surgery	LMWH, or ADPW, or IPC
Hip fracture surgery	LMWH or ADPW
Neurosurgery	
Intracranial neurosurgery	IPC with or without ES; LDUH and postoperative LMWH are acceptable alternatives; IPC or ES plus LDUH or LMWH may be more effective than either modality alone in high-risk patients.
Acute spinal cord injury	LMWH; IPC and ES may have additional benefit when used with LMWH. In the rehabilitation phase, conversion to full-dose warfarin may provide ongoing protection.
Trauma	
With an identifiable risk factor for thromboembolism	LMWH; IPC or ES if there is a contraindication to LMWH; consider duplex ultrasound screening in very high risk patients; IVC filter insertion if proximal DVT is identified and anticoagulation is contraindicated.

Medical patients	
Acute myocardial infarction	Subcutaneous LDUH, or full-dose heparin; if heparin is contraindicated, IPC and ES may provide some protection.
Ischemic stroke with impaired mobility	LMWH or LDUH or danaparoid; IPC or ES if anticoagulants are contraindicated
General medical patients with clinical risk factors; especially patients with cancer, congestive heart failure, or severe pulmonary disease	Low-dose LMWH, or LDUH
Cancer patients with indwelling central venous catheters	Warfarin, 1 mg/d, or LMWH

¹Recommendations assembled from Geerts WH et al: Prevention of venous thromboembolism. Chest 2001;119(Suppl):132.

Key:
ADPW = adjusted-dose perioperative warfarin: begin 5-10 mg the day of or the day following surgery; adjust dose to INR 2.0-3.0
DVT = deep venous thrombosis
ES = elastic stockings
IPC = intermittent pneumatic compression
IVC = inferior vena cava
LDUH = low-dose unfractionated heparin: 5000 units subcutaneously every 8-12 hours starting 1-2 hours before surgery.
LMWH = low-molecular weight heparin. See Table 9-24 for dosing regimens.

Table 9-22. Selected low-molecular-weight heparin and heparinoid regimens to prevent venous thromboembolism.¹

Risk Group	Drug	Dose ²	Administration Regimen	Cost ³
General surgery, moderate risk	Dalteparin (Fragmin)	2500 units	1-2 h preop and qd postop	\$15.35/dose
	Enoxaparin (Lovenox)	20 mg	1-2 h preop and qd postop	\$18.35/dose
	Nadroparin (Fraxiparin)	2850 units	2-4 h preop and qd postop	No price available: Not available in USA
General surgery, high risk	Tinzaparin (Innohep)	3500 units	2 h preop and qd postop	\$29.40/dose
	Dalteparin (Fragmin)	5000 units	8-12 preop and qd postop	\$24.90/dose
	Danaparoid (Orgaran)	750 units	1-4 h preop and Q 12 h postop	\$141.31/dose
Orthopedic surgery	Enoxaparin (Lovenox)	40 mg	1-2 h preop and qd postop	\$25.68/dose
	Enoxaparin (Lovenox)	30 mg	q 12 h starting 8-12 h postop	\$1.27/dose
	Dalteparin (Fragmin)	5000 units	8-12 h preop and qd starting 12-24 h postop	\$24.90/dose
	Dalteparin (Fragmin)	2,500 units	6-8 h postop then 5,000 units qd	\$15.35/dose
	Danaparoid (Orgaran)	750 units	1-4 preop and q 12 h postop	\$141.31/dose
	Enoxaparin (Lovenox)	30 mg	q 12 h starting 12-24 h postop	\$19.27/dose
	Enoxaparin (Lovenox)	40 mg	qd starting 10-12 h preop	\$25.68/dose
	Nadroparin (Fraxiparin)	38 units/kg	12 h preop, 12 h postop, and qd on postop days 1, 2, 3; then increase to 57 units/kg qd	No price available: Not available in USA.
	Tinzaparin (Innohep)	75 units/kg	qd starting 12-24 h postop	\$37.80/dose (60 kg pt).
	Tinzaparin (Innohep)	4500 units	12 h preop and qd postop	\$37.80/dose
Major trauma	Enoxaparin (Lovenox)	30 mg	q12h starting 12-36 h postinjury if hemo statically stable	\$19.27/dose
Acute spinal cord injury	Enoxaparin (Lovenox)	30 mg	q12h	\$19.27/dose
Medical conditions	Dalteparin (Fragmin)	2500 units	qd	\$15.35/dose
	Danaparoid (Orgaran)	750 units	q12h	\$141.31/dose
	Enoxparin (Lovenox)	40 mg	qd	\$25.68/dose
	Nadroparin (Fraxiparin)	2850 units	qd	No price available: Not available in USA.

 - TABLES
 - Table 9-22. Selected low-molecular-weight heparin and heparinoid regimens to prevent venous thromboembolism.
-

Table 9-23. Intravenous heparin dosing based on body weight.¹

Initial dosing

1. Load with 80 units/kg IV, then
2. Initiate a maintenance infusion at 18 units/kg/h
3. Check activated partial thromboplastin time (aPTT) in 6 hours

Dose adjustment schedule based on aPTT results

< 35 s (< 1.25 × control)	Rebolus with 80 units/kg; increase infusion by 4 units/kg/h
35-45 s (1.2-1.5 × control)	Rebolus with 40 units/kg; increase infusion by 2 units/kg/h
46-70 s (1.5-2.3 × control)	No change
71-90 s (2.3-3 × control)	Decrease infusion rate by 2 units/kg/h
> 90 s (> 3 × control)	Stop infusion for 1 hour, then decrease infusion by 3 units/kg/h

Repeat aPTT every 6 hours for the first 24 hours. If the aPTT is 46-70 s after 24 hours, then recheck once daily every morning. If the aPTT is outside this therapeutic range at 24 hours, continue checking every 6 hours until it is 46-70 s. Once it has been in the therapeutic range on two consecutive measurements after 24 hours, check once daily every morning.

Table 9-30. Characteristics of important exudative pleural effusions.

Etiology or Type of Effusion	Gross Appearance	White Blood Cell Count (cells/μL)	Differential ¹	Red Blood Cell Count (cells/μL)	Glucose	Comments
Malignant effusion	Turbid to bloody; occasionally serous	1000 to < 100,000	M	100 to several hundred thousand	Equal to serum levels; < 60 mg/dL in 15% of cases	Eosinophilia uncommon; good results on cytology
Uncomplicated parapneumonic effusion	Clear to turbid	5000-25,000	P	< 5000	Equal to serum levels	Tube thoracostomy usually effective
Empyema	Turbid to purulent	25,000-100,000	P	< 5000	Less than serum levels; often very low	Drainage necessary; chest suggests anaerobic infection
Tuberculosis	Serous to serosanguineous	5000-10,000	M	< 10,000	Equal to serum levels; occasionally < 60 mg/dL	Protein may exceed serum eosinophils (> 1%) may cells (> 5%) may be seen
Rheumatoid effusion	Turbid; greenish-yellow	1000-20,000	M or P	< 1000	< 40 mg/dL	Secondary empyema LDH, low complement rheumatoid factor crystals are characteristic
Pulmonary infarction	Serous to grossly bloody	1000-50,000	M or P	100 to > 100,000	Equal to serum levels	Variable findings; chest features
Esophageal rupture	Turbid to purulent; red-brown	< 5000 to > 50,000	P	1000-10,000	Usually low	High amylase level pneumothorax in effusion usually strongly suggests
Pancreatitis	Turbid to serosanguineous	1000-50,000	P	1000-10,000	Equal to serum levels	Usually left-sided

¹M = mononuclear cell predominance; P = polymorphonuclear leukocyte predominance.

Figure 9-3. a, b) Two simple algorithms to guide evaluation of suspected venous thromboembolism. a) The standard algorithm is based on the results of ventilation-perfusion lung scanning using PIOPED data. Management of patients with ventilation-perfusion lung scans of low and indeterminate probability must always be guided by clinical judgment based upon cumulative clinical information and the degree of suspicion of pulmonary thromboembolism. The second algorithm uses D-dimer, helical CT, and venous ultrasonography to describe an evidence-based, efficient evaluation that reflects emerging practice. This second algorithm does not have the depth of experience of the standard V/Q approach but anticipates a shift toward use of helical CT as the primary diagnostic test in pulmonary thromboembolism.

■ SYMPTOMS & SIGNS

COMMON SYMPTOMS

The most common symptoms of heart disease are dyspnea, chest pain, palpitations, syncope or presyncope, and fatigue. None are specific, and interpretation depends on the entire clinical picture and, in many cases, diagnostic testing.

Dyspnea

Dyspnea due to heart disease is precipitated or exacerbated by exertion and results from elevated left atrial and pulmonary venous pressures or from hypoxia. The former are most commonly caused by left ventricular systolic dysfunction, left ventricular diastolic dysfunction (due to hypertrophy, fibrosis, or pericardial disease), or valvular obstruction. The acute onset or worsening of left atrial hypertension may result in **pulmonary edema**. **Hypoxia** may be due to pulmonary edema or intracardiac shunting. Dyspnea should be quantified by the amount of activity that precipitates it. Dyspnea is also a common symptom of pulmonary disease, and the etiologic distinction may be difficult. Shortness of breath is also found in sedentary or obese individuals, anxiety states, anemia, and many other illnesses.

Orthopnea is dyspnea that occurs in recumbency and results from an increase in central blood volume. Orthopnea may also result from pulmonary disease and obesity. **Paroxysmal nocturnal dyspnea** is shortness of breath that occurs abruptly 30 minutes to 2 hours after going to bed and is relieved by sitting up or standing up; this symptom is more specific for cardiac disease. Both are more specific for cardiac diseases than exertional dyspnea, but neither is diagnostic of heart failure.

Chest Pain or Discomfort

Chest pain and other forms of discomfort are common symptoms that can occur as a result of pulmonary, pleural, or musculoskeletal disease, esophageal or other gastrointestinal disorders, cervicothoracic nerve root irritation, or anxiety states, as well as many cardiovascular diseases. Myocardial ischemia is the most frequent cause of cardiac chest pain, but it is often experienced more as a sensation of discomfort than actual pain, thereby increasing the potential for neglect on the part of the patient and misdiagnosis by the physician. This is usually described as dull, aching, or as a sensation of "pressure," "tightness," "squeezing," or "gas," rather than as sharp or spasmodic. **Ischemic symptoms** usually subside within 5-20 minutes but may last longer. Protracted episodes often represent **myocardial infarction**. The pain is commonly accompanied by a sense of anxiety or uneasiness. The location is usually retrosternal or left precordial. Though the pain may radiate to or be localized in the throat, lower jaw, shoulders, inner arms, upper abdomen, or back, it nearly always also involves the sternal region. Ischemic pain is often precipitated by exertion, cold temperature, meals, stress, or combinations of these factors and is usually relieved by rest, but many episodes do not conform to these patterns. It is not related to position or respiration and is usually not elicited by chest palpation. In myocardial infarction, a precipitating factor is frequently not apparent.

Hypertrophy of either ventricle and aortic valvular disease may also give rise to ischemic pain or pain with less typical features. Myocarditis, cardiomyopathy, primary pulmonary hypertension, and mitral valve prolapse are associated with chest pain atypical for angina pectoris. Pericarditis may produce pain that changes with position or respiration. Aortic dissection produces an instantaneous onset of tearing pain of great intensity that often radiates to the back.

Lee TH et al: Evaluation of the patient with acute chest pain. N Engl J Med 2000;342:1187. [\[PMID: 10770985\]](#)

Palpitations, Dizziness, Syncope

Palpitations, or awareness of the heartbeat, may be a normal phenomenon or may reflect increased cardiac or stroke output in patients with many noncardiac conditions (eg, exercise, thyrotoxicosis, anemia, anxiety). It may also be due to cardiac abnormalities that increase stroke volume (regurgitant valvular disease, bradycardia) or may be a manifestation of cardiac dysrhythmias. Ventricular premature beats may be sensed as extra or "skipped" beats. Supraventricular or ventricular tachycardia may be felt as rapid, regular or irregular palpitations or "fluttering"; many patients are asymptomatic, however.

If the abnormal rhythm is associated with a sufficient decline in arterial pressure or cardiac output, it may—especially in the upright position—impair cerebral blood flow, causing dizziness, blurring of vision, loss of consciousness (syncope), or other symptoms. However, **dizziness** in particular is very nonspecific and only infrequently is a symptom of cardiac disease or dysrhythmia.

Cardiogenic syncope most commonly results from sinus node arrest or exit block, atrioventricular conduction block, or ventricular tachycardia or fibrillation. It is associated with few prodromal symptoms and may thus be an occasion for injuries. The absence of premonitory symptoms helps distinguish cardiogenic syncope from vasovagal faints, postural hypotension, or seizure but is not a reliable screening tool. Although recovery is often immediate, some patients may exhibit seizure-like movements. Aortic valve disease and hypertrophic obstructive cardiomyopathy may also cause syncope, which is usually exertional or postexertional. Another form of syncope is termed **neurocardiogenic syncope**, commonly known as vasovagal syncope. In this syndrome, there is an inappropriate increase in vagal efferent activity, often resulting from a precedent increase in sympathetic cardiac stimulation. Syncope may follow a brief period of diaphoresis and presyncopal symptoms, or it may be abrupt in onset, mimicking arrhythmia-induced syncope.

FUNCTIONAL CLASSIFICATION OF HEART DISEASE

In the management of patients with heart disease, it is important to quantify and closely follow the severity of symptoms. A commonly used classification system is that of the New York Heart Association, shown below. However, in following individual patients, it is better to document specific activities that produce symptoms, such as walking distance, stairs climbed, or activities of daily living.

Class I: No limitation of physical activity. Ordinary physical activity does not cause undue fatigue, dyspnea, or anginal pain.

Class II: Slight limitation of physical activity. Ordinary physical activity results in symptoms.

Class III: Marked limitation of physical activity. Comfortable at rest, but less than ordinary activity causes symptoms.

Class IV: Unable to engage in any physical activity without discomfort. Symptoms may be present even at rest.

SIGNS OF HEART DISEASE

Although the cardiovascular examination centers on the heart, peripheral signs are often invaluable.

Appearance

While cardiac patients may appear healthy and comfortable at rest, many with acute myocardial infarction appear anxious and restless. **Diaphoresis** suggests hypotension or a hyperadrenergic state, such as during pericardial tamponade, tachyarrhythmias, or myocardial infarction. Patients with severe congestive heart failure or other chronic low cardiac output states may appear **cachectic**.

Cyanosis may be central, due to arterial desaturation, or peripheral, reflecting impaired tissue delivery of adequately saturated blood in low-output states, polycythemia, or peripheral vasoconstriction. Central cyanosis may be caused by pulmonary disease, left heart failure, or right-to-left shunting; the latter will not be improved by increasing the inspired oxygen concentration. **Pallor** usually indicates anemia but may be a sign of low cardiac output.

Vital Signs

Although the normal **heart rate** usually ranges from 50 to 90 beats/min, both slower and more rapid rates may occur in normal individuals or may reflect noncardiac conditions such as anxiety or pain, medication effect, fever, thyroid disease, pulmonary disease, anemia, or hypovolemia. If symptoms or clinical suspicion warrants, an electrocardiogram (ECG) should be performed to diagnose arrhythmia, conduction disturbance, or other abnormality. The range of normal **blood pressure** is wide, but even in asymptomatic individuals systolic pressures below 90 mm Hg or above 140 mm Hg and diastolic pressures above 90 mm Hg warrant further clinical evaluation and follow-up. Initially elevated pressures may decline if the patient is allowed to relax and rest comfortably. **Tachypnea** is also nonspecific, but pulmonary disease and heart failure should be considered when respiratory rates exceed 16/min under resting conditions. **Periodic breathing** (Cheyne-Stokes respiration) is not uncommon in severe heart failure.

Peripheral Pulses & Venous Pulsations

Diminished peripheral pulses most commonly result from arteriosclerotic peripheral vascular disease and may be accompanied by localized **bruits**. Asymmetry of pulses should also arouse suspicion of coarctation of the aorta or aortic dissection. **Exaggerated pulses** may indicate aortic regurgitation, coarctation, patent ductus arteriosus, or other conditions that increase stroke volume. The carotid pulse is a valuable aid to assessment of left ventricular ejection. It has a **delayed upstroke** in aortic stenosis and a **bisferiens** quality (two palpable peaks) in mixed aortic stenosis and regurgitation or hypertrophic obstructive cardiomyopathy. **Pulsus paradoxus** (a decrease in systolic blood pressure during inspiration greater than the normal 10 mm Hg) is a valuable sign of pericardial tamponade, though it also occurs in asthma and chronic obstructive pulmonary disease. **Pulsus alternans**, in which the amplitude of the pulse alternates every other beat during sinus rhythm, occurs when cardiac contractility is very depressed or with large pericardial effusions.

Jugular venous pulsations provide insight into right atrial pressure. They indicate (1) **elevated central venous pressure** if they are more than 3 vertical centimeters above the angle of Louis, (2) increased central blood volume if they rise more than 1 cm with sustained (30 seconds) right upper quadrant abdominal pressure (**hepatojugular reflux**), (3) tricuspid obstruction or pulmonary hypertension if the a wave is exaggerated, and (4) tricuspid regurgitation if **large cv** waves are seen. The latter may be associated with hepatic pulsations. Atrioventricular dissociation due to conduction block or ventricular arrhythmia can be recognized by intermittent **cannon a waves**.

Drazner MH et al: Prognostic importance of elevated jugular venous pressure and a third heart sound in patients with heart failure. *N Engl J Med* 2001;345:574. [PMID: 11529211]

Pulmonary Examination

Rales heard at the lung bases are a sign of congestive heart failure but may be caused by similarly localized pulmonary disease. **Wheezing** and **rhonchi** suggest obstructive pulmonary disease but may occur in left heart failure. **Pleural effusions** with bibasilar percussion dullness and reduced breath sounds are common in congestive heart failure and are more frequent or larger on the right.

Precordial Pulsations

A **parasternal lift** usually indicates right ventricular hypertrophy, pulmonary hypertension (pulmonary artery systolic pressure > 50 mm Hg), or left atrial enlargement; pulmonary artery pulsations may also be visible. The left ventricular **apical impulse**, if sustained and enlarged, suggests myocardial hypertrophy or dysfunction. If it is very prominent but not sustained, the apical impulse may indicate volume overload or high-output states. Additional precordial pulsations may reflect regional abnormalities of left ventricular contraction.

Heart Sounds & Murmurs

Auscultation is diagnostic of—or helpful in diagnosis of—many heart diseases, including cardiac failure. Specific findings are discussed under diagnostic headings.

The **first heart sound** (S_1), the closing of the mitral valve and tricuspid valve, may be diminished with severe left ventricular dysfunction or accentuated with mitral stenosis or short PR intervals. S_2 , the closing of the atrioventricular valve and pulmonary valve, is usually split, with the two components (aortic preceding pulmonary) being separated more during inspiration; **splitting** is *fixed* in atrial septal defect, *wide* with right bundle branch block, and *absent* or *reversed* (**paradoxical splitting**) with aortic stenosis, left ventricular failure, or left bundle branch block. With normal splitting, an accentuated P_2 is an important sign of pulmonary hypertension. **Third and fourth heart sounds** (ventricular and atrial gallops, respectively) indicate ventricular volume overload or impaired compliance and may be heard over either ventricle. An apical S_3 is a normal finding in younger individuals and in pregnancy. Additional auscultatory findings include sharp, high-pitched sounds classified as "**clicks**." These may be early systolic and represent **ejection sounds** (as with a bicuspid aortic valve or pulmonary stenosis) or may occur in mid or late systole, indicating myxomatous changes in the mitral valve.

While many **murmurs** indicate valvular disease, a soft, short systolic murmur, usually localized along the left sternal border or toward the apex, may be innocent, reflecting pulmonary flow. **Innocent murmurs** often vary with inspiration, diminish in the upright position, and are most frequently heard in thin individuals. **Systolic murmurs** are **pansystolic (holosystolic)** when they merge with the first sound and persist through all of systole or "**ejection**" **murmurs** when they begin after the first sound and end before the second sound, with a peak in early or mid systole. The former represent mitral regurgitation if maximal at the apex or in the axilla and tricuspid regurgitation or ventricular septal defect if best heard at the sternal border. Short aortic ejection murmurs with a preserved A_2 are common in older individuals, especially when hypertension has been present, and even if they are moderately loud they usually reflect thickening (sclerosis) of the valve rather than stenosis. Association of murmurs with palpable vibrations ("**thrills**") is always clinically significant, as are **diastolic murmurs**. Further evaluation is warranted when the patient has symptoms of possible cardiac origin. Some studies suggest that one should have a low threshold for evaluating murmurs with echocardiograms.

Richardson TR et al: Bedside cardiac examination: constancy in a sea of change. *Curr Probl Cardiol* 2000;25:783. [PMID: 11082789]

Edema

Subcutaneous fluid collections appear first in the lower extremities in ambulatory patients or in the sacral region of bedridden individuals. In heart disease, edema results from elevated right atrial pressures. Right heart failure most commonly results from left heart failure, although the right-sided signs may predominate. Other cardiogenic causes of edema include pericardial disease, right-sided valve lesions, and cor pulmonale. Edema may also be due to peripheral venous insufficiency, venous obstruction, nephrotic syndrome, cirrhosis, premenstrual fluid retention, drugs (especially vasodilators such as calcium channel blockers or salt-retaining medications such as nonsteroidal anti-inflammatory agents), or it may be idiopathic.

■ DIAGNOSTIC TESTING

The **chest x-ray** provides information about heart size, the pulmonary circulation (with characteristic signs suggesting both pulmonary artery or pulmonary venous hypertension), primary pulmonary disease, and aortic abnormalities. The **echocardiogram** provides much more reliable information about chamber size, hypertrophy, pericardial effusions, valvular abnormalities, and congenital abnormalities and has replaced the x-ray for evaluation of cardiac disease. The **electrocardiogram (ECG)** indicates cardiac rhythm, reveals conduction abnormalities, and provides evidence of ventricular hypertrophy, myocardial infarction, or ischemia. Nonspecific ST segment and T wave changes may reflect these processes but are also noted with electrolyte imbalance, drug effects, and many other conditions. Routine x-rays and ECGs are not recommended to screen for heart disease and have a limited role in the follow-up of patients with known heart disease. However, a baseline ECG is helpful in older patients.

NONINVASIVE DIAGNOSTIC TESTING

Noninvasive diagnostic procedures are growing in number and application. However, they are frequently overutilized. The clinician should carefully consider what question is being asked and how the results will alter patient management before ordering these tests. They have limited applicability in screening for asymptomatic

disease and should not be substituted for a careful clinical evaluation.

The most versatile and generally informative noninvasive technique is **echocardiography**, which plays a crucial role in the evaluation of patients with most cardiac symptoms and conditions, including congenital, valvular, coronary, and cardiomyopathic heart disease. An overview of echocardiography and its applications is presented below, as is a brief discussion of the evolving role of cardiac MRI. Other specialized noninvasive cardiac testing procedures, such as stress testing, ambulatory electrocardiography, cardiac nuclear medicine tests, and cardiac computed tomography are discussed in conjunction with their major applications.

Echocardiography

Echocardiography provides measurements of left ventricular size, function, and thickness. Left ventricular regional wall motion can be assessed, and the size of all four cardiac chambers can be determined. The morphology of the heart valves can be examined. Hypertrophic cardiomyopathy, pericardial effusion, mitral valve prolapse, valvular vegetations, and cardiac tumors may all be diagnosed. **Doppler ultrasound** provides a quantitative or qualitative estimation of transvalvular gradients, pulmonary artery pressure, valvular regurgitation, and intraventricular shunts. Doppler measurements, especially of mitral valve inflow patterns, are also frequently used to evaluate diastolic function, but changes related to aging and the effects of heart rate, blood pressure, and valvular regurgitation often make these measurements unreliable. **Color Doppler** visually demonstrates patterns and directionality of flow; it has been particularly useful in evaluating congenital heart disease. However, Doppler studies frequently detect *clinically insignificant* valvular regurgitation; care should be taken not to overinterpret those findings.

Transesophageal echocardiography is used to improve the quality of echocardiograms, to derive information about posterior structures (especially the atria and atrioventricular valves) and prosthetic valves, and to monitor patients during surgery. It is superior to surface echocardiography in diagnosing left atrial thrombi, valvular vegetations, and eccentric mitral regurgitant jets (especially with prosthetic valves). The absence of atrial thrombi identifies patients in atrial fibrillation at low risk for embolization, thus facilitating early cardioversion. It is also quite sensitive in detecting aortic dissection and severe atherosclerosis of the ascending aorta, which may be the source for transient ischemic attacks or embolic strokes.

Stress echocardiography is used to enhance the information available from ECGs and as an alternative to nuclear medicine procedures. Echocardiograms may be performed during or immediately following exercise. Transient depression of segmental wall motion during or following stress suggests ischemia. Improvement in wall motion during low-dose dobutamine infusions is an indicator of myocardial viability. Dobutamine infusions can also be utilized as a form of stress testing in patients unable to exercise.

J Am Coll Cardiol 1999;33:586. [PMID: 9973044]

Magnetic Resonance Imaging (MRI)

Cardiac MRI continues to evolve rapidly. Currently available systems provide high-quality and high-resolution images of cardiac and adjacent vascular structures, making this a preferred technique to evaluate many cardiac conditions, including pericardial and congenital abnormalities. MRI also provides excellent images that can be used to quantify cardiac function and structure. With the use of gadolinium contrast agents, MRI has been used to assess myocardial perfusion and viability.

Botnar RM et al: Coronary magnetic resonance angiography. Cardiol Rev 2001;9:77. [PMID: 11209146]

CARDIAC CATHETERIZATION & ANGIOGRAPHY

Although cardiac catheterization and angiography remain the standard tests for assessment of many hemodynamic and anatomic abnormalities of the heart, they have often been supplanted by echocardiography and other imaging modalities for the initial and serial evaluation of many conditions. Nonetheless, "invasive" procedures (ie, those involving the use of intravascular and intracardiac catheters), when appropriately employed, remain invaluable in the management of most patients with congenital, valvular, and coronary heart disease.

Right heart catheterization is convenient to perform in the laboratory, at the bedside, or in the operating room. It allows measurement of right atrial, right ventricular, pulmonary artery and pulmonary capillary wedge pressures (the latter an indicator of left atrial pressure), oxygen saturation, and cardiac output. These data may diagnose intracardiac shunts, physiologically significant pericardial disease, and right-sided valve lesions and can distinguish between cardiac and pulmonary disease. Hemodynamic monitoring may be very helpful in the assessment and treatment of shock, heart failure, complicated myocardial infarction, respiratory failure, and postoperative hemodynamic instability. However, this procedure is not without risk—complications include pneumothorax, bleeding, arrhythmias, pulmonary artery rupture, pulmonary emboli, and infection. Therefore, the role of this procedure remains unsettled, though the available evidence indicates that appropriate use of pulmonary artery catheters to guide therapy may reduce morbidity. Bedside echocardiography can be used to assess left ventricular function, pericardial effusion, valvular abnormalities, intracardiac shunts, and pulmonary artery and central venous pressures when the need for continuous monitoring is not anticipated.

Left heart catheterization is performed to assess the cardiac valves and left ventricular function. Mitral stenosis and aortic stenosis are quantified by measuring the pressure gradients across the valves and, taking flow into account, the estimated valve areas. Mitral and aortic regurgitation are assessed semiquantitatively from contrast injections in the left ventricle and aorta, respectively. The ejection fraction and regional wall motion are assessed by contrast left ventriculograms. The severity of stenotic valve lesions can usually also be measured by echocardiography, though regurgitant lesions may be more difficult to quantify. Left ventricular function can also be assessed by echocardiography and nuclear scintigraphy. Therefore, the main indications for left heart catheterization are for confirmation of the need for valve surgery and for obtaining coronary angiograms. Increasingly, the catheterization laboratory is used for performing coronary interventions.

■ CONGENITAL HEART DISEASE

Congenital lesions account for only about 2% of heart disease that presents in adulthood. Only the most common acyanotic lesions are discussed here. The review articles cited below provide further discussion of the major congenital conditions that affect adults.

PULMONARY STENOSIS

Essentials of Diagnosis

- No symptoms in patients with mild or moderately severe lesions.
- Severe cases may present with right-sided heart failure and cause sudden death.
- High-pitched systolic ejection murmur maximal in the second left interspace. P₂ delayed and soft or absent. Ejection click often present. Increased right ventricular impulse.

- Palpable thrill at second left intercostal space.
- Right ventricular hypertrophy on ECG; pulmonary artery dilation on x-ray. Echo-Doppler diagnostic.

General Considerations

Stenosis of the pulmonary valve or infundibulum increases the resistance to outflow, raises the right ventricular pressure, and limits pulmonary blood flow. In the absence of associated shunts, arterial saturation is normal, but severe stenosis causes peripheral cyanosis by reducing cardiac output. Clubbing and polycythemia do not develop unless a patent foramen ovale or atrial septal defect is present, permitting right-to-left shunting.

Clinical Findings

A. Symptoms and Signs

Mild cases (right ventricular-pulmonary artery gradient < 30 mm Hg) are asymptomatic. Moderate to severe stenosis (gradients 50 to > 80 mm Hg) may cause dyspnea on exertion, syncope, chest pain, and eventually right ventricular failure.

There is a palpable parasternal lift. A loud, harsh systolic murmur and a prominent thrill are present in the left second and third interspaces parasternally; the murmur is in the third and fourth interspaces in infundibular stenosis. The second sound is obscured by the murmur in severe cases; the pulmonary component is diminished, delayed, or absent. Both components are audible in mild cases. A right-sided S₄ and a prominent a wave in the venous pulse are present in severe cases.

B. Electrocardiography and Chest X-Ray

Right axis deviation or right ventricular hypertrophy is noted; peaked P waves provide evidence of right atrial overload. Heart size may be normal on radiographs, or there may be a prominent right ventricle and atrium or gross cardiac enlargement, depending upon the severity. There is often poststenotic dilation of the main and left pulmonary arteries. Pulmonary vascularity is normal or diminished.

C. Diagnostic Studies

Echocardiography usually demonstrates the anatomic abnormality and assesses right ventricular size and function. Doppler ultrasound can estimate the gradient accurately; its findings are usually confirmed by cardiac catheterization.

Prognosis & Treatment

Patients with mild pulmonary stenosis may have a normal life span. Moderate stenosis may be asymptomatic in childhood and adolescence, but symptoms may appear as patients grow older. Severe stenosis is associated with sudden death and can cause heart failure in the 20s and 30s.

Symptomatic patients or those with evidence of right ventricular hypertrophy and resting gradients over 75-80 mm Hg require correction in most cases. Percutaneous balloon valvuloplasty has proved successful and is usually the treatment of choice. Surgery can be performed with an operative mortality rate of 2-4% and an excellent long-term result in most cases.

COARCTATION OF THE AORTA

Essentials of Diagnosis

- Infants may have severe heart failure; children and adults are usually asymptomatic, presenting with hypertension.
- Absent or weak femoral pulses.
- Systolic pressure higher in upper extremities than in lower extremities; diastolic pressures are similar.
- Harsh systolic murmur heard in the back.
- ECG shows left ventricular hypertrophy; chest x-ray shows rib notching; echo-Doppler is diagnostic.

General Considerations

Coarctation of the aorta consists of localized narrowing of the aortic arch just distal to the origin of the left subclavian artery. Collateral circulation develops through the intercostal arteries and the branches of the subclavian arteries. Coarctation is one of the causes of secondary hypertension and should be considered in young patients with elevated blood pressure. A bicuspid aortic valve is also present in 25% of cases.

Clinical Findings

A. Symptoms and Signs

If cardiac failure does not occur in infancy, there are usually no symptoms until the hypertension produces left ventricular failure or cerebral hemorrhage; the latter may also occur from associated cerebral aneurysms. Strong arterial pulsations are seen in the neck and suprasternal notch. Hypertension is present in the arms, but the pressure is normal or low in the legs. This difference is exaggerated by exercise. Femoral pulsations are weak and are delayed in comparison with the brachial pulse. Patients with large collaterals may have relatively small gradients but still have severe coarctation. Late systolic ejection murmurs at the base are often heard better posteriorly, especially over the spinous processes. There may be an associated aortic insufficiency murmur due to a bicuspid aortic valve.

B. Electrocardiography and Chest X-Ray

The ECG usually shows left ventricular hypertrophy. Radiography shows scalloping of the ribs due to enlarged collateral intercostal arteries, dilation of the left subclavian artery and poststenotic aortic dilation, and left ventricular enlargement.

C. Diagnostic Studies

Measurement of the gradient across the lesion by catheterization and aortography remain the primary methods of diagnosis. MRI is a useful imaging adjunct, and Doppler ultrasound can also estimate the severity of obstruction.

Prognosis & Treatment

Cardiac failure is common in infancy and in older untreated patients; it is uncommon in late childhood and young adulthood. Most untreated patients with the adult form of coarctation die before age 50 from the complications of hypertension, rupture of the aorta, infective endarteritis, or cerebral hemorrhage (associated in some cases with congenital cerebral aneurysms). Aortic dissection also occurs with increased frequency in coarctation.

Resection of the coarcted site has a surgical mortality rate of 1-4%. The risks of the disease are such, however, that all coarctations in patients up to age 20 years should be resected. In patients under 40 years of age, surgery is advisable if the patient has refractory hypertension or significant left ventricular hypertrophy. The surgical mortality rate rises considerably in patients over age 50, making surgery of doubtful value. Balloon angioplasty of the stenosis has been accomplished successfully and may become the procedure of choice, but aortic tears have been described. About one-fourth of corrected patients continue to be hypertensive years after surgery and they have all the complications associated with hypertension.

O'Sullivan JJ et al: Prevalence of hypertension in children after early repair of coarctation of the aorta: a cohort study using casual and 24 hour blood pressure measurement. Heart 2002 88:163. [PMID: 12117846]

ATRIAL SEPTAL DEFECT & PATENT FORAMEN OVALE

Essentials of Diagnosis

- Usually asymptomatic until middle age.
- Right ventricular lift; S₂ widely split and fixed.
- Grade I-III/VI systolic ejection murmur at pulmonary area.
- ECG shows right ventricular conduction delay; x-ray shows dilated pulmonary arteries and increased vascularity; echo-Doppler usually diagnostic.

- Residual patent foramen ovale can lead to paradoxical emboli and cerebrovascular events.

General Considerations

The most common form of atrial septal defect (80% of cases) is persistence of the ostium secundum in the mid septum; less commonly, the ostium primum (which is low in the septum) persists, in which case mitral or tricuspid abnormalities may also be present. A third form is the sinus venosus defect of the upper part of the septum. This is often associated with partial anomalous drainage of the pulmonary veins into the superior vena cava. In all cases, normally oxygenated blood from the higher-pressure left atrium passes into the right atrium, increasing right ventricular output and pulmonary blood flow.

Although most individuals with an atrial septal defect have relatively small amounts of left-to-right shunting, those with moderate to severe shunts are at risk of developing severe pulmonary hypertension due to irreversible pulmonary vascular disease. This may then lead to Eisenmenger's syndrome, which is characterized by right-to-left shunting and cyanosis. Atrial septal defects also predispose to atrial fibrillation and paradoxical right-to-left emboli.

Not uncommonly, there is incomplete closure of the septum secundum, leaving a small residual opening or patent foramen ovale. Very small ones can be detected in approximately 25% of autopsies, while large defects (0.5-1 cm) are present in 6%.

Clinical Findings

A. Symptoms and Signs

Most patients with small or moderate defects and those with patent foramen ovale are asymptomatic. With large shunts, exertional dyspnea or cardiac failure may develop, most commonly in the fourth decade or later. Prominent right ventricular and pulmonary artery pulsations are readily visible and palpable. A moderately loud systolic ejection murmur can be heard in the second and third interspaces parasternally as a result of increased pulmonary artery flow. S_2 is widely split and does not vary with breathing.

B. Electrocardiography and Chest X-Ray

Right axis deviation or right ventricular hypertrophy may be present in ostium secundum defects. Incomplete or complete right bundle branch block is present in nearly all cases of atrial septal defect, and superior axis deviation is noted in ostium primum defect. With sinus venosus defects, the P axis is leftward of +15 degrees. The chest radiograph shows large pulmonary arteries, increased pulmonary vascularity, an enlarged right atrium and ventricle, and a small aortic knob.

C. Diagnostic Studies

Echocardiography can demonstrate right ventricular volume overload with a large right ventricle and atrium, and sometimes the defect itself. Echocardiography with saline bubble contrast and Doppler flow studies can demonstrate shunting. A transesophageal echo is helpful when transthoracic echo quality is not optimal, and it improves the sensitivity for small shunts and patent foramen ovale. Radionuclide flow studies quantify left-to-right shunting, and MRI can also elucidate the anatomy. Cardiac catheterization remains the definitive diagnostic procedure, since it can demonstrate an increase in oxygen saturation between the venae cavae and right ventricle due to the admixture of oxygenated blood from the left atrium, quantify the shunt, and measure pulmonary vascular resistance. Right and left ventricular contrast angiography may demonstrate associated valvular abnormalities or anomalous pulmonary venous drainage.

Prognosis & Treatment

Patients with small shunts may live a normal life span. Large shunts cause disability by age 40. Raised pulmonary vascular resistance secondary to pulmonary hypertension rarely occurs in childhood or young adult life in secundum defects but is more common in primum defects. After age 40, pulmonary hypertension, cardiac arrhythmias (especially atrial fibrillation), and heart failure may occur in secundum defects. Paradoxical systemic arterial embolization is a concern, especially in patients with pulmonary hypertension or venous thrombosis. Patent foramen ovales are not associated with significant shunting and therefore are asymptomatic. However, they are the lesion responsible for most paradoxical emboli and are one of the most frequent causes of cryptogenic strokes. However, the risk for such events is relatively low except in patients with associated atrial septal aneurysms, who require aggressive anticoagulation or closure of the defect. Infective endocarditis does not occur with increased frequency.

Small atrial septal defects do not require surgery. The risks are now sufficiently low so that patients with left-to-right shunts and pulmonary-to-systemic flow ratios between 1.5 and 2.0 may be operated on if the total clinical picture warrants. Ratios exceeding 2.0 are an indication for surgical closure of the defect.

Transcatheter techniques are now widely used for closing atrial septal defects and patent foramen ovales. These involve the deployment of an umbrella-like occlusion device from a femoral venous approach. The devices work best in patients with centrally located secundum defects.

Surgery should be withheld from patients with pulmonary hypertension with reversed (right-to-left) shunting (Eisenmenger's syndrome) because of the risk of acute right heart failure. Relocation of pulmonary veins is required in patients with partial anomalous venous drainage. In ostium primum defects, in addition to closure of the defect, suture of the valve clefts—especially those of the mitral valve—is advisable if mitral regurgitation of any significant degree is present. The surgical mortality rate is low (< 1%) in patients under age 45 who are not in cardiac failure and those who have systolic pulmonary artery pressures less than 60 mm Hg. It increases to 5-10% in patients over age 40 with cardiac failure or with systolic pulmonary artery pressures greater than 60 mm Hg.

VENTRICULAR SEPTAL DEFECT

Essentials of Diagnosis

- Adults asymptomatic if defect is small to moderate.
- Grade II-VI/VI pansystolic murmur maximal at the left sternal border; associated thrill common.
- ECG may show left ventricular hypertrophy—or right ventricular hypertrophy if shunt is reversed; x-ray shows increased pulmonary vascularity. Echo-Doppler is diagnostic.

General Considerations

In this lesion, a persistent opening in the upper interventricular septum resulting from failure of fusion with the aortic septum permits blood to pass from the high-pressure left ventricle into the low-pressure right ventricle. The subsequent natural history and pathophysiology depend on the size of the defect and the magnitude of left-to-right shunting. Large defects are associated with early left ventricular failure. Chronic but more moderate left-to-right shunts may lead to pulmonary vascular disease and right-sided failure. Many ventricular defects close spontaneously in early childhood.

Clinical Findings

A. Symptoms and Signs

The clinical features are dependent upon the size of the defect and the presence or absence of a raised pulmonary vascular resistance. Large shunts are associated with loud, harsh holosystolic murmurs in the left third and fourth interspaces along the sternum and, in some cases, middiastolic flow murmurs and an S_3 at the apex. Smaller shunts may produce only an early systolic murmur or a diamond-shaped murmur. A systolic thrill is common. Clinical evidence of pulmonary hypertension is often more informative than the murmur itself. High defects may be associated with aortic regurgitation owing to prolapse of a valve leaflet.

B. Electrocardiography and Chest X-Ray

The ECG may be normal or may show right, left, or biventricular hypertrophy, depending on the size of the defect and the pulmonary vascular resistance. With large shunts, the right or left ventricle (or both), the left atrium, and the pulmonary arteries are enlarged, and pulmonary vascularity is increased on chest radiographs. If pulmonary vascular disease evolves, an enlarged pulmonary artery with diminished distal vascularity is seen.

C. Diagnostic Studies

Echocardiography can demonstrate chamber size and may demonstrate the defect. Doppler ultrasound can qualitatively assess the magnitude of shunting and the pulmonary artery pressure. Magnetic resonance imaging can often visualize the defect, while radionuclide flow studies quantify pulmonary-to-systemic flow ratios. Cardiac catheterization permits definitive diagnosis in all but the most trivial defects; it is the only technique that can measure pulmonary vascular resistance.

Prognosis & Treatment

Patients with the typical murmur as the only abnormality have a normal life expectancy except for the threat of infective endocarditis. Endocarditis is more typical of smaller shunts. Antibiotic prophylaxis is mandatory. With large shunts, congestive heart failure may develop early in life, and survival beyond age 40 is unusual. Shunt reversal occurs in an estimated 25% of patients, producing Eisenmenger's syndrome.

Small shunts (pulmonary-to-systemic flow ratio < 1.5) in asymptomatic patients do not require surgery. Defects causing large shunts should be repaired to prevent pulmonary hypertension or late heart failure. Once pulmonary hypertension is present (systolic pulmonary arterial pressures > 85 mm Hg), the surgical mortality risk is at least 50%. If right-to-left shunting is present (Eisenmenger's syndrome), surgery is contraindicated. Many defects (up to 40%) close spontaneously. Therefore, surgery should be deferred until late childhood unless there are signs of heart failure or pulmonary hypertension. Surgical mortality rates are low (2-3%). Some defects can be closed percutaneously.

Marshalland AC et al: Closing ventricular septal defects in the cardiac catheterization laboratory. Heart Dis 2002;4:51. [PMID: 11975833]

PATENT DUCTUS ARTERIOSUS

Essentials of Diagnosis

- Adults with small or moderately large patent ductus are usually asymptomatic at least until middle age.
- Widened pulse pressure; loud S₂.
- Continuous murmur over pulmonary area; thrill common.
- Echo-Doppler is helpful, but the lesion is best visualized by aortography.

General Considerations

The embryonic ductus arteriosus fails to close normally and persists as a shunt connecting the left pulmonary artery and aorta, usually near the origin of the left subclavian artery. Prior to birth, the ductus is kept patent by the effect of circulating prostaglandins; in early infancy, a patent ductus can often be closed by administration of intravenous indomethacin (0.2 mg/kg intravenously). If the defect is not closed, blood flows continuously from the aorta through the ductus into the pulmonary artery in both systole and diastole; the defect is a form of arteriovenous fistula, increasing the work of the left ventricle. If it remains open, obliterative changes in the pulmonary arterioles can cause pulmonary hypertension, with reversal of the direction of shunting. Then the shunt is bidirectional or right-to-left (Eisenmenger's syndrome). This complication does not correlate with shunt size.

Clinical Findings

A. Symptoms and Signs

There are no symptoms unless left ventricular failure or pulmonary hypertension develops. The heart is of normal size or slightly enlarged, with a hyperdynamic apical impulse. The pulse pressure is wide, and diastolic pressure is low. A continuous rough "machinery" murmur, accentuated in late systole at the time of S₂, is heard best in the left first and second interspaces at the left sternal border. Thrills are common.

B. Electrocardiography and Chest X-Ray

A normal tracing or left ventricular hypertrophy is found, depending upon the magnitude of shunting. On chest radiographs, the heart is normal in size and contour, or there may be left ventricular and left atrial enlargement. The pulmonary artery, aorta, and left atrium are prominent.

C. Diagnostic Studies

Echocardiography quantifies left ventricular and atrial size. MRI can demonstrate the abnormality, and the magnitude of the shunt can also be determined by radionuclide flow studies. Cardiac catheterization establishes the presence and severity of a left-to-right shunt and whether pulmonary hypertension is present; angiography can define its anatomy.

Prognosis & Treatment

Large shunts cause a high mortality rate from cardiac failure early in life. Smaller shunts are compatible with long survival, congestive heart failure being the most common complication. Infective endocarditis or endarteritis may also occur, and antibiotic prophylaxis is required. A small percentage of patients develop pulmonary hypertension and reversal of shunt (right- to-left shunting), such that the lower legs, especially the toes, appear cyanotic and clubbed in contrast to normally pink fingers. At this stage, the patient is inoperable.

Surgical ligation of the patent ductus can be accomplished with excellent results in uncomplicated patients. Recent experience with transcatheter closure has also been favorable, indicating that where available, this newer option is the procedure of choice for most patients. Closure is recommended for children or adults with symptoms or large shunts. Asymptomatic adults with no left ventricular hypertrophy and small left-to-right shunts are at low risk of developing pulmonary hypertension or congestive heart failure. The indications for closure of a patent ductus arteriosus in the presence of pulmonary hypertension are controversial. Opinion favors closure whenever the pulmonary vascular resistance is low and the flow through the ductus is from left to right.

■ VALVULAR HEART DISEASE

While most cases of valvular disease in the United States were at one time due to rheumatic heart disease (still true in developing countries), other causes are now more common. The typical findings of each lesion are described in [Table 10-1](#). [Table 10-2](#) shows how to use bedside maneuvers to distinguish murmurs.

Echocardiography yields information about valve morphology, left ventricular mass and function, and atrial and ventricular chamber size. Doppler ultrasound provides quantitative measurements of transvalvular gradients and pulmonary artery pressure and gives more qualitative estimates of valvular regurgitation. The prevalence of mild or even moderate valvular regurgitation is not small, and care must be taken not to overestimate the importance of these findings. Transesophageal echo (TEE) often provides improved image quality. Valve morphology (particularly with prosthetic valves), vegetations, thrombi, and eccentric regurgitant jets are more easily identified with TEE.

The now withdrawn diet medications fenfluramine and dexfenfluramine may be associated with valvular heart disease, but whether these agents cause clinically significant valvular abnormalities remains controversial. Recent data suggest that this is, if anything, a rare occurrence.

MITRAL STENOSIS

Essentials of Diagnosis

- Dyspnea, orthopnea, and paroxysmal nocturnal dyspnea.
- Symptoms often precipitated by onset of atrial fibrillation or pregnancy.
- Prominent mitral first sound, opening snap (usually), and apical diastolic crescendo rumble.
- ECG shows left atrial abnormality and, commonly, atrial fibrillation. Echo-Doppler confirms diagnosis and quantitates severity.

General Considerations

Nearly all patients with mitral stenosis have underlying rheumatic heart disease, though a history of rheumatic fever is often absent.

Clinical Findings

A. Symptoms and Signs

A characteristic finding of mitral stenosis is a localized middiastolic murmur low in pitch whose duration varies with the severity of the stenosis and the heart rate ([Table 10-1](#)). Because it is thickened, the valve opens in early diastole with an opening snap. The sound is sharp, is widely distributed over the chest, and occurs early after A_2 in severe and later in milder varieties of mitral stenosis. In severe mitral stenosis with low flow across the mitral valve, the murmur may be soft and difficult to find, but the opening snap can usually be heard. If the patient has both mitral stenosis and mitral regurgitation, the dominant features may be the systolic murmur of mitral regurgitation with or without a short diastolic murmur and a delayed opening snap.

When the valve has narrowed to less than 1.5 cm^2 (normal, $4\text{--}6 \text{ cm}^2$), the left atrial pressure must rise to maintain normal flow across the valve and a normal cardiac output. This results in a pressure difference between the left atrium and left ventricle during diastole. The pressure gradient and the length of the diastolic murmur reflect the severity of mitral stenosis; they persist throughout diastole when the lesion is severe or when the ventricular rate is rapid.

In mild cases, left atrial pressure and cardiac output may be essentially normal and the patient asymptomatic, but in moderate stenosis (valve area $< 1.5 \text{ cm}^2$)—especially with tachycardia, which shortens diastole and increases mitral flow rate—dyspnea and fatigue appear as the left atrial pressure rises. With severe stenosis, the left atrial pressure is high enough to produce pulmonary venous congestion at rest and reduce cardiac output, with resulting dyspnea, fatigue, and right heart failure. Recumbency at night further increases the pulmonary blood volume, causing orthopnea and paroxysmal nocturnal dyspnea. Severe pulmonary congestion may also be initiated by any acute respiratory infection, excessive salt and fluid intake, endocarditis, or recurrence of rheumatic carditis. As a result of long-standing pulmonary venous hypertension, anastomoses develop between the pulmonary and bronchial veins in the form of bronchial submucosal varices. These often rupture, producing mild or severe hemoptysis. In a few patients, the pulmonary arterioles become narrowed; this greatly increases the pulmonary artery pressure and accelerates the development of right ventricular hypertrophy and failure. These patients have relatively little dyspnea but experience fatigue on exertion.

Fifty to 80 percent of patients develop paroxysmal or chronic atrial fibrillation that, until the ventricular rate is controlled, may precipitate dyspnea or pulmonary edema.

B. Diagnostic Studies

Echocardiography is the most valuable technique for assessing mitral stenosis. The valve is thickened, opens poorly, and closes slowly. The anterior and posterior leaflets are fixed and move together, rather than in opposite directions. Left atrial size can be determined by echocardiography: increased size denotes an increased likelihood of atrial fibrillation or systemic emboli. The mitral valve area can be measured, and the gradient and pulmonary artery pressure can be estimated by Doppler techniques. Echocardiography also detects atrial myxoma, which sometimes presents clinically in a fashion resembling mitral stenosis.

Because echocardiography and careful symptom evaluation provide most of the needed information, cardiac catheterization is employed primarily to detect associated valve, coronary, or myocardial disease—usually after the decision to intervene has been made.

Treatment & Prognosis

Mitral stenosis may be present for a lifetime with few or no symptoms, or it may become severe in a few years. In most cases, there is a long asymptomatic phase, followed by subtle limitation of activity. Pregnancy and its associated increase in cardiac output and the transmitral pressure gradient often precipitate symptoms. The onset of atrial fibrillation often precipitates more severe symptoms, which usually improve with control of the ventricular rate or restoration of sinus rhythm. Conversion to and subsequent maintenance of sinus rhythm is most commonly successful when the duration of atrial fibrillation is brief ($< 6\text{--}12$ months) and the left atrium is not severely dilated (diameter $< 4.5 \text{ cm}$). Once atrial fibrillation occurs, the patient should receive warfarin anticoagulation therapy even if sinus rhythm is restored, since atrial fibrillation often recurs even with antiarrhythmic therapy and 20-30% of these patients will have systemic embolization if untreated. Systemic embolization in the presence of only mild to moderate disease is not an indication for surgery but should be treated with warfarin anticoagulation.

Indications for relieving the stenosis include the following: (1) uncontrollable pulmonary edema, (2) limiting dyspnea and intermittent pulmonary edema, (3) evidence of pulmonary hypertension with right ventricular hypertrophy or hemoptysis, (4) limitation of activity despite ventricular rate control and medical therapy, and (5) recurrent systemic emboli despite anticoagulation with moderate or severe stenosis.

Open mitral commissurotomy may be effective in patients without substantial mitral regurgitation. Replacement of the valve is indicated when combined stenosis and insufficiency are present or when the mitral valve is so distorted and calcified that a satisfactory valvulotomy is not possible. Operative mortality rates are low: 1-3% in most institutions. Balloon valvuloplasty is effective in patients without accompanying regurgitation. Initial success rates are high, especially if valve calcification is not excessive. The rate of restenosis is lower than that with aortic stenosis. As a result, this option appears to be a suitable alternative to surgery for many patients in experienced centers.

Problems associated with prosthetic valves are thrombosis (especially at the mitral position), paravalvular leak, endocarditis, and degenerative changes in tissue valves. Warfarin anticoagulant therapy is mandatory with mechanical prostheses and is usually employed for at least the initial 3 months with bioprostheses, especially if the patient has significant left atrial enlargement. If atrial fibrillation persists postoperatively, ongoing anticoagulation is required.

MITRAL REGURGITATION (MITRAL INSUFFICIENCY)

Essentials of Diagnosis

- Variable causes determine clinical presentation.
- May be asymptomatic for many years (or for life) or may cause left-sided heart failure.
- Pansystolic murmur at the apex, radiating into the axilla; associated with S_3 .
- ECG shows left atrial abnormality or atrial fibrillation and left ventricular hypertrophy; x-ray shows left atrial and ventricular enlargement. Echo-Doppler confirms diagnosis and estimates severity.

General Considerations

Mitral regurgitation may result from many processes. Rheumatic disease is associated with a thickened valve with reduced mobility and often a mixed picture of stenosis and regurgitation. In developed countries, more common causes of mitral regurgitation include myxomatous degeneration (eg, **mitral valve prolapse** with or without connective tissue diseases such as Marfan's syndrome), infective endocarditis, and subvalvular dysfunction (due to papillary muscle dysfunction or ruptured chordae tendineae). Cardiac tumors, chiefly left atrial myxoma, are a rare cause of mitral regurgitation.

Clinical Findings

A. Symptoms and Signs

During left ventricular systole, the mitral leaflets do not close normally, and blood is ejected into the left atrium as well as through the aortic valve. The net effect is an

increased volume load on the left ventricle, and the presentation depends on the rapidity with which the lesion develops. In acute regurgitation, left atrial pressure rises abruptly, leading to pulmonary edema if severe. When it is chronic, the left atrium enlarges progressively, but the pressure in pulmonary veins and capillaries rises only transiently during exertion. Exertional dyspnea and fatigue progress gradually over many years.

Mitral regurgitation leads to left atrial enlargement and may cause subsequent atrial fibrillation. Systemic embolization is relatively unusual compared with other conditions causing atrial fibrillation. Mitral regurgitation may predispose to infective endocarditis.

Clinically, mitral regurgitation is characterized by a pansystolic murmur maximal at the apex, radiating to the axilla and occasionally to the base; a hyperdynamic left ventricular impulse and a brisk carotid upstroke; and a prominent third heart sound. Left atrial enlargement is usually considerable in chronic mitral regurgitation; the degree of left ventricular enlargement usually reflects the severity of regurgitation. Calcification of the mitral valve is less common than in pure mitral stenosis. Hemodynamically, left ventricular volume overload may ultimately lead to left ventricular failure and reduced cardiac output, but for many years the left ventricular end-diastolic pressure and the cardiac output may be normal at rest, even with considerable increase in left ventricular volume.

Nonrheumatic mitral regurgitation may develop abruptly, such as with papillary muscle dysfunction following myocardial infarction, valve perforation in infective endocarditis, or ruptured chordae tendineae in mitral valve prolapse. In acute mitral regurgitation, patients are in sinus rhythm rather than atrial fibrillation and have little or no enlargement of the left atrium, no calcification of the mitral valve, no associated mitral stenosis, and in many cases little left ventricular dilation.

Myxomatous mitral valve ("floppy" or "billowing" mitral valve, or mitral valve prolapse) is usually asymptomatic but may be associated with nonspecific chest pain, dyspnea, fatigue, or palpitations. Most patients are female, many are thin, and some have minor chest wall deformities. There are characteristic midsystolic clicks, which may be multiple, often but not always followed by a late systolic murmur. These findings are accentuated in the standing position. The diagnosis is primarily clinical but can be confirmed echocardiographically. Its significance is in dispute because of the frequency with which it is diagnosed in healthy young women (up to 10%), but in occasional patients this lesion is not benign. Patients who have only a midsystolic click usually have no sequelae, but patients with a late or pansystolic murmur may develop significant mitral regurgitation, often due to rupture of chordae tendineae. The need for valve replacement is commonest in men and increases with aging, so that approximately 2% of patients with clinically significant regurgitation over age 60 will require surgery. Infective endocarditis may occur, chiefly in patients with murmurs; such patients should have antibiotic prophylaxis prior to dental work and surgical procedures. β -Adrenergic blocking agents are often effective for supraventricular arrhythmias. Sudden death is rare in mitral prolapse, but when symptomatic ventricular tachycardia is present, aggressive management with an implantable cardioverter-defibrillator is usually indicated. An association between mitral prolapse and embolic cerebrovascular events has also been reported but not confirmed in subsequent studies. Echocardiographic evidence of marked thickening or redundancy of the valve is associated with a higher incidence of most complications.

Papillary muscle dysfunction or infarction following acute myocardial infarction is less common. When mitral regurgitation is due to papillary dysfunction, it may subside as the infarction heals or left ventricular dilation diminishes. If severe regurgitation persists, these patients have a poor prognosis with or without surgery. Transient—but sometimes severe—mitral regurgitation may occur during episodes of myocardial ischemia. Patients with dilated cardiomyopathies of any origin may have **secondary mitral regurgitation** due to papillary muscle dysfunction or dilation of the mitral annulus. In these, mitral valve replacement has been considered contraindicated because of the poor risk:benefit ratio and deterioration of left ventricular function postoperatively. However, several groups have reported good results with mitral valve repair in patients with left ventricular ejection fractions greater than 30% and secondary mitral insufficiency.

B. Diagnostic Studies

Echocardiography is useful in demonstrating the underlying pathologic process (rheumatic, prolapse, flail leaflet), and Doppler techniques provide qualitative and semiquantitative estimates of the severity of mitral regurgitation. It should be noted that Doppler also detects clinically insignificant regurgitation in many normal individuals, and this finding must be interpreted in the context of the clinical presentation. The accompanying information concerning left ventricular size and function, left atrial size, pulmonary artery pressure, and right ventricular function can be invaluable in planning treatment as well as in recognizing associated lesions. Transesophageal echocardiography may reveal the cause of regurgitation and identify candidates for valvular repair. Nuclear medicine techniques as well as MRI permit measurement of left ventricular function and estimation of the severity of regurgitation.

Cardiac catheterization provides accurate assessment of regurgitation and, additionally, of left ventricular function and pulmonary artery pressure. Coronary angiography is often indicated to determine the presence of coronary artery disease prior to valve surgery.

Treatment & Prognosis

Acute mitral regurgitation due to endocarditis, myocardial infarction, and ruptured chordae tendineae often requires emergency surgery. Some patients can be stabilized with vasodilators or intra-aortic balloon counterpulsation, which reduces the amount of regurgitant flow by lowering systemic vascular resistance. Patients with chronic lesions may remain asymptomatic for many years. Operation is usually necessary when patients develop symptoms. However, because progressive and irreversible deterioration of left ventricular function may occur prior to the onset of symptoms, early operation is indicated even in asymptomatic patients with a declining ejection fraction (< 55-60%) or marked left ventricular dilation (end-systolic dimension > 4.5-5 cm on echocardiography).

There has been growing success with valve repair in nonrheumatic lesions, which avoids the complications of prosthetic valves described earlier. In addition, left ventricular function is better preserved when the subvalvular structures can be maintained intact by valve repair. Selected patients with poor left ventricular function and severe mitral regurgitation may benefit from this intervention. Mitral valve surgery is increasingly being performed using the appreciably less invasive thoracoscopic approach.

AORTIC STENOSIS

Essentials of Diagnosis

- In adults, usually asymptomatic until middle or old age.
- Delayed and diminished carotid pulses.
- Soft, absent, or paradoxically split S₂.
- Harsh systolic murmur, sometimes with thrill along left sternal border, often radiating to the neck; may be louder at apex in older patients.
- ECG usually shows left ventricular hypertrophy; calcified valve on x-ray or fluoroscopy; echo-Doppler is diagnostic in most cases.

General Considerations

Aortic valvular stenosis may follow rheumatic fever but is more commonly caused by progressive valvular calcification. This may occur in younger patients with a congenitally bicuspid valve or in elderly individuals with normal three-cusp valves. In the latter group, the aortic valve becomes sclerotic and, with further calcification, stenotic. Approximately 25% of patients over age 65 and 35% of those over age 70 have echocardiographic evidence of sclerosis, which appears to be related to atherosclerotic vascular disease and is associated with a higher rate of vascular events. About 10-20% of these will progress to hemodynamically significant aortic stenosis over a period of 10-15 years. Thus, aortic stenosis has become the most common surgical valve lesion in developed countries. Degenerative valve disease is three to four times more frequent in men than in women and is more common in smokers and hypertensives. Valvular stenosis must be distinguished from supra-avalvular obstruction and from outflow obstruction of the left ventricular infundibulum, both relatively rare.

Clinical Findings

A. Symptoms and Signs

Slightly narrowed, thickened, or roughened valves (aortic sclerosis) or aortic dilation may produce the typical murmur and thrill without causing significant hemodynamic effects. In mild or moderate cases, the characteristic signs are a systolic ejection murmur at the aortic area transmitted to the neck and apex; in severe cases, a palpable left ventricular heave or thrill, a weak to absent aortic second sound, or reversed splitting of the second sound are present (see [Table 10-1](#)). When the valve area is less than 0.8-1 cm² (normal, 3-4 cm²), ventricular systole becomes prolonged and the typical carotid pulse pattern of delayed upstroke and low amplitude is

present, but this may be an unreliable finding in older patients with extensive arteriosclerotic vascular disease. Left ventricular hypertrophy increases progressively, with resulting elevations in ventricular end-diastolic pressure. Cardiac output is maintained until the stenosis is severe (with a valve area $< 0.8 \text{ cm}^2$). Patients may present with left ventricular failure, angina pectoris, or syncope.

Symptoms of failure may be sudden in onset or may progress gradually. Angina pectoris frequently occurs in aortic stenosis. One-half of patients with calcific aortic stenosis and angina have significant associated coronary artery disease, whereas coronary disease is noted at only half this rate in the absence of angina. Syncope is typically exertional and may be due to arrhythmias (usually ventricular tachycardia but sometimes sinus bradycardia), hypotension, or decreased cerebral perfusion resulting from increased blood flow to exercising muscle without compensatory increase in cardiac output. Sudden death may occur but is rarely the initial manifestation of aortic stenosis in previously asymptomatic patients.

B. Diagnostic Studies

The clinical assessment of aortic stenosis may be difficult, especially in older patients. The ECG reveals left ventricular hypertrophy or suggestive repolarization changes in most patients but may be normal in up to 10%. The chest radiograph may show a normal or enlarged cardiac silhouette, calcification of the aortic valve, and dilation and calcification of the ascending aorta. The echocardiogram provides useful data about aortic valve calcification and opening and left ventricular thickness and function, while Doppler can estimate the aortic valve gradient. These data can reliably exclude or diagnose severe stenosis. In patients with moderate obstruction, especially with low cardiac output or concomitant regurgitation, these evaluations may be inaccurate.

Cardiac catheterization is the definitive diagnostic procedure. The valve gradient is measured and the valve area calculated; a valve area below 0.8 cm^2 indicates severe stenosis. Aortic regurgitation can be quantified by aortic root angiography. Coronary arteriography should be performed in most adults with aortic stenosis to assess for concomitant coronary disease.

Prognosis & Treatment

Following the onset of heart failure, angina, or syncope, the prognosis without surgery is poor (50% 3-year mortality rate). Medical treatment may stabilize patients in heart failure, but surgery is indicated for all symptomatic patients, including those with left ventricular dysfunction, which often improves postoperatively. Valve replacement is usually not indicated in asymptomatic individuals. Exceptions are those with declining left ventricular function, very severe left ventricular hypertrophy, and very high gradients ($> 80 \text{ mm Hg}$) or severely reduced valve areas ($= 0.7 \text{ cm}^2$).

The surgical mortality rate for valve replacement is 2-5%, but it rises to 10% above the age of 75. Mortality rates are substantially higher when left ventricular function is depressed or when severe coronary disease and prior myocardial infarctions are present. Severe coronary lesions are usually bypassed at the same time. Anticoagulation with warfarin is required for mechanical prostheses but is not essential with bioprostheses. Although bioprosthetic valves have hitherto undergone degenerative changes and required replacement within 7-10 years (sometimes within 3 years), newer ones may be more durable. Some centers have begun performing the Ross procedure, which entails switching the patient's pulmonary valve to the aortic position and placing a bioprosthesis in the pulmonary position. Because bioprostheses do not deteriorate as fast on the right side of the heart, this procedure has produced excellent long-term results without anticoagulation.

Although percutaneous balloon valvuloplasty can produce short-term reductions in the severity of aortic stenosis, restenosis occurs rapidly in most adults who have calcified valves. Except in adolescents, balloon valvuloplasty should be reserved for individuals who are poor candidates for surgery or as an intermediate procedure to stabilize high-risk patients prior to surgery.

AORTIC REGURGITATION (CHRONIC REGURGITATION)

Essentials of Diagnosis

- Usually asymptomatic until middle age; presents with left-sided failure or chest pain.
- Wide pulse pressure with associated peripheral signs.
- Hyperactive, enlarged left ventricle.
- Diastolic murmur along left sternal border.
- ECG shows left ventricular hypertrophy; x-ray shows left ventricular dilation. Echo-Doppler confirms diagnosis and estimates severity.

General Considerations

Rheumatic aortic regurgitation has become less common than in the preantibiotic era, but nonrheumatic causes are frequent and are the major cause of isolated aortic regurgitation. These include congenitally bicuspid valves, infective endocarditis, and hypertension. Many patients have aortic regurgitation secondary to aortic root diseases such as cystic medial necrosis, Marfan's syndrome, aortic dissection, ankylosing spondylitis, Reiter's syndrome, and syphilis.

Clinical Findings

A. Symptoms and Signs

The clinical presentation is determined by the rapidity with which regurgitation develops. In chronic regurgitation, the only sign for many years may be a soft aortic diastolic murmur. As the valve deformity increases, larger amounts regurgitate, diastolic blood pressure falls, and the left ventricle progressively enlarges. Most patients remain asymptomatic even at this point, and an often prolonged plateau phase, characterized by stable left ventricular dilation, occurs. Left ventricular failure is a late event and may be sudden in onset. Exertional dyspnea and fatigue are the most frequent symptoms, but paroxysmal nocturnal dyspnea and pulmonary edema may also occur. Angina pectoris or atypical chest pain may be present. Associated coronary artery disease and syncope are less common than in aortic stenosis.

Hemodynamically, because of compensatory left ventricular dilation, patients eject a large stroke volume which is adequate to maintain forward cardiac output until late in the course of the disease. Left ventricular diastolic pressure remains normal also but may abruptly rise when heart failure occurs. Abnormal left ventricular systolic function, as manifested by reduced ejection fraction and increasing end-systolic left ventricular volume, is a late sign.

The major physical findings relate to the wide arterial pulse pressure. The pulse has a rapid rise and fall (water-hammer pulse or Corrigan's pulse), with an elevated systolic and low diastolic pressure, owing to the large stroke volume and rapid diastolic runoff back into the left ventricle, respectively. The large stroke volume is also responsible for characteristic findings such as Quincke's pulses (subungual capillary pulsations), Duroziez's sign (diastolic murmur over a partially compressed peripheral artery, commonly the femoral), and Musset's sign (head bob with each pulse). The apical impulse is prominent, laterally displaced, and usually hyperdynamic and may be sustained. The murmur itself may be quite soft and localized; the aortic diastolic murmur is high-pitched and decrescendo. A mid or late diastolic low-pitched mitral murmur (Austin Flint murmur) may be heard in advanced aortic regurgitation, owing to obstruction of mitral flow produced by partial closure of the mitral valve by the regurgitant jet.

When aortic regurgitation develops acutely (as in aortic dissection or infective endocarditis), left ventricular failure, manifested primarily as pulmonary edema, may develop rapidly, and surgery is urgently required. Patients with acute aortic regurgitation do not have the dilated left ventricle of chronic aortic regurgitation. In the same way, the diastolic murmur is shorter and may be minimal in intensity, and the pulse pressure may not be widened, making clinical diagnosis difficult.

B. Diagnostic Studies

The ECG usually shows moderate to severe left ventricular hypertrophy. Radiographs show cardiomegaly with left ventricular prominence.

Echocardiography can demonstrate whether the lesion involves the aortic root or if valvular disease is present. Serial assessments of left ventricular size and function are critical in determining the timing for valve replacement. Doppler techniques can qualitatively estimate the severity of regurgitation, though it should be noted that "mild" regurgitation is not uncommon and should not be overinterpreted. Scintigraphic studies can quantify left ventricular function and functional reserve during exercise—a useful predictor of prognosis.

Cardiac catheterization can help quantify severity and is used to evaluate the coronary and aortic root anatomy preoperatively.

Treatment & Prognosis

Aortic regurgitation that appears or worsens during or after an episode of infective endocarditis or aortic dissection may lead to acute severe left ventricular failure or subacute progression over weeks or months. The former usually presents as pulmonary edema; surgical replacement of the valve is indicated even during active infection. These patients may be transiently improved or stabilized by vasodilators.

Chronic regurgitation has a long natural history, but the prognosis without surgery becomes poor when symptoms occur. Vasodilators, such as hydralazine, nifedipine, and angiotensin-converting enzyme inhibitors, can reduce the severity of regurgitation, and prophylactic treatment may postpone or avoid surgery in asymptomatic patients with severe regurgitation and dilated left ventricles. Beta-blocker therapy may slow the rate of aortic dilation in Marfan's syndrome. Surgery is usually indicated once aortic regurgitation causes symptoms. Surgery is also indicated for those with few or no symptoms who present with significant left ventricular dysfunction (ejection fraction < 45- 50%) or who exhibit progressive deterioration of left ventricular function, irrespective of symptoms. Although the operative mortality rate is higher when left ventricular function is severely impaired, valve replacement or repair is still indicated, since left ventricular function often improves somewhat and the long-term prognosis is thereby enhanced.

The operative mortality rate is usually in the 3-5% range. Aortic regurgitation due to aortic root disease requires repair or replacement of the root, a more difficult operation. Following surgery, left ventricular size usually decreases and left ventricular function improves, except where dysfunction has been present chronically.

TRICUSPID STENOSIS

Tricuspid stenosis is usually rheumatic in origin. It should be suspected when "right heart failure" appears in the course of mitral valve disease, marked by hepatomegaly, ascites, and dependent edema. It may also occur in carcinoid syndrome. The typical diastolic rumble along the lower left sternal border mimics mitral stenosis. In sinus rhythm, a presystolic liver pulsation may be found.

Hemodynamically, a diastolic pressure gradient of 5-15 mm Hg is found across the tricuspid valve in conjunction with raised pressure in the right atrium and jugular veins, with prominent a waves and with a slow y descent because of slow right ventricular filling.

Echocardiography usually demonstrates the lesion, and Doppler flow studies can measure the gradient; accompanying valve lesions can also be detected. Right heart catheterization is diagnostic.

Acquired tricuspid stenosis may be amenable to valvotomy under direct vision, but it usually requires a prosthetic valve replacement. Although experience is limited, balloon valvuloplasty may be the initial procedure of choice in many patients.

TRICUSPID REGURGITATION

Tricuspid regurgitation may occur in a variety of situations other than disease of the tricuspid valve itself. The most common is right ventricular overload resulting from left ventricular failure due to any cause. Tricuspid regurgitation occurs in association with right ventricular and inferior myocardial infarction. Tricuspid valve endocarditis and resulting regurgitation are common in intravenous drug users. Other causes include the carcinoid syndrome, lupus erythematosus, and myxomatous degeneration of the valve (associated with mitral valve prolapse). Ebstein's anomaly, a congenital defect of the tricuspid valve, often presents in adults as massive right-sided cardiomegaly due to tricuspid regurgitation.

The symptoms and signs of tricuspid regurgitation are identical to those resulting from right ventricular failure due to any cause. In the presence of mitral valve disease, the tricuspid valvular lesion can be suspected on the basis of early onset of right heart failure and a harsh systolic murmur along the lower left sternal border which is separate from the mitral murmur and which often increases in intensity during and just after inspiration.

Hemodynamically, tricuspid regurgitation is characterized by a prominent regurgitant systolic v wave in the right atrium and jugular venous pulse, with a rapid y descent and a small or absent x descent. The regurgitant wave, like the systolic murmur, is increased with inspiration, and its size depends upon the size of the right atrium. In tricuspid regurgitation, especially with right ventricular failure, an inspiratory S₃ may be present.

Tricuspid regurgitation secondary to severe mitral valve disease or other left-sided lesions may regress when the underlying disease is corrected. When surgery is required, valve repair or valvuloplasty of the tricuspid ring is often preferable to valve replacement. Replacement of the tricuspid valve is infrequently done now.

CHOICE & MANAGEMENT OF PROSTHETIC VALVES

Valve repair may be useful for tricuspid, mitral, and occasionally aortic regurgitation. Likewise, percutaneous or open valvulotomy may be indicated in mitral, pulmonary, and tricuspid stenosis. Nonetheless, the number of valve replacement procedures continues to increase as a result of the aging of the population. The choice of a mechanical device versus a bioprosthesis is often a difficult one, balancing the risk of chronic anticoagulation and thromboembolism (mechanical) versus the need for eventual reoperation (bioprosthesis). In general, otherwise healthy patients below age 65 should receive mechanical valves unless anticoagulation is contraindicated, because their life expectancy is greater than the durability of tissue prostheses. Furthermore, deterioration of bioprostheses is accelerated in younger patients. In patients with a small left ventricular cavity or aortic annulus, mechanical disk valves have significant hemodynamic advantages. Finally, patients who will require anticoagulation in any case, such as those in atrial fibrillation, should receive mechanical valves. Bioprostheses are preferable in older patients with life expectancies less than 10 years and when anticoagulation is contraindicated. However, hemodialysis patients should not receive tissue valves because they have a high failure rate. As noted previously, the Ross procedure offers another option in younger patients with aortic stenosis.

The identification of valve dysfunction may be difficult, but Doppler echocardiography, especially via the transesophageal approach, can identify regurgitation and stenosis in most cases. In patients with mechanical valves, careful anticoagulation is required with a target INR of 3.0-4.0. Anticoagulation should rarely be discontinued. For elective surgery, oral warfarin can be stopped 2-3 days preoperatively with heparin coverage until effective anticoagulation is resumed. Management of anticoagulation during pregnancy is difficult, since warfarin may be teratogenic in the first trimester and should be discontinued in advance of delivery. Some experts recommend substitution with low-molecular-weight heparin in the first trimester. In one controlled study, aspirin, 100 mg daily, in addition to warfarin, reduced emboli and the mortality rate.

■ CORONARY HEART DISEASE (ATHEROSCLEROTIC CORONARY ARTERY DISEASE; ISCHEMIC HEART DISEASE)

Coronary heart disease, or atherosclerotic coronary artery disease, is the commonest cause of cardiovascular disability and death in the United States. Men are more often affected than women by an overall ratio of 4:1, but before age 40 the ratio is 8:1, and after age 70 it is 1:1. In men, the peak incidence of clinical manifestations is at age 50-60; in women, at age 60-70.

Risk Factors for Coronary Artery Disease

Epidemiologic studies have identified a number of important risk factors for premature coronary artery disease. These include a positive family history (particularly when onset is before age 50), age, male gender, blood lipid abnormalities, diabetes mellitus, insulin resistance and the metabolic syndrome, hypertension, physical inactivity, cigarette smoking, elevated blood homocysteine levels, markers of inflammation such as C-reactive protein (CRP) and hyperfibrinogenemia, and hypoestrogenemia in women. Interventions to lessen some of these risk factors, such as lipid abnormalities, hypertension, and smoking, reduce the risk for subsequent coronary events. However, the benefit of reducing homocysteine levels is less clear, and hormone replacement therapy has been associated with an early increase in coronary risk. Patients with clinical manifestations of coronary disease before age 50 often have one or more of these predisposing risk factors, though many do not. The conventional risk factors are less closely linked to the onset of coronary disease in later years.

Overwhelming evidence indicates that abnormalities of lipid metabolism play a direct role in the pathophysiology of this condition. Risk increases progressively with higher levels of LDL cholesterol and declines with higher levels of HDL cholesterol. Therefore, the ratio of LDL to HDL cholesterol provides a composite marker of risk, with ratios below 3 indicating a lower risk and ratios above 5 indicating a higher risk. Other abnormalities of lipid metabolism also play a role in the pathogenesis of coronary artery disease, and these should be sought in individuals with otherwise unexplained premature disease. Among the patterns associated with increased atherosclerosis are elevated levels of apolipoprotein(a) and of small, dense LDL lipoprotein particles. These lipoproteins and their accompanying lipids appear more likely to pass into the vessel wall and may be more difficult to clear. Accumulating evidence suggests that hypertriglyceridemia is an independent risk factor for coronary artery disease as well. Elevated triglyceride levels often occur in association with other lipid abnormalities, including low levels of HDL cholesterol and elevated concentrations of lipoprotein(a) and small, dense LDL particles. Some experts advocate the use of non-HDL cholesterol, which accounts for several atherogenic lipids, as the preferred risk indicator.

It is now clear that markers of inflammation are another strong risk factor for coronary artery disease. CRP is the best-characterized inflammatory marker, but others include serum fibrinogen and the erythrocyte sedimentation rate and perhaps homocysteine as well. Although CRP levels > 10 ug/mL are often found in systemic inflammation, levels < 1, 1-3, and > 3 ug/mL, respectively, identify patients at low, intermediate, and high risk for future cardiovascular events. The prognostic value of CRP levels is independent and additive to lipid levels. CRP levels are often elevated in patients who have other conditions associated with accelerated atherosclerosis, such as diabetes, the metabolic syndrome, and obesity. In patients presenting with acute coronary syndromes, these elevations identify a group that is at high risk for early recurrent events.

Pathophysiology

Knowledge concerning the pathophysiology of atherosclerosis and the clinical presentations of coronary artery disease is accumulating rapidly. Abnormal lipid metabolism or excessive intake of cholesterol and saturated fats—especially when superimposed on a genetic predisposition—initiates the atherosclerotic process. The initial step is the "fatty streak," or subendothelial accumulation of lipids and lipid-laden monocytes (macrophages). Low-density lipoproteins (LDLs) are the major atherogenic lipid. High-density lipoproteins (HDLs), in contrast, are protective and probably assist in the mobilization of LDLs. The pathogenetic role of other lipids, including triglycerides, is less clear. LDLs undergo in situ oxidation, which makes them more difficult to mobilize as well as locally cytotoxic.

Macrophages migrate into the subendothelial space and take up lipids, giving them the appearance of "foam" cells. As the plaque progresses, smooth muscle cells also migrate into the lesion. At this stage, the lesion may be hemodynamically insignificant, but endothelial function is abnormal and its ability to limit the entry of lipoproteins into the vessel wall is impaired. If the plaque remains stable, a fibrous cap forms, the lesion becomes calcified, and the vessel lumen slowly becomes narrowed.

Although many atherosclerotic plaques remain stable or progress only gradually, others may rupture, with a resulting extrusion of lipids and tissue factors that result in a cascade of events culminating in intravascular thrombosis. The outcome of these events is determined by whether the vessel becomes occluded or whether thrombolysis occurs, either spontaneously or as the result of treatment, and whether the plaque subsequently becomes stabilized. The result may be partial or complete vessel occlusion (causing the symptoms of unstable angina or myocardial infarction), or the plaque may become restabilized, often with more severe stenosis.

Several features are associated with enhanced plaque vulnerability, including a higher lipid content, a higher concentration of macrophages, and a very thin fibrous cap. Lesions with these characteristics are often the culprit lesions in young individuals, in whom acute myocardial infarction or sudden death is the first manifestation of coronary disease; this abrupt progression explains why most infarctions do not occur at the site of preexisting critical stenosis. Conversely, the relatively greater reduction in clinical events than in lesion severity in lipid-lowering treatment trials is probably explained by the regression or prevention of these early nonfibrotic lesions.

Recent observations have resurrected an old theory that atherosclerosis progresses as the result of an inflammatory response in the vessel wall, perhaps initiated or worsened by an infectious agent. High levels of CRP may not only be a marker of inflammation and risk but may play a pathogenetic role in the atherosclerotic process. CRP is present in plaques and can activate endothelial cells to express adhesion molecules and chemotactic substances that attract macrophages as well as inhibit NO synthase, thus promoting lipid deposition and plaque instability. A number of infectious agents, including *Chlamydia pneumoniae*, cytomegalovirus, and *Helicobacter pylori*, have been indirectly implicated in initiating or accelerating the inflammatory response, but confirmation thus far is lacking and randomized trials have not demonstrated benefit from antibiotic therapy.

Primary & Secondary Prevention of Coronary Heart Disease

Although many risk factors for coronary artery disease are not modifiable, it is now clear that interventions such as smoking cessation, treatment of dyslipidemia, and lowering of blood pressure can both prevent coronary disease and delay its progression and complications after it is manifest. Treatment of lipid abnormalities delays the progression of atherosclerosis and in some cases produces regression. Even in the absence of regression, fewer new lesions develop, endothelial function may be restored, and coronary event rates are markedly reduced in patients with clinical evidence of atherosclerosis.

A series of clinical trials has demonstrated the efficacy of lowering LDL cholesterol with HMG-CoA reductase inhibitors (statins) in preventing death, coronary events, and strokes. Beneficial results have been found in patients who have already experienced coronary events (secondary prevention), in those at particularly high risk for events (diabetics and patients with peripheral artery disease), and those with elevated LDL cholesterol without multiple risk factors. Benefits occurred regardless of age, race, or the presence of hypertension. Therefore, aggressive lipid-lowering therapy should be implemented in all patients with dyslipidemia and coronary artery, cerebrovascular, or peripheral vascular disease. Furthermore, there is now clear evidence that reduction of LDL cholesterol can prevent coronary events and stroke in patients without clinically manifest atherosclerosis (primary prevention) and LDL levels as low as 130 mg/dL. The recently reported Heart Protection Study demonstrated more than 20% reductions in vascular events in patients with prior myocardial infarction, stroke, peripheral vascular disease, or diabetes with total cholesterol levels as low as 135 mg/dL, a substantial number of whom had LDL cholesterol levels under 100 mg/dL. This result suggests that all patients at significant risk for vascular events should receive a statin regardless of their cholesterol level—and, by implication, that these agents may work by additional mechanisms that are unrelated to lipid lowering.

Treatment of abnormally low HDL levels or elevations of lipoprotein(a) and small, dense LDL particles is more difficult, but oral niacin in high dosages (2-3 g/d or more) may be effective. A trial in postinfarction patients has demonstrated that an increase in HDL levels with gemfibrozil (600 mg twice daily) in patients with relatively low LDL levels prolongs reinfarction-free survival. The value of reducing elevated triglyceride levels is less clear, but since elevated triglycerides are often associated with other lipid abnormalities, treatment of high-risk patients with niacin, gemfibrozil, or fenofibrate for levels above 400 mg/dL is appropriate.

Since LDL oxidation appears to play a role in the atherogenicity of lipid molecules that have passed into the vessel wall, antioxidant therapy has been advocated as a preventive measure. Thus far, however, there are few data to support this popular concept, and many large, well-controlled studies have failed to demonstrate a benefit with vitamin E therapy. Indeed, there have been no positive prospective trials with any antioxidant agent. Antioxidant therapy may hinder the effectiveness of niacin and statin therapy.

Elevated plasma homocysteine levels are associated with an increased risk of vascular events. Although homocysteine levels can be reduced with dietary supplements of folic acid (1 mg/d) in combination with vitamin B₆ and vitamin B₁₂, it is not clear that this reduces clinical events in individuals with coronary artery disease.

Antiplatelet therapy is another very effective preventive measure. Aspirin (325 mg every other day) in males over the age of 50 reduces the incidence of myocardial infarction. Whether this approach should be employed in the general population or only in those at higher risk is unclear, and the optimal dosage is not known. A prudent approach would be to administer 81-325 mg daily to men with multiple coronary risk factors or concomitant diabetes starting at age 45-50 if no contraindication is present. The same approach is probably warranted for women, commencing 5-10 years later. The previously mentioned GISSI Prevention Trial found a significant mortality reduction with omega-3 fatty acid administration (1 g daily)—which has an antiplatelet effect—in postinfarction patients.

The effect of hormone replacement therapy in postmenopausal women has now been clarified, and it is clear that combined estrogen-progesterone therapy is not protective. Control of blood pressure has now been shown to prevent infarctions in older patients. Although unproved, it seems likely that control of blood pressure in younger individuals also prevents subsequent coronary events. The role of exercise remains controversial. Although individuals who exercise for at least 30 minutes a

week are at lower risk for subsequent coronary events, it is difficult to be certain that this outcome relates specifically to exercise rather than a generally healthy lifestyle.

The Heart Outcomes Prevention Evaluation (HOPE) trial demonstrated that the ACE inhibitor ramipril reduces fatal and nonfatal vascular events (cardiovascular deaths, nonfatal myocardial infarctions, and nonfatal strokes) by 20-25% in patients at high risk, including diabetics with additional risk factors or patients with clinical coronary, cerebral, or peripheral arterial atherosclerotic disease. Thus, the role of ACE inhibitors in secondary prevention appears to be expanding beyond patients with heart failure or left ventricular systolic dysfunction.

The decrease in number of coronary deaths over the last 2 decades may be due to a decrease in the prevalence of risk factors but probably also reflects improvements in medical therapy, the role of coronary care units, better treatment of angina, arrhythmias, and heart failure, and improved survival after coronary revascularization in some patient subsets.

BR>**Pathophysiology of Myocardial Ischemia & Acute Coronary Syndromes**

Advanced coronary atherosclerosis and even complete occlusion may remain clinically silent. There is only a modest correlation between the clinical symptoms and the anatomic extent of disease. At present, the only means of determining the location and extent of narrowing is coronary arteriography, although ischemia can be recognized by other less invasive studies. Myocardial ischemia may be provoked by either increased myocardial oxygen requirements (exercise, mental stress, or spontaneous fluctuations in heart rate and blood pressure) or by decreased oxygen supply (caused by coronary vasospasm, platelet plugging, or partial thrombosis). Abnormal endothelial function appears to play a role in the fluctuating threshold for ischemia; impaired release of nitric oxide (endothelium-derived relaxing factor) may permit unopposed vasoconstriction and facilitate platelet adhesion.

In angina pectoris, increased oxygen demand is the most frequent mechanism. In contrast, the acute coronary syndromes of unstable angina and myocardial infarction are caused by plaque disruption, platelet plugging, and coronary thrombosis. Of interest is the predilection for these episodes to occur in the early morning or shortly after arising. The outcome of this series of events is determined by whether the vessel becomes occluded or whether thrombolysis occurs, either spontaneously or as a result of treatment, and whether the plaque subsequently becomes stabilized. Thus, therapy is primarily directed toward inhibition of platelet activity (aspirin, clopidogrel, IIb/IIIa receptor antagonists), antithrombotic agents (the heparins), and thrombolysis in acute syndromes and toward minimizing myocardial oxygen requirements—as well as preventive measures—in chronic angina.

Some episodes of myocardial ischemia are painful, causing angina pectoris; others are completely silent. Many silent episodes are brought on by emotional and mental stress. In patients with diagnosed coronary disease, as evidenced by prior myocardial infarction or angina, silent ischemic episodes have the same prognostic import as painful ones. The prognosis for patients with only silent ischemia is not well established, nor is the potential benefit of preventing silent ischemia.

Myocardial Hibernation & Stunning

Areas of myocardium that are persistently underperfused but still viable may develop sustained contractile dysfunction. This phenomenon, which is termed myocardial hibernation, appears to represent an adaptive response but may lead to left ventricular failure. It is important to recognize this phenomenon, since this form of dysfunction is reversible following coronary revascularization. Hibernating myocardium can be identified by radionuclide testing, positron emission tomography, contrast-enhanced MRI, or its retained response to inotropic stimulation with dobutamine. A related phenomenon, termed myocardial stunning, is the occurrence of persistent contractile dysfunction following prolonged or repetitive episodes of myocardial ischemia.

ANGINA PECTORIS

Essentials of Diagnosis

- Precordial chest pain, usually precipitated by stress or exertion, relieved rapidly by rest or nitrates.
- Electrocardiographic or scintigraphic evidence of ischemia during pain or stress testing.
- Angiographic demonstration of significant obstruction of major coronary vessels.

General Considerations

Angina pectoris is usually due to atherosclerotic heart disease. Coronary vasospasm may occur at the site of a lesion or, less frequently, in apparently normal vessels. Other unusual causes of coronary artery obstruction such as congenital anomalies, emboli, arteritis, or dissection may cause ischemia or infarction. Angina may also occur in the absence of coronary artery obstruction as a result of severe myocardial hypertrophy, severe aortic stenosis or regurgitation, or in response to increased metabolic demands, as in hyperthyroidism, marked anemia, or paroxysmal tachycardias with rapid ventricular rates. Rarely, angina occurs with angiographically normal coronary arteries and without other identifiable causes. This presentation has been labeled syndrome X and is most likely due to inadequate flow reserve in the

resistance vessels (microvasculature). Although treatment is often not very successful in relieving symptoms, the prognosis of syndrome X is good.

Clinical Findings

A. History

The diagnosis of angina pectoris depends principally upon the history, which should specifically include the following information.

1. Circumstances that precipitate and relieve angina—Angina occurs most commonly during activity and is relieved by resting. Exertion that involves straining the thoracic or upper extremity muscles (eg, lifting or walking rapidly uphill) precipitates attacks most consistently. Patients prefer to remain upright rather than lie down. The amount of activity required to produce angina may be relatively consistent under comparable physical and emotional circumstances or may vary from day to day. It is usually less after meals, during excitement, or on exposure to cold. The threshold for angina is often lower in the morning or after strong emotion; the latter can provoke attacks in the absence of exertion. In addition, discomfort may occur during sexual activity, at rest, or at night as a result of coronary spasm.

2. Characteristics of the discomfort—Patients often do not refer to angina as "pain" but as a sensation of tightness, squeezing, burning, pressing, choking, aching, bursting, "gas," indigestion, or an ill-characterized discomfort. It is often characterized by clenching a fist over the mid chest. The distress of angina is rarely sharply localized and is not spasmodic.

3. Location and radiation—The distribution of the distress may vary widely in different patients but is usually the same for each patient unless unstable angina or myocardial infarction supervenes. In 80-90% of cases, the discomfort is felt behind or slightly to the left of the mid sternum. When it begins farther to the left or, uncommonly, on the right, it characteristically moves centrally substernally. Although angina may radiate to any dermatome from C8 to T4, it radiates most often to the left shoulder and upper arm, frequently moving down the inner volar aspect of the arm to the elbow, forearm, wrist, or fourth and fifth fingers. Radiation to the right shoulder and distally is less common, but the characteristics are the same. Occasionally, angina may be felt initially in the lower jaw, the back of the neck, the interscapular area, high in the left back, or in the volar aspect of the wrist. If the patient identifies the site of pain by pointing to the area of the apical impulse with one finger, angina is unlikely.

4. Duration of attacks—Angina is of short duration and subsides completely without residual discomfort. If the attack is precipitated by exertion and the patient promptly stops to rest, it usually lasts less than 3 minutes. Attacks following a heavy meal or brought on by anger often last 15-20 minutes. Attacks lasting more than 30 minutes are unusual and suggest the development of unstable angina, myocardial infarction, or an alternative diagnosis.

5. Effect of nitroglycerin—The diagnosis of angina pectoris is strongly supported if sublingual nitroglycerin invariably shortens an attack and if prophylactic nitrates permit greater exertion or prevent angina entirely.

6. Risk factors—The presence of risk factors described previously makes the diagnosis of angina more likely, but their absence does not exclude angina since most patients do not have a risk profile markedly different from that of the general population.

B. Signs

Examination during a spontaneous or induced attack frequently reveals a significant elevation in systolic and diastolic blood pressure, although hypotension may also occur. Occasionally, a gallop rhythm and an apical systolic murmur due to transient mitral regurgitation from papillary muscle dysfunction are present during pain only. Supraventricular or ventricular arrhythmias may be present, either as the precipitating factor or as a result of ischemia.

It is important to detect signs of diseases that may contribute to or accompany atherosclerotic heart disease, eg, diabetes mellitus (retinopathy or neuropathy), xanthelasma, tendinous xanthomas, hypertension, thyrotoxicosis, myxedema, or peripheral vascular disease. Aortic stenosis or regurgitation, hypertrophic cardiomyopathy, and mitral valve prolapse should be sought, since they may produce angina or other forms of chest pain.

Differential Diagnosis

Angina can usually be diagnosed from a proper history. When atypical features are present—such as prolonged duration (hours or days) or darting, knifelike pains at the apex or over the precordium—ischemia is less likely.

Anterior chest wall syndrome is characterized by sharply localized tenderness of intercostal muscles. Inflammation of the chondrocostal junctions, which may be warm, swollen, and red, may result in diffuse chest pain that is also reproduced by local pressure (Tietze's syndrome). Intercostal neuritis (due to herpes zoster, diabetes mellitus, etc) also mimics angina.

Cervical or thoracic spine disease involving the dorsal roots produces sudden sharp, severe chest pain suggesting angina in location and "radiation" but related to specific movements of the neck or spine, recumbency, and straining or lifting. Pain due to cervical or thoracic disk disease involves the outer or dorsal aspect of the arm and the thumb and index fingers rather than the ring and little fingers.

Peptic ulcer, chronic cholecystitis, esophageal spasm, and functional gastrointestinal disease may produce pain suggestive of angina pectoris. Reflux esophagitis is characterized by lower chest and upper abdominal pain after heavy meals, occurring in recumbency or upon bending over. The pain is relieved by antacids, sucralfate, H₂ receptor antagonists, or proton pump inhibitors. The picture may be especially confusing because ischemic pain may also be associated with upper gastrointestinal symptoms, and esophageal motility disorders may be improved by nitrates and calcium channel blockers. Assessment of esophageal motility may be necessary.

Degenerative and inflammatory lesions of the left shoulder and thoracic outlet syndromes may cause chest pain due to nerve irritation or muscular compression; the symptoms are usually precipitated by movement of the arm and shoulder and are associated with paresthesias.

Spontaneous pneumothorax may cause chest pain as well as dyspnea and may create confusion with angina as well as myocardial infarction. Even the ECG may resemble infarction because of changes in voltage from the pneumothorax. The same is true of pneumonia and pulmonary embolization. Dissection of the thoracic aorta can cause severe chest pain that is commonly felt in the back; it is sudden in onset, reaches maximum intensity immediately, and may be associated with changes in pulses. Other cardiac disorders such as mitral valve prolapse, hypertrophic cardiomyopathy, myocarditis, pericarditis, aortic valve disease, or right ventricular hypertrophy may cause atypical chest pain or even myocardial ischemia. Noninvasive testing and, in many cases, cardiac catheterization may be required to establish the diagnosis.

Evaluation of Patients with Angina Pectoris

A. Laboratory Findings

Serum lipid levels should be determined in all patients with suspected angina. Anemia and diabetes may also be investigated if clinically appropriate.

B. Electrocardiography

The resting ECG is normal in about a quarter of patients with angina. In the remainder, abnormalities include old myocardial infarction, nonspecific ST-T changes, atrioventricular or intraventricular conduction defects, and changes of left ventricular hypertrophy. During anginal episodes, the characteristic electrocardiographic change is horizontal or downsloping ST segment depression that reverses after the ischemia disappears. T wave flattening or inversion may also occur. Less frequently, ST segment elevation is observed; this finding suggests severe (transmural) ischemia and often occurs with coronary spasm.

C. Exercise Electrocardiography BR>Exercise testing is the most useful noninvasive procedure for evaluating the patient with angina. Ischemia that is not present at rest is detected by precipitation of typical chest pain or ST segment depression (or, rarely, elevation). Exercise testing is often combined with scintigraphic studies or echocardiography (see below), but in patients without baseline ST segment abnormalities or in whom anatomic localization is not necessary, the exercise ECG should be the initial procedure because of considerations of cost and convenience.

Exercise testing can be done on a motorized treadmill or with a bicycle ergometer. A variety of exercise protocols are utilized, the most common being the Bruce protocol, which increases the treadmill speed and elevation every 3 minutes until limited by symptoms. At least two electrocardiographic leads should be monitored continuously.

1. Precautions and risks—The usually quoted risk of exercise testing is one infarction or death per 1000 tests, but individuals who continue to have pain at rest or minimal activity are at higher risk and should not be tested. Many of the traditional exclusions, such as recent myocardial infarction or congestive heart failure, are no longer employed *if the patient is stable and ambulatory*, but aortic stenosis remains a contraindication. While most tests are carried to a symptom-limited end point (except submaximal testing early postinfarction), the test should be terminated when hypotension, significant ventricular or supraventricular arrhythmias, more than mild to moderate angina, or more than 3- to 4-mm ST segment depression occurs.

2. Indications—Exercise testing is employed (1) to confirm the diagnosis of angina; (2) to determine the severity of limitation of activity due to angina; (3) to assess

prognosis in patients with known coronary disease, including those recovering from myocardial infarction, by detecting groups at high or low risk; (4) to evaluate responses to therapy; and (5) less successfully, to screen asymptomatic populations for silent coronary disease. The latter application is controversial. Because false-positive tests often exceed true positives, leading to much patient anxiety and self-imposed or mandated disability, exercise testing of asymptomatic individuals should be done only for those at high risk (usually a strong family history of premature coronary disease or hyperlipidemia), those whose occupations place them or others at special risk (eg, airline pilots), and older individuals commencing strenuous activity.

3. Interpretation—The usual electrocardiographic criterion for a positive test is 1 mm (0.1 mV) horizontal or downsloping ST segment depression (beyond baseline) measured 80 ms after the J point. By this criterion, 60-80% of patients with anatomically significant coronary disease will have a positive test, but 10-30% of those without significant disease will also be positive. False-positives are uncommon when a 2-mm depression is present. Additional information is inferred from the time of onset and duration of the electrocardiographic changes, their magnitude and configuration, blood pressure and heart rate changes, the duration of exercise, and the presence of associated symptoms. In general, patients exhibiting more severe ST segment depression (> 2 mm) at low workloads (< 6 minutes on the Bruce protocol) or heart rates (< 70% of age-predicted maximum)—especially when the duration of exercise and rise in blood pressure are limited or when hypotension occurs during the test—have more severe disease and a poorer prognosis. Depending on symptom status, age, and other factors, such patients should be referred for coronary arteriography and possible revascularization. On the other hand, less impressive positive tests in asymptomatic patients are often "false-positives." Therefore, exercise testing results that do not conform to the clinical picture should be confirmed by stress scintigraphy or echocardiography.

D. Scintigraphic Assessment of Ischemia

Two nuclear medicine studies provide additional information about the presence, location, and extent of coronary artery disease.

1. Myocardial perfusion scintigraphy—This test provides images in which radionuclide uptake is proportionate to blood flow at the time of injection. Thallium-201, technetium-99m sestamibi, and tetrofosmin are most frequently used. Areas of diminished uptake reflect relative hypoperfusion (compared to other myocardial regions). If the radiotracer is injected during exercise or dipyridamole- or adenosine-induced coronary vasodilation, scintigraphic defects indicate a zone of hypoperfusion that may represent either ischemia or scar. If the myocardium is viable, as relative blood flow equalizes over time or during a scintigram performed under resting conditions, these defects tend to "fill in" or reverse, indicating reversible ischemia. Defects observed when the radiotracer is injected at rest or still present 3-4 hours after an injection during exercise or pharmacologic vasodilation (intravenous adenosine or dipyridamole) usually indicate myocardial infarction (old or recent) but may be present with severe ischemia. Occasionally, other conditions, including infiltrative diseases (sarcoidosis, amyloidosis), left bundle branch block, and dilated cardiomyopathy, may produce resting or persistent perfusion defects.

In experienced laboratories, stress perfusion scintigraphy is positive in 75-90% of patients with anatomically significant coronary disease and in 20-30% of those without it. False-positive tests may occur as a result of diaphragmatic attenuation or, in women, attenuation through breast tissue. Tomographic imaging (SPECT) can reduce the severity of artifacts. Gated imaging allows for analysis of ventricular size, ejection fraction, and regional wall motion.

Myocardial scintigraphy is indicated (1) when the resting ECG makes an exercise ECG difficult to interpret (LBBB, baseline ST-T changes, low voltage, etc), (2) for confirmation of the results of the exercise ECG when they are contrary to the clinical impression (eg, a positive test in an asymptomatic patient), (3) to localize the region of ischemia, (4) to distinguish ischemic from infarcted myocardium, (5) to assess the completeness of vascularization following bypass surgery or coronary angioplasty, or (6) as a prognostic indicator in patients with known coronary disease.

2. Radionuclide angiography—This procedure images the left ventricle and measures its ejection fraction and wall motion. In coronary disease, resting abnormalities usually represent infarction, and those that occur only with exercise usually indicate stress-induced ischemia. Normal subjects usually exhibit an increase in ejection fraction with exercise or no change; patients with coronary disease may exhibit a decrease. Exercise radionuclide angiography has approximately the same sensitivity as thallium-201 scintigraphy, but it is less specific in older individuals and those with other forms of heart disease. The indications are similar to those for thallium-201 scintigraphy.

3. Positron emission tomography (PET)—PET utilizes positron emitting agents to demonstrate either perfusion or metabolism of myocardium. PET can accurately distinguish transiently dysfunctional ("stunned") myocardium from scar by showing persistent glycolytic metabolism with the tracer fluorodeoxyglucose (FDG) in regions with reduced blood flow. A nearby cyclotron is required to produce this tracer, but the newer SPECT camera can provide acceptable images without the more expensive PET technology.

E. Echocardiography

Echocardiography can image the left ventricle and reveal segmental wall motion abnormalities, which may indicate ischemia or prior infarction. It is a convenient technique for assessing left ventricular function, which is an important indicator of prognosis and determinant of therapy. Echocardiograms performed during supine exercise or immediately following upright exercise may demonstrate exercise-induced segmental wall motion abnormalities as an indicator of ischemia. This technique requires considerable expertise; however, in experienced laboratories, the test accuracy is comparable to that obtained with scintigraphy—though a higher proportion of tests are technically inadequate. Pharmacologic stress with high-dose (20-40 ug/kg/min) dobutamine can be used as an alternative to exercise. Echo contrast agents allow for perfusion imaging and may improve the diagnostic accuracy of this form of testing.

F. Newer Imaging Modalities

Many new imaging techniques have been developed, but their application in cardiovascular disease remains to be determined. **Computed tomography (CT scan)** can image the heart and, with contrast medium, the vascular system, but the relatively slow speed of most instruments limits its utility. The main application of CT is the evaluation of pericardial disease. **Ultrafast** or **electron beam CT (EBCT)** involves a specially designed instrument with high temporal resolution. Its availability is limited, but it provides excellent assessments of cardiac structure and function. EBCT is increasingly being used to detect and quantify coronary artery calcification, but proper application of this highly sensitive test is uncertain. False-negative studies may occur in patients under 50 years of age, and positive studies in older patients do not necessarily provide a quantitative assessment of the severity of coronary arteriosclerosis. Thus, although this test can stratify patients into lower and higher risk groups, the appropriate management of individual patients with asymptomatic coronary artery calcification—beyond aggressive risk factors modification—is unclear.

Cardiac magnetic resonance imaging (MRI) is an evolving modality that provides high-resolution images of the heart and great vessels without radiation exposure or use of iodinated contrast media. It provides excellent anatomic definition, permitting assessment of pericardial disease, neoplastic disease of the heart, myocardial thickness, chamber size, and many congenital heart defects. It is the best noninvasive test for nonemergently evaluating dissection of the aorta. Rapid acquisition sequences can produce excellent cine-mode images demonstrating left ventricular function and wall motion, and it is thus a useful alternative when the echocardiogram is suboptimal. Recent advances have been made in imaging the proximal coronary arteries and assessing myocardial perfusion with paramagnetic contrast agents, but these applications remain investigational.

G. Ambulatory Electrocardiographic Monitoring

With current ambulatory electrocardiographic recorders and with trained technicians, episodes of ischemic ST segment depression can be monitored. In patients with coronary artery disease, these episodes usually signify ischemia, even when asymptomatic ("silent"). In many, silent episodes are more frequent than symptomatic ones. In most cases, they occur in patients with other evidence of ischemia, and they respond to the same treatments, so that the role of ambulatory monitoring is unclear, as is the benefit of abolishing all such episodes in patients who are otherwise being managed properly.

H. Coronary Angiography

Selective coronary arteriography is the definitive diagnostic procedure for coronary artery disease. It can be performed with low mortality (about 0.1%) and morbidity (1-5%), but the cost is high, and with currently available noninvasive techniques it is usually not indicated solely for diagnosis.

Coronary arteriography should be performed in the following groups:

(1) Patients being considered for coronary artery revascularization because of limiting stable angina who have failed to improve on an adequate medical regimen.

(2) Patients in whom coronary revascularization is being considered because the clinical presentation (unstable angina, postinfarction angina, etc) or noninvasive testing suggests high-risk disease (see Indications for Revascularization).

(3) Patients with aortic valve disease who also have angina pectoris, in order to determine whether the angina is due to accompanying coronary disease. Coronary angiography is also performed in asymptomatic older patients undergoing valve surgery so that concomitant bypass may be done if the anatomy is propitious.

(4) Patients who have had coronary revascularization with subsequent recurrence of symptoms, to determine whether bypass grafts or native vessels are occluded.

(5) Patients with cardiac failure in whom a surgically correctable lesion, such as left ventricular aneurysm, mitral regurgitation, or reversible ischemic dysfunction, is suspected.

(6) Patients surviving sudden death or with symptomatic or life-threatening arrhythmias in whom coronary artery disease may be a correctable cause.

(7) Patients with chest pain of uncertain cause or cardiomyopathy of unknown cause.

Coronary arteriography visualizes the location and severity of stenoses. Narrowing greater than 50% of the luminal diameter is considered clinically significant, although most lesions producing ischemia are associated with narrowing in excess of 70%. This information has important prognostic value, since mortality rates are progressively higher in patients with one-, two-, and three-vessel disease and those with left main coronary artery obstruction (ranging from 1% per year to 25% per year). In those with strongly positive exercise ECGs or scintigraphic studies, three-vessel or left main disease may be present in 75-95% depending upon the criteria employed. Coronary arteriography also shows whether the obstructions are amenable to bypass surgery or percutaneous transluminal coronary angioplasty (PTCA).

Coronary angiography may underestimate the degree of atherosclerosis because it images only the lumen of the vessel. If there is concentric plaque with arterial enlargement (remodeling), then the lumen may appear relatively normal. Intravascular ultrasound (IVUS) utilizes a small ultrasound transducer that can be positioned within the artery and image beneath the endothelial surface. This technique is useful when the angiogram is equivocal as well as for assessing the results of angioplasty or stenting.

I. Left Ventricular Angiography

Left ventricular angiography is usually performed at the same time as coronary arteriography. Global and regional left ventricular function are visualized, as well as mitral regurgitation if present. Left ventricular function is the major determinant of prognosis in stable coronary disease and of the risk of bypass surgery.

Coronary Vasospasm & Angina with Normal Coronary Arteriograms

Although most symptoms of myocardial ischemia result from fixed stenosis of the coronary arteries or intraplaque hemorrhage or thrombosis at the site of lesions, some ischemic events may be precipitated or exacerbated by coronary vasoconstriction.

Spasm of the large coronary arteries with resulting decreased coronary blood flow may occur spontaneously or may be induced by exposure to cold, emotional stress, or vasoconstricting medications, such as ergot derivative drugs. Spasm may occur both in normal and in stenosed coronary arteries and may be silent or result in angina pectoris. Even myocardial infarction may occur as a result of spasm in the absence of visible obstructive coronary heart disease, although most instances of such coronary spasm occur in the presence of coronary stenosis.

Cocaine can induce myocardial ischemia and infarction by causing coronary artery vasoconstriction or by increasing myocardial energy requirements.

Prinzmetal's (variant) angina is a clinical syndrome in which chest pain occurs without the usual precipitating factors and is associated with ST segment elevation rather than depression. It often affects women under 50 years of age. It characteristically occurs in the early morning, awakening patients from sleep, tends to involve the right coronary artery, and is apt to be associated with arrhythmias or conduction defects. There may be no fixed stenoses. Ischemia usually results from coronary vasoconstriction and may be diagnosed by challenge with ergonovine (a vasoconstrictor).

Patients with this pattern of pain or any chest pain syndrome associated with ST segment elevation should undergo coronary arteriography to determine whether fixed stenotic lesions are present. If they are, aggressive medical therapy or revascularization is indicated, since this may represent an unstable phase of the disease. If significant lesions are not seen and spasm is suspected, ergonovine may be administered intravenously to precipitate vasospasm. This must be done cautiously and with nitroglycerin prepared for intracoronary administration, since irreversible spasm may lead to infarction. Episodes respond well to nitrates or calcium channel blockers, and both drugs are effective prophylactically. By allowing unopposed α_1 -mediated vasoconstriction, beta-blockers have exacerbated coronary vasospasm, but they may have a role in management of patients in whom spasm is associated with fixed stenoses.

There is a growing consensus that myocardial ischemia may also occur in patients with normal coronary arteries as a result of disease of the coronary microcirculation or abnormal vascular reactivity. This has been termed syndrome X.

Treatment

A. Treatment of Acute Attack

Sublingual nitroglycerin is the drug of choice; it acts in about 1-2 minutes. Nitrates decrease arteriolar and venous tone, reduce preload and afterload, and lower the oxygen demand of the heart. Nitrates may also improve myocardial blood flow by dilating collateral channels and, in the presence of increased vasomotor tone, coronary stenoses. As soon as the attack begins, one fresh tablet is placed under the tongue. This may be repeated at 3- to 5-minute intervals. The dosage (0.3, 0.4, or 0.6 mg) and the number of tablets to be used before seeking further medical attention must be individualized. Nitroglycerin buccal spray is also available as a metered (0.4 mg) delivery system. It has the advantage of being more convenient for patients who have difficulty handling the pills and of being more stable. Nitroglycerin should also be used prophylactically before activities likely to precipitate angina. Pain not responding to three tablets or lasting more than 20 minutes may represent evolving infarction, and the patient should be instructed to seek immediate medical attention.

B. Prevention of Further Attacks

1. Aggravating factors—Angina may be aggravated by hypertension, left ventricular failure, arrhythmia (usually tachycardias), strenuous activity, cold temperatures, and emotional states. These factors should be identified and treated or avoided where possible.

2. Nitroglycerin—Nitroglycerin, 0.3-0.6 mg sublingually or 0.4-0.8 mg translingually by spray, should be taken 5 minutes before any activity likely to precipitate angina. Sublingual isosorbide dinitrate (2.5-10 mg) is only slightly longer-acting than sublingual nitroglycerin.

3. Long-acting nitrates—A number of longer-acting nitrate preparations are available. These include isosorbide dinitrate, 10-40 mg orally three times daily; isosorbide mononitrate, 10-40 mg orally twice daily or 60-120 mg once daily in a sustained-release preparation; oral sustained-release nitroglycerin preparations, 6.25-12.5 mg two to four times daily; nitroglycerin ointment, 6.25-25 mg applied two to four times daily; and transdermal nitroglycerin patches that deliver nitroglycerin at a predetermined rate (usually 5-20 mg/24 h). The main limitation to chronic nitrate therapy is tolerance, which occurs to some degree in most patients. The degree of tolerance can be limited by utilizing a regimen which includes a minimum 8- to 10-hour period per day without nitrates. Isosorbide dinitrate given three times daily, with the last dose after dinner, is the most commonly used approach, but longer-acting isosorbide mononitrate is becoming more popular. Because it is the active metabolite of the dinitrate, isosorbide mononitrate has more consistent bioavailability. Transdermal nitrate preparations should be removed overnight in most patients.

Nitrate therapy is often limited by headache. Other side effects include nausea, light-headedness, and hypotension.

4. Beta-blockers—Beta-blockers prevent angina by reducing myocardial oxygen requirements during exertion and stress. This is accomplished by reducing the heart rate, myocardial contractility, and, to a lesser extent, blood pressure. The beta-blockers are the only antianginal agents that have been demonstrated to prolong life in patients with coronary disease (post-myocardial infarction). They are at least as effective at relieving angina as alternative agents in studies employing exercise testing, ambulatory monitoring, and symptom assessment. As a result, they should be considered for first-line therapy in most patients with chronic angina.

In the United States, only propranolol, metoprolol, nadolol, and atenolol are approved for angina. Nonetheless, all available beta-blockers appear to be effective for angina, though those with intrinsic sympathomimetic activity, such as pindolol, are less desirable because they may exacerbate angina in some individuals and have not been effective in secondary prevention trials. The pharmacology and side effects of the beta-blockers are discussed in [Chapter 11 \(Table 11-6\)](#). The dosages of all these drugs when given for angina are similar. The major contraindications are bronchospastic disease, bradyarrhythmias, and overt heart failure.

5. Calcium channel blocking agents—Verapamil, diltiazem, and the dihydropyridine group of calcium blockers are chemically and pharmacologically heterogeneous agents that prevent angina by reducing myocardial oxygen requirements and by inducing coronary artery vasodilation. Myocardial oxygen demand is lessened by reducing blood pressure, left ventricular wall stress, and, in the case of verapamil and diltiazem, resting or exercise heart rate. Though these agents are all potent coronary vasodilators, it is unclear whether they improve myocardial blood flow in most patients with stable exertional angina. In those with coronary vasospasm, the calcium channel blockers may be the agents of choice.

Most calcium channel blockers have negative inotropic, chronotropic, and dromotropic properties in vitro, but the reflex sympathetic response may obscure these effects in vivo (except in the presence of beta blockade or severely depressed left ventricular function). Unlike the beta-blockers, calcium channel blockers have not reduced mortality postinfarction and in some cases have increased ischemia and mortality rates. This appears to be the case with some dihydropyridines and with diltiazem and verapamil in patients with clinical heart failure or moderate to severe left ventricular dysfunction. A recent meta-analysis suggested that short-acting nifedipine in moderate to high doses causes an increase in mortality in patients early after myocardial infarction or with unstable angina. It is uncertain whether these findings are relevant to longer-acting dihydropyridines, and data with verapamil and diltiazem suggest that these latter agents are safe in postinfarction patients with preserved left ventricular function. Nevertheless, considering the uncertainties and the lack of demonstrated favorable effect on outcomes, calcium channel blockers should be considered third-line anti-ischemic drugs in the postinfarction patient. Similarly, with the exception of amlodipine, which in the PRAISE trial proved safe in patients with heart failure, these agents should be avoided in patients with congestive heart failure or low ejection fractions.

The pharmacologic effects and side effects of the calcium channel blockers are discussed in [Chapter 11](#) and summarized in [Table 11-8](#). Although all have been shown to be efficacious for angina, not all preparations and agents are approved for this indication. By and large, diltiazem and verapamil are preferable as first-line agents because they produce less reflex tachycardia and because the former, at least, may cause fewer side effects. Nifedipine, nicardipine, and amlodipine are also approved agents for angina. Isradipine, felodipine, and nisoldipine are not approved for angina but probably are as effective as the other dihydropyridines.

6. Alternative and combination therapies—Patients who do not respond to one class of antianginal medication often respond to another. It may, therefore, be worthwhile to use an alternative agent before progressing to combinations. If the patient remains symptomatic, a beta-blocker and a long-acting nitrate or a beta-blocker and a calcium channel blocker (other than verapamil, where the risk of atrioventricular block or heart failure is higher) are the most appropriate combinations. A few patients will have a further response to a regimen including all three agents.

7. Platelet-inhibiting agents—Coronary thrombosis is responsible for most episodes of myocardial infarction and many unstable ischemic syndromes. Several studies have demonstrated the benefit of anti-platelet drugs following unstable angina and infarction. Therefore, unless contraindicated, small doses of aspirin (81-325 mg daily or 325 mg every other day) should be prescribed for patients with angina. Clopidogrel is an antiplatelet agent that acts by inhibiting ADP-induced platelet aggregation. Unlike its older congener ticlopidine, clopidogrel does not cause agranulocytosis but may rarely induce thrombotic thrombocytopenic purpura. It can reduce cardiac events in patients with acute coronary syndromes and is an appropriate alternative in aspirin-intolerant patients.

8. Risk reduction—As discussed above, patients with coronary disease should undergo aggressive risk factor modification. This approach, with a particular focus on lowering LDL cholesterol to = 100 mg/dL, not only prevents future events but may markedly improve symptomatic angina. Indeed, the Atorvastatin Versus Revascularization Treatment (AVERT) trial showed that patients randomized to aggressive lipid-lowering and medical therapy tended to have fewer subsequent ischemic events.

9. Revascularization—The indications for coronary artery revascularization and the choice of procedure are discussed below.

Prognosis

The prognosis of angina pectoris has improved with advances in the understanding of its pathophysiology and in pharmacologic therapy. Mortality rates vary depending on the number of vessels diseased, the severity of obstruction, the status of left ventricular function, and the presence of complex arrhythmias. In patients with stable symptoms and normal ejection fractions (> 55%, depending on the laboratory), the mortality rate is 1-2% per year. However, the outlook in individual patients is unpredictable, and nearly half of the deaths are sudden. Therefore, risk stratification is often attempted. Patients with accelerating symptoms have a poorer outlook. Among stable patients, those whose exercise tolerance is severely limited by ischemia (less than 6 minutes on the Bruce treadmill protocol) and those with extensive ischemia by exercise electrocardiography or scintigraphy have more severe anatomic disease and a poorer prognosis.

REVASCULARIZATION PROCEDURES FOR PATIENTS WITH ANGINA PECTORIS

Indications

The indications for coronary artery revascularization in patients with angina pectoris are often debated. There is general agreement that otherwise healthy patients in the following groups should undergo revascularization: (1) patients with unacceptable symptoms despite medical therapy to its tolerable limits, (2) patients with left main coronary artery stenosis greater than 50% with or without symptoms, (3) patients with three-vessel disease with left ventricular dysfunction (ejection fraction < 50% or previous transmural infarction), (4) patients with unstable angina who after symptom control by medical therapy continue to exhibit ischemia on exercise testing or monitoring, and (5) post-myocardial infarction patients with continuing angina or severe ischemia on noninvasive testing. (See sections on Unstable Angina and Myocardial Infarction.)

In addition, many cardiologists feel that patients with less severe symptoms should be revascularized if they have two-vessel disease associated with underlying left ventricular dysfunction, anatomically critical lesions (> 90% proximal stenoses, especially of the proximal left anterior descending artery), or physiologic evidence of severe ischemia (early positive exercise tests, large exercise-induced thallium scintigraphic defects, or frequent episodes of ischemia on ambulatory monitoring). This trend toward aggressive intervention has accelerated as a result of the growing use of coronary angioplasty and stenting. While such patients are at increased risk, it has not been proved that their prognosis is better after coronary revascularization by either surgery or angioplasty.

Type of Procedure

A. Coronary Artery Bypass Grafting (CABG)

CABG can be accomplished with a very low mortality rate (1-3%) in otherwise healthy patients with preserved cardiac function. However, the mortality rate of this procedure rises to 4-8% in older individuals and in patients who have had a prior CABG. Increasingly, younger individuals with focal lesions of one or several vessels are undergoing coronary angioplasty as the initial revascularization procedure.

Grafts employing one or both internal mammary arteries (usually to the left anterior descending artery or its branches) provide the best long-term results in terms of patency and flow. Segments of the saphenous vein (or, less optimally, other veins) or the radial artery interposed between the aorta and the coronary arteries distal to the obstructions are also utilized. One to five distal anastomoses are commonly performed. After successful surgery, symptoms generally abate. The need for antianginal medications diminishes, and left ventricular function may improve.

Minimally invasive surgical techniques utilize different approaches to the heart than standard sternotomy and cardiopulmonary bypass. The surgical approach may involve a limited sternotomy, lateral thoracotomy (MIDCAB), or thoracoscopy (port-access). These approaches may be used in conjunction with standard cardiopulmonary bypass, with peripheral cardiopulmonary bypass, or with operating on the beating heart utilizing a mechanical coronary stabilizer. Avoiding bypass may lessen the risk of cerebral complications. These techniques allow earlier postoperative mobilization and discharge. They are more technically demanding, usually not suitable for more than two grafts, and do not have established durability.

The operative mortality rate is increased in patients with poor left ventricular function (left ventricular ejection fraction < 35%) or those requiring additional procedures (valve replacement or ventricular aneurysmectomy). Patients over 70 years of age, patients undergoing repeat procedures or those with important noncardiac disease (especially renal insufficiency and diabetes) or poor general health also have higher operative mortality and morbidity rates, and full recovery is slow. Thus, CABG should be reserved for more severely symptomatic patients in this group. Early (1-6 months) graft patency rates average 85-90% (higher for internal mammary grafts), and subsequent graft closure rates are about 4% annually. Early graft failure is common in vessels with poor distal flow, while late closure is more frequent in patients who continue smoking and those with untreated hyperlipidemia. Antiplatelet therapy with aspirin improves graft patency rates. Smoking cessation and vigorous treatment of blood lipid abnormalities are necessary, with a goal for LDL cholesterol of = 100 mg/dL and of HDL cholesterol = 45 mg/dL. Repeat revascularization (see below) is often necessitated by progressive native vessel disease and graft occlusions. Reoperation is technically demanding and less often fully successful than the initial operation.

B. Percutaneous Transluminal Coronary Angioplasty (PTCA) and Stenting

Coronary artery stenoses can be effectively dilated by inflation of a balloon under high pressure. This procedure is performed in the cardiac catheterization laboratory under local anesthesia either at the same time as diagnostic coronary arteriography or at a later time. The mechanism of dilation involves both rupture of the atheromatous plaque and remodeling of the vessel.

This procedure was at one time reserved for proximal single-vessel disease, but now it is widely employed in multivessel disease with multiple lesions, though only rarely in left main disease. PTCA is possible but often less successful in bypass graft stenoses. Bypass graft patients with multivessel disease have lower mortality rates and fewer nonfatal myocardial infarctions with surgery than with percutaneous interventions. Optimal lesions for PTCA are relatively proximal, noneccentric, free of significant calcification or plaque dissection, and removed from the origin of large branches. With improved catheter systems, experienced operators are able to successfully dilate 90% of lesions attempted. The major early complication is intimal dissection with vessel occlusion. This can usually be treated by repeat PTCA or by deployment of an intracoronary stent. The use of platelet glycoprotein IIb/IIIa inhibitors (abciximab, tirofiban) has markedly reduced the rate of acute vessel closure. Placement of intracoronary stents improves initial results, especially with complex and long lesions. Although the early experience with stents was complicated by an unacceptable rate of acute thrombosis, this problem has largely been prevented by aggressive antithrombotic therapy (chronic aspirin plus clopidogrel for 30 days, with acute use of platelet glycoprotein IIb/IIIa inhibitors in high-risk patients). Restenosis rates have fallen with the use of stents. Stents are now used in the majority of patients undergoing percutaneous revascularization.

The major limitation with PTCA has been restenosis, which occurs in the first 6 months in 30-40% of vessels dilated, though it can often be treated successfully by repeat PTCA. Factors associated with higher restenosis rates include diabetes, small luminal diameter, longer and more complex lesions, and lesions at coronary ostia or in the left anterior descending coronary artery. The use of stents has reduced the restenosis rate by half. Coated stents that elute antiproliferative agents such as sirolimus or paclitaxel have restenosis rates of < 10%. These devices are likely to have significant impact on clinical practice, leading to increased use of percutaneous interventions in patients with multiple and less favorable lesions. However, caution is required in adopting new practices, since follow-up with coated stents is relatively limited and the incidence of late stent thrombosis seems to be increasing. Currently, recurrent in-stent restenosis is treated with brachytherapy, but restenting with coated stents is also being employed.

The number of PTCA and stenting procedures now exceeds the number of CABG operations, but the justification for many of the procedures performed in patients with stable angina is unclear. Several studies have shown PTCA to be superior to medical therapy for symptom relief but not in preventing infarction or death. In patients with no or only mild symptoms, aggressive lipid-lowering and antianginal therapy may be preferable to PTCA.

Several studies of PTCA versus CABG in patients with multivessel disease have been reported. The consistent finding has been comparable mortality and infarction rates over follow-up periods of 1-3 years but a high rate (approximately 40%) of repeat procedures following PTCA. As a result, the choice of revascularization procedure is often a matter of patient preference. However, it should be noted that less than 20% of patients with multivessel disease met the entry criteria, so these results cannot be generalized to all multivessel disease patients. Outcomes with percutaneous revascularization in diabetics have been inferior to those with CABG. However, these trials preceded the widespread use of stenting.

C. Experimental Approaches

Several experimental approaches have been studied in patients with refractory angina who are not candidates for percutaneous or surgical revascularization procedures. Lasers have been used either from the epicardial surface of the left ventricle during surgery or from the ventricular cavity by catheter-based techniques. Several studies have reported an improvement in symptoms, but this has not been associated with objective evidence of improved perfusion, raising the possibility of a placebo effect. Other studies have evaluated intracoronary injections of growth factors such as vascular endothelial growth factor (VEGF) or fibroblast growth factors, but thus far there is little evidence of benefit. Lastly, mechanical extracorporeal counterpulsation, which entails repetitive inflation of a high-pressure chamber surrounding the lower half of the body during the diastolic phase of the cardiac cycle for daily 1-hour sessions over a period of 7 weeks, has been advocated. Although modest increases in exercise tolerance have been reported, the response has been variable, often time-limited, and not shown to be associated with improved myocardial perfusion—so again, a placebo effect may be responsible.

Summary of Results of Treatment

Several randomized trials have shown that over follow-up periods of several years, the mortality and infarction rates with percutaneous revascularization and CABG are generally comparable. An exception may be diabetic patients, who have had better outcomes with CABG. Recovery after PTCA is obviously faster, but the intermediate-term success rate of CABG is higher both because of the high restenosis rate with PTCA and, less importantly, with stenting. The increasing popularity of PTCA and stenting primarily reflects the lower cost and shorter hospitalization, the perception that CABG is best done only once and can be reserved for later, and the preference of patients for less invasive treatment. These arguments make PTCA the procedure of choice for revascularization of single-vessel disease, though this is not usually indicated except when symptoms are refractory. The situation is less clear with multivessel disease. It should also be noted that the excellent outcome of patients treated medically has made it difficult to show an advantage with either revascularization approach except in patients who remain symptom-limited or have left main lesions or three-vessel disease and left ventricular dysfunction. The expected availability of drug-eluting stents may shift the balance toward percutaneous revascularization in the future.

UNSTABLE ANGINA

Most clinicians use the term "unstable angina" to denote an accelerating or "crescendo" pattern of pain in cases where previously stable angina occurs with less exertion or at rest, lasts longer, and is less responsive to medication. Coronary angiography has shown that a high proportion of patients with this pattern of symptoms have "complex" coronary stenoses characterized by plaque rupture, ulceration, or hemorrhage with subsequent thrombus formation. This inherently unstable situation may progress to complete occlusion and infarction or may heal, with reendothelialization and a return to a stable though possibly more severe pattern of ischemia. New-onset angina is sometimes considered unstable, but if it is exertional and responsive to rest and medication, it does not carry the same poor prognosis.

Diagnosis

Most patients with unstable angina will exhibit electrocardiographic changes during pain—commonly ST segment depression or T wave flattening or inversion but sometimes, and more ominously, ST segment elevation. They may exhibit signs of left ventricular dysfunction during pain and for a time thereafter.

Chest pain is one of the most frequent reasons for emergency department visits, and the consequences of misdiagnosis are significant (clinically for false-negative diagnoses and economically for false-positives). Up to half of patients have noncardiac diagnoses, and even many of those with coronary disease are at low risk for early events (< 1% 30-day event rate). However, those with recent, prolonged, or recurrent episodes and accompanying electrocardiographic changes indicative of ischemia (ST segment depression > 1 mm, ischemic ST segment elevation, T wave inversions, or new LBBB) may have much higher event rates. Many hospitals have developed **chest pain observation units** to provide a longer period of observation and immediate testing in patients determined to be at low risk in order to improve the triage process. In many cases those who have not experienced new chest pain and have no electrocardiographic changes or cardiac enzyme elevations undergo treadmill exercise tests or imaging procedures to exclude ischemia at the end of a 6-24 hour period and are discharged directly from the emergency department if these tests are negative.

Treatment

A. General Measures

Treatment of unstable angina should be multifaceted and vigorous. Patients should be hospitalized, maintained at bed rest or at very limited activity, monitored, and given supplemental oxygen. Sedation with a benzodiazepine agent may help if anxiety is present. The systolic blood pressure is usually maintained at 100-120 mm Hg, except in previously severe hypertensives, and the heart rate should be lowered to 60/min.

B. Anticoagulation, Antiplatelet, and Thrombolytic Therapy

Because intravascular thrombosis plays a prominent role in the pathophysiology of unstable angina and its progression to myocardial infarction, antithrombotic therapy is an important part of treatment for unstable angina. Most patients should receive a combination of two or more agents. Aspirin, 325 mg daily, should be commenced on admission, and intravenous heparin should be started if symptoms have been recent (past 24 hours) or if they recur. Heparin therapy, when necessary, should be continued for at least 2 days. Several trials have shown that low-molecular-weight heparin is marginally superior to unfractionated heparin in preventing recurrent ischemic events in the setting of acute coronary syndromes. Enoxaparin (1 mg/kg subcutaneously every 12 hours) is the best-studied member of this class of agents. The Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial demonstrated a 20% reduction in the composite end point of cardiovascular death, myocardial infarction, and stroke with the addition of clopidogrel (300 mg loading dose, 75 mg daily for 12 months) in patients with non-ST segment elevation acute coronary syndromes.

The administration of drugs that block the platelet glycoprotein IIb/IIIa receptor is a useful adjunct in high-risk patients (usually defined by fluctuating ST segment depression or positive biomarkers) with unstable angina, particularly when they are undergoing PTCA or stenting. The short-acting small molecule inhibitors have been the best-studied agents in the nonintervention setting. Both tirofiban, 0.4 ug/kg/ min for 30 minutes followed by 0.1 ug/kg/min, and eptifibatide, 180 ug/kg bolus followed by a continuous infusion of 0.1 ug/kg/min, have been shown to be effective in unstable angina and non-Q wave myocardial infarction when added to heparin. Downward dose adjustments are required in patients with reduced renal function.

Since in unstable angina the vessel usually remains patent and the thrombi are undergoing continuous spontaneous formation and thrombolysis, thrombolytic therapy has not been effective in improving the outcome.

C. Nitroglycerin

The nitrates are first-line anti-ischemic therapy for unstable angina. Nonparenteral therapy with sublingual or oral agents or nitroglycerin ointment is usually sufficient. If pain persists or recurs, intravenous nitroglycerin should be started. The usual initial dosage is 10 ug/min. The dosage should be titrated to 1 ug/kg/min over 30-60 minutes and further increased as tolerated if pain recurs. Dosages up to 10 ug/kg/min or higher may be used. Tolerance to continuous nitrate infusion is common. Careful—usually continuous—blood pressure monitoring is required when intravenous nitroglycerin is used.

D. Beta-Blockers

These agents are also a part of the initial treatment of unstable angina unless otherwise contraindicated. If the patient has no physical findings of heart failure, these agents can usually be started without measurements of left ventricular function. Patients with evidence of large or multiple old infarctions are an exception. The pharmacology of these agents is discussed in [Chapter 11](#) and summarized in [Table 11-6](#). Use of agents with intrinsic sympathomimetic activity should be avoided in this setting. The goal of acute treatment is to reduce the heart rate below 60-70/min. Oral medication is adequate in most patients, but intravenous treatment with metoprolol, given as three 5- mg doses 5 minutes apart, achieves a more rapid effect. Oral therapy should be aggressively titrated upward as blood pressure permits.

E. Calcium Channel Blockers

Calcium channel blockers have not been shown to favorably affect outcome in unstable angina, and they should be used primarily as third-line therapy in patients with continuing symptoms on nitrates and beta-blockers or those who are not candidates for these drugs. In the presence of nitrates and without accompanying beta-blockers, diltiazem or verapamil is preferred, since nifedipine and the other dihydropyridines are more likely to cause reflex tachycardia or hypotension. The initial dosage should be low, but upward titration should proceed rapidly.

F. Intra-aortic Balloon Counterpulsation (IABC)

IABC can both reduce myocardial energy requirements (systolic unloading) and improve diastolic coronary blood flow. This approach is sometimes employed to stabilize patients prior to angiography or revascularization, but with modern techniques it is rarely necessary.

Prognosis & Indications for Revascularization

Over 90% of patients can be rendered pain-free with these measures. Patients who do not become ischemia-free on medical therapy should have early coronary arteriography and revascularization. Controlled trials have reported mixed results as to whether a strategy of routine coronary angiography and revascularization is superior to aggressive medical therapy and selective revascularization in patients with recurrent ischemia or very positive stress tests. Recent trials that have employed both platelet glycoprotein IIb/IIIa antagonists and stents in the majority of patients have favored an early but not necessarily immediate invasive strategy (eg, within several days and prior to discharge). Depending on the stringency of the definition of unstable angina, 10-30% of patients will have an early infarction, and the 1-year mortality rate is 10-20%. Elevated troponin I or T concentrations and "silent" ST segment shifts have both identified patients at higher risk for subsequent myocardial infarction or recurrence of severe ischemia. These markers identify a subset of patients who benefit from the early use of glycoprotein IIb/IIIa receptor antagonists and, most likely, early revascularization.

Because recurrent episodes, infarction, and sudden death may occur following relief of unstable angina, additional evaluations should be performed in patients who have been stabilized, consisting of either (1) early exercise or pharmacologic stress testing to identify high-risk subsets for further invasive evaluation, or (2) coronary arteriography. The choice of approach should be individualized based on the patient's age and general health as well as the severity of symptoms and signs of ischemia. The artery responsible for the ischemia can usually be determined from electrocardiographic or scintigraphic changes during pain, and the lesion is often amenable to PTCA. If revascularization is not performed, long-term management is the same as that outlined for stable angina pectoris.

ACUTE MYOCARDIAL INFARCTION

Essentials of Diagnosis

- Sudden but not instantaneous development of prolonged (> 30 minutes) anterior chest discomfort (sometimes felt as "gas" or pressure) that may produce arrhythmias, hypotension, shock, or cardiac failure.
- Rarely painless, masquerading as acute congestive heart failure, syncope, stroke, or shock.
- Electrocardiography: ST segment elevation or depression, evolving Q waves, symmetric inversion of T waves.
- Elevation of cardiac enzymes (CK-MB, troponin T, or troponin I).
- Appearance of segmental wall motion abnormality by imaging techniques.

General Considerations

Myocardial infarction results from prolonged myocardial ischemia, precipitated in most cases by an occlusive coronary thrombus at the site of a preexisting (though not necessarily severe) atherosclerotic plaque. More rarely, infarction may result from prolonged vasospasm, inadequate myocardial blood flow (eg, hypotension), or excessive metabolic demand. Very rarely, myocardial infarction may be caused by embolic occlusion, vasculitis, aortic root or coronary artery dissection, or aortitis. Cocaine is a cause of infarction, which should be considered in young individuals without risk factors.

The location and extent of infarction depend upon the anatomic distribution of the occluded vessel, the presence of additional stenotic lesions, and the adequacy of collateral circulation. Thrombosis in the anterior descending branch of the left coronary artery results in infarction of the anterior left ventricle and interventricular septum. Occlusion of the left circumflex artery produces anterolateral or posterolateral infarction. Right coronary thrombosis leads to infarction of the posteroinferior portion of the left ventricle and may involve the right ventricular myocardium and interventricular septum. The arteries supplying the atrioventricular node and the sinus node more commonly arise from the right coronary; thus, atrioventricular block at the nodal level and sinus node dysfunction occur more frequently during inferior or right-sided infarctions. Individual variation in coronary anatomy and the presence of collateral vessels can make the prediction of coronary anatomy from infarct location imperfect.

Infarctions are often classified as transmural if the classic electrocardiographic evolution of ST segment elevation to Q waves was observed or nontransmural or subendocardial if pain, enzyme elevations, and ST-T wave changes occurred in the absence of new Q waves. However, on pathologic examination, most infarctions involve the subendocardium predominantly, and some transmural extension is common even in the absence of Q waves. Thus, a better classification is Q wave versus non-Q wave infarction. The latter generally results from incomplete occlusion or spontaneous lysis of the thrombus and often signifies the presence of additional jeopardized myocardium; it is associated with a higher incidence of reinfarction and recurrent ischemia.

The size and anatomic location of an infarction determine the acute course, the early complications, and the long-term prognosis. Hemodynamic stability is related to extent of necrosis. In small infarctions, cardiac function is normal, whereas with more extensive damage, early heart failure and hypotension (cardiogenic shock) may appear. Preventing extension of an infarct and subsequent myocardial injury is a major goal of early management. The complications of acute infarction are discussed below.

Clinical Findings

A. Symptoms

1. Premonitory pain—One-third of patients give a history of alteration in the pattern of angina, recent onset of typical or atypical angina, or unusual "indigestion" or pressure or squeezing felt in the chest.

2. Pain of infarction—Most infarctions occur at rest unlike anginal episodes, and more commonly in the early morning. The pain is similar to angina in location and radiation but is more severe, and it builds up rapidly or in waves to maximum intensity over a few minutes or longer. Nitroglycerin has little effect; even opioids may not relieve the pain.

3. Associated symptoms—Patients may break out in a cold sweat, feel weak and apprehensive, and move about, seeking a position of comfort. They prefer not to lie quietly. Light-headedness, syncope, dyspnea, orthopnea, cough, wheezing, nausea and vomiting, or abdominal bloating may be present singly or in any combination.

4. Painless infarction—In a minority of cases, pain is absent or minor and is overshadowed by the immediate complications. As many as 25% of infarctions are detected on routine ECG without there having been any recallable acute episode.

5. Sudden death and early arrhythmias—Approximately 20% of patients with acute infarction will die before reaching the hospital; these deaths are usually in the first hour and are chiefly due to ventricular fibrillation.

B. Signs

1. General—Patients usually appear anxious and are often sweating profusely. The heart rate may range from marked bradycardia (most commonly in inferior infarction) to tachycardia resulting from increased sympathetic nervous system activity, low cardiac output, or arrhythmia. The blood pressure may be high, especially in former hypertensives, or low in patients with shock. Respiratory distress usually indicates heart failure. Fever, usually low-grade, may appear after 12 hours and persist for several days.

2. Chest—Clear lung fields are a good prognostic sign, but basilar rales are common and do not necessarily indicate heart failure. More extensive rales or diffuse wheezing suggests pulmonary edema.

3. Heart—The cardiac examination may be unimpressive or very abnormal. An abnormally located ventricular impulse often represents the dyskinetic infarcted region. Jugular venous distention reflects right atrial hypertension, which may indicate right ventricular infarction or elevated left ventricular filling pressures. The absence of elevated central venous pressure, however, does not indicate normal left atrial or left ventricular diastolic pressures. Soft heart sounds may indicate left ventricular dysfunction. Atrial gallops (S₄) are the rule, whereas ventricular gallops (S₃) are less common and indicate significant left ventricular dysfunction. Mitral regurgitation murmurs are not uncommon and usually indicate papillary muscle dysfunction or, rarely, rupture. Pericardial friction rubs are uncommon in the first 24 hours but may appear later.

4. Extremities—Edema is usually not present. Cyanosis and cold temperature indicate low output. The peripheral pulses should be noted, since later shock or emboli may alter the examination.

C. Laboratory Findings

The most valuable laboratory tests are cardiac-specific markers of myocardial damage, including quantitative determinations of CK-MB, troponin I, and troponin T. All are relatively specific for necrosis (the troponins somewhat more so), though they may be elevated following severe ischemic episodes. Each of these tests may become positive as early as 4-6 hours after the onset of a myocardial infarction and should be abnormal by 8-12 hours. Circulating levels of troponins may remain elevated for 5-7 days or longer and should obviate the use of less specific LDH isoenzyme assays.

D. Electrocardiography

Most patients with acute infarction have ECG changes, and a normal tracing is rare. The extent of the electrocardiographic abnormalities provides only a crude estimate of the magnitude of infarction. The classic evolution of changes is from peaked ("hyperacute") T waves, to ST segment elevation, to Q wave development, to T wave inversion. This may occur over a few hours to several days. The evolution of new Q waves (> 30 ms in duration and 25% of the R wave amplitude) is diagnostic, but Q waves do not occur in 30-50% of acute infarctions (subendocardial or non-Q wave infarctions). If these patients have an appropriate clinical presentation, characteristic cardiac enzymes, and ST segment changes (usually depression) or T wave inversion lasting at least 48 hours, they are classified as having non-Q wave infarctions.

E. Chest X-Ray

The chest x-ray may demonstrate signs of congestive heart failure, but these changes often lag behind the clinical findings. Signs of aortic dissection should be sought as a possible alternative diagnosis.

F. Echocardiography

Echocardiography provides convenient bedside assessment of left ventricular global and regional function. This can help with the diagnosis and management of infarction; echocardiography has been used successfully to make judgments about admission and management of patients with suspected infarction, since normal wall motion makes an infarction unlikely. Doppler echocardiography is probably the most convenient procedure for diagnosing postinfarction mitral regurgitation or ventricular septal defect.

G. Scintigraphic Studies

Technetium-99m pyrophosphate scintigraphy can be used to diagnose acute myocardial infarction. When injected at least 18 hours postinfarction, the radiotracer complexes with calcium in necrotic myocardium to provide a "hot spot" image of the infarction. This test is insensitive to small infarctions, and false-positive studies occur, so its use is limited to patients in whom the diagnosis by electrocardiography and enzymes is not possible—principally those who present several days after the event or have intraoperative infarctions. Radiolabeled antimyosin antibody fragments are more sensitive and specific imaging agents, but scintigraphy must be performed 24 and 48 hours postinjection, so this test has limited clinical utility in the diagnosis of acute myocardial infarction.

Scintigraphy with thallium-201 or the newer technetium-based perfusion tracers will demonstrate "cold spots" in regions of diminished perfusion, which usually represent infarction when the radio-tracer is administered at rest, but abnormalities do not distinguish recent from old damage.

Radionuclide angiography demonstrates akinesis or dyskinesis in areas of infarction and also measures ejection fraction, which can be valuable. Right ventricular dysfunction may indicate infarction of this chamber.

H. Hemodynamic Measurements

These can be invaluable in managing the complicated patient. Their use is described below and in [Table 10-3](#).

Treatment

A. Aspirin

All patients with definite or suspected myocardial infarction should receive aspirin at a dose of 162 mg or 325 mg at once regardless of whether thrombolytic therapy is being considered or the patient has been taking aspirin. Chewable aspirin provides more rapid blood levels. Patients with a definite aspirin allergy may be treated with clopidogrel 300 mg, though the onset of its effectiveness will be slower.

B. Thrombolytic Therapy

Thrombolytic therapy reduces mortality and limits infarct size in patients with acute myocardial infarction associated with ST segment elevation (defined as = 0.1 mV in two inferior or lateral leads or two contiguous precordial leads), or with new-onset LBBB. The greatest benefit occurs if treatment is initiated within the first 3 hours, when a 50% or greater reduction in mortality rate can be achieved. The magnitude of benefit declines rapidly thereafter, but a 10% relative mortality reduction can be achieved up to 12 hours after the onset of chest pain. The survival benefit is greatest in patients with large—usually anterior—infarctions. Patients without ST segment elevation (previously labeled "non-Q wave" infarctions) generally have incomplete or partially recanalized occlusions and have not benefited from thrombolysis. Thrombolytic therapy has also not been shown to improve the prognosis of patients with prior coronary artery bypass grafting, presumably because it is ineffective in opening bypass grafts.

Major bleeding complications occur in 0.5-5% of patients, the most serious of which is intracranial hemorrhage. The major risk factors for intracranial bleeding are age over 65 years, hypertension at presentation, low body weight (< 70 kg), and the use of clot-specific thrombolytic agents (alteplase, reteplase, tenecteplase). Although patients over age 75 have a much higher mortality rate with acute myocardial infarction and, therefore, potentially greater benefit, the risk of severe bleeding is also much higher and the net benefit is less clear. Patients presenting more than 12 hours after the onset of chest pain may also derive a small benefit, particularly if pain and ST segment elevation persist, but rarely does this benefit outweigh the attendant risk.

Therefore, the current recommendation is to administer thrombolytic therapy to patients with ST segment elevation infarctions who are under 75 years of age and present within 6-12 hours of the onset of symptoms. Contraindications include previous hemorrhagic stroke, other strokes, or cerebrovascular events within 1 year, known intracranial neoplasm, current blood pressure > 180 mm Hg systolic or 110 mm Hg diastolic, active internal bleeding (excluding menstruation), or suspected aortic dissection. Relative contraindications are blood pressure > 180/110 mm Hg at presentation, other intracerebral pathology not listed above as a contraindication, known bleeding diathesis, trauma within 2-4 weeks, major surgery within 3 weeks, prolonged (> 10 minutes) or traumatic cardiopulmonary resuscitation, recent (within 2-4 weeks) internal bleeding, noncompressible vascular punctures, active diabetic retinopathy, pregnancy, active peptic ulcer disease, a history of severe hypertension, current use of anticoagulants (INR > 2.0-3.0), and prior allergic reaction or exposure within 2 years to streptokinase or anistreplase.

Five thrombolytic agents are available for acute myocardial infarction and are characterized in [Table 10-4](#).

Streptokinase was the first thrombolytic agent to be extensively evaluated. It is less clot-specific and has subsequently proved to produce rapid but less effective coronary artery reopening than the newer agents, although the mortality differences are small. Streptokinase has a tendency to induce sometimes severe hypotension, particularly if infused rapidly. This can be managed by slowing or interrupting the infusion and administering fluids. There is little evidence that adjunctive heparin is beneficial in patients given streptokinase, unlike when it is administered with the more clot-specific agents. Allergic reactions, including anaphylaxis, occur in 1-2% of patients, and this agent should generally not be administered to patients with prior exposure.

Anistreplase (anisoylated plasminogen streptokinase activator complex; APSAC) is a conjugate of streptokinase that is inactive until the anisoyl group is hydrolyzed, which occurs gradually after injection (half-time 90 minutes). Thus, it can be injected as a bolus but will provide continuing thrombolytic activity. Otherwise, it has most of the same features of streptokinase, including the potential to produce allergic reactions and hypotension. Newer agents that can also be administered as boluses have largely supplanted it.

Alteplase (recombinant tissue plasminogen activator; t-PA) is a naturally occurring thrombolytic factor that is theoretically thrombus-specific. In the first GUSTO trial, which compared t-PA with streptokinase, the 30-day mortality rate with t-PA was one absolute percentage point lower (one additional life saved per 100 patients treated), though there was also a small *increase* in the rate of intracranial hemorrhage. An angiographic substudy confirmed a higher 90-minute patency rate and a higher rate of normal (TIMI grade 3) flow in patients. Alteplase has a shorter half-life than streptokinase and is associated with a higher rate of early reocclusion, thus necessitating the concomitant use of intravenous heparin. Alteplase has since become the most widely used thrombolytic therapy in the United States despite a considerably higher price than that of streptokinase.

Two additional clot-specific agents are now available. **Reteplase** is a recombinant plasminogen activator closely related to t-PA. In comparative trials it appears to have efficacy similar to that of alteplase, but it has a longer duration of action and can be administered as two boluses 30 minutes apart. **Tenecteplase** (TNK-t-PA) is a genetically engineered mutant of native t-PA that has reduced plasma clearance, increased fibrin sensitivity, and increased resistance to plasminogen activator inhibitor-1. It can be given as a single weight-adjusted bolus. In a large comparative trial, this agent was quite comparable to t-PA with regard to both efficacy and safety.

Selection of a thrombolytic agent: Although there continues to be heated discussion about which agent to use, the relatively small differences in efficacy between

them are minor compared with the potential benefit of treating a greater proportion of appropriate candidates in a more prompt manner. The principal objective should be to administer a thrombolytic agent within 30 minutes of presentation—or even during transport. The evidence does suggest that the clot-specific agents (alteplase, reteplase, and tenecteplase) are marginally more effective than streptokinase, and thus they are generally favored by most cardiologists. These agents do produce slightly higher rates of intracranial bleeding and require intravenous coadministration of heparin, which also increases bleeding risk. As a result, streptokinase may be preferable in patients at higher risk of this complication, particularly older patients with elevated blood pressures. Streptokinase and anistreplase should be avoided in patients with previous allergic reactions or recent exposure to either. Because of their potential for substantially lowering blood pressure, they should also be avoided in patients who present with hypotension. The ability to administer tenecteplase as a single bolus is an attractive feature that may facilitate earlier treatment. The combination of a reduced-dose thrombolytic given with a platelet glycoprotein IIb/IIIa antagonist has been investigated in several trials, with variable evidence of greater efficacy but a definite increase in bleeding complications.

Postthrombolytic management: After completion of the thrombolytic infusion, aspirin should be continued. Anticoagulation with intravenous heparin (60 units/kg bolus to a maximum of 4000 units, followed by an infusion of 12 units/kg/min adjusted to maintain an aPTT of 50-75 seconds) is continued for at least 24 hours after alteplase, reteplase, or tenecteplase but is optional in patients receiving streptokinase. Prophylactic treatment with antacids and an H₂ blocker is indicated.

Reperfusion rates of 40-80% can be expected, determined primarily by the interval between onset of the infarction and treatment. Reperfusion is recognized clinically by the abrupt cessation of pain, the occurrence of ventricular arrhythmias (most characteristically accelerated idioventricular rhythm), the rapid evolution of the ECG to Q waves, and an early peak of CK (by 12 hours); however, all of these signs may be misleading. Even with anticoagulation, 10-20% of reperfused vessels will reocclude during hospitalization. This is usually recognized by the recurrence of pain and ST segment elevation and is treated by readministration of a thrombolytic agent or immediate angiography and PTCA.

The optimal management of myocardial infarction after thrombolysis is controversial but has been clarified considerably by the TIMI 2 trial. Patients with recurrent ischemic pain prior to discharge should undergo catheterization and, if indicated, revascularization. Asymptomatic, clinically stable patients should undergo predischARGE evaluation to determine whether residual jeopardized myocardium is present. This can be accomplished by submaximal exercise or pharmacologic stress scintigraphy. Those with significantly positive tests or a low threshold for symptomatic ischemia should undergo angiography and revascularization where feasible. Patients with negative tests have an excellent prognosis without intervention, though they may require revascularization for symptoms at a later time.

C. Acute PTCA and Stenting for ST Segment Elevation Myocardial Infarction

Immediate coronary angiography and PTCA or stenting of the infarct-related artery is an increasingly utilized alternative to thrombolysis. It is the approach of choice in patients with absolute and many relative contraindications to thrombolytic therapy. The results of this approach in specialized centers are excellent, exceeding those obtainable by thrombolytic therapy even in good candidates, but this experience may not be generalizable to centers and operators with less experience or expertise. Stenting—in conjunction with platelet glycoprotein IIb/IIIa antagonists—is now widely used in acute myocardial infarction patients. In the subgroup of patients with cardiogenic shock, early catheterization and percutaneous or surgical revascularization is the preferred management, because thrombolysis has not improved their dismal prognosis. Because an acute interventional approach carries a lower risk of hemorrhagic complications, it may also be the preferred strategy in older patients.

D. Initial Management of Non-ST-Segment Elevation Myocardial Infarction

Patients presenting with an acute myocardial infarction without ST segment elevation or evolving Q waves generally do not have persistent thrombotic coronary occlusions (with the exception of LBBB or anterior ST segment depressions that may represent reciprocal changes from a true posterior infarction). Thrombolytic therapy is not appropriate in these patients, and in general their management should be similar to that of patients with unstable angina, who usually have the same underlying pathophysiology. This is described in the previous section, and includes aspirin, heparin, platelet glycoprotein IIb/IIIa antagonists, beta-blockers, and nitrates. As is the case with unstable angina, controversy continues over whether there is an advantage to a routine strategy of early coronary angiography, but patients with continuing or recurrent ischemia or very positive stress tests should undergo angiography and revascularization when appropriate.

E. General Measures

CCU monitoring should be instituted as soon as possible. Uncomplicated patients can be transferred to a telemetry unit after 24-48 hours. Activity should initially be limited to bed rest but can be advanced within 24 hours. Progressive ambulation should be started after 24-72 hours if tolerated. Low-flow oxygen therapy (2-4 L/min) should be given if oxygen saturation is reduced.

F. Analgesia

An initial attempt should be made to relieve pain with sublingual nitroglycerin. However, if no response occurs after two or three tablets, intravenous opioids provide the most rapid and effective analgesia and may also reduce pulmonary congestion. Morphine sulfate, 4-8 mg, or meperidine, 50-75 mg, should be given. Subsequent small doses can be given every 15 minutes until pain abates.

G. Beta-Adrenergic Blocking Agents

Several studies have shown modestly improved short-term survival when intravenous beta-blockers (metoprolol, 5 mg intravenously every 5 minutes for three doses) are given immediately after acute myocardial infarction. These agents reduce the duration of ischemic pain and the incidence of ventricular fibrillation. A favorable effect appears to persist even after thrombolytic therapy. Beta-blockade should be avoided in patients with decompensated heart failure, asthma, or high degrees of atrioventricular block.

H. Nitrates

Nitroglycerin is the agent of choice for recurrent ischemic pain and is useful in lowering blood pressure or relieving pulmonary congestion. However, routine nitrate administration is not recommended, since no improvement in outcome has been observed in the ISIS-4 or GISSI-3 trials, in which a total of over 70,000 patients were randomized to nitrate treatment or placebo.

I. Angiotensin-Converting Enzyme (ACE) Inhibitors

A series of trials (SAVE, AIRE, SMILE, TRACE, GISSI-III, and ISIS-IV) have shown both short- and long-term improvement in survival with ACE inhibitor therapy. The benefits are greatest in patients with low ejection fractions, large infarctions, or clinical evidence of heart failure, and only these patients should receive chronic ACE inhibitor therapy for postinfarction indications. Acute short-term treatment may improve survival in a broader group of patients, but this is uncertain. Treatment should be commenced carefully in the first postinfarction day if the patient is not hypotensive. When there is no evidence of heart failure or when a very large infarction is not present, ACE inhibitors should be considered only after the administration of thrombolytic therapy, aspirin, beta-blockers, and, if the patient has evidence of continuing ischemia, nitrates.

J. Antiarrhythmic Prophylaxis

The incidence of ventricular fibrillation in hospitalized patients is approximately 5%, with 80% of episodes occurring in the first 12-24 hours. Prophylactic lidocaine infusions (1-2 mg/min) prevent most episodes, but this therapy has not reduced the mortality rate and it increases the risk of asystole, so this approach is no longer recommended except in patients with nonsustained ventricular tachycardia. Intravenous magnesium sulfate has been effective in one study, but ISIS-4 did not report a benefit with routine magnesium administration.

K. Calcium Channel Blockers

There are no studies to support the use of calcium channel blockers in most acute myocardial infarction patients—and indeed, they have the potential to exacerbate ischemia and cause death from reflex tachycardia or myocardial depression. One exception is that diltiazem and verapamil appear to prevent reinfarction and ischemia in the subset of patients with non-Q wave infarction. Diltiazem is preferable because it causes less myocardial depression. The dosage is 240-360 mg daily. Otherwise, long-acting calcium channel blockers should be reserved for management of hypertension or ischemia as second- or third-line drugs after beta-blockers and nitrates.

L. Anticoagulation

With the exception of patients undergoing thrombolysis and subsequent heparin therapy, the use of full anticoagulation in the acute setting remains controversial. Patients who will be at bed rest or on limited activity status for some time should be given prophylaxis for deep vein thrombosis (5000 units of heparin subcutaneously every 12 hours) unless contraindicated. Aspirin, 325 mg daily, should be continued also unless contraindicated.

Complications

A variety of complications can occur after myocardial infarction even when treatment is initiated promptly.

A. Postinfarction Ischemia

Approximately 30% of patients will have angina postinfarction. This is more common in patients with angina prior to infarction and in non-ST segment elevation infarction. Postinfarction angina is associated with increased short- and long-term mortality. The underlying mechanism is usually inadequate blood flow through a recanalized vessel or reocclusion. Vigorous medical therapy should be instituted, including nitrates and beta-blockers as well as aspirin, heparin, and platelet glycoprotein IIb/IIIa antagonists. Most patients with postinfarction angina—and all who are refractory to medical therapy—should undergo early catheterization and revascularization by PTCA or CABG.

B. Arrhythmias

Abnormalities of rhythm and conduction are common.

1. Sinus bradycardia—This is most common in inferior infarctions or may be precipitated by medications. Observation or withdrawal of the offending agent is usually sufficient. If accompanied by signs of low cardiac output, atropine, 0.5-1 mg intravenously, is usually effective. Temporary pacing is rarely required.

2. Supraventricular tachyarrhythmias—Sinus tachycardia is common and may reflect either increased adrenergic stimulation or hemodynamic compromise due to hypovolemia or pump failure. In the latter, beta blockade is contraindicated. Supraventricular premature beats are common and may be premonitory for atrial fibrillation. Electrolyte abnormalities and hypoxia should be corrected and causative agents (especially aminophylline) stopped. Atrial fibrillation should be rapidly controlled or converted to sinus rhythm. Intravenous beta-blockers such as metoprolol (2.5-5 mg/h) or short-acting esmolol (50-200 ug/ kg/min) are the agents of choice if cardiac function is adequate. Intravenous diltiazem (5-15 mg/h) may be used if beta-blockers are contraindicated or ineffective. Digoxin (0.5 mg as initial dose, then 0.25 mg every 90-120 minutes [up to 1-1.25 mg] for a loading dose, followed by 0.25 mg daily if renal function is normal) is preferable if heart failure is present with atrial fibrillation, but the onset of action is delayed. Electrical cardioversion (commencing with 100 J) may be necessary if atrial fibrillation is complicated by hypotension, heart failure, or ischemia, but the arrhythmia often recurs. A short course of a class Ia agent such as procainamide or quinidine may be required in addition to digoxin, a beta-blocker, or a calcium channel blocker to maintain sinus rhythm. Amiodarone (150 mg intravenous bolus and then 15-30 mg/h intravenously, or rapid oral loading with 400 mg three times daily) may be helpful to restore or maintain sinus rhythm.

3. Ventricular arrhythmias—Ventricular arrhythmias are most common in the first few hours after infarction. Ventricular premature beats may be premonitory for ventricular tachycardia or fibrillation but generally should not be treated in the absence of nonsustained ventricular tachycardia (usually more than six consecutive beats). In the latter case, prophylactic lidocaine has been shown to prevent subsequent sustained ventricular tachycardia or fibrillation but does not improve survival in patients who are being monitored. Prophylactic lidocaine may be started as a 1- mg/kg bolus followed by an infusion of 2 mg/min. Toxicity (tremor, anxiety, confusion, seizures) is common, especially in older patients and those with hypotension, heart failure, or liver disease.

Ventricular tachycardia should be treated with a 1- mg/kg bolus of lidocaine if the patient is stable or by electrical cardioversion (100-200 J) if not. If the arrhythmia cannot be suppressed with lidocaine, procainamide (100-mg boluses over 1-2 minutes every 5 minutes to a cumulative dose of 750-1000 mg) or intravenous amiodarone (150 mg over 10 minutes, which may be repeated as needed, followed by 360 mg over 6 hours and then 540 mg over 18 hours) should be initiated, followed by an infusion of 20-80 mg/kg/min. Ventricular fibrillation is treated electrically (300-400 J). Unresponsive ventricular fibrillation should be treated with additional amiodarone and repeat cardioversion while CPR is administered.

Accelerated idioventricular rhythm is a regular, wide-complex rhythm at a rate of 70-100/min. It often follows reperfusion and usually does not require specific therapy.

4. Conduction disturbances—All degrees of atrioventricular block may occur in the course of acute myocardial infarction. Block at the level of the atrioventricular node is more common than infranodal block and occurs in approximately 20% of inferior myocardial infarctions. First-degree block is the most common and requires no treatment. Second-degree block is usually of the Mobitz type I form (Wenckebach), is often transient, and requires treatment only if associated with a heart rate slow enough to cause symptoms. Complete atrioventricular block occurs in up to 5% of acute inferior infarctions, usually is preceded by Mobitz I second-degree block, and generally resolves spontaneously, though it may persist for hours to several weeks. The escape rhythm originates in the distal atrioventricular node or atrioventricular junction and hence has a narrow QRS complex and is reliable, albeit often slow (30-50 beats/min). Treatment is often necessary because of resulting hypotension and low cardiac output. Intravenous atropine (1 mg) usually restores atrioventricular conduction temporarily, but if the escape complex is wide or if repeated atropine treatments are needed, temporary ventricular pacing is indicated. The prognosis for these patients is only slightly worse than that of patients who do not develop atrioventricular block.

In anterior infarctions, the site of block is distal, below the atrioventricular node, and usually a result of extensive damage of the His-Purkinje system and bundle branches. New first-degree block (prolongation of the PR interval) is unusual in anterior infarction; Mobitz type II atrioventricular block or complete heart block may be preceded by intraventricular conduction defects or may occur abruptly. The escape rhythm, if present at all, is an unreliable wide-complex idioventricular rhythm. Urgent ventricular pacing is mandatory, but even with successful pacing, morbidity and mortality are high because of the extensive myocardial damage. New conduction abnormalities such as right or left bundle branch block or fascicular blocks may presage progression, often sudden, to second- or third-degree atrioventricular block. Temporary ventricular pacing is recommended for new-onset alternating bilateral bundle branch block, bifascicular block, or bundle branch block with worsening first-degree atrioventricular block. Patients with anterior infarction who progress to second- or third-degree block even transiently should be considered for insertion of a prophylactic permanent ventricular pacemaker before discharge.

C. Myocardial Dysfunction

The severity of cardiac dysfunction is proportionate to the extent of myocardial necrosis but is exacerbated by preexisting dysfunction and ongoing ischemia. Patients who have normal blood pressure, no signs of heart failure, and normal urine output have a good prognosis. Those with hypotension or evidence of more than mild heart failure should have bedside right heart catheterization and continuous measurements of arterial pressure. These measurements permit the accurate assessment of cardiac function, facilitate the correct choice of therapy, and provide important prognostic information. [Table 10-3](#) categorizes patients based upon these hemodynamic findings.

1. Acute left ventricular failure—Basilar rales are common in acute myocardial infarction, but dyspnea, more diffuse rales, and arterial hypoxemia usually indicate left ventricular failure. Since both the physical examination and chest x-ray correlate poorly with hemodynamic measurements and since the central venous pressure does not correlate with the pulmonary capillary wedge pressure (PCWP), right heart catheterization may be essential in monitoring therapy. General measures include supplemental oxygen to increase arterial saturation to above 95% and elevation of the trunk. Diuretics are usually the initial therapy unless right ventricular infarction is present. Intravenous furosemide (10-40 mg) or bumetanide (0.5-1 mg) is preferred because of the reliably rapid onset and short duration of action of these drugs. Higher dosages can be given if an inadequate response occurs. Morphine sulfate (4 mg intravenously followed by increments of 2 mg) is valuable in acute pulmonary edema.

Diuretics are usually effective; however, since most patients with acute infarction are not volume overloaded, the hemodynamic response may be limited and may be associated with hypotension. Vasodilators will reduce PCWP and improve cardiac output by a combination of venodilation (increasing venous capacitance) and arteriolar dilation (reducing afterload and left ventricular wall stress). In mild heart failure, sublingual isosorbide dinitrate (2.5-10 mg every 2 hours) or nitroglycerin ointment (6.25-25 mg every 4 hours) may be adequate to lower PCWP. In more severe failure, especially if cardiac output is reduced, sodium nitroprusside is the preferred agent. It should be initiated only with hemodynamic monitoring; the initial dosage should be low (0.25 ug/kg/min) to avoid excessive hypotension, but the

dosage can be increased by increments of 0.5 ug/kg/min every 5-10 minutes up to 5-10 ug/kg/min until the desired hemodynamic response (PCWP < 18 mm Hg, CI > 2.5) is obtained. Excessive hypotension (mean blood pressure < 65-75 mm Hg) or tachycardia (> 10/min increase) should be avoided. Combination of nitroprusside with inotropic agents may be necessary to preserve blood pressure or maximize benefit.

Intravenous nitroglycerin (starting at 10 ug/min) is usually less effective but may lower PCWP with less hypotension. Oral or transdermal vasodilator therapy with nitrates or angiotensin-converting enzyme inhibitors is often necessary after the initial 24-48 hours (see below).

Inotropic agents should be avoided if possible, because they often increase heart rate and myocardial oxygen requirements. Dobutamine has the best hemodynamic profile, increasing cardiac output and modestly lowering PCWP, usually without excessive tachycardia, hypotension, or arrhythmias. The initial dosage is 2.5 ug/kg/min, and it may be increased by similar increments up to 15-20 ug/kg/min at intervals of 5-10 minutes. Dopamine is more useful in the presence of hypotension (see below), since it produces peripheral vasoconstriction, but it has a less beneficial effect on PCWP. Amrinone is a positive inotrope and vasodilator that produces hemodynamic effects similar to those of dobutamine but with a greater decrease in PCWP. However, its longer duration of action makes it less useful in unstable situations. Milrinone is a more potent and newer congener of amrinone with fewer side effects. It should be commenced in a loading dose of 50 ug/kg over 10 minutes, followed by an infusion of 0.375-0.75 ug/kg/min. Digoxin has not been helpful in acute infarction except to control the ventricular response in atrial fibrillation, but it may be beneficial if chronic heart failure persists.

2. Hypotension and shock—Patients with hypotension (systolic blood pressure < 100 mm Hg, individualized depending on prior blood pressure) and signs of diminished perfusion (low urine output, confusion, cold extremities) should be hemodynamically monitored. Up to 20% will have findings indicative of intravascular hypovolemia (due to diaphoresis, vomiting, decreased venous tone, medications—such as diuretics, nitrates, morphine, beta-blockers, calcium channel blockers, and thrombolytic agents—and lack of oral intake). These should be treated with successive boluses of 100 mL of normal saline until PCWP reaches 15-18 mm Hg to determine whether cardiac output and blood pressure respond. Pericardial tamponade due to hemorrhagic pericarditis (especially after thrombolytic therapy or cardiopulmonary resuscitation) or ventricular rupture should be considered and excluded by echocardiography if clinically indicated. Right ventricular infarction, characterized by a normal PCWP but elevated right atrial pressure, can produce hypotension. This is discussed below.

Most hypotensive patients will have moderate to severe left ventricular dysfunction; pathologic studies indicate that more than 20% of the left ventricle is infarcted (> 40% in cardiogenic shock). If hypotension is only modest (systolic pressure > 90 mm Hg) and the PCWP is elevated, diuretics and an initial trial of nitroprusside (see above for dosing) are indicated. If the blood pressure falls, inotropic support will need to be added or substituted. Such patients may also be treated with intra-aortic balloon counterpulsation (IABC). This device unloads the left ventricle during systole and increases diastolic coronary artery filling pressure. It often facilitates the use of vasodilators in patients who previously did not tolerate them.

Dopamine is the most appropriate pressor for cardiogenic hypotension. It should be initiated at a rate of 2-4 ug/kg/min and increased at 5-minute intervals to the appropriate hemodynamic end point. At low dosages (< 5 ug/kg/min), it improves renal blood flow; at intermediate dosages (2.5-10 ug/kg/min), it stimulates myocardial contractility; at higher dosages (> 8 ug/kg/min), it is a potent α_1 -adrenergic agonist. In general, blood pressure and cardiac index rise, but PCWP does not fall.

Dopamine may be combined with nitroprusside or dobutamine (see above for dosing), or the latter may be used in its place if hypotension is not severe. Amrinone and milrinone have hemodynamic effects similar to those of dobutamine, but their longer duration of action precludes rapid dosage adjustment. Norepinephrine (0.1-0.5 ug/kg/min) is the usual pressor of last resort, since isoproterenol and epinephrine produce less vasoconstriction and do not increase coronary perfusion pressure (aortic diastolic pressure), and both tend to worsen the balance between myocardial oxygen delivery and utilization.

Patients with cardiogenic shock not due to hypovolemia have a poor prognosis, with 30-day mortality rates of 50-80%. If they do not respond rapidly, IABC should be instituted. Surgically implanted ventricular assist devices may be used in extreme cases. Early cardiac catheterization and coronary angiography followed by percutaneous or surgical revascularization offer the best chance of survival, particularly in patients under 75 years of age.

D. Right Ventricular Infarction

Right ventricular infarction is present in one-third of patients with inferior wall infarction but is clinically significant in less than 50% of these. It presents as hypotension with relatively preserved left ventricular function and should be considered whenever patients with inferior infarction exhibit signs of low cardiac output and raised venous pressure. Hypotension is often exacerbated by medications that decrease intravascular volume or produce venodilation, such as diuretics, nitrates, and narcotics. Right atrial pressure and jugular venous pulsations are high, while PCWP is normal or low and the lungs are clear. The diagnosis is suggested by ST segment elevation in right-sided anterior chest leads. The diagnosis can be confirmed by echocardiography or hemodynamic measurements. When hypotension is present, hemodynamic measurements are necessary to monitor therapy. Treatment consists of fluid loading to improve left ventricular filling; inotropic agents may also be useful.

E. Mechanical Defects

Partial or complete rupture of a papillary muscle or of the interventricular septum occurs in less than 1% of acute myocardial infarctions and carries a poor prognosis. These complications occur in both anterior and inferior infarctions, usually 3-7 days after the acute event. They are detected by the appearance of a new systolic murmur and clinical deterioration, often with pulmonary edema. The two lesions are distinguished by the location of the murmur (apical versus parasternal) and by Doppler echocardiography. Hemodynamic monitoring is essential for appropriate management and demonstrates an increase in oxygen saturation between the right atrium and pulmonary artery in ventricular septal defect and, often, a large v wave with mitral regurgitation. Treatment by nitroprusside and, preferably, IABC reduces the regurgitation or shunt, but surgical correction is mandatory. In patients remaining hemodynamically unstable or requiring continuous parenteral pharmacologic treatment or counterpulsation, early surgery is recommended, though mortality rates are high (15% to nearly 100%, depending on residual ventricular function and clinical status). Patients who are stabilized medically can have delayed surgery with lower risks (10-25%).

F. Myocardial Rupture

Complete rupture of the left ventricular free wall occurs in less than 1% of patients and usually results in immediate death. It occurs 2-7 days postinfarction, usually involves the anterior wall, and is more frequent in older women. Incomplete or gradual rupture may be sealed off by the pericardium, creating a **pseudoaneurysm**. This may be recognized by echocardiography, radionuclide angiography, or left ventricular angiography, often as an incidental finding. It demonstrates a narrow-neck connection to the left ventricle. Early surgical repair is indicated, since delayed rupture is common.

G. Left Ventricular Aneurysm

Ten to 20 percent of patients surviving an acute infarction develop a left ventricular aneurysm, a sharply delineated area of scar that bulges paradoxically during systole. This usually follows anterior Q wave infarctions. Aneurysms are recognized by persistent ST segment elevation (beyond 4-8 weeks), and a wide neck from the left ventricle can be demonstrated by echocardiography, scintigraphy, or contrast angiography. They rarely rupture but may be associated with arterial emboli, ventricular arrhythmias, and congestive heart failure. Surgical resection may be performed for these indications if other measures fail. The best results (mortality rates of 10-20%) are obtained when the residual myocardium contracts well and when significant coronary lesions supplying adjacent regions are bypassed.

H. Pericarditis

The pericardium is involved in approximately 50% of infarctions, but pericarditis is often not clinically significant. Twenty percent of patients with Q wave infarctions will have an audible friction rub if examined repetitively. Pericardial pain occurs in approximately the same proportion after 2-7 days and is recognized by its variation with respiration and position (improved by sitting). Often, no treatment is required, but aspirin (650 mg every 4-6 hours) or indomethacin (25 mg three or four times daily) will usually relieve the pain. Anticoagulation should be avoided, since hemorrhagic pericarditis may result.

One week to 12 weeks after infarction, Dressler's syndrome (post-myocardial infarction syndrome) occurs in less than 5% of patients. This is an autoimmune phenomenon and presents as pericarditis with associated fever, leukocytosis, and, occasionally, pericardial or pleural effusion. It may recur over months. Treatment is the same as for other forms of pericarditis. A short course of corticosteroids may help if nonsteroidal agents do not relieve symptoms.

I. Mural Thrombus

Mural thrombi are common in large anterior infarctions but not in infarctions at other locations. Arterial emboli occur in approximately 2% of patients with known infarction, usually within 6 weeks. Anticoagulation with heparin followed by short-term (3-month) warfarin therapy prevents most emboli and should be considered in all patients with large anterior infarctions. Mural thrombi can be detected by echocardiography or CT scan (MRI has yielded frequent false-positive results) but with only moderate reliability, and only a small percentage (up to 25%) embolize, so these procedures should not be relied upon for determining the need for anticoagulation.

Postinfarction Management

Twenty percent of patients with acute myocardial infarction die before they reach the hospital. Mortality rates in hospitalized patients range from 5% to 15% and are determined chiefly by the size of the infarction and the age and general condition of the patient. Patients developing heart failure or hypotension have high early mortality rates. Several classification criteria have been developed to estimate early prognosis for survival. The most accurate is hemodynamic subsetting (Table 10-3). The prognosis after discharge is determined by three major factors: the degree of left ventricular dysfunction, the extent of residual ischemic myocardium, and the presence of ventricular arrhythmias. The mortality rate in the first year after discharge is approximately 6-8%, with over half of deaths occurring in the first 3 months, chiefly in patients with postinfarction heart failure. Subsequently, the mortality rate averages 4% per year.

A. Risk Stratification

A number of findings indicate increased risk after infarction. These include: (1) postinfarction angina; (2) non-Q wave infarction; (3) heart failure; (4) left ventricular ejection fraction less than 40%; (5) stress-induced ischemia, diagnosed by electrocardiography, scintigraphy, or echocardiography; and (6) ventricular ectopy (> 10 VPB/h). Patients with postinfarction angina should undergo coronary arteriography. Authorities differ about which tests should be performed routinely in other patients, but in most a noninvasive assessment of left ventricular function and residual ischemia is appropriate. Significant left ventricular dysfunction is most likely with anterior infarction or multiple infarctions. In such patients, noninvasive assessment of left ventricular function by echocardiography or scintigraphy will help assess prognosis and facilitate medical management. If the ejection fraction is less than 40%, coronary angiography may be indicated, as this is a high-risk subset in which revascularization may improve prognosis. ACE inhibitor therapy is also indicated in patients with reduced ejection fractions. Submaximal exercise or pharmacologic stress testing before discharge or a maximal test after 3-6 weeks (the latter being more sensitive for ischemia) helps patients and physicians plan the return to normal activity. Imaging in conjunction with stress testing adds additional sensitivity for ischemia and provides localizing information. Both exercise and pharmacologic stress imaging have successfully predicted subsequent outcome. One of these tests should usually be employed prior to discharge in patients who have received thrombolytic therapy as a means of selecting appropriate candidates for coronary angiography.

Ambulatory electrocardiographic monitoring for arrhythmias is of less clear value; though it has some prognostic value beyond measurements of left ventricular function, no benefit from antiarrhythmic therapy for asymptomatic patients has been demonstrated. Ischemia detected during ambulatory monitoring is an indicator of poor prognosis, but it is unclear how much additional information is obtained in patients who have also undergone exercise testing or scintigraphic studies. The role of other procedures such as assessment of heart rate variability or baroreceptor testing is uncertain.

A conservative approach to postinfarction evaluation would include measurement of left ventricular function in patients with signs of heart failure or large infarctions and a test for ischemia in patients without recurrent chest pain. The latter should occur before discharge if the patient has undergone thrombolytic therapy but may be delayed for 3-6 weeks in most other patients.

B. Secondary Prevention

Postinfarction management should begin with identification and modification of risk factors. Treatment of hyperlipidemia and smoking cessation both prevent recurrent infarction and death. LDL cholesterol levels should be lowered below 100 mg/dL with drug therapy (usually a statin) commencing prior to discharge. Blood pressure control and exercise are also recommended.

Beta-blockers improve survival rates, primarily by reducing the incidence of sudden death in high-risk subsets of patients, though their value may be less in uncomplicated patients with small infarctions and normal exercise tests. No advantage of one preparation over another has been demonstrated except that those with intrinsic sympathomimetic activity have not proved beneficial in postinfarction patients.

Antiplatelet agents are beneficial; aspirin (325 mg daily) is recommended, but clopidogrel (75 mg daily) is also effective. Warfarin anticoagulation for 3 months reduces the incidence of arterial emboli after large anterior infarctions, and according to the results of at least one study it improves long-term prognosis. An advantage to combining aspirin and warfarin has not been demonstrated except perhaps in patients with atrial fibrillation.

Calcium channel blockers have not been shown to improve prognoses overall and should not be prescribed purely for secondary prevention. Antiarrhythmic therapy other than with beta-blockers has not been shown to be effective except in patients with symptomatic arrhythmias. Amiodarone has been studied in several trials of postinfarction patients with either left ventricular dysfunction or frequent ventricular ectopy. Although survival was not improved, amiodarone was not harmful—unlike other agents in this setting. Therefore, it is the agent of choice for individuals with symptomatic postinfarction supraventricular arrhythmias, although emerging data suggest that implantable defibrillators are the preferred option for ventricular arrhythmias.

Cardiac rehabilitation programs and exercise training can be of considerable psychologic benefit, but it is not known whether they alter prognosis.

C. ACE Inhibitors in Patients With Left Ventricular Dysfunction

Patients who sustain substantial myocardial damage often experience subsequent progressive left ventricular dilation and dysfunction, leading to clinical heart failure and reduced long-term survival. In patients with ejection fractions less than 40%, long-term ACE inhibitor therapy prevents left ventricular dilation and the onset of heart failure and prolongs survival. The Heart Outcomes Prevention Evaluation (HOPE) also demonstrated a reduction of approximately 20% in mortality rates and the occurrence of nonfatal myocardial infarction and stroke with ramipril treatment of postinfarction patients without confirmed left ventricular systolic dysfunction. Therefore, ACE inhibitor therapy should be strongly considered in this broader group of patients—and especially in diabetics and patients with even mild systolic hypertension, in whom the greatest benefit was observed.

D. Revascularization

Because of the increasing use of thrombolytic therapy and accumulating experience with PTCA, the indications for revascularization are rapidly evolving. Postinfarction patients who appear likely to benefit from early revascularization if the anatomy is appropriate are (1) those who have undergone thrombolytic therapy and have residual symptoms or laboratory evidence of ischemia, (2) patients with left ventricular dysfunction (ejection fraction < 30-40%) and evidence of ischemia, (3) patients with non-Q wave infarction and evidence of more than mild ischemia, and (4) patients with markedly positive exercise tests and multivessel disease. The value of revascularization in the following groups is less clear: (1) patients treated with thrombolytic agents with little evidence of reperfusion or residual ischemia, (2) patients with left ventricular dysfunction but no detectable ischemia, and (3) patients with preserved left ventricular function who have mild ischemia and are not symptom-limited. Patients who survive infarctions without complications, have preserved left ventricular function (ejection fraction > 50%), and have no exercise-induced ischemia have an excellent prognosis and do not require invasive evaluation.

■ DISTURBANCES OF RATE & RHYTHM

Abnormalities of cardiac rhythm and conduction can be lethal (sudden cardiac death), symptomatic (syncope, near syncope, dizziness, or palpitations), or asymptomatic. They are dangerous to the extent that they reduce cardiac output, so that perfusion of the brain or myocardium is impaired, or tend to deteriorate into more serious arrhythmias with the same consequences. Stable supraventricular tachycardia is generally well tolerated in patients without underlying heart disease but may lead to myocardial ischemia or congestive heart failure in patients with coronary disease, valvular abnormalities, and systolic or diastolic myocardial dysfunction. Ventricular tachycardia, if prolonged (lasting more than 10-30 seconds), often results in hemodynamic compromise and is more likely to deteriorate into ventricular fibrillation.

Whether slow heart rates produce symptoms at rest or on exertion depends upon whether cerebral perfusion can be maintained, which is generally a function of whether the patient is upright or supine and whether left ventricular function is adequate to maintain stroke volume. If the heart rate abruptly slows, as with the onset of complete heart block or sinus arrest, syncope or convulsions may result.

Arrhythmias are detected either because they present with symptoms or because they are detected during the course of monitoring. Arrhythmias causing sudden death, syncope, or near syncope require further evaluation and treatment unless they are related to conditions that are unlikely to recur (eg, electrolyte abnormalities or acute myocardial infarction). In contrast, there is controversy over when and how to evaluate and treat rhythm disturbances that are not symptomatic but are possible markers for more serious abnormalities (eg, nonsustained ventricular tachycardia). This uncertainty reflects two issues: (1) the difficulty of reliably stratifying patients into high-risk and low-risk groups, and (2) the lack of treatments which are both effective and safe. Thus, screening patients for these so-called "premonitory" abnormalities is often not productive.

A number of procedures are employed to evaluate patients with symptoms who are felt to be at risk for life-threatening arrhythmias, including in-hospital and ambulatory electrocardiographic monitoring, event recorders (instruments that can be worn for prolonged periods in order to record or transmit rhythm tracings when infrequent episodes occur), exercise testing, intracardiac electrophysiologic studies (to assess sinus node function, atrioventricular conduction, and inducibility of arrhythmias), signal-averaged ECGs, and tests of autonomic nervous system function (especially tilt-table testing). These are discussed below and in the subsequent sections on individual rhythm disturbance and symptomatic presentation. In general, these techniques are more successful in diagnosing symptomatic arrhythmias than in predicting the outcome of asymptomatic ones.

MECHANISMS OF ARRHYTHMIAS

Susceptibility to arrhythmias results from genetic abnormalities (most often affecting ion channels) and acquired structural heart disease. Susceptibility may be increased by electrolyte abnormalities, hormonal imbalances (thyrotoxicosis, hypercatecholamine states), hypoxia, drug effects (such as QT interval prolongation or changes in automaticity, conduction, and refractoriness), and myocardial ischemia. Most arrhythmias can be classified as (1) disorders of impulse formation or automaticity and (2) abnormalities of impulse conduction, (3) reentry, and (4) triggered activity.

Altered automaticity is the mechanism for sinus node arrest, many premature beats, and automatic rhythms as well as an initiating factor in reentry arrhythmias.

Abnormalities of impulse conduction can occur at the sinus or atrioventricular node, in the intraventricular conduction system, and within the atria or ventricles. These are responsible for sinoatrial exit block, for atrioventricular block at the node or below, and for establishing reentry circuits.

Reentry is the underlying mechanism for many arrhythmias, including premature beats, most paroxysmal supraventricular tachycardias, and atrial flutter. For reentry to occur, there must be an area of unidirectional block with an appropriate delay to allow repeat depolarization at the site of origin. Reentry is confirmed if the arrhythmia can be terminated by interruption of the circuit by a spontaneous or induced premature beat.

Triggered activity occurs when afterdepolarizations (abnormal electrical activity persisting after repolarization) reach the threshold level required to trigger a new depolarization. This may be the mechanism of ventricular tachycardia in the prolonged QT syndrome and in some cases of digitalis toxicity.

TECHNIQUES FOR EVALUATING RHYTHM DISTURBANCES

Electrocardiographic Monitoring

The ideal way of establishing a causal relationship between a symptom and a rhythm disturbance is to demonstrate the presence of the rhythm during the symptom. Unfortunately, this is not always easy because symptoms are usually sporadic.

Patients with aborted sudden death and recent or recurrent syncope are often monitored in the hospital. Those with less ominous symptoms may be monitored as outpatients. When episodes are infrequent, use of an event recorder is preferable to 24-hour continuous monitoring. Exercise testing may be helpful when the symptoms are associated with exertion or stress. If symptomatic bradyarrhythmias or supraventricular tachyarrhythmias are detected, therapy can usually be initiated without additional diagnostic studies. Further electrophysiologic studies may be useful in evaluating ventricular tachyarrhythmias.

Caution is required before attributing a patient's symptom to rhythm or conduction abnormalities observed during monitoring without concomitant symptoms. In many cases, the symptoms are due to a different arrhythmia or to noncardiac causes. For instance, dizziness or syncope in older patients may be unrelated to concomitantly observed bradycardia, sinus node abnormalities, or ventricular ectopy. Ambulatory monitoring is frequently used to quantify ventricular ectopy and detect asymptomatic ventricular tachycardia in post-myocardial infarction or heart failure patients. Unfortunately, while asymptomatic ventricular arrhythmias have concerning prognostic implications, there are few data to support specific therapeutic intervention. Thus, monitoring in asymptomatic individuals is usually not indicated.

Crawford MH et al: ACC/AHA Guidelines for Ambulatory Electrocardiography. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to Revise the Guidelines for Ambulatory Electrocardiography). Developed in collaboration with the North American Society for Pacing and Electrophysiology. J Am Coll Cardiol 1999;34:912. [\[PMID: 10483977\]](#)

Heart Rate Variability

Although it has long been appreciated that there are periodical fluctuations in heart rate even under basal conditions, considerable recent interest has been focused on measurements of **heart rate variability**. These measurements can be made under controlled conditions in the electrocardiography laboratory or from recordings obtained during ambulatory monitoring. Greater fluctuations in heart rate correspond to greater parasympathetic activity, and several studies have indicated that greater heart rate variability is associated with a better prognosis and fewer life-threatening arrhythmias in a variety of cardiac conditions. More recently, analyses have employed frequency transformation of RR cycle length variability to provide indices of the relative balance between parasympathetic and sympathetic activity, with the greater contribution of the parasympathetic system being considered to confer a better prognosis. In studies of postinfarction patients and patients with symptomatic arrhythmias, these indices have had some prognostic value. However, adequate data are not yet available to support routine use of this technique in clinical practice.

Pumpura J et al: Functional assessment of heart rate variability: physiological basis and practical applications. Int J Cardiol 2002;84:1. [\[PMID: 12104056\]](#)

Signal-Averaged ECG

Another technique is the **signal-averaged ECG**. Most commonly, an orthogonal three-lead system is employed to record 300 consecutive beats during basal conditions. Using appropriate electrical filtering and computer averaging of the signal, very low frequency signals called "late potentials" can be identified in the period following the QRS complex. Abnormal late potentials are considered markers for potential ventricular arrhythmias. Adequate data are not yet available to define the role of this technique with confidence, but it may be useful in detecting groups of patients at increased risk for arrhythmic events after myocardial infarction. Approximately one-third of post-myocardial infarction patients will have abnormal late potentials, and these individuals are at higher risk for arrhythmic events, though the positive predictive value of this finding is relatively low (10-15%). More importantly, the absence of late potentials identifies a group of patients at low risk for arrhythmic events, so post-myocardial infarction patients found to have frequent ventricular ectopy or nonsustained ventricular tachycardia in the absence of late potentials may not require further investigation or treatment. The prognostic value of late potentials in patients with chronic ischemic heart disease who are more than 6-12 months removed from myocardial infarction and in patients with other forms of heart disease is not yet known.

Gomes JA et al: Prediction of long-term outcomes by signal-averaged electrocardiography in patients with unsustained ventricular tachycardia, coronary artery disease and left ventricular dysfunction. *Circulation* 2001;104:436. [PMID: 11468206]

Electrophysiologic Testing

Electrophysiologic testing employing intracardiac electrocardiographic recordings and programmed atrial or ventricular (or both) stimulation is useful in the diagnosis and management of complex arrhythmias. The primary indications for electrophysiologic testing are (1) evaluation of recurrent syncope of possible cardiac origin when the ambulatory ECG has not provided the diagnosis, (2) differentiation of supraventricular from ventricular arrhythmias, (3) evaluation of therapy in patients with accessory atrioventricular pathways, (4) evaluation of the efficacy of pharmacotherapy in survivors of aborted sudden death or other patients with symptomatic or life-threatening ventricular tachycardia, and (5) evaluation of patients for catheter ablation procedures or antitachycardia devices.

Autonomic Testing (Tilt-Table Testing)

In many patients with recurrent syncope or near syncope, arrhythmias are not the cause. This is particularly true when the patient has no evidence of associated heart disease by history, examination, standard ECG, or noninvasive testing. Syncope may be neurocardiogenic in origin, mediated by excessive vagal stimulation, or an imbalance between sympathetic and parasympathetic autonomic activity. With assumption of upright posture, there is venous pooling in the lower limbs. However, instead of the normal response, which consists of an increase in heart rate and vasoconstriction, a sympathetically mediated increase in myocardial contractility activates mechanoreceptors that trigger reflex bradycardia and vasodilation. Autonomic testing is an important component of the evaluation in these individuals and should usually precede invasive electrophysiologic procedures. Carotid sinus massage in patients who do not have carotid bruits or a history of cerebral vascular disease can precipitate sinus node arrest or atrioventricular block in patients with carotid sinus hypersensitivity. Head-up tilt-table testing can identify patients whose syncope may be on a vasovagal basis. Although different testing protocols are employed, passive tilting to at least 70 degrees for 10-40 minutes—in conjunction with isoproterenol infusion, if necessary—is typical. Syncope due to bradycardia, hypotension, or both will occur in approximately one-third of patients with recurrent syncope. Some recent studies have suggested that, at least with some of the more extreme protocols, false-positive responses may occur.

Fitzpatrick AP et al: Tilt methodology in reflex syncope: emerging evidence. *J Am Coll Cardiol* 2000;36:179. [PMID: 10898431]

Antiarrhythmic Drugs (Table 10-5)

Antiarrhythmic drugs have limited efficacy and produce frequent side effects. They are often divided into four classes based upon their electropharmacologic actions. Some have multiple actions.

Class I agents block membrane sodium channels. Three subclasses are further defined by the effect of agents on the Purkinje fiber action potential. Class Ia drugs slow the rate of rise of the action potential ($V_{\max}$) and prolong its duration, thus slowing conduction and increasing refractoriness. Class Ib agents shorten action potential duration; they do not affect conduction or refractoriness. Class Ic agents prolong $V_{\max}$ and slow repolarization, thus slowing conduction and prolonging refractoriness, but more so than class Ia drugs.

Class II agents are the beta-blockers, which decrease automaticity, prolong atrioventricular conduction, and prolong refractoriness.

Class III agents block potassium channels and prolong repolarization, widening the QRS and prolonging the QT interval. They decrease automaticity and conduction and prolong refractoriness.

Class IV agents are the calcium channel blockers, which decrease automaticity and atrioventricular conduction.

Although the in vitro electrophysiologic effects of most of these agents have been defined, their use remains largely empirical. All can exacerbate arrhythmias (proarrhythmic effect), and most depress left ventricular function.

The risk of antiarrhythmic agents has been highlighted by the Cardiac Arrhythmia Suppression Trial (CAST), in which two class Ic agents (flecainide, encainide) and a class Ia agent (moricizine) increased mortality rates in patients with asymptomatic ventricular ectopy after myocardial infarction. A similar result has been reported with D-sotalol, a class III agent without the beta-blocking activity of D,L-sotalol, the currently marketed formulation. Therefore, these agents (and perhaps any antiarrhythmic drug) should not be used except for life-threatening ventricular arrhythmias and symptomatic supraventricular tachyarrhythmias.

The use of antiarrhythmic agents for specific arrhythmias is discussed below.

Radiofrequency Ablation for Cardiac Arrhythmias

Catheter ablation techniques have become the primary modality for treatment of many arrhythmias. This growing trend reflects the increasing ability to localize the origin or conduction pathways of many arrhythmias, the improved technology for delivering radiofrequency energy, and growing dissatisfaction with the efficacy and safety of pharmacologic therapy. Ablation has become the primary modality of therapy for many symptomatic supraventricular arrhythmias, including atrioventricular nodal reentry tachycardia, reentry tachycardias involving accessory pathways, paroxysmal atrial tachycardia, inappropriate sinus tachycardia, and automatic junctional tachycardia. Many laboratories have achieved reasonable success rates in preventing atrial flutter with radiofrequency techniques. Ablation of atrial fibrillation is more complex and involves electrical isolation of the pulmonary veins, which are often the site of initiation of atrial fibrillation, or placing linear lesions within the atria to prevent spread of the rhythm. Catheter ablation of ventricular arrhythmias has proved more difficult. Three specific forms of ventricular tachycardia, however, have proved to be amenable to radiofrequency ablation. These include bundle-branch reentry, tachycardia originating in the right ventricular outflow tract, and some tachycardias originating in the left side of the interventricular septum. Other forms of ventricular tachycardia, particularly in patients with coronary artery disease, may be amenable to ablation, but experience thus far is limited.

These procedures are generally safe, though there is a low incidence of perforation of the atria or right ventricle that results in pericardial tamponade and sufficient damage to the atrioventricular node to require permanent cardiac pacing in less than 5% of patients. In addition, some procedures involve transeptal or retrograde left ventricular catheterization, with the attendant potential complications of aortic perforation, damage to the heart valves, or left-sided emboli.

SUPRAVENTRICULAR ARRHYTHMIAS

1. Sinus Arrhythmia, Bradycardia, & Tachycardia

Sinus arrhythmia is a cyclic increase in normal heart rate with inspiration and decrease with expiration. It results from reflex changes in vagal influence on the normal pacemaker and disappears with breath holding or increase of heart rate due to any cause. It has no clinical significance. It is common in both the young and the elderly.

Sinus bradycardia is a heart rate slower than 50/min due to increased vagal influence on the normal pacemaker or organic disease of the sinus node. The rate usually increases during exercise or administration of atropine. In healthy individuals, and especially in patients who are in excellent physical condition, sinus bradycardia to a rate of 50 or even lower is a normal finding. However, severe sinus bradycardia may be an indication of sinus node pathology (see below), especially in elderly patients and individuals with heart disease. It may cause weakness, confusion, or syncope if cerebral perfusion is impaired. Atrial and ventricular ectopic rhythms are more apt to occur with slow sinus rates. Pacing may be required if symptoms correlate with the bradycardia.

Sinus tachycardia is defined as a heart rate faster than 100 beats/min that is caused by rapid impulse formation from the normal pacemaker; it occurs with fever, exercise, emotion, pain, anemia, heart failure, shock, thyrotoxicosis, or in response to many drugs. Alcohol and alcohol withdrawal are common causes of sinus

tachycardia and other supraventricular arrhythmias. The onset and termination are usually gradual, in contrast to paroxysmal supraventricular tachycardia due to reentry. The rate infrequently exceeds 160/min but may reach 180/min in young persons. The rhythm is basically regular, but serial 1-minute counts of the heart rate indicate that it varies five or more beats per minute with changes in position, with breath holding, or with sedation. Rare individuals have persistent or episodic "inappropriate" sinus tachycardia that may be very symptomatic or may lead to left ventricular contractile dysfunction. Radiofrequency modification of the sinus node has mitigated this problem.

Mangrum JM et al: The evaluation and management of bradycardia. N Engl J Med 2000;342:703. [\[PMID: 10706901\]](#)

2. Atrial Premature Beats (Atrial Extrasystoles)

Atrial premature beats occur when an ectopic focus in the atria fires before the next sinus node impulse or a reentry circuit is established. The contour of the P wave usually differs from the patient's normal complex. The subsequent R-R cycle length is usually unchanged or only slightly prolonged. Such premature beats occur frequently in normal hearts and are never a sufficient basis for a diagnosis of heart disease. Speeding of the heart rate by any means usually abolishes most premature beats. Early atrial premature beats may cause aberrant QRS complexes (wide and bizarre) or may be nonconducted to the ventricles because the latter are still refractory.

3. Differentiation of Aberrantly Conducted Supraventricular Beats from Ventricular Beats

This distinction can be very difficult in patients with a wide QRS complex; it is important because of the differing prognostic and therapeutic implications of each type. Findings favoring a ventricular origin include (1) atrioventricular dissociation, (2) a QRS duration exceeding 0.14 s, (3) capture or fusion beats (infrequent), (4) left axis deviation with right bundle branch block morphology, (5) monophasic (R) or biphasic (qR, QR, or RS) complexes in V₁, and (6) a qR or QS complex in V₆.

Supraventricular origin is favored by (1) a triphasic QRS complex, especially if there was initial negativity in leads I and V₆, (2) ventricular rates exceeding 170/min, (3) QRS duration longer than 0.12 s but not longer than 0.14 s, and (4) the presence of preexcitation syndrome.

The relationship of the P waves to the tachycardia complex is helpful. A 1:1 relationship usually means a supraventricular origin, except in the case of ventricular tachycardia with retrograde P waves. If the P waves are not clearly seen, Lewis leads (in which the right arm electrode is placed in the V₁ position two interspaces higher than usual and the left arm electrode is placed in the usual V₁ position) may be employed. This accentuates the size of the P waves. Esophageal leads, in which the electrode is placed directly posterior to the left atrium, achieve the same effect even more clearly. Right atrial electrograms may also help to clarify the diagnosis by accentuating the P waves.

4. Paroxysmal Supraventricular Tachycardia

This is the commonest paroxysmal tachycardia and often occurs in patients without structural heart disease. Attacks begin and end abruptly and may last a few seconds to several hours or longer. The heart rate may be 140-240/min (usually 160-220/min) and is perfectly regular (despite exercise or change in position). The P wave usually differs in contour from sinus beats. Patients may be asymptomatic except for awareness of rapid heart action, but some experience mild chest pain or shortness of breath, especially when episodes are prolonged, even in the absence of associated cardiac abnormalities. Paroxysmal supraventricular tachycardia may result from digitalis toxicity and then is commonly associated with atrioventricular block.

The most common mechanism for paroxysmal supraventricular tachycardia is reentry, which may be initiated or terminated by a fortuitously timed atrial or ventricular premature beat. The reentry circuit most commonly involves dual pathways (a slow and a fast pathway) within the atrioventricular node. This is referred to as AV nodal reentry tachycardia (AVNRT). Less commonly, reentry is due to an accessory pathway between the atria and ventricles (AVRT). Approximately one-third of patients with supraventricular tachycardia have aberrant pathways to the ventricles. The pathophysiology and management of arrhythmias due to accessory pathways differs in important ways and is discussed separately below.

Treatment of the Acute Attack

In the absence of heart disease, serious effects are rare, and most attacks break spontaneously. Particular effort should be made to terminate the attack quickly if cardiac failure, syncope, or anginal pain develops or if there is underlying cardiac or (particularly) coronary disease. Because reentry is the most common mechanism for paroxysmal atrial tachycardia, effective therapy requires that conduction be interrupted at some point in the reentry circuit.

A. Mechanical Measures

A variety of methods have been used to interrupt attacks, and patients may learn to perform these themselves. These include Valsalva's maneuver, stretching the arms and body, lowering the head between the knees, coughing, and breath holding. Carotid sinus massage is often performed by physicians but should be avoided if the patient has carotid bruits or a history of transient cerebral ischemic attacks. Firm but gentle pressure and massage are applied first over the right carotid sinus for 10-20 seconds and, if unsuccessful, then over the left carotid sinus. *Pressure should not be exerted on both sides at the same time!* Continuous electrocardiographic or auscultatory monitoring of the heart rate is essential so that pressure can be relieved as soon as the rhythm is broken or if excessive bradycardia occurs. Carotid sinus pressure will interrupt up to half of the attacks, especially if the patient has received a digitalis glycoside or other agent (such as adenosine or a calcium channel blocker) that delays atrioventricular conduction. These maneuvers stimulate the vagus nerve, delay atrioventricular conduction, and block the reentry mechanism, terminating the arrhythmia.

B. Drug Therapy

If mechanical measures fail, two rapidly acting intravenous agents will terminate more than 90% of episodes. Intravenous adenosine has a very brief duration of action and minimal negative inotropic activity. A 6-mg bolus is administered. If no response is observed after 1-2 minutes, a second 12-mg bolus should be given, followed by a third if necessary. Since the half-life of adenosine is less than 10 seconds, the drug must be given rapidly (in 1-2 seconds from a peripheral intravenous line); use half the dose if given through a central line. Adenosine is very well tolerated, but nearly 20% of patients will experience transient flushing, and some patients experience severe chest discomfort.

Calcium channel blockers also rapidly induce atrioventricular block and break most episodes of reentry supraventricular tachycardia. Intravenous verapamil may be given as a 2.5-mg bolus, followed by additional doses of 2.5-5 mg every 1-3 minutes up to a total of 20 mg if blood pressure and rhythm are stable. If the rhythm recurs, further doses can be given. Oral verapamil, 80-120 mg every 4-6 hours, can be used as well in stable patients who are tolerating the rhythm without difficulty, but avoid it if there is any concern that the arrhythmia may be ventricular in origin. Intravenous diltiazem (0.25 mg/kg over 2 minutes, followed by a second bolus of 0.35 mg/kg if necessary and then an infusion of 5-15 mg/h) may cause less hypotension and myocardial depression.

Esmolol, a short-acting beta-blocker, may also be effective; the initial dose is 500 ug/kg intravenously over 1 minute followed by an infusion of 25-200 ug/min. Parasympathetic stimulating drugs such as edrophonium, 5-10 mg intravenously, which delay atrioventricular conduction, may break the reentry mechanism. Because it frequently causes nausea and vomiting, it should be used only if the previously discussed agents fail. Metaraminol or phenylephrine, alpha-adrenergic stimulants that activate the baroreceptors by raising the blood pressure and causing vagal stimulation, can break attacks but should be used cautiously because they may provoke excessive hypertension. Digoxin is effective, but it often requires several hours to safely administer an adequate dose. An initial dose of 0.5-0.75 mg intravenously over 20 minutes, followed by 0.25-mg or 0.125-mg increments every 2-4 hours up to a total of 1-1.25 mg, is used. Intravenous procainamide may terminate supraventricular tachycardia; however, since it facilitates atrioventricular conduction and an initial increase in rate may occur, it is usually not given until after digoxin, verapamil, or a beta-blocker has been administered.

C. Cardioversion

If the patient is hemodynamically stable or if adenosine and verapamil are contraindicated or ineffective, synchronized electrical cardioversion (beginning at 100 J) is almost universally successful. If digitalis toxicity is present or strongly suspected, as in the case of paroxysmal tachycardia with block, electrical cardioversion should be avoided.

Prevention of Attacks

A. Radiofrequency Ablation

Because of concerns about the safety and the intolerability of antiarrhythmic medications, radiofrequency ablation is the preferred approach to patients with recurrent symptomatic reentry supraventricular tachycardia, whether it is due to dual pathways within the atrial ventricular node or to accessory pathways.

B. Drugs

Digoxin orally is the usual drug of first choice because of its convenience and efficacy. Verapamil, alone or in combination with digitalis, is a second choice. (**Note:** Verapamil increases digoxin serum levels.) Beta-blockers are also effective. Patients who do not respond to agents that increase refractoriness of the atrioventricular node may be treated with class Ia (disopyramide, quinidine, procainamide), class Ic (propafenone), or class III (sotalol, amiodarone) drugs. In patients with evidence of structural heart disease, either sotalol or amiodarone is probably a better choice because of the lower incidence of ventricular proarrhythmia during chronic therapy.

Hebbar AK et al: Management of common arrhythmias: Part I. Supraventricular arrhythmias. Am Fam Physician 2002;65: 2479. [PMID: 12086237]

5. Supraventricular Tachycardias Due to Accessory Atrioventricular Pathways (Preexcitation Syndromes)

Pathophysiology & Clinical Findings

Accessory pathways between the atria and the ventricle which avoid the conduction delay of the atrioventricular node predispose to reentry tachycardias, such as AVRT and atrial flutter, and to atrial fibrillation. These may be wholly or partly within the node (Mahaim fibers), yielding a short PR interval and normal QRS morphology (**Lown-Ganong-Levine syndrome**). More commonly, they make direct connections between the atria and ventricle through Kent bundles (**Wolff-Parkinson-White syndrome**). This produces a short PR interval but an early delta wave at the onset of the wide, slurred QRS complex owing to early ventricular depolarization of the region adjacent to the pathway. While the morphology and polarity of the delta wave can suggest the location of the bypass tract, mapping by intracardiac recordings is required for precise anatomic localization.

Accessory pathways occur in 0.1-0.3% of the population and facilitate reentry arrhythmias owing to the disparity in refractory periods of the atrioventricular node and accessory pathway. Whether the tachycardia is associated with a narrow or wide QRS complex is determined by whether antegrade conduction is through the node (narrow) or the bypass tract (wide). Many patients with Wolff-Parkinson-White syndrome never conduct in an antegrade direction through the bypass tract, which is therefore "concealed." Orthodromic tachycardia is a reentrant rhythm that conducts antegrade down the AV node and retrograde up the accessory pathway, resulting in a narrow QRS complex. Antidromic tachycardia conducts down the accessory pathway and retrograde through the AV node, resulting in a wide QRS complex. Since accessory pathways are less refractory than specialized conduction tissue, tachycardias proceeding in this direction have the potential to be more rapid. Up to 30% of patients with Wolff-Parkinson-White syndrome will develop atrial fibrillation or flutter with antegrade conduction down the accessory pathway and a rapid ventricular response.

Treatment

Some patients have a delta wave found incidentally on electrocardiography. In the absence of palpitations, lightheadedness, or syncope, these patients do not require specific therapy. They should be advised to report the onset of any of these symptoms.

A. Radiofrequency Ablation

As with AVNRT, radiofrequency ablation has become the procedure of choice in patients with accessory pathways and recurrent symptoms. Patients with preexcitation syndromes who have episodes of atrial fibrillation or flutter should be tested by induction of atrial fibrillation in the electrophysiologic laboratory, noting duration of the RR cycle; if it is less than 220 ms, a short refractory period is present. These individuals are at highest risk for sudden death, and prophylactic ablation is indicated. Success rates for ablation of accessory pathways with radiofrequency catheters exceed 90% in appropriate patients.

B. Pharmacologic Therapy

Narrow-complex reentry rhythms involving a bypass tract can be managed as discussed for AVNRT. Atrial fibrillation and flutter must be managed differently, since agents such as digoxin, calcium channel blockers, and even beta-blockers may decrease the refractoriness of the accessory pathway or increase that of the AV node, leading to sometimes faster ventricular rates. Therefore, these agents should be avoided. The class Ia antiarrhythmics, as well as the newer class Ic and class III agents, will increase the refractoriness of the bypass tract and are the drugs of choice for wide-complex tachycardias. If hemodynamic compromise is present, electrical cardioversion is warranted.

Long-term therapy often involves a combination of agents that increase refractoriness in the bypass tract (class Ia or Ic agents) and in the atrioventricular node (verapamil, digoxin, and beta-blockers), provided that atrial fibrillation or flutter with short RR cycle lengths is not present (see above). Sotalol and amiodarone are effective in refractory cases. Patients who are difficult to manage should undergo electrophysiologic evaluation.

Antz M et al: Risk of sudden death after successful accessory atrioventricular pathway ablation in resuscitated patients with Wolff-Parkinson-White syndrome. J Cardiovasc Electrophysiol 2002;13:231. [PMID: 11942588]

6. Atrial Fibrillation

Atrial fibrillation is the commonest chronic arrhythmia, with an incidence and prevalence that rise with age, so that it affects nearly 10% of individuals over age 80. It occurs in rheumatic and other forms of valvular heart disease, dilated cardiomyopathy, atrial septal defect, hypertension, and coronary heart disease as well as in patients with no apparent cardiac disease; it may be the initial presenting sign in thyrotoxicosis, and this condition should be excluded with the initial episode. Atrial fibrillation often appears paroxysmally before becoming the established rhythm. Pericarditis, chest trauma, thoracic or cardiac surgery, or pulmonary disease (as well as medications such as theophylline and beta-adrenergic agonists) may cause attacks in patients with normal hearts. Acute alcohol excess and alcohol withdrawal—and, in predisposed individuals, even consumption of small amounts of alcohol—may precipitate atrial fibrillation. This latter presentation, which is often termed "holiday heart," is usually transient and self-limited. Short-term rate control usually suffices as treatment.

Atrial fibrillation is the only common arrhythmia in which the ventricular rate is rapid and the rhythm very irregular. The atrial rate is 400-600/min, but most impulses are blocked at the atrioventricular node. The ventricular response is completely irregular, ranging from 80 to 180/min in the untreated state. Because of the varying stroke volumes resulting from varying periods of diastolic filling, not all ventricular beats produce a palpable peripheral pulse. The difference between the apical rate and the pulse rate is the "pulse deficit"; this deficit is greater when the ventricular rate is high.

Atrial fibrillation itself is rarely life-threatening; however, it can have serious consequences if the ventricular rate is sufficiently rapid to precipitate hypotension, myocardial ischemia, or tachycardia-induced myocardial dysfunction. Although many patients—particularly older or inactive individuals—have relatively few symptoms if the rate is controlled, some patients are aware of the irregular rhythm and may experience it as very uncomfortable. Perhaps the most serious consequence of atrial fibrillation is the propensity for thrombus formation due to stasis in the atria (particularly the atrial appendages) and consequent embolization, most devastatingly to the cerebral circulation. Overall, the rate of stroke is approximately five events per 100 patient-years of follow-up. However, patients with significant obstructive valvular disease, chronic heart failure or left ventricular dysfunction, diabetes, hypertension, or age over 75 years and those with a history of prior embolic events are at substantially higher risk (up to nearly 20 events per 100 patient-years in patients with multiple risk factors). Patients with one or more of these risk factors for stroke should be treated with warfarin. Patients with none of these factors may be treated with aspirin if conditions are present that increase the risk of warfarin. Patients below the age of 60-65 years without any of these stroke risk factors ("lone atrial fibrillation") may be treated with aspirin or no antithrombotic therapy.

Newly Diagnosed Atrial Fibrillation

A. Initial Management

The approach to the initial management of atrial fibrillation depends on the clinical presentation. If, as is often the case—particularly in older individuals—the patient presents without symptoms, hemodynamic instability, or evidence of important precipitating conditions (such as silent myocardial infarction or ischemia, decompensated heart failure, pulmonary embolus, or hemodynamically significant valvular disease), hospitalization is usually not necessary. In most such cases, atrial fibrillation is an unrecognized chronic or paroxysmal condition and should be managed accordingly (see below).

In contrast, if the patient is hemodynamically unstable—usually as a result of a rapid ventricular rate or associated cardiac or noncardiac conditions—hospitalization and immediate treatment of atrial fibrillation are required. Urgent cardioversion is usually indicated in patients with shock or severe hypotension, pulmonary edema, or ongoing myocardial infarction or ischemia. Although if atrial fibrillation has been present for more than 48 hours there is a potential risk of thromboembolism, the need for immediate rate control in these very unstable patients outweighs that risk. Electrical cardioversion is usually preferred in unstable patients. An initial shock with 100-200 J is administered in synchrony with the R wave. If sinus rhythm is not restored, an additional attempt with 360 J is indicated. If this fails, cardioversion may be successful after loading with intravenous ibutilide (1 mg over 10 minutes, repeated in 10 minutes if necessary) or intravenous procainamide (500-1000 mg administered at a rate of 20 mg/min with careful monitoring of blood pressure).

In less unstable patients or those at particularly high risk for embolism (underlying mitral stenosis, a history of prior emboli, or severe heart failure), a strategy of rate control is appropriate. A rate control strategy is appropriate both when the conditions that precipitated atrial fibrillation are likely to persist (such as following cardiac or noncardiac surgery, respiratory failure, or pericarditis) and when these conditions might resolve spontaneously over a period of hours to days (such as alcohol-induced atrial fibrillation, electrolyte or fluid imbalances, excessive exposure to theophylline or sympathomimetic agents, or some of the same previously cited conditions). The choice of agent is guided by the hemodynamic status of the patient, associated conditions, and the urgency of achieving rate control. Although both hypotension and

heart failure may improve when the ventricular rate is slowed, calcium channel blockers and beta-blockers may themselves precipitate hemodynamic deterioration. Digoxin is less risky, but even when used aggressively (0.5 mg intravenously over 30 minutes, followed by increments of 0.25 mg every 1-2 hours to a total dose of 1-1.5 mg over 24 hours in patients not previously receiving this agent), rate control is rather slow and may be inadequate, particularly in patients with sympathetic activation. In the setting of myocardial infarction or ischemia, beta-blockers are the preferred agent. The most frequently used agents are either metoprolol (administered as a 5-mg intravenous bolus, repeated twice at intervals of 5 minutes and then given as needed by repeat boluses or orally at total daily doses of 50-400 mg) or, in very unstable patients, esmolol (0.5 mg/kg intravenously, repeated if necessary, followed by a titrated infusion of 0.05-0.2 mg/kg/min). If hypertension is present or beta-blockers are contraindicated, calcium channel blockers are immediately effective. Diltiazem (20-mg bolus, repeated after 15 minutes if necessary, followed by a maintenance infusion of 5-15 mg/h) is the preferred calcium blocker if hypotension or left ventricular dysfunction is present. Otherwise, verapamil (5-10 mg intravenously over 2-3 minutes, repeated after 30 minutes if necessary) may be used. Amiodarone, even when administered intravenously, has a relatively slow onset but is often a useful adjunct when rate control with the previously cited agents is incomplete or contraindicated or when cardioversion is planned in the near future.

If rate control proves unsuccessful or early cardioversion is considered necessary and the duration of atrial fibrillation exceeds 2-3 days or is unknown, a strategy of transesophageal echo-guided cardioversion should be considered. By this approach, the presence of atrial thrombus is excluded and electrical cardioversion is attempted while the patient remains under sedation. If thrombus is present, the cardioversion is delayed until after a 3- to 4-week period of therapeutic anticoagulation. In any case, because atrial contractile activity may not recover for several weeks after restoration of sinus rhythm in patients who have been in atrial fibrillation for more than several days, cardioversion is usually followed by anticoagulation for at least 1 month unless it is contraindicated.

B. Subsequent Management

Up to two-thirds of patients experiencing a first episode of atrial fibrillation will spontaneously revert to sinus rhythm within 24 hours. If atrial fibrillation persists or has been present for more than a week, spontaneous conversion is unlikely. In most such cases early cardioversion is not required, so management consists of rate control and anticoagulation whether or not the patient has been admitted to hospital. Rate control is usually relatively easy to achieve with beta-blockers, rate-slowing calcium blockers, and digoxin, used as single agents or more often in combination. Good rate control should consist of a ventricular rate between 50 and 100 beats/min with usual daily activities and a ventricular rate not exceeding 120 beats/min except with moderate to strenuous activity. In older patients, who often have diminished atrioventricular nodal function and relatively limited activity, this can often be achieved with a single agent. Most younger or more active individuals require a combination of two agents. Choice of the initial medication is best based on the presence of accompanying conditions: Hypertensive patients should be given beta-blockers or calcium blockers; coronary patients should usually receive a beta-blocker; and heart failure patients should be given digoxin or a beta-blocker. Adequacy of rate control should be evaluated by recording the apical pulse rate both at rest and with an appropriate level of activity (such as after brisk walking around the corridor or climbing stairs).

Anticoagulation with warfarin to an INR target of 2.0-3.0 should be established and maintained as long as the patient is in atrial fibrillation. The only exception is the patient with "lone atrial fibrillation" (eg, no evidence of associated heart disease, hypertension, atherosclerotic vascular disease, or diabetes) who is under age 60. Cardioversion, if planned, should be performed after at least 3 weeks of anticoagulation at a therapeutic level. Except in patients with mitral stenosis or a history of prior embolic events or those with demonstrated thrombus on transesophageal echocardiography, it is not necessary to achieve therapeutic anticoagulation levels in hospital, so the use of intravenous heparin or low-molecular-weight heparin while transitioning to oral warfarin is not necessary.

C. Rate Control or Elective Cardioversion

Two recent large randomized controlled trials (the 4060-patient Atrial Fibrillation Follow-up Investigation of Rhythm Management, or AFFIRM trial, and the Rate Control Versus Electrical Cardioversion for Persistent Atrial Fibrillation, or RACE trial) compared strategies of rate control and rhythm control. In both, a strategy of rate control and chronic anticoagulation was associated with no higher rates of death or stroke—both, if anything, favored rate control—and only a modestly increased risk of hemorrhagic events than a strategy of restoring sinus rhythm and maintaining it with antiarrhythmic drug therapy. Of note is that exercise tolerance and quality of life were not significantly better in the rhythm control group. Nonetheless, the decision as to whether to attempt to restore sinus rhythm following the initial episode remains controversial. Elective cardioversion following an appropriate period of anticoagulation is generally recommended for the initial episode in patients in whom atrial fibrillation is thought to be of recent onset and when there is an identifiable precipitating factor. Similarly, cardioversion is appropriate in patients who remain symptomatic from the rhythm despite aggressive efforts to achieve rate control. However, it should be noted that even in patients for whom this is the initial episode of atrial fibrillation, the recurrence rate is sufficiently high that longer-term anticoagulation is generally appropriate until persistence of sinus rhythm can be confirmed for at least 6 months.

In cases where elective cardioversion is required, it may be accomplished electrically (as described above) or pharmacologically. Intravenous ibutilide may also be used as described above in a setting where the patient can undergo continuous electrocardiographic monitoring for at least 3 hours following administration. In patients in whom a decision has been made to continue antiarrhythmic therapy to maintain sinus rhythm (see next paragraph), cardioversion can be attempted with an agent that is being considered for long-term use. For instance, after therapeutic anticoagulation has been established, amiodarone can be initiated on an outpatient basis (300-400 mg twice daily for 2 weeks, followed by 200 mg twice daily for at least a 2-4 weeks and then a chronic dose of 200 mg daily). Since amiodarone increases the prothrombin time in patients taking warfarin and digoxin levels, careful monitoring of anticoagulation and drug levels is required. Other agents that may be used for both cardioversion and maintenance therapy include propafenone (150-300 mg twice daily; should be avoided in patients with structural heart disease), flecainide (50-150 mg twice daily; should be avoided in patients with structural heart disease), and dofetilide (0.5 mg twice daily; downward dose adjustment is required with renal dysfunction and dosing must be initiated in hospital because of risk of torsade de pointes). Sotalol (80-160 mg twice daily; should be initiated in hospital in patients with structural heart disease because of risk of torsade de pointes) is not very effective for converting atrial fibrillation but can be used to maintain sinus rhythm following cardioversion.

Unfortunately, sinus rhythm will persist in only 25% of patients who have had a sustained (lasting more than several days) or recurrent episode of atrial fibrillation. However, if the patient is treated chronically with an antiarrhythmic agent, sinus rhythm will persist in approximately 50%. The most commonly employed medications are amiodarone, sotalol, propafenone, flecainide, and dofetilide, but the latter four agents are associated with a clear risk of proarrhythmia, and amiodarone frequently causes other adverse effects. Therefore, it may be prudent to determine whether atrial fibrillation recurs during a period of 6 months without antiarrhythmic drugs during which anticoagulation is maintained. If it does recur, the decision as to whether to restore sinus rhythm and initiate chronic antiarrhythmic therapy can be based on how well the patient tolerates atrial fibrillation. In such a patient, chronic anticoagulation is probably indicated in any case, because of the high rate of recurrence and the likely occurrence of asymptomatic paroxysmal episodes.

Paroxysmal & Refractory Atrial Fibrillation

A. Recurrent Paroxysmal Atrial Fibrillation

It is now well established that patients with recurrent paroxysmal atrial fibrillation are at similar stroke risk as those who are in atrial fibrillation chronically. While these episodes may be apparent to the patient, many are not recognized and may be totally asymptomatic. Thus, ambulatory electrocardiographic monitoring or event recorders are indicated in those in whom paroxysmal atrial fibrillation is suspected. Antiarrhythmic agents are usually not successful in preventing paroxysmal atrial fibrillation episodes. However, immediate self-administered treatment with an antiarrhythmic agent (experience is perhaps greatest with propafenone, 300 mg orally, repeated once after 2-3 hours if necessary) may interrupt symptomatic episodes, and chronic use of a beta-blocker or rate-slowing calcium channel blocker may reduce the severity of symptoms. In any case, chronic anticoagulation is indicated except in those who are under 60-65 years of age and have no additional stroke risk factors (see above).

B. Refractory Atrial Fibrillation

Because of trial results indicating that important adverse clinical outcomes (death, stroke, hemorrhage, heart failure) are no more common with rate control than rhythm control, atrial fibrillation should generally be considered refractory if it causes persistent symptoms or limits activity. This is much more likely in younger individuals and those who are very active or engage in strenuous exercise. Even in such individuals, two-drug or three-drug combinations of a beta-blocker, rate-slowing calcium blocker, and digoxin usually can prevent excessive ventricular rates, though in some cases they are associated with excessive bradycardia during sedentary periods. If rapid ventricular rates persist, amiodarone may be substituted for or added to these agents.

If no drug works, radiofrequency AV node ablation and permanent pacing ensure rate control and may facilitate a more physiologic rate response to activity. There is growing experience with focal ablation of foci in the pulmonary veins that initiate atrial fibrillation, following which sinus rhythm may be restored or maintained. A surgical approach called the Maze procedure can also be used to eliminate the multiple reentry circuits that cause atrial fibrillation, and implantable atrial defibrillators can be used to convert paroxysmal episodes. The role of these latter procedures is limited, however.

7. Atrial Flutter

Atrial flutter is less common than fibrillation. It occurs most often in patients with COPD but may be seen also in those with rheumatic or coronary heart disease, congestive heart failure, atrial septal defect, or surgically repaired congenital heart disease. Ectopic impulse formation occurs at atrial rates of 250-350/min, with transmission of every second, third, or fourth impulse through the atrioventricular node to the ventricles. Ventricular rate control is accomplished using the same agents utilized in atrial fibrillation, but it is much more difficult with atrial flutter than with atrial fibrillation. Conversion of atrial flutter to sinus rhythm with class I antiarrhythmic agents is also difficult to achieve, and administration of these drugs has been associated with slowing of the atrial flutter rate to the point where 1:1 atrioventricular conduction can occur at rates in excess of 200/min, with subsequent hemodynamic collapse. The intravenous class III antiarrhythmic agent ibutilide has been significantly more successful in converting atrial flutter. About 50-70% of patients return to sinus rhythm within 60-90 minutes following the infusion of 1-2 mg of this agent. Electrical cardioversion is also very effective for atrial flutter, with approximately 90% of patients converting following shocks of as little as 25-50 J.

The persistence of atrial contractile function in this arrhythmia provides some protection against thrombus formation, though the risk of systemic embolization remains slightly increased. Precardioversion anticoagulation is not necessary for atrial flutter of less than 48 hours' duration except in the setting of mitral valve disease. However, anticoagulation is prudent in chronic atrial flutter, particularly since transient periods of atrial fibrillation are common in these patients.

Chronic atrial flutter is often a difficult management problem, since rate control is difficult. Amiodarone is probably the pharmacologic agent of choice, since it has the potential of both maintaining sinus rhythm and helping with rate control when flutter recurs.

Atrial flutter can follow a typical or atypical reentry circuit around the atrium. The anatomy of the typical circuit has been well defined and allows for radiofrequency ablation within the atrium to interrupt the circuit and eliminate atrial flutter. This technique should be considered in patients refractory to drug therapy.

8. Multifocal (Chaotic) Atrial Tachycardia

This is a rhythm characterized by varying P-wave morphology (by definition, three or more foci) and markedly irregular PP intervals. The rate is usually between 100 and 140/min, and atrioventricular block is unusual. Most patients have severe associated COPD. Treatment of the underlying condition is the most effective approach; verapamil, 240-480 mg daily in divided doses, is also of value in some patients.

McCord J et al: Multifocal atrial tachycardia. Chest 1998;113: 203. [\[PMID: 9440591\]](#)

9. Atrioventricular Junctional Rhythm

The atrial-nodal junction or the nodal-His bundle junctions may assume pacemaker activity for the heart, usually at a rate of 40-60/min. This may occur in patients with myocarditis, coronary artery disease, and digitalis toxicity as well as in individuals with normal hearts. The rate responds normally to exercise, and the diagnosis is often an incidental finding on electrocardiographic monitoring, but it can be suspected if the jugular venous pulse shows cannon a waves. Junctional rhythm is often an escape rhythm because of depressed sinus node function with sinoatrial block or delayed conduction in the atrioventricular node. **Nonparoxysmal junctional tachycardia** results from increased automaticity of the junctional tissues in digitalis toxicity or ischemia and is associated with a narrow QRS complex and a rate usually less than 120-130/min. It is usually considered benign when it occurs in acute myocardial infarction, but the ischemia that induces it may also cause ventricular tachycardia and ventricular fibrillation.

VENTRICULAR ARRHYTHMIAS

1. Ventricular Premature Beats (Ventricular Extrasystoles)

Ventricular premature beats are characterized by wide QRS complexes that differ in morphology from the patient's normal beats. They are usually not preceded by a P wave, although retrograde ventriculoatrial conduction may occur. Unless the latter is present, there is a fully compensatory pause (ie, without change in the PP interval). Bigeminy and trigeminy are arrhythmias in which every second or third beat is premature; these patterns confirm a reentry mechanism for the ectopic beat. Exercise generally abolishes premature beats in normal hearts, and the rhythm becomes regular. The patient may or may not sense the irregular beat, usually as a skipped beat. Ambulatory electrocardiographic monitoring or monitoring during graded exercise may reveal more frequent and complex ventricular premature beats than occur in a single routine ECG. An increased frequency of ventricular premature beats during exercise is associated with a higher risk of cardiovascular mortality, though there is no evidence that specific therapy has a role.

Sudden death occurs more frequently (presumably as a result of ventricular fibrillation) when ventricular premature beats occur in the presence of organic heart disease but not in individuals with no known cardiac disease. If no associated cardiac disease is present and if the ectopic beats are asymptomatic, no therapy is indicated. If they are frequent, electrolyte abnormalities (especially hypo- or hyperkalemia and hypomagnesemia), hyperthyroidism, and occult heart disease should be excluded. Pharmacologic treatment is indicated only for patients who are symptomatic. Because of concerns about worsening arrhythmia and sudden death with most antiarrhythmic agents, beta-blockers are the agents of first choice. If the underlying condition is mitral prolapse, hypertrophic cardiomyopathy, left ventricular hypertrophy, or coronary disease—or if the QT interval is prolonged—beta-blocker therapy is appropriate. The class I and III agents (see [Table 10-5](#)) are all effective in reducing ventricular premature beats but often cause side effects and may exacerbate serious arrhythmias in 5-20% of patients. Therefore, every attempt should be made to avoid using class I or III antiarrhythmic agents in patients without symptoms.

Jouven X et al: Long-term outcome in asymptomatic men with exercise-induced premature ventricular depolarizations. N Engl J Med 2000;343:826. [\[PMID: 10995861\]](#)

2. Ventricular Tachycardia

Ventricular tachycardia is defined as three or more consecutive ventricular premature beats. The usual rate is 160-240/min and is moderately regular but less so than atrial tachycardia. The distinction from aberrant conduction of supraventricular tachycardia may be difficult. The usual mechanism is reentry, but abnormally triggered rhythms occur. Ventricular tachycardia is either nonsustained (lasting less than 30 seconds) or sustained. It may be asymptomatic or associated with syncope or milder symptoms of impaired cerebral perfusion.

Ventricular tachycardia is a frequent complication of acute myocardial infarction and dilated cardiomyopathy but may occur in chronic coronary disease, hypertrophic cardiomyopathy, mitral valve prolapse, myocarditis, and in most other forms of myocardial disease. **Torsade de pointes**, a form of ventricular tachycardia in which QRS morphology twists around the baseline, may occur spontaneously in the setting of hypokalemia or hypomagnesemia or after any drug that prolongs the QT interval; it has a particularly poor prognosis. In nonacute settings, most patients with ventricular tachycardia have known or easily detectable cardiac disease, and the finding of ventricular tachycardia is an unfavorable prognostic sign.

Treatment

A. Acute Ventricular Tachycardia

The treatment of acute ventricular tachycardia is determined by the degree of hemodynamic compromise and the duration of the arrhythmia. The management of ventricular tachycardia in acute infarction has been discussed. In other patients, if ventricular tachycardia causes hypotension, heart failure, or myocardial ischemia, synchronized DC cardioversion with 100-360 J should be performed immediately. If the patient is tolerating the rhythm, lidocaine, 1 mg/kg as an intravenous bolus injection, may terminate it. If the patient is stable and lidocaine is not effective, use a trial of intravenous procainamide, 20 mg/min intravenously (up to 1000 mg), followed by an infusion of 20-80 ug/kg/min. Intravenous amiodarone is often effective when these approaches are not. This formulation is much more bioavailable than the oral form, so more rapid loading can be achieved. It is usually initiated with a rapid loading infusion of 150 mg over 10 minutes, followed by a slow infusion of 1 mg/min for 6 hours and then a maintenance infusion of 0.5 mg/min for an additional 18-42 hours. Supplemental infusions of 150 mg over 10 minutes can be given for recurrent ventricular tachycardia. Bretylium, 5 mg/kg intravenously over 3-5 minutes, repeated after 20 minutes if necessary, followed by an infusion of 1-2 mg/min, is also an alternative. Empiric magnesium replacement (1 g intravenously) may help. Ventricular tachycardia can also be terminated by ventricular overdrive pacing, and this approach is useful when the rhythm is recurrent.

B. Chronic Recurrent Ventricular Tachycardia

1. Sustained ventricular tachycardia—Patients with symptomatic or sustained ventricular tachycardia in the absence of a reversible precipitating cause (acute myocardial infarction or ischemia, electrolyte imbalance, drug toxicity, etc) are at high risk for recurrence. In those with significant left ventricular dysfunction, subsequent sudden death is common. Several trials, including the Antiarrhythmic Drug Versus Implantable Defibrillator (AVID) and the Canadian Implantable Defibrillator trials, strongly suggest that these patients should be managed with implantable cardioverter-defibrillator devices (ICDs). In those with preserved left ventricular function, the mortality rate is lower and treatment with amiodarone, optimally in combination with a beta-blocker, may be adequate. Sotalol may be an alternative, though there is less supporting evidence. The role of electrophysiologic studies in this group is less clear than was previously thought, but they may help identify patients who are candidates for radiofrequency ablation of a ventricular tachycardia focus. This is particularly the case for arrhythmias that originate in the right ventricular outflow tract (appearing as LBBB with inferior axis on the surface ECG), the posterior fascicle (RBBB, superior axis morphology), or sustained bundle branch reentry. As experience accumulates, it is likely that other forms of ventricular tachycardia will be amenable to radiofrequency ablation.

2. Nonsustained ventricular tachycardia (NSVT)— NSVT is defined as runs of three or more ventricular beats lasting less than 30 seconds. These may be symptomatic (usually experienced as light-headedness) or asymptomatic. In individuals without heart disease, NSVT is not clearly associated with a poor prognosis. However, in patients with structural heart disease, particularly when they have reduced ejection fractions, there is an increased risk of subsequent symptomatic ventricular tachycardia or sudden death. Beta-blockers reduce these risks in patients who have coronary disease with significant left ventricular systolic dysfunction (ejection fractions < 35-40%), but if sustained ventricular tachycardia has been induced during electrophysiologic testing, an implantable defibrillator may be indicated. In patients with chronic heart failure and reduced ejection fractions—whether due to coronary disease or primary cardiomyopathy and regardless of the presence of asymptomatic ventricular arrhythmias—beta-blockers reduce the incidence of sudden death by 40-50% and should be routine therapy (see section on Heart Failure).

Although there are no definitive data with amiodarone in this group, trends from a number of studies suggest that it may be beneficial. Other antiarrhythmic agents should generally be avoided because their proarrhythmic risk appears to outweigh any benefit, even in patients with inducible arrhythmias that are successfully suppressed in the electrophysiology laboratory.

3. Ventricular Fibrillation & Sudden Death

Sudden cardiac death is defined as unexpected nontraumatic death in clinically well or stable patients who die within 1 hour after onset of symptoms. The causative rhythm in most cases is ventricular fibrillation, which is usually preceded by ventricular tachycardia except in the setting of acute ischemia or infarction. Complete heart block and sinus node arrest may also cause sudden death. A disproportionate number of sudden deaths occur in the early morning hours. Over 75% of victims of sudden cardiac death have severe coronary artery disease. Many have old infarctions. Sudden death may be the initial manifestation of coronary disease in up to 20% of patients and accounts for approximately 50% of deaths from coronary disease. When ventricular fibrillation occurs in the initial 24 hours after infarction, long-term management is no different from that of other patients with acute infarction. Other conditions that predispose to sudden death include severe left ventricular hypertrophy, hypertrophic cardiomyopathy, congestive cardiomyopathy, aortic stenosis, pulmonary stenosis, primary pulmonary hypertension, cyanotic congenital heart disease, atrial myxoma, mitral valve prolapse, hypoxia, electrolyte abnormalities, prolonged QT interval syndrome, and conduction system disease. Late potentials (after the QRS complex) on a signal-averaged surface ECG in patients with prior myocardial infarction may identify a group of patients at risk of ventricular arrhythmias and sudden death.

Unless ventricular fibrillation occurred shortly after myocardial infarction, is associated with ischemia, or is seen with an unusual correctable process (such as an electrolyte abnormality, drug toxicity, or aortic stenosis), surviving patients require evaluation and intervention since recurrences are frequent. Exercise testing or coronary arteriography should be performed to exclude coronary disease as the underlying cause, since revascularization may prevent recurrence. Conduction disturbances should be managed as described in the next section. If prodromal supraventricular arrhythmias or ventricular arrhythmias, such as sustained or nonsustained ventricular tachycardia, are found by ambulatory electrocardiographic monitoring, their elimination by pharmacologic therapy or ablation may prevent further episodes. There is growing consensus that if myocardial infarction or ischemia, other precipitating causes of ventricular fibrillation, or bradyarrhythmias and conduction disturbances are not found to be the cause of the sudden death episode, an implantable defibrillator is the treatment of choice for appropriate patients. In addition, there is evidence from the MADIT II study and other reports that in a patient with a prior myocardial infarction and severe left ventricular dysfunction, prophylactic implantation of a defibrillator reduces the risk of death—though the cost of doing so in all such patients would be very high.

4. Accelerated Idioventricular Rhythm

Accelerated idioventricular rhythm is a regular wide- complex rhythm with a rate of 60-120/min, usually with a gradual onset. Because the rate is often similar to the sinus rate, fusion beats and alternating rhythms are common. Two mechanisms have been invoked: (1) an escape rhythm due to suppression of higher pacemakers resulting from sinoatrial and atrioventricular block or from depressed sinus node function, and (2) slow ventricular tachycardia due to increased automaticity or, less frequently, reentry. It occurs commonly in acute infarction and following reperfusion after thrombolytic drugs. The incidence of associated ventricular fibrillation is much less than that of ventricular tachycardia with a rapid rate, and treatment is not indicated unless there is hemodynamic compromise or more serious arrhythmias. This rhythm also is common in digitalis toxicity.

Accelerated idioventricular rhythm must be distinguished from the idioventricular or junctional rhythm with rates less than 40-45/min that occurs in the presence of complete atrioventricular block. Atrioventricular dissociation—where ventricular rate exceeds sinus—but not atrioventricular block occurs in most cases of accelerated idioventricular rhythm.

5. Long QT Syndrome

Congenital long QT syndrome is an uncommon disease that is characterized by recurrent syncope, a long QT interval (usually 0.5-0.7 s), documented ventricular arrhythmias, and sudden death. It may occur in the presence (Jervell syndrome, Lange-Nielsen syndrome) or absence (Romano-Ward syndrome) of congenital deafness. Inheritance may be autosomal recessive or autosomal dominant (Romano-Ward). Specific genetic mutations affecting membrane potassium and sodium channels have been identified and help delineate the mechanisms of susceptibility to arrhythmia.

Beta-blockers are the most effective therapy for congenital long QT syndrome and are often used in conjunction with permanent pacemakers, since low heart rates predispose to ventricular arrhythmias. Agents that prolong the QT (classes Ia, Ic, and III) are contraindicated. ICDs are effective in patients who continue to have life-threatening ventricular arrhythmias while taking beta-blockers. Refractory acute arrhythmic episodes may be treated by local anesthetic block of the left stellate ganglion, and recurrent episodes can be treated by resection of this ganglion as well as of the first three to five thoracic ganglia.

Acquired long QT interval secondary to use of antiarrhythmic agents or antidepressant drugs, electrolyte abnormalities, myocardial ischemia, or significant bradycardia may result in ventricular tachycardia (particularly torsade de pointes, ie, twisting about the baseline into varying QRS morphology). Notably, many drugs that are in some settings effective for the treatment of ventricular arrhythmias prolong the QT interval. Prudence dictates that drug therapy which prolongs the QT interval beyond 500 ms be discontinued.

The management of **torsade de pointes** differs from that of other forms of ventricular tachycardia. Class I, Ic, or III antiarrhythmics, which prolong the QT interval, should be avoided—or withdrawn immediately if being used. Intravenous beta-blockers may be effective, especially in the congenital form; intravenous magnesium should be given acutely. An effective approach is temporary ventricular or atrial pacing, which can both break and prevent the rhythm.

■ BRADYCARDIAS & CONDUCTION DISTURBANCES

Abnormalities of conduction can occur between the sinus node and atrium, within the atrioventricular node, and in the intraventricular conduction pathways.

SICK SINUS SYNDROME

This imprecise diagnosis is applied to patients with sinus arrest, sinoatrial exit block (recognized by a pause equal to a multiple of the underlying PP interval or progressive shortening of the PP interval prior to a pause), or persistent sinus bradycardia. These rhythms are often caused or exacerbated by drug therapy (digitalis, calcium channel blockers, beta-blockers, sympatholytic agents, antiarrhythmics), and agents that may be responsible should be withdrawn prior to making the diagnosis. Another presentation is of recurrent supraventricular tachycardias (paroxysmal reentry tachycardias, atrial flutter, and atrial fibrillation), associated with bradyarrhythmias ("tachy-brady syndrome"). The long pauses that often follow the termination of tachycardia cause the associated symptoms.

Sick sinus syndrome occurs most commonly in elderly patients. The pathologic changes are usually nonspecific, characterized by patchy fibrosis of the sinus node and cardiac conduction system. Sick sinus syndrome may be caused by other conditions, including sarcoidosis, amyloidosis, Chagas' disease, and various cardiomyopathies. Coronary disease is an uncommon cause.

Most patients with electrocardiographic evidence of sick sinus syndrome are asymptomatic, but rare individuals may experience syncope, dizziness, confusion, palpitations, heart failure, or angina. Because these symptoms are either nonspecific or are due to other causes, it is essential that they be demonstrated to coincide temporally with arrhythmias. This may require prolonged ambulatory monitoring or the use of an event recorder. Pharmacologic therapy for sick sinus syndrome has been difficult, but recent studies have indicated that oral theophylline may be effective, especially when sinus bradycardia is the major manifestation. Most symptomatic patients will require permanent pacing. Dual-chamber pacing is preferred because ventricular pacing is associated with a higher incidence of subsequent atrial fibrillation, and subsequent atrioventricular block occurs at a rate of 2% per year. Treatment of associated tachyarrhythmias is often difficult without first instituting pacing, since digoxin and other antiarrhythmic agents may exacerbate the bradycardia. Unfortunately, symptomatic relief following pacing has not been consistent, largely because of inadequate documentation of the etiologic role of bradyarrhythmias in producing the symptom. Furthermore, many of these patients may have associated ventricular arrhythmias that may require treatment; however, carefully selected patients may become asymptomatic with permanent pacing alone.

ATRIOVENTRICULAR BLOCK

Atrioventricular block is categorized as first-degree (PR interval > 0.21 s with all atrial impulses conducted), second-degree (intermittent blocked beats), or third-degree (complete heart block, in which no supraventricular impulses are conducted to the ventricles).

Second-degree block is subclassified. In **Mobitz type I (Wenckebach)** atrioventricular block, the atrioventricular conduction time (PR interval) progressively lengthens, with the RR interval shortening, before the blocked beat; this phenomenon is almost always due to abnormal conduction within the atrioventricular node. In **Mobitz type II** atrioventricular block, there are intermittently nonconducted atrial beats not preceded by lengthening AV conduction. It is usually due to block within the His bundle system. The classification as Mobitz type I or Mobitz type II is only partially reliable, because patients may appear to have both types on the surface ECG, and one cannot predict the site of origin of the 2:1 atrioventricular block from the ECG. The width of the QRS complexes assists in determining whether the block is nodal or infranodal. When they are narrow, the block is usually nodal; when they are wide, the block is usually infranodal. Electrophysiologic studies may be necessary for accurate localization. Management of atrioventricular block in acute myocardial infarction has already been discussed. This section deals with patients in the nonischemic setting.

First-degree and Mobitz type I block may occur in normal individuals with heightened vagal tone. They may also occur as a drug effect (especially digitalis, calcium channel blockers, beta-blockers, or other sympatholytic agents), often superimposed on organic disease. These disturbances also occur transiently or chronically due to ischemia, infarction, inflammatory processes, fibrosis, calcification, or infiltration. The prognosis is usually good, since reliable alternative pacemakers arise from the atrioventricular junction below the level of block if higher degrees of block occur.

Mobitz type II block is almost always due to organic disease involving the infranodal conduction system. In the event of progression to complete heart block, alternative pacemakers are not reliable. Thus, prophylactic ventricular pacing is required.

Complete (third-degree) heart block is a more advanced form of block often due to a lesion distal to the His bundle and associated with bilateral bundle branch block. The QRS is wide and the ventricular rate is slower, usually less than 50/min. Transmission of atrial impulses through the atrioventricular node is completely blocked, and a ventricular pacemaker maintains a slow, regular ventricular rate, usually less than 45/min. Exercise does not increase the rate. The first heart sound varies in intensity; wide pulse pressure, a changing systolic blood pressure level, and cannon venous pulsations in the neck are also present. Patients may be asymptomatic or may complain of weakness or dyspnea if the rate is less than 35/min; symptoms may occur at higher rates if the left ventricle cannot increase its stroke output. During periods of transition from partial to complete heart block, some patients have ventricular asystole that lasts several seconds to minutes. Syncope occurs abruptly.

Patients with episodic or chronic infranodal complete heart block require permanent pacing, and temporary pacing is indicated if implantation of a permanent pacemaker is delayed.

Bourke JP: Atrioventricular block and problems with atrioventricular conduction. *Clin Geriatr Med* 2002;18:229. [\[PMID: 12180245\]](#)

ATRIOVENTRICULAR DISSOCIATION

When a ventricular pacemaker is firing at a rate faster than or close to the sinus rate (accelerated idioventricular rhythm, ventricular premature beats, or ventricular tachycardia), atrial impulses arriving at the atrioventricular node when it is refractory may not be conducted. This phenomenon is atrioventricular dissociation but does not necessarily indicate atrioventricular block. No treatment is required aside from management of the causative arrhythmia.

INTRAVENTRICULAR CONDUCTION DEFECTS

Intraventricular conduction defects, including bundle branch block, are common in individuals with otherwise normal hearts and in many disease processes, including ischemic heart disease, inflammatory disease, infiltrative disease, cardiomyopathy, and postcardiotomy. Below the atrioventricular node and bundle of His, the conduction system trifurcates into a right bundle and anterior and posterior fascicles of the left bundle. Conduction block in each of these fascicles can be recognized on the surface ECG. Although such conduction abnormalities are often seen in normal hearts, they are more commonly due to organic heart disease—either an isolated process of fibrosis and calcification or more generalized myocardial disease. Bifascicular block is present when two of these—right bundle, left anterior and posterior hemibundle—are involved. Trifascicular block is defined as right bundle branch block with alternating left hemiblock, alternating right and left bundle branch block, or bifascicular block with documented prolonged infranodal conduction (long His-ventricular interval).

The prognosis of intraventricular block is generally that of the underlying myocardial process. Patients with no apparent heart disease have an overall survival rate similar to that of matched controls. However, left bundle branch block—but not right—is associated with a higher risk of development of overt cardiac disease and cardiac mortality. Even in bifascicular block, the incidence of occult complete heart block or progression to it is low, and pacing is not usually warranted. In patients with symptoms (eg, syncope) consistent with heart block and intraventricular block, pacing should be reserved for those with documented concomitant complete heart block on monitoring or those with a very prolonged HV interval (> 90 ms) with no other cause for symptoms. Even in the latter group, prophylactic pacing has not improved the prognosis significantly, probably because of the high incidence of ventricular arrhythmias in the same population.

PERMANENT PACING

The indications for permanent pacing have been discussed: symptomatic bradyarrhythmias, asymptomatic Mobitz II atrioventricular block, or complete heart block. The versatility of pacemaker generator units has increased markedly, and dual-chamber multiple programmable units are being implanted with increasing frequency. A standardized nomenclature for pacemaker generators is employed, usually consisting of four letters. The first letter refers to the chamber which is stimulated (A = atrium, V = ventricle, D = dual, for both). The second letter refers to the chamber where sensing occurs (also A, V, or D). The third position refers to the sensory mode (I = inhibition by a sensed impulse, T = triggering by a sensed impulse, D = dual modes of response). The fourth letter refers to the programmability or rate modulation capacity (usually P for programming for two functions, M for programming more than two, and R for rate modulation).

A pacemaker that senses and paces in both chambers is the most physiologic approach to pacing patients who remain in sinus rhythm. Atrioventricular synchrony is particularly important in patients in whom atrial contraction produces a substantial increment in stroke volume and in those in whom sensing the atrial rate to provide rate-responsive ventricular pacing is useful. Dual-chamber pacing is most useful for individuals with left ventricular systolic or—perhaps more importantly—diastolic dysfunction and for physically active individuals. In patients with single-chamber pacemakers, the lack of an atrial kick may lead to the so-called pacemaker syndrome, in which the patient experiences signs of low cardiac output while upright. Uncontrolled data suggest that chronic dual-chamber pacing is associated with a lower incidence of chronic atrial fibrillation than single-chamber ventricular pacing. However, patients with intermittent or potential bradyarrhythmias or conduction disturbances in whom pacing is primarily prophylactic should undergo ventricular pacing.

Pulse generators are also available that can increase their rate in response to motion or respiratory rate when the atrial rate is not an indication of the optimal heart rate. These are most useful in active individuals. Follow-up after pacemaker implantation, usually by telephonic monitoring, is essential. All pulse generators and lead systems have an early failure rate that is now below 5% and an expected battery life varying from 4 to 10 years.

EVALUATION OF SYNCOPE

Syncope, defined as a transient loss of consciousness and postural tone due to inadequate cerebral blood flow with prompt recovery without resuscitative measures, is a common clinical problem, especially in the elderly. Thirty percent of the adult population will experience at least one episode, and syncope accounts for approximately 3% of emergency room visits. Causes include cardiac abnormalities (either disturbances of rhythm or hemodynamics), vascular disorders, or neurologic processes. A specific cause is identified in about 50% of cases during the initial evaluation. The prognosis is relatively benign except when accompanying cardiac disease is present. Syncope is more likely to occur in patients with known heart disease, older men, and young women (who are prone to vasovagal episodes). Syncope is characteristically abrupt in onset, often resulting in injury, transient (lasting for seconds to a few minutes), and followed by prompt recovery or full consciousness.

Vasomotor syncope may be due to excessive vagal tone or impaired reflex control of the peripheral circulation. The most frequent type of vasodepressor syncope is vasovagal hypotension or the "common faint," which is often initiated by stressful, painful, or claustrophobic experience, especially in young women. Premonitory symptoms, such as nausea, diaphoresis, tachycardia, and pallor, are usual. Episodes can be aborted by lying down or removing the inciting stimulus. Enhanced vagal tone with resulting hypotension is the cause of syncope in carotid sinus hypersensitivity and postmicturition syncope; vagal-induced sinus bradycardia, sinus arrest, and atrioventricular block are common accompaniments and may themselves be the cause of syncope. Carotid sinus massage under carefully monitored conditions or tilt-table testing may be diagnostic (see above under Autonomic Testing). Treatment consists largely of counseling patients to avoid predisposing situations. Paradoxically, beta-blockers may be helpful in patients with altered autonomic function uncovered by head-up tilt testing. Permanent pacing may benefit patients with documented bradycardic responses.

Orthostatic (postural) hypotension is another common cause of vasomotor syncope, especially in the elderly, in diabetics or other patients with autonomic neuropathy, in patients with blood loss or hypovolemia, and in patients taking vasodilators, diuretics, and adrenergic blocking drugs. In addition, a syndrome of chronic idiopathic orthostatic hypotension exists primarily in older men. In most of these conditions, the normal vasoconstrictive response to assuming upright posture, which compensates for the abrupt decrease in venous return, is impaired. A greater than normal decline (20 mm Hg) in blood pressure immediately upon arising from the supine to the standing position is observed, with or without tachycardia depending on the status of autonomic (baroreceptor) function. Studying patients with a tilt table can establish the diagnosis with more certainty. Autonomic function can be assessed by observing blood pressure and heart rate responses to Valsalva's maneuver and by tilt testing. In older patients, vasoconstrictor abnormalities and autonomic insufficiency are perhaps the most common causes of syncope. Thus, tilt testing should be employed before proceeding to invasive studies unless clinical and ambulatory electrocardiographic evaluation suggest a cardiac abnormality.

Cardiogenic syncope can occur on a mechanical or arrhythmic basis. Mechanical problems that can cause syncope include aortic stenosis (where syncope may occur from autonomic reflex abnormalities or ventricular tachycardia), pulmonary stenosis, hypertrophic obstructive cardiomyopathy, congenital lesions associated with pulmonary hypertension or right-to-left shunting, and left atrial myxoma obstructing the mitral valve. Episodes are commonly exertional or postexertional. More commonly, cardiac syncope is due to disorders of automaticity (sick sinus syndrome), conduction disorders (atrioventricular block), or tachyarrhythmias (especially ventricular tachycardia and supraventricular tachycardia with rapid ventricular rate).

The evaluation for syncope depends on findings from the history and physical examination (especially orthostatic blood pressure evaluation, examination of carotid and other arteries, cardiac examination, and, if appropriate, carotid sinus massage). The resting ECG may reveal arrhythmias, evidence of accessory pathways, prolonged QT interval, and other signs of heart disease (such as infarction or hypertrophy). If the history is consistent with syncope, ambulatory electrocardiographic monitoring is essential. This may need to be repeated several times, since yields increase with longer periods of monitoring, at least up to 3 days. Event recorder and transtelephone electrocardiographic monitoring may be helpful in patients with intermittent presyncopal episodes. Electrophysiologic studies to assess sinus node function and atrioventricular conduction and to induce supraventricular or ventricular tachycardia are indicated in patients with recurrent episodes and nondiagnostic ambulatory ECGs. They reveal an arrhythmic cause in 20-50% of patients, depending on the study criteria, and are most often diagnostic when the patient has had multiple episodes and has identifiable cardiac abnormalities.

RECOMMENDATIONS FOR RESUMPTION OF DRIVING

An important management problem in patients who have experienced syncope, symptomatic ventricular tachycardia, or aborted sudden death is to provide recommendations concerning automobile driving. According to a survey published in 1991, only eight states had specific laws dealing with this issue, whereas 42 had laws restricting driving in patients with seizure disorders. There are not adequate data to support driving restrictions in patients with asymptomatic arrhythmias, though patients with frequent nonsustained ventricular tachycardia, associated heart disease, and significant left ventricular dysfunction are at high enough risk to warrant cautioning. Patients with syncope or aborted sudden death thought to have been due to temporary factors (acute myocardial infarction, bradyarrhythmias subsequently treated with permanent pacing, drug effect, electrolyte imbalance) should be strongly advised after recovery not to drive for at least 1 month. Other patients with symptomatic ventricular tachycardia or aborted sudden death, whether treated pharmacologically, with antitachycardia devices, or with ablation therapy, should not drive for at least 6 months. Longer restrictions are warranted in many such patients if spontaneous arrhythmias persist. The physician should comply with local regulations and consult local authorities concerning individual cases.

■ CARDIAC FAILURE

Essentials of Diagnosis

- Left ventricular failure: Exertional dyspnea, cough, fatigue, orthopnea, paroxysmal nocturnal dyspnea, cardiac enlargement, rales, gallop rhythm, and pulmonary venous congestion.
- Right ventricular failure: Elevated venous pressure, hepatomegaly, dependent edema; usually due to left ventricular failure.
- Assessment of left ventricular function is a crucial part of diagnosis and management.

Epidemiology

Heart failure is a common syndrome that is increasing in incidence and prevalence. Approximately 5 million patients in the United States have heart failure, and there are nearly 500,000 new cases each year. It is primarily a disease of aging, with over 75% of existing and new cases occurring in individuals over age 65. The prevalence of heart failure rises from < 1% in individuals below 60 to nearly 10% in those over age 80.

Pathophysiology

Systolic function of the heart is governed by four major determinants: the contractile state of the myocardium, the preload of the ventricle (the end-diastolic volume and the resultant fiber length of the ventricles prior to onset of the contraction), the afterload applied to the ventricles (the impedance to left ventricular ejection), and the heart rate.

Cardiac function may be inadequate as a result of alterations in any of these determinants. In most instances, the primary derangement is depression of myocardial contractility caused either by loss of functional muscle (due to myocardial infarction, etc) or by processes diffusely affecting the myocardium. However, the heart may fail as a pump because preload is excessively elevated, such as in valvular regurgitation, or when afterload is excessive, such as in aortic stenosis or in severe hypertension. Pump function may also be inadequate when the heart rate is too slow or too rapid. While the normal heart can tolerate wide variations in preload, afterload, and heart rate, the diseased heart often has limited reserve for such alterations. Finally, cardiac pump function may be supranormal but nonetheless inadequate when metabolic demands or requirements for blood flow are excessive. This situation is termed **high-output heart failure** and, though uncommon, tends to be specifically treatable. Causes of high output include thyrotoxicosis, severe anemia, arteriovenous shunting (including dialysis fistulas), Paget's disease of bone, and thiamin deficiency (beriberi).

Manifestations of cardiac failure can also occur as a result of isolated or predominant **diastolic dysfunction** of the heart. In these cases, filling of the left or right ventricle is abnormal, either because myocardial relaxation is impaired or because the chamber is noncompliant ("stiff") due to excessive hypertrophy or changes in composition of the myocardium. Even though contractility may be preserved, diastolic pressures are elevated and cardiac output may be reduced, potentially causing fluid retention, dyspnea, and exercise intolerance.

When the heart fails, a number of adaptations occur both in the heart and systemically. If the stroke volume of either ventricle is reduced by depressed contractility or excessive afterload, end-diastolic volume and pressure in that chamber will rise. This increases end-diastolic myocardial fiber length, resulting in a greater systolic shortening (Starling's law of the heart). If the condition is chronic, ventricular dilation will occur. While this may restore resting cardiac output, the resulting chronic elevation of diastolic pressures will be transmitted to the atria and to the pulmonary and systemic venous circulation. Ultimately, increased capillary pressure may lead to transudation of fluid with resulting pulmonary or systemic edema. Reduced cardiac output, particularly if associated with reduced arterial pressure or perfusion of the kidneys, will also activate several neural and humoral systems. Increased activity of the sympathetic nervous system will stimulate myocardial contractility, heart rate, and venous tone; the latter change results in a rise in the effective central blood volume, which serves to further elevate preload. Though these adaptations are designed to increase cardiac output, they may themselves be deleterious. Thus, tachycardia and increased contractility may precipitate ischemia in patients with underlying coronary artery disease, and the rise in preload may worsen pulmonary congestion. Sympathetic nervous system activation also increases peripheral vascular resistance; this adaptation is designed to maintain perfusion to vital organs, but when it is excessive it may itself reduce renal and other tissue blood flow. Peripheral vascular resistance is also a major determinant of left ventricular afterload, so that excessive sympathetic activity may further depress cardiac function.

One of the more important effects of lower cardiac output is reduction of renal blood flow and glomerular filtration rate, which leads to sodium and fluid retention. The renin-angiotensin-aldosterone system is also activated, leading to further increases in peripheral vascular resistance and left ventricular afterload as well as sodium and fluid retention. Heart failure is associated with increased circulating levels of arginine vasopressin, which also serves as a vasoconstrictor and inhibitor of water excretion. While release of atrial natriuretic peptide is increased in heart failure owing to the elevated atrial pressures, there is evidence of resistance to its natriuretic and vasodilating effects.

Myocardial failure is characterized by two hemodynamic derangements, and the clinical presentation is determined by their severity. The first is reduction in cardiac reserve, ie, the ability to increase cardiac output in response to increased demands imposed by exercise or even ordinary activity. The second abnormality, elevation of ventricular diastolic pressures, is primarily a result of the compensatory processes in systolic heart failure but is the primary derangement in diastolic heart failure.

Heart failure may be right-sided or left-sided. Patients with the picture of **left heart failure** have symptoms of low cardiac output and elevated pulmonary venous pressure; dyspnea is the predominant feature. Signs of fluid retention predominate in **right heart failure**, with the patient exhibiting edema, hepatic congestion, and, on occasion, ascites. Most patients exhibit symptoms or signs of both right- and left-sided failure, and left ventricular dysfunction is the primary cause of right ventricular failure. Surprisingly, some individuals with severe left ventricular dysfunction will display few signs of left heart failure and appear to have isolated right heart failure. Indeed, they may be clinically indistinguishable from patients with cor pulmonale, who have right heart failure secondary to pulmonary disease.

Although this section primarily concerns cardiac failure due to systolic left ventricular dysfunction, patients with **diastolic heart failure** experience many of the same symptoms and may be difficult to distinguish clinically. Diastolic pressures are elevated even though diastolic volumes are normal or small. These pressures are transmitted to the pulmonary and systemic venous systems, resulting in dyspnea and edema. The most frequent cause of diastolic cardiac dysfunction is left ventricular hypertrophy, commonly resulting from hypertension, but conditions such as hypertrophic or restrictive cardiomyopathy, diabetes, and pericardial disease can produce the same clinical picture. While diuretics are often useful in these patients, the other therapies discussed in this section (digitalis, vasodilators, inotropic agents) may be inappropriate.

Causes & Prevention of Cardiac Failure

The syndrome of cardiac failure can be produced by many diseases. In developed countries, coronary artery disease with resulting myocardial infarction and loss of functioning myocardium (ischemic cardiomyopathy) is the commonest cause. Systemic hypertension remains an important cause of congestive heart failure and, even more commonly in the United States, an exacerbating factor in patients with cardiac dysfunction due to other causes such as coronary artery disease. A number of other processes may present with dilated or congestive cardiomyopathy, which is characterized by left ventricular or biventricular dilation and generalized systolic dysfunction. These are discussed elsewhere in this chapter, but the most common are alcoholic cardiomyopathy, viral myocarditis (including infections by HIV), and dilated cardiomyopathies with no obvious underlying cause (idiopathic cardiomyopathy). Rare causes of dilated cardiomyopathy include infiltrative diseases

(hemochromatosis, sarcoidosis, amyloidosis, etc), other infectious agents, metabolic disorders, cardiotoxins, and drug toxicity. Valvular heart diseases—particularly degenerative aortic stenosis and chronic aortic or mitral regurgitation—are not infrequent causes of heart failure.

Since many of the processes leading to heart failure are of long standing and progress gradually, heart failure is often preventable by early detection of patients at risk and early intervention. The importance of these approaches is emphasized by guidelines that have incorporated a classification of heart failure that includes four stages ([Table 10-6](#)). **Stage A** includes patients at risk of developing heart failure (such as patients with hypertension or coronary artery disease) without current or previous symptoms or identifiable structural abnormalities of the myocardium. In the majority of these patients, development of heart failure can be prevented with interventions such as the aggressive treatment of hypertension, modification of coronary risk factors, and reduction of excessive alcohol intake ([Figure 10-1](#)). **Stage B** includes patients who have structural heart disease but no current or previously recognized symptoms of heart failure. Examples include patients with previous myocardial infarction, other causes of reduced systolic function, left ventricular hypertrophy, or asymptomatic valvular disease. Both ACE inhibitors and beta-blockers prevent heart failure in the first two of these conditions, and more aggressive treatment of hypertension and early surgical intervention are effective in the latter two. **Stages C and D** include patients with clinical heart failure and the relatively small group of patients who have become refractory to the usual therapies, respectively. These are discussed below.

Prognosis

Once manifest, heart failure carries a poor prognosis. The 5-year survival rate is less than 50% overall. Mortality rates vary from < 5% per year in those with no or few symptoms to > 30% per year in those with severe and refractory symptoms. In general, men have a poorer prognosis than women because they are more likely to have coronary artery disease, which is associated with a higher mortality rate and less likely to have diastolic heart failure, which has a lower mortality rate. These figures emphasize the critical importance of early detection and intervention. The prognosis of heart failure has improved in the last two decades, probably at least in part because of the more widespread use of ACE inhibitors and beta-blockers, which markedly improve survival.

Clinical Findings

A. Symptoms

The symptoms of cardiac failure have been discussed in part in earlier sections. The most common complaint is shortness of breath, chiefly exertional dyspnea at first and then progressing to orthopnea, paroxysmal nocturnal dyspnea, and rest dyspnea. A more subtle and often overlooked symptom of heart failure is a chronic nonproductive cough, which is often worse in the recumbent position. Nocturia due to excretion of fluid retained during the day and increased renal perfusion in the recumbent position is a common nonspecific symptom of heart failure. Patients with heart failure also complain of fatigue and exercise intolerance. These symptoms correlate poorly with the degree of cardiac dysfunction and result in part from changes in peripheral blood flow and blood flow to skeletal muscle which are part of the syndrome of heart failure. Patients with right heart failure may experience right upper quadrant pain due to passive congestion of the liver, loss of appetite and nausea due to edema of the gut or impaired gastrointestinal perfusion, and peripheral edema.

Cardiac failure may present acutely in a previously asymptomatic patient. Causes include myocardial infarction, myocarditis, and acute valvular regurgitation due to endocarditis or other conditions. These patients usually present with pulmonary edema. The management of acute heart failure has been discussed under myocardial infarction and centers around initial stabilization with diuretics and parenteral vasodilators or inotropic agents.

Patients with episodic symptoms may be having left ventricular dysfunction due to intermittent ischemia. This potentially reversible form of heart failure should be considered, especially in patients with angina pectoris and those with diabetes mellitus. Patients may also present with acute exacerbations of chronic, stable heart failure. Exacerbations are usually caused by alterations in therapy (or patient noncompliance), excessive salt and fluid intake, arrhythmias, excessive activity, pulmonary emboli, intercurrent infection, or progression of the underlying disease.

Patients with heart failure are often categorized by the New York Heart Association classification as class I (asymptomatic), class II (symptomatic with moderate activity), class III (symptomatic with mild activity), or class IV (symptomatic at rest). However, this classification has major limitations in that patient reports are highly subjective and in that symptoms vary from day to day. In any case, the classification is insufficiently sensitive to be useful in predicting outcomes or assessing the results of treatment.

B. Signs

Many patients with heart failure, including some with severe symptoms, appear comfortable at rest. Others will be dyspneic during conversation or minor activity, and those with long-standing severe heart failure may appear cachectic or cyanotic. The vital signs may be normal, but tachycardia, hypotension, and reduced pulse pressure may be present. Patients often show signs of increased sympathetic nervous system activity, including cold extremities and diaphoresis. Important peripheral signs of heart failure can be detected by examination of the neck, the lungs, the abdomen, and the extremities. Right atrial pressure may be estimated through the height of the pulsations in the jugular venous system. In addition to the height of the venous pressure, abnormal pulsations such as regurgitant v waves should be sought. Examination of the carotid pulse may allow estimation of pulse pressure as well as detection of aortic stenosis. The thyroid examination is important, since occult hyperthyroidism and hypothyroidism are readily treatable causes of heart failure. In the lungs, crackles at the lung bases reflect transudation of fluid into the alveoli. Pleural effusions may cause bibasilar dullness to percussion. Expiratory wheezing and rhonchi may be signs of heart failure. Patients with severe right heart failure may have hepatic enlargement—tender or nontender—due to passive congestion. Systolic pulsations may be felt in tricuspid regurgitation. Sustained moderate pressure on the liver may increase jugular venous pressure (a positive hepatojugular reflux is an increase of > 1 cm). Ascites may also be present. Peripheral pitting edema is a common sign in patients with right heart failure and may extend into the thighs and abdominal wall.

The cardiac examination has been discussed. Cardinal signs in heart failure are a parasternal lift, indicating pulmonary hypertension; an enlarged and sustained left ventricular impulse, indicating left ventricular dilation and hypertrophy; a diminished first heart sound, suggesting impaired contractility; and S₃ gallops originating in the left and sometimes the right ventricle. An S₄ is usually present in diastolic heart failure. Murmurs should be sought to exclude primary valvular disease; secondary mitral regurgitation and tricuspid regurgitation murmurs are common in patients with dilated ventricles. In chronic heart failure, many of the expected signs of heart failure may be absent despite markedly abnormal cardiac function and hemodynamic measurements.

C. Laboratory Findings

A blood count may reveal anemia, a cause of high-output failure and an exacerbating factor in other forms of cardiac dysfunction. Biochemical studies may show renal insufficiency as a possible compounding factor. Renal function tests also determine whether cardiac failure is associated with prerenal azotemia. Serum electrolytes may disclose hypokalemia, which increases the risk of arrhythmias; hyperkalemia, which may limit the use of inhibitors of the renin-angiotensin system; or hyponatremia, an indicator of marked activation of the renin-angiotensin system and a poor prognostic sign. Thyroid function should be assessed in older patients to detect occult thyrotoxicosis or myxedema. In unexplained cases, appropriate biopsies may lead to a diagnosis of amyloidosis, and additional assessment should include iron studies to exclude hemochromatosis. Myocardial biopsy may exclude specific causes of dilated cardiomyopathy but rarely reveals specific reversible diagnoses.

Assays of serum "B-type" natriuretic peptide (BNP) or amino terminal pro-BNP can be a useful adjunct to the clinical history and physical examination in the diagnosis of heart failure. BNP is expressed primarily in the ventricles and is elevated when ventricular filling pressures are high. It is quite sensitive in patients with symptomatic heart failure—whether due to systolic or to diastolic dysfunction—but less specific in older patients, women, and patients with COPD. The roles of these assays in screening asymptomatic individuals or as a guide to management have not been established.

D. Electrocardiography and Chest X-Ray

Electrocardiography may indicate an underlying or secondary arrhythmia, myocardial infarction, or nonspecific changes that often include low voltage, intraventricular conduction defects, left ventricular hypertrophy, and nonspecific repolarization changes. Chest radiographs provide information about the size and shape of the cardiac

silhouette. Cardiomegaly is an important finding. Evidence of pulmonary venous hypertension includes relative dilation of the upper lobe veins, perivascular edema (haziness of vessel outlines), interstitial edema, and alveolar fluid. In acute heart failure, these findings correlate moderately well with pulmonary venous pressure. However, patients with chronic heart failure may show relatively normal pulmonary vasculature despite markedly elevated pressures. Pleural effusions are common and tend to be bilateral or right-sided.

E. Additional Studies

Many studies have indicated that the clinical diagnosis of systolic myocardial dysfunction is often inaccurate. The primary confounding conditions are diastolic dysfunction of the heart with decreased relaxation and filling of the left ventricle (particularly in hypertension and in hypertrophic states) and pulmonary disease. Since heart failure patients usually have significant resting electrocardiographic abnormalities, stress imaging procedures such as perfusion scintigraphy or dobutamine echocardiography are often indicated.

The most useful test is the echocardiogram. This will reveal the size and function of both ventricles and of the atria. It will also allow detection of pericardial effusion, valvular abnormalities, intracardiac shunts, and segmental wall motion abnormalities suggestive of old myocardial infarction as opposed to more generalized forms of dilated cardiomyopathy.

Radionuclide angiography measures left ventricular ejection fraction and permits analysis of regional wall motion. This test is especially useful when echocardiography is technically suboptimal, such as in patients with severe pulmonary disease. When myocardial ischemia is suspected as a cause of left ventricular dysfunction, stress testing should be performed.

F. Cardiac Catheterization

In most patients with heart failure, clinical examination and noninvasive tests can determine left ventricular size and function well enough to confirm the diagnosis. Left heart catheterization is necessary when significant valvular disease must be excluded and when the presence and extent of coronary artery disease must be determined. The latter is particularly important when left ventricular dysfunction may be partially reversible by revascularization. The combination of angina or noninvasive evidence of significant myocardial ischemia with symptomatic heart failure is often an indication for coronary angiography if the patient is a potential candidate for revascularization. Right heart catheterization may be useful to select and monitor therapy in patients refractory to standard therapy.

Pharmacologic Treatment

The treatment of chronic heart failure is discussed here. Acute heart failure and pulmonary edema are discussed in the next section.

A. Correction of Reversible Causes

The major reversible causes of chronic heart failure include valvular lesions, myocardial ischemia, uncontrolled hypertension, arrhythmias (especially persistent tachycardias), alcohol- or drug-induced myocardial depression, intracardiac shunts, and high-output states. Calcium channel blockers, antiarrhythmic drugs, and nonsteroidal anti-inflammatory agents are important causes of worsening heart failure. Some metabolic and infiltrative cardiomyopathies may be partially reversible, or their progression may be slowed; these include hemochromatosis, sarcoidosis, and amyloidosis. Reversible causes of diastolic dysfunction include pericardial disease and left ventricular hypertrophy due to hypertension. Once it is established that there is no reversible component, the measures outlined below are appropriate.

B. Diet and Activity

Patients should routinely practice moderate salt restriction (2-2.5 g sodium or 5-6 g salt per day). More severe sodium restriction is usually difficult to achieve and unnecessary because of the availability of potent diuretic agents. In severe heart failure, restriction of activity may facilitate temporary recompensation. However, in stable patients, a prudent increase in activity or a regular exercise regimen can be encouraged. Indeed, a gradual exercise program is associated with diminished symptoms and substantial increases in exercise capacity.

C. Diuretic Therapy

Diuretics are the most effective means of providing symptomatic relief to patients with moderate to severe congestive heart failure. Few patients with symptoms or signs of fluid retention can be optimally managed without a diuretic. However, excessive diuresis can lead to electrolyte imbalance and neurohormonal activation. A combination of a diuretic and an ACE inhibitor should be the initial treatment in most symptomatic patients. When fluid retention is mild, thiazide diuretics or a similar type of agent (hydrochlorothiazide, 25-100 mg; metolazone, 2.5-5 mg; chlorthalidone, 25-50 mg; etc) may be sufficient. These agents block sodium reabsorption in the cortical diluting segment at the terminal portion of the loop of Henle and in the proximal portion of the distal convoluted tubule. The result is natriuresis and kaliuresis. These agents also have weak carbonic anhydrase inhibitor activity, which results in proximal tubule inhibition of sodium reabsorption. Thiazide or related diuretics often provide better control of hypertension than short-acting loop agents.

The thiazides are generally ineffective when the glomerular filtration rate falls below 30-40 mL/min, a not infrequent occurrence in patients with severe heart failure. Metolazone maintains its efficacy down to a glomerular filtration rate of approximately 20-30 mL/min. Adverse reactions include hypokalemia and intravascular volume depletion with resulting prerenal azotemia, skin rashes, neutropenia and thrombocytopenia, hyperglycemia, hyperuricemia, and hepatic dysfunction (see [Table 11-5](#)).

Patients with more severe heart failure should be treated with one of the loop diuretics. These include furosemide (20-320 mg daily), bumetanide (1-8 mg daily), and torsemide (20-200 mg daily). These agents have a rapid onset and a relatively short duration of action. In patients with preserved renal function, two or more doses are preferable to a single larger dose. In acute situations or when gastrointestinal absorption is in doubt, they should be given intravenously. The loop diuretics inhibit chloride reabsorption in the ascending limb of the loop of Henle, which results in natriuresis, kaliuresis, and metabolic alkalosis. They are active even in severe renal insufficiency, but larger doses (up to 500 mg of furosemide or equivalent) may be required. The major adverse reactions include intravascular volume depletion, prerenal azotemia, and hypotension. Hypokalemia, particularly with accompanying digitalis therapy, is a major problem. Less common side effects include skin rashes, gastrointestinal distress, and ototoxicity (the latter more common with ethacrynic acid and possibly less common with bumetanide).

The potassium-sparing agents spironolactone, triamterene, and amiloride are often useful in combination with the loop diuretics and thiazides. Triamterene and amiloride act on the distal tubule to reduce potassium secretion. Their diuretic potency is only mild and not adequate for most patients with heart failure, but they may minimize the hypokalemia induced by more potent agents. Side effects include hyperkalemia, gastrointestinal symptoms, and renal dysfunction. Spironolactone is a specific inhibitor of aldosterone, which is often increased in congestive heart failure and has important effects beyond potassium retention (see below). Its onset of action is slower than the other potassium-sparing agents, and its side effects include gynecomastia. Combinations of potassium supplements or angiotensin-converting enzyme inhibitors and potassium-sparing drugs can produce hyperkalemia but have been used with success in patients with persistent hypokalemia.

Patients with refractory edema may respond to combinations of a loop diuretic and thiazide-like agents. Metolazone, because of its maintained activity with renal insufficiency, is the most useful agent for such a combination. Extreme caution must be observed with this approach, since massive diuresis and electrolyte imbalances often occur; 2.5 mg of metolazone should be added to the previous dosage of loop diuretic. In many cases this is necessary only once or twice a week, but dosages up to 10 mg daily have been used in some patients.

D. Inhibitors of the Renin-Angiotensin-Aldosterone System

The renin-angiotensin-aldosterone system is activated early in the course of heart failure and plays an important role in the progression of this syndrome. Inhibition of this system with ACE inhibitors should be considered part of the initial therapy of this syndrome based on their favorable effects on prognosis.

1. Angiotensin-converting enzyme inhibitors—ACE inhibitors block the renin-angiotensin-aldosterone system by inhibiting the conversion of angiotensin I to angiotensin II, producing vasodilation by limiting angiotensin II-induced vasoconstriction, and decreasing sodium retention by reducing aldosterone secretion. Since angiotensin-converting enzyme is also involved in the degradation of bradykinin, ACE inhibitors result in higher bradykinin levels, which in turn stimulate the synthesis of prostaglandins and nitric oxide. Experimental data and hemodynamic studies in patients indicate that these latter actions may be important. Although the other vasodilators tend to stimulate the renin-angiotensin system and often lose part of their effect due to the resulting fluid retention, tolerance to the ACE inhibitors is uncommon.

Many ACE inhibitors are available (see [Table 11-7](#)), and at least seven have been shown to be effective for the treatment of heart failure or the related indication of postinfarction left ventricular dysfunction. ACE inhibitors reduce mortality by approximately 20% in patients with symptomatic heart failure and have been shown also to

prevent hospitalizations, increase exercise tolerance, and reduce symptoms in these patients. As a result, ACE inhibitors should be part of first-line treatment of patients with symptomatic left ventricular systolic dysfunction (ejection fraction < 40%), usually in combination with a diuretic. They are also indicated for the management of patients with reduced ejection fractions without symptoms because they prevent the progression to clinical heart failure.

Because ACE inhibitors may induce significant hypotension, particularly following the initial doses, they must be started with caution. Hypotension is most prominent in patients with already low blood pressures (systolic pressure < 100 mm Hg), hypovolemia, prerenal azotemia (especially if it is diuretic-induced), and hyponatremia (an indicator of activation of the renin-angiotensin system). These patients should generally be started at low dosages (captopril 6.25 mg three times daily, enalapril 2.5 mg daily, or the equivalent), but other patients may be started at twice these dosages. Within several days (for those with the markers of higher risk) or at most 2 weeks, patients should be questioned about symptoms of hypotension, and both renal function and K^+ levels should be monitored.

ACE inhibitors should be titrated to the dosages proved effective in clinical trials (captopril 50 mg three times daily, enalapril 10 mg twice daily, lisinopril 10 mg daily, or the equivalent) over a period of 1-3 months. The large majority of patients will tolerate these doses. Asymptomatic hypotension is not a contraindication to up-titrating or continuing ACE inhibitors. Some patients exhibit rises in serum creatinine or K^+ , but they do not require discontinuation if the levels stabilize—even at values as high as 3 mg/dL and 5.5 meq/L, respectively. Renal dysfunction is more frequent in diabetics, older patients, and those with low systolic pressures, and these groups should be monitored more closely. The most common side effects of ACE inhibitors in heart failure patients are dizziness (often not related to the level of blood pressure) and cough, though the latter is as often due to heart failure or intercurrent pulmonary conditions as to the ACE inhibitor.

2. Angiotensin II receptor blockers—Another approach to inhibiting the renin-angiotensin-aldosterone system is the use of specific angiotensin II receptor blockers (see [Table 11-7](#)), which will block or decrease most of the effects of the system. In addition, since there are alternative pathways of angiotensin II production in many tissues, the receptor blockers may provide more complete system blockade.

However, these agents do not share the effects of ACE inhibitors on other potentially important pathways that produce increases in bradykinin, prostaglandins, and nitric oxide in the heart, blood vessels, and other tissues. The recently completed Valsartan in Heart Failure Trial (Val-HeFT) examined the efficacy of adding valsartan to ACE inhibitor therapy. No benefit in survival was observed and only a modest reduction in hospitalizations; however, in the small subset of patients without background ACE inhibitor therapy, valsartan significantly reduced both mortality and hospitalizations for heart failure. Therefore, angiotensin receptor blockers should be considered as alternatives to ACE inhibitors in ACE-intolerant patients.

3. Spironolactone—There is growing evidence that aldosterone may mediate some of the major effects of renin-angiotensin-aldosterone system activation, such as myocardial remodeling and fibrosis, as well as sodium retention and potassium loss at the distal tubules. Thus, spironolactone should be considered as a neurohormonal antagonist rather than narrowly as a potassium-sparing diuretic. The RALES trial compared spironolactone 25 mg daily with placebo in patients with advanced heart failure already receiving ACE inhibitors and diuretics and showed a 29% reduction in mortality as well as similar decreases in other clinical end points. Hyperkalemia was uncommon in this severe heart failure population, which was maintained on high doses of diuretic, but potassium levels should be monitored closely (after 1 and 4 weeks of therapy) in patients receiving ACE inhibitors. Neither the efficacy nor the safety of spironolactone has been established in the large majority of patients with mild or moderate heart failure who are taking low doses of diuretics, though this agent may be considered in patients who require potassium supplementation. A more selective aldosterone inhibitor, eplerenone, also appears effective in preventing left ventricular remodeling.

E. Beta-Blockers

Although beta-blockers have traditionally been considered contraindicated in patients with heart failure because they may block the compensatory actions of the sympathetic nervous system, there is now strong evidence that these agents have important beneficial effects in this patient population. The mechanism of this benefit remains unclear, but it is likely that chronic elevations of catecholamines and sympathetic nervous system activity cause progressive myocardial damage, leading to worsening left ventricular function and dilation. The primary evidence for this hypothesis is that over a period of 3-6 months, beta-blockers produce consistent substantial rises in ejection fraction (averaging 10% absolute increase) and reductions in left ventricular size and mass.

Clinical trial results have been reported in nearly 14,000 patients (ranging from asymptomatic post-myocardial infarction left ventricular dysfunction to severe heart failure with left ventricular ejection fractions < 35-40%) receiving ACE inhibitors and diuretics randomized to beta-blockers or placebo. Carvedilol, a nonselective β_1 and β_2 receptor blocker with additional weak alpha-blocking activity, was the first beta-blocker approved for heart failure in the United States after showing a reduction in death and hospitalizations in four smaller studies with a total of nearly 1100 patients. Subsequently, trials with two β_1 -selective agents, bisoprolol (CIBIS II, with 2647 patients) and sustained-release metoprolol (MERIT, with nearly 4000 patients), both showed 35% reductions in mortality as well as fewer hospitalizations. Recently, a trial using carvedilol in 2200 patients with severe (NYHA class III/IV) heart failure was terminated ahead of schedule because of a 35% reduction in mortality. In these trials, there were reductions in sudden deaths and deaths from worsening heart failure, and benefits were seen in patients with underlying coronary disease and those with primary cardiomyopathies. In all these studies, the beta-blockers were generally well tolerated, with similar numbers of withdrawals in the active and placebo groups. This has led to a strong recommendation that *stable* patients (defined as having no recent deterioration or evidence of volume overload) with mild, moderate, and even severe heart failure should be treated with a beta-blocker unless there is a noncardiac contraindication. In the COPERNICUS trial, carvedilol was both well tolerated and highly effective in reducing both mortality and heart failure hospitalizations in a group of patients with severe (NYHA class III or IV) symptoms, but care was taken to ensure that they were free of fluid retention at the time of initiation. In this study, one death was prevented for every 13 patients treated for 1 year—as dramatic an effect as has been seen with a pharmacologic therapy in the history of cardiovascular medicine. It is not known whether there are differences between beta-blockers, but a trial comparing carvedilol and metoprolol (COMET) is ongoing and should be reported in 2003.

Since even apparently stable patients may deteriorate when beta-blockers are initiated, this must be done gradually and with great care. Carvedilol is initiated at a dosage of 3.125 mg twice daily and may be increased to 6.25, 12.5, and 25 mg twice daily at intervals of approximately 2 weeks. The protocols for sustained-release metoprolol use were started at 12.5 or 25 mg daily and doubled at intervals of 2 weeks to a target dose of 200 mg daily (using the Toprol XL sustained-release preparation). Bisoprolol was administered at a dosage of 1.25, 2.5, 3.75, 5, 7.5, and 10 mg daily, with increments at 1- to 4-week intervals. More gradual up-titration is often more convenient and may be better tolerated.

Patients should be instructed to monitor their weights at home as an indicator of fluid retention and to report any increase or change in symptoms immediately. Before each dose increase, the patient should be seen and examined to ensure that there has not been fluid retention or worsening of symptoms. If heart failure worsens, this can usually be managed by increasing diuretic doses and delaying further increases in beta-blocker doses, though downward adjustments or discontinuation is sometimes required. Carvedilol, because of its alpha-blocking activity, may cause dizziness or hypotension. This can usually be managed by reducing the doses of other vasodilators and by slowing the pace of dose increases.

F. Digitalis Glycosides

The digitalis glycosides (primarily digoxin) are the only orally active positive inotropic agents currently available. They bind to the sodium-potassium ATPase on the sarcolemmal membrane, inhibiting the sodium pump and thereby increasing intracellular sodium. This facilitates sodium-calcium exchange, with a resultant increase in cytosolic calcium, which enhances contractile protein cross-bridge formation and force generation. The digitalis glycosides also have electrophysiologic effects that may be beneficial or deleterious in individual patients. The primary therapeutic effect is an enhancement of cardiac parasympathetic tone, which delays atrioventricular conduction and reduces sinus node automaticity, thereby decreasing the ventricular response in patients with atrial fibrillation and slightly slowing the rate of patients in sinus rhythm. However, the increase in intracellular calcium and sodium may enhance automaticity of latent pacemakers, increasing the excitability of ventricular myocytes and inducing ventricular arrhythmias, especially when hypokalemia or myocardial ischemia is present.

Although the digitalis glycosides were once the mainstay of congestive heart failure treatment, their use in patients who are in sinus rhythm has declined because they lack the benefits of the neurohormonal antagonists on prognosis and because safety concerns persist. However, their efficacy in reducing the symptoms of heart failure has been established in at least four multicenter trials which have demonstrated that digoxin withdrawal is associated with worsening symptoms and signs of heart failure, more frequent hospitalizations for decompensation, and reduced exercise tolerance. This was also seen in the 6800-patient Digitalis Investigators Group (DIG) trial, though that study found no benefit (or harm) with regard to survival. A reduction in deaths due to progressive heart failure was balanced by an increase in deaths due to ischemic and arrhythmic events. Based on these results, digoxin should be used for patients who remain symptomatic when taking diuretics and ACE inhibitors as well as for heart failure patients who are in atrial fibrillation and require rate control.

Digoxin, the only widely employed digitalis preparation, has a half-life of 24-36 hours and is eliminated almost entirely by the kidneys. The oral maintenance dose may range from 0.125 mg three times weekly to 0.5 mg daily. It is lower in patients with renal dysfunction, in older patients, and in those with smaller lean body mass. Although a loading dose of 0.75-1.25 mg (depending primarily on lean body size) over 24-48 hours may be given if an early effect is desired, in most patients with chronic heart failure it is sufficient to begin with the expected maintenance dose (usually 0.125-0.25 mg daily). Amiodarone, quinidine, propafenone, and verapamil are among the drugs that may increase digoxin levels up to 100%. It is prudent to measure a blood level after 7-14 days (and at least 6 hours after the last dose was administered). Most of the positive inotropic effect is apparent with serum digoxin levels between 0.7 and 1.2 ng/mL, and levels above this range may be associated with a higher risk of arrhythmias and lower survival rates, though clinically evident toxicity is rare with levels below 1.8 ng/mL. Once an appropriate maintenance dose is established, subsequent levels are usually not indicated unless there is a change in renal function or medications that affect digoxin levels or a significant deterioration in cardiac status that may be associated with reduced clearance.

Digoxin toxicity has become less frequent as there has been a better appreciation of its pharmacology, but the therapeutic-to-toxic ratio is quite narrow. Symptoms of digitalis toxicity include anorexia, nausea, headache, blurring or yellowing of vision, and disorientation. Cardiac toxicity may take the form of atrioventricular conduction

or sinus node depression; junctional, atrial, or ventricular premature beats or tachycardias; or ventricular fibrillation. Potassium administration (following serum potassium measurement, since severe toxicity may be associated with hyperkalemia) is usually indicated for the tachyarrhythmias even when levels are in the normal range, but may worsen conduction disturbances. Lidocaine or phenytoin may be useful for ventricular arrhythmias, as is overdrive pacing, but quinidine, amiodarone, and propafenone should be avoided because they will increase digoxin levels. Electrical cardioversion should be avoided if possible, since it may cause intractable ventricular fibrillation or cardiac standstill. Pacing is indicated for third-degree AV block (complete heart block) and symptomatic or severe block (heart rate < 40/min) if they persist after treatment with atropine. Digoxin immune fab (ovine) are available for life-threatening toxicity or large overdoses, but it should be remembered that their half-life is shorter than that of digoxin and so repeat administration may be required.

G. Vasodilators

Agents that dilate arteriolar smooth muscle and lower peripheral vascular resistance reduce left ventricular afterload. Medications that diminish venous tone and increase venous capacitance reduce the preload of both ventricles as their principal effect. Since most patients with moderate to severe heart failure have both elevated preload and reduced cardiac output, the maximum benefit of vasodilator therapy can be achieved by an agent or combination of agents with both actions. Many patients with heart failure have mitral or tricuspid regurgitation; agents that reduce resistance to ventricular outflow tend to redirect regurgitant flow in a forward direction.

Although vasodilators that are also neurohumoral antagonists—specifically, the ACE inhibitors—improve prognosis, such a benefit is less clear with the direct-acting vasodilators. The combination of hydralazine and isosorbide dinitrate has also improved survival, but to a lesser extent than ACE inhibitors.

The intravenous vasodilating drugs and their dosages have been discussed elsewhere in this chapter (in the section on complications in acute myocardial infarction).

1. Nitrates—Intravenous vasodilators (sodium nitroprusside or nitroglycerin) are used primarily for acute or severely decompensated chronic heart failure, especially when accompanied by hypertension or myocardial ischemia. If neither of the latter is present, therapy is best initiated and adjusted based on hemodynamic measurements. Starting dosages of both agents are 10-20 ug/kg/min with upward titration by increments of 10 ug/kg/min as frequently as every 5-10 minutes. Dosages above 200 ug/kg/min are usually not required.

Isosorbide dinitrate, 20-80 mg orally three times daily, has proved effective in several small studies. Nitroglycerin ointment, 12.5-50 mg (1-4 in) every 6-8 hours, appears to be equally effective although somewhat inconvenient for long-term therapy. The nitrates are moderately effective in relieving shortness of breath, especially in patients with mild to moderate symptoms, but less successful—probably because they have little effect on cardiac output—in advanced heart failure. Nitrate therapy is generally well tolerated, but headaches and hypotension may limit the dose of all agents. The development of tolerance to chronic nitrate therapy is now generally acknowledged. This is minimized by intermittent therapy, especially if a daily 8- to 12-hour nitrate-free interval is employed, but probably develops to some extent in most patients receiving these agents. Transdermal nitroglycerin patches have no sustained effect in patients with heart failure and should not be employed for this indication.

2. Nesiritide—This new agent, a recombinant form of human brain natriuretic peptide, is a potent vasodilator that reduces ventricular filling pressures and improves cardiac output. Its hemodynamic effects resemble those of intravenous nitroglycerin with a more predictable dose-response curve and a longer duration of action. In clinical studies, nesiritide (administered as 2 ug/kg by intravenous bolus injection followed by an infusion of 0.01 ug/kg/min, which may be up-titrated if needed) produced a rapid improvement in both dyspnea and hemodynamics. The primary adverse effect is hypotension, which may be symptomatic and sustained. Since most patients with acute heart failure respond well to conventional therapy, the role of nesiritide may be primarily in patients who continue to be symptomatic after initial treatment with diuretics and nonparenteral nitrates.

3. Hydralazine—Oral hydralazine is a potent arteriolar dilator and markedly increases cardiac output in patients with congestive heart failure. However, as a single agent, it has not been shown to improve symptoms or exercise tolerance during chronic treatment. The combination of nitrates and oral hydralazine produces greater hemodynamic effects.

Hydralazine therapy is frequently limited by side effects. Approximately 30% of patients are unable to tolerate the relatively high doses required to produce hemodynamic improvement in heart failure (200-400 mg daily in divided doses). The major side effect is gastrointestinal distress, but headaches, tachycardia, and hypotension are relatively common. Angiotensin receptor blockers have largely supplanted the use of the hydralazine-isosorbide dinitrate combination in ACE-intolerant patients.

H. Positive Inotropic Agents

The digitalis derivatives are the only available oral inotropic agents in the United States. A number of other oral positive inotropic agents have been investigated for the chronic treatment of heart failure, but all have increased mortality without convincing evidence of improvement in symptoms. Intravenous agents, such as the β_1 agonist dobutamine and the phosphodiesterase inhibitor milrinone, are sometimes employed on a long-term or intermittent basis. The limited available data suggest that continuous therapy is also likely to increase mortality; intermittent inotropic therapy has never been evaluated in controlled trials, and its use is largely based on anecdotal experience. A recent randomized placebo-controlled trial of 950 patients evaluating intravenous milrinone in patients admitted for decompensated heart failure who had no definite indications for inotropic therapy showed no benefit in terms of survival, decreasing length of admission, or preventing readmission—and significantly increased rates of sustained hypotension and atrial fibrillation. Thus, the role of positive inotropic agents appears to be limited to patients with symptoms and signs of low cardiac output (primarily hypoperfusion and deteriorating renal function) and those who fail to respond to intravenous diuretics. In some cases, dobutamine or milrinone may help maintain patients who are awaiting cardiac transplantation.

I. Calcium Channel Blockers

First-generation calcium channel blockers may accelerate the progression of congestive heart failure. However, two trials with amlodipine in patients with severe heart failure showed that this agent was safe, though not superior to placebo. These agents should be avoided unless they are being utilized to treat associated angina or hypertension, and for these indications amlodipine is the calcium channel blocker of choice.

J. Anticoagulation

Patients with left ventricular failure and reduced ejection fractions are at somewhat increased risk of developing intracardiac thrombi and systemic arterial emboli. However, this risk appears to be primarily in patients who are in atrial fibrillation or who have large recent (within 3-6 months) myocardial infarctions. These groups should be anticoagulated. Other heart failure patients have embolic rates of approximately two per 100 patient-years of follow-up, which approximates the rate of major bleeding, and routine anticoagulation does not appear warranted except in patients with prior embolic events or mobile left ventricular thrombi.

K. Antiarrhythmic Therapy and Implantable Cardioverter Defibrillators (ICDs)

Patients with moderate to severe heart failure have a high incidence of both symptomatic and asymptomatic arrhythmias. Although fewer than 10% of patients have syncope or presyncope resulting from ventricular tachycardia, ambulatory monitoring reveals that up to 70% of patients have asymptomatic episodes of nonsustained ventricular tachycardia. These arrhythmias indicate a poor prognosis independent of the severity of left ventricular dysfunction, but many of the deaths are probably not arrhythmia-related. Beta-blockers, because of their marked favorable effect on prognosis in general and on the incidence of sudden death specifically, should be initiated in these as well as other heart failure patients. Empiric antiarrhythmic therapy has not proved beneficial in patients with asymptomatic ventricular arrhythmias, and most other agents are contraindicated because of their proarrhythmic effects in this population and their adverse effect on cardiac function.

Patients with aborted sudden death, hemodynamically unstable ventricular arrhythmias, and unexplained cardiogenic syncope are at high risk for fatal ventricular arrhythmias. If these patients have a reasonable life expectancy and stable, nonrefractory heart failure, an implantable defibrillator is the approach of choice (again in conjunction with beta blockade). There are not sufficient data on which to base firm recommendations for the management of patients with asymptomatic nonsustained ventricular arrhythmias. Beta-blockers are the first line of therapy, but there is no evidence that antiarrhythmic drugs are beneficial, and they carry substantial risk (with the exception of amiodarone). In the second Multicenter Automatic Defibrillator Implantation Trial (MADIT II), 1232 patients with prior myocardial infarction and an ejection fraction = 30% without a history of symptomatic ventricular arrhythmias were randomized to an ICD or a control group. Mortality was 31% lower in the ICD group, which translated into nine lives saved for each 100 patients who received a device and were followed for 3 years. The potential implications of this result are enormous, since this translates into an estimated cost of \$300,000 per life saved. Before acting on this result, corroborative data should be awaited from the ongoing Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT). Patients in this larger trial appear to be more symptomatic and more aggressively treated. Importantly, it includes a third arm in which patients have been randomized to amiodarone.

Nonpharmacologic Treatment

A. Case Management and Exercise Training

Thirty to 50 percent of congestive heart failure patients who are hospitalized will be readmitted within 3-6 months. Strategies to prevent clinical deterioration, such as case management, home monitoring of weight and clinical status, and patient adjustment of diuretics, can prevent rehospitalizations and should be part of the treatment regimen of advanced heart failure.

Exercise training improves activity tolerance in significant part by reversing the peripheral abnormalities associated with heart failure and deconditioning. Whether formal exercise programs are more beneficial than individual activity prescriptions is unknown, but stable patients should be encouraged to remain active and engage in appropriate aerobic exercise.

B. Coronary Revascularization

Since underlying coronary artery disease is the cause of heart failure in the majority of patients, coronary revascularization may both improve symptoms and prevent progression. However, trials have not been performed in patients with symptomatic heart failure. Nonetheless, patients with angina who are candidates for surgery should be evaluated for revascularization, usually by coronary angiography. Noninvasive testing for ischemic but viable myocardium may be a more appropriate first step in patients with known coronary disease but no current clinical evidence of ischemia. The benefit of evaluating patients with heart failure of new onset without angina or prior myocardial infarction is limited. In general, bypass surgery is preferable to PTCA in the setting of heart failure because it provides more complete revascularization.

C. Biventricular Pacing (Resynchronization)

Many patients with heart failure due to systolic dysfunction have abnormal intraventricular conduction that results in dyssynchronous and hence inefficient contractions. Several studies have evaluated the efficacy of "multisite" pacing, using leads that stimulate the right ventricle from the apex and the left ventricle from the lateral wall via the coronary sinus. Patients with wide QRS complexes (generally = 140 ms), reduced ejection fractions, and severe symptoms have been evaluated. Results from studies with up to 6 months of follow-up have reported an increase in ejection fraction and improvement in symptoms and exercise tolerance. Definitive data on mortality or morbidity are not yet available. Nonetheless, this appears to be a promising therapeutic approach in patients who remain symptomatic despite aggressive medical therapy. Devices that combine biventricular pacing and ICD capabilities are also available.

D. Cardiac Transplantation

Because of the poor prognosis of patients with advanced heart failure, cardiac transplantation has become widely used. Since the advent of cyclosporine immunosuppressive therapy and more careful screening of donor hearts, the survival of patients after cardiac transplantation has increased considerably. Many centers now have 1-year survival rates exceeding 80-90%, and 5-year survival rates above 70%. Infections, hypertension, and renal dysfunction caused by cyclosporine, rapidly progressive coronary atherosclerosis, and immunosuppressant-related cancers have been the major complications. The high cost and limited number of donor organs require careful patient selection early in the course.

E. Other Surgical Treatment Options

Several surgical procedures for severe heart failure have received considerable publicity. Cardiomyoplasty is a procedure in which the latissimus dorsi muscle is wrapped around the heart and stimulated to contract synchronously with it. In ventricular reduction surgery, a large part of the anterolateral wall is resected to make the heart function more efficiently. Both approaches are too risky in end-stage patients and have not been shown to improve prognosis or symptoms in controlled studies, and for these reasons they have largely been dropped. Externally powered and implantable ventricular assist devices can be used in patients who require ventricular support either to allow the heart to recover or as a bridge to transplantation. The latest-generation devices are small enough to allow patients unrestricted mobility and even discharge from the hospital. However, complications are frequent, including bleeding, thromboembolism, and infection, and the cost is very high, exceeding \$200,000 in the initial 1-3 months.

While 1-year survival was improved in a recent randomized trial, all patients died by 26 months.

F. Palliative Care

Despite the technologic advances of recent years, including cardiac resynchronization, implantable defibrillators, left ventricular assist devices, and totally implantable artificial hearts, it should be remembered that many patients with chronic heart failure are elderly and have multiple comorbidities. Many of them will not experience meaningful improvements in survival with aggressive therapy, and the goal of management should be symptomatic improvement and palliation (see [Chapter 5](#)).

ACUTE HEART FAILURE & PULMONARY EDEMA

Essentials of Diagnosis

- Acute onset or worsening of dyspnea at rest.
- Tachycardia, diaphoresis, cyanosis.
- Pulmonary rales, rhonchi; expiratory wheezing.
- X-ray shows interstitial and alveolar edema with or without cardiomegaly.
- Arterial hypoxemia.

General Considerations

Typical causes of acute cardiogenic pulmonary edema include acute myocardial infarction or severe ischemia, exacerbation of chronic heart failure, acute volume overload of the left ventricle (valvular regurgitation), and mitral stenosis. By far the most common presentation in developed countries is one of acute or subacute deterioration of chronic heart failure, precipitated by discontinuation of medications, excessive salt intake, myocardial ischemia, tachyarrhythmias (especially rapid atrial fibrillation), or intercurrent infection. Often in the latter group, there is preceding volume overload with worsening edema and progressive shortness of breath for which earlier intervention can usually avoid the need for hospital admission.

Clinical Findings

Acute pulmonary edema presents with a characteristic clinical picture of severe dyspnea, the production of pink, frothy sputum, and diaphoresis and cyanosis. Rales are present in all lung fields, as are generalized wheezing and rhonchi. Pulmonary edema may appear acutely or subacutely in the setting of chronic heart failure or may be the first manifestation of cardiac disease, usually acute myocardial infarction, which may be painful or silent. Less severe decompensations usually present with dyspnea at rest and rales and other evidence of fluid retention but without severe hypoxia.

A number of noncardiac conditions can also produce pulmonary edema. This occurs either because of imbalance in the Starling forces (either a decrease in plasma proteins or an increase in pulmonary venous pressure) or a functional or anatomic abnormality of the alveolar-capillary membrane. Causes include intravenous narcotics, increased intracerebral pressure, high altitude, sepsis, several medications, inhaled toxins, transfusion reactions, shock, and disseminated intravascular coagulation. These are distinguished from cardiogenic pulmonary edema by the clinical setting, the history, and the physical examination. Conversely, in most patients with cardiogenic pulmonary edema, an underlying cardiac abnormality can usually be detected clinically or by the ECG, chest x-ray, or echocardiogram.

The chest radiograph reveals signs of pulmonary vascular redistribution, blurriness of vascular outlines, increased interstitial markings, and, characteristically, the butterfly pattern of distribution of alveolar edema. The heart may be enlarged or normal in size depending on whether heart failure was previously present. Assessment of cardiac function by echocardiography is important, since a substantial proportion of patients have normal ejection fractions with elevated atrial pressures due to diastolic dysfunction. In cardiogenic pulmonary edema, the pulmonary capillary wedge pressure is invariably elevated, usually over 25 mm Hg. In noncardiogenic pulmonary edema, the wedge pressure may be normal or even low.

Treatment

In full-blown pulmonary edema, the patient should be placed in a sitting position with legs dangling over the side of the bed; this facilitates respiration and reduces venous return. Oxygen is delivered by mask to obtain an arterial PO₂ greater than 60 mm Hg. Noninvasive pressure support ventilation may improve oxygenation and prevent severe CO₂ retention while pharmacologic interventions take effect. However, if respiratory distress remains severe, endotracheal intubation and mechanical ventilation may be necessary.

Morphine is highly effective in pulmonary edema and may be helpful in less severe decompensations when the patient is uncomfortable. The initial dosage is 2-8 mg intravenously (subcutaneous administration is effective in milder cases) and may be repeated after 2-4 hours. Morphine increases venous capacitance, lowering left atrial pressure, and relieves anxiety, which can reduce the efficiency of ventilation. However, morphine may lead to CO₂ retention by reducing the ventilatory drive. It should be avoided in patients with narcotic-induced pulmonary edema, who may improve with narcotic antagonists, and in those with neurogenic pulmonary edema.

Intravenous diuretic therapy (furosemide, 40 mg, or bumetanide, 1 mg—or higher doses if the patient has been receiving chronic diuretic therapy) is usually indicated even if the patient has not exhibited prior fluid retention. These agents produce venodilation prior to the onset of diuresis.

Nitrate therapy accelerates clinical improvement by reducing both blood pressure and left ventricular filling pressures. Sublingual nitroglycerin or isosorbide dinitrate, topical nitroglycerin, or intravenous nitrates will ameliorate dyspnea rapidly prior to the onset of diuresis, and these agents are particularly valuable in patients with accompanying hypertension. Intravenous nesiritide (recombinant B-type natriuretic peptide), when given as a bolus followed by an infusion, improves dyspnea more rapidly than intravenous nitroglycerin, though this may reflect the cautious way in which nitroglycerin is up-titrated by many practitioners. This agent, as well as nitrates, may precipitate hypotension, especially since these agents are used in combination with multiple drugs that lower blood pressure. In patients with low-output states—particularly when hypotension is present—positive inotropic agents are indicated. These approaches to treatment have been discussed previously.

Bronchospasm may occur in response to pulmonary edema and may itself exacerbate hypoxemia and dyspnea. Treatment with inhaled beta-adrenergic agonists or intravenous aminophylline may be helpful, but both may also provoke tachycardia and supraventricular arrhythmias.

In most cases, pulmonary edema responds rapidly to therapy. When the patient has improved, the cause or precipitating factor should be ascertained. In patients without prior heart failure, evaluation should include echocardiography and in many cases cardiac catheterization and coronary angiography. Patients with acute decompensation of chronic heart failure should be treated to achieve a euvolemic state and have their medical regimen optimized. Generally, an oral diuretic and an ACE inhibitor should be initiated, with efficacy and tolerability confirmed prior to discharge. In selected patients, early but careful initiation of beta-blockers in low doses should be considered.

■ MYOCARDITIS & THE CARDIOMYOPATHIES

ACUTE MYOCARDITIS

Acute myocarditis causes focal or diffuse inflammation of the myocardium. Most cases are infectious, caused by viral, bacterial, rickettsial, spirochetal, fungal, or parasitic agents; however, toxins, drugs, and immunologic disorders can also cause myocarditis.

1. Infectious Myocarditis

Essentials of Diagnosis

- Often follows an upper respiratory infection.
- May present with chest pain (pleuritic or nonspecific) or signs of heart failure.
- ECG may show sinus tachycardia, other arrhythmias, nonspecific repolarization changes, intraventricular conduction abnormalities.
- Echocardiogram documents cardiomegaly and contractile dysfunction.
- Myocardial biopsy, though not sensitive, may reveal a characteristic inflammatory pattern.

General Considerations

Viral myocarditis is the most common form and is usually caused by coxsackieviruses, but a host of other agents have also been responsible. Rickettsial myocarditis occurs with scrub typhus, Rocky Mountain spotted fever, and Q fever. Diphtheritic myocarditis is caused by the exotoxin and often is manifested by conduction abnormalities as well as heart failure.

Chagas' disease, caused by the insect-borne protozoan *Trypanosoma cruzi*, is a common form of myocarditis in Central and South America; the major clinical manifestations appear after a latent period of more than a decade. At this stage, patients present with cardiomyopathy, conduction disturbances, and sudden death. Associated gastrointestinal involvement (megaesophagus and megacolon) is the rule. Toxoplasmosis causes myocarditis that is usually asymptomatic but can lead to heart failure. Among parasitic infections, trichinosis is the most common cause of cardiac involvement. The potential for the HIV virus to cause myocarditis is now well recognized, though the prevalence of this complication is not known. In addition, other infectious myocarditides are more common in patients with AIDS.

Giant cell myocarditis is a rare idiopathic disorder characterized by giant cell and lymphocyte infiltration of the heart muscle. Patients usually die from ventricular arrhythmias or heart failure but occasionally respond to immunosuppressive therapy or early transplantation.

Clinical Findings

A. Symptoms and Signs

Patients may present several days to a few weeks after the onset of an acute febrile illness or a respiratory infection or with heart failure without antecedent symptoms. The onset of heart failure may be gradual or may be abrupt and fulminant. Pleural-pericardial chest pain is common. Examination reveals tachycardia, gallop rhythm, and other evidence of heart failure or conduction defect. It is likely that most myocarditides are subclinical, though they may present later as idiopathic cardiomyopathy or with ventricular arrhythmias.

B. Electrocardiography and Chest X-Ray

Nonspecific ST-T changes and conduction disturbances are common. Ventricular ectopy may be the initial and only clinical finding. Chest x-ray is nonspecific, but cardiomegaly is frequent.

C. Diagnostic Studies

Echocardiography provides the most convenient way of evaluating cardiac function and can exclude many other processes. Gallium-67 scintigraphy has been reported to yield cardiac uptake in acute or subacute myocarditis. Paired serum viral titers and serologic tests for other agents may indicate the cause.

D. Endomyocardial Biopsy

Pathologic examinations may reveal a lymphocytic inflammatory response with necrosis, but the patchy distribution of abnormalities makes the test relatively insensitive. This picture defines an "active" inflammatory stage and may persist for many months.

Treatment & Prognosis

Specific antimicrobial therapy is indicated when an infecting agent is identified. Immunosuppressive therapy with corticosteroids and other agents has been felt by some to improve the outcome when the process is acute (< 6 months) and if the biopsy suggests ongoing inflammation. However, controlled trials have not been positive, so the value of routine myocardial biopsies in patients presenting with an acute myocarditic picture is uncertain; immunosuppressive therapy without histologic confirmation is unwise. Otherwise, treatment is directed toward the manifestations of heart failure and arrhythmias.

Many cases resolve spontaneously, but in others cardiac function deteriorates progressively and may lead to dilated cardiomyopathy. Many cases of dilated cardiomyopathy may represent the end stage of viral myocarditis.

Rassi A et al: Chagas' heart disease. Clin Cardiol 2000;23:883. [\[PMID: 11129673\]](#)

2. Drug-Induced & Toxic Myocarditis

A variety of medications, illicit drugs, and toxic substances can produce acute or chronic myocardial injury; the clinical presentation varies widely. Doxorubicin and other cytotoxic agents, emetine, and catecholamines (especially with pheochromocytoma) can produce a pathologic picture of inflammation and necrosis together with clinical heart failure and arrhythmias; toxicity of the first two is dose-related. The phenothiazines, lithium, chloroquine, disopyramide, antimony-containing compounds, and arsenicals can also cause electrocardiographic changes, arrhythmias, or heart failure. Hypersensitivity reactions to sulfonamides, penicillins, and aminosalicyclic acid as well as other drugs can result in cardiac dysfunction. Radiation can cause an acute inflammatory reaction as well as a chronic fibrosis of heart muscle, usually in conjunction with pericarditis.

The incidence of cocaine cardiotoxicity has increased markedly. Cocaine can cause coronary artery spasm, myocardial infarction, arrhythmias, and myocarditis. Because many of these processes are believed to be mediated by cocaine's inhibitory effect on norepinephrine reuptake by sympathetic nerves, beta-blockers have been used therapeutically. In coronary spasm, calcium channel blockers are more appropriate.

Gharib MI et al: Chemotherapy-induced cardiotoxicity: current practice and prospects of prophylaxis. Eur J Heart Fail 2002;4:235. [\[PMID: 12034146\]](#)

THE CARDIOMYOPATHIES

The cardiomyopathies are a heterogeneous group of entities affecting the myocardium primarily and not associated with the major causes of cardiac disease, ie, ischemic heart disease, hypertension, valvular disease, or congenital defects. While some have specific causes, many cases are idiopathic. There is now general agreement on a classification based upon general features of presentation and pathophysiology ([Table 10-7](#)).

Franz WM et al: Cardiomyopathies: from genetics to the prospect of treatment. Lancet 2001;358:1627. [\[PMID: 11716909\]](#)

1. Primary Dilated Cardiomyopathy

Essentials of Diagnosis

- Symptoms and signs of heart failure.
- ECG may show low QRS voltage, nonspecific repolarization abnormalities, intraventricular conduction abnormalities.
- Chest X-ray shows cardiomegaly.
- Echocardiogram confirms left ventricular dilation, thinning, and global dysfunction.

General Considerations

Dilated cardiomyopathies usually present with symptoms and signs of congestive heart failure (most commonly dyspnea). Occasionally, symptomatic ventricular arrhythmias are the presenting event. Left ventricular dilation and systolic dysfunction are essential for diagnosis. A growing number of cardiomyopathies due to genetic abnormalities are being recognized, but these still represent a small minority of cases. Often no cause can be identified, but chronic alcohol abuse and unrecognized myocarditis are probably frequent causes. Amyloidosis, sarcoidosis, hemochromatosis, and diabetes all may present as dilated cardiomyopathies as well as with a restrictive picture. Histologically, the picture is one of extensive fibrosis unless a specific diagnosis is established.

Clinical Findings

A. Symptoms and Signs

In most patients, symptoms of heart failure develop gradually. They may be recognized because of asymptomatic cardiomegaly or electrocardiographic abnormalities, including arrhythmias. The initial presentation may be severe biventricular failure. The physical examination reveals cardiomegaly, S₃ gallop rhythm, and often a murmur of functional mitral regurgitation. Signs of left- and right-sided failure may be present on initial examination, a clue to a process involving the heart diffusely.

B. Electrocardiography and Chest X-Ray

The major findings are listed in [Table 10-7](#).

C. Diagnostic Studies

An echocardiogram is indicated to exclude unsuspected valvular or other lesions and confirm the presence of dilated cardiomyopathy. Exercise thallium-201 scintigraphy may suggest the possibility of underlying coronary disease if a large reversible defect is found, but false-positives occur in cardiomyopathy. Cardiac catheterization is seldom of specific value unless myocardial ischemia or left ventricular aneurysm is suspected. The serum ferritin is an adequate screening study for hemochromatosis.

Treatment

Few cases of cardiomyopathy are amenable to specific therapy. Alcohol use should be discontinued. There is often marked recovery of cardiac function following a period of abstinence in alcoholic cardiomyopathy. Endocrine causes (thyroid dysfunction, acromegaly, pheochromocytoma) should be treated. Immunosuppressive therapy is not indicated in chronic dilated cardiomyopathy. The management of congestive heart failure is outlined in the section on heart failure.

Prognosis

The prognosis of dilated cardiomyopathy without clinical heart failure is variable, with some patients remaining stable, some deteriorating gradually, and others declining rapidly. Once heart failure is manifest, the natural history is similar to that of other causes of heart failure. Arterial and pulmonary emboli are more common in

dilated cardiomyopathy than in ischemic cardiomyopathy; suitable candidates may benefit from chronic anticoagulation. Those patients whose disease progresses may require treatment for severe dyspnea (see above) and ultimately need high-quality palliative care (see [Chapter 5](#)).

2. Hypertrophic Cardiomyopathy

Essentials of Diagnosis

- May present with dyspnea, chest pain, syncope.
- Examination shows sustained apical impulse, S₄, systolic ejection murmur.
- ECG shows left ventricular hypertrophy, occasionally septal Q waves in the absence of infarction.
- Echocardiogram shows hypertrophy, which may be asymmetric; usually shows normal or enhanced contractility and signs of dynamic obstruction.

General Considerations

Myocardial hypertrophy unrelated to any pressure or volume overload tends to impinge upon the left ventricular cavity. The interventricular septum may be disproportionately involved (asymmetric septal hypertrophy), but in some cases the hypertrophy is localized to the apex. The left ventricular outflow tract is often narrowed during systole between the bulging septum and an anteriorly displaced anterior mitral valve leaflet, causing a dynamic obstruction (hence the name idiopathic hypertrophic subaortic stenosis; IHSS). The obstruction is worsened by factors that increase myocardial contractility (sympathetic stimulation, digoxin, postextrasystolic beat) or that decrease left ventricular filling (Valsalva's maneuver, peripheral vasodilators).

Hypertrophic cardiomyopathy is in some cases inherited as an autosomal dominant trait with variable penetrance caused by mutations of a number of genes, most of which code for myosin heavy chains or proteins regulating calcium handling. It is becoming clear that the prognosis is related to the specific gene mutation. These patients usually present in early adulthood. Others are elderly, and many of those patients have a long history of hypertension. Some cases occur sporadically.

Except in late stages, hypertrophic cardiomyopathy is characterized by a small, hypercontractile left ventricle. Although dyspnea is a common symptom, it results mainly from markedly impaired diastolic compliance rather than systolic dysfunction or outflow obstruction.

Clinical Findings

A. Symptoms and Signs

The most frequent symptoms are dyspnea and chest pain. Syncope is also common and is typically postexertional, when diastolic filling diminishes and outflow obstruction increases. Arrhythmias are an important problem. Atrial fibrillation is a long-term consequence of chronically elevated left atrial pressures and is a poor prognostic sign. Ventricular arrhythmias are also common, and sudden death may occur, often in athletes after extraordinary exertion.

Features on physical examination are a bisferiens carotid pulse, triple apical impulse (due to the prominent atrial filling wave and early and late systolic impulses), and a loud S₄. In cases with outflow obstruction, a loud systolic murmur is present that increases with upright posture or Valsalva's maneuver and decreases with squatting.

B. Electrocardiography and Chest X-Ray

Left ventricular hypertrophy is nearly universal. Exaggerated septal Q waves inferolaterally may suggest myocardial infarction. The chest x-ray is often unimpressive.

C. Diagnostic Studies

The echocardiogram is diagnostic, revealing asymmetric left ventricular hypertrophy, systolic anterior motion of the mitral valve, early closing followed by reopening of the aortic valve, a small and hypercontractile left ventricle, and delayed relaxation and filling of the left ventricle during diastole. Doppler ultrasound reveals turbulent flow and a dynamic gradient across the aortic valve and, commonly, mitral regurgitation. Cardiac catheterization may confirm the gradient but adds little to echocardiographic studies.

Treatment

Beta-blockers should be the initial drug in symptomatic individuals, especially when dynamic outflow obstruction is noted on the echocardiogram. Dyspnea, angina, and arrhythmias respond in about 50% of patients. Calcium channel blockers, especially verapamil, have also been effective in symptomatic patients. Their effect may be due primarily to improved diastolic function, but their vasodilating actions may also increase outflow obstruction. Excision of part of the myocardial septum has been successful in patients with severe symptoms when performed by surgeons experienced with the procedure. Dual-chamber pacing may prevent the progression of hypertrophy and obstruction. Nonsurgical septal ablation has been performed by injection of alcohol into septal branches of the left coronary artery. Patients with malignant ventricular arrhythmias and unexplained syncope in the presence of a positive family history for sudden death are probably best managed with an implantable defibrillator.

Prognosis

The natural history of hypertrophic cardiomyopathy is highly variable. Several specific mutations are associated with a higher incidence of early malignant arrhythmias and sudden death, and definition of the genetic abnormality provides the best estimate of prognosis. Some patients remain asymptomatic for many years or for life. Sudden death, especially during exercise, may be the initial event. Indeed, hypertrophic cardiomyopathy is the pathologic feature most frequently associated with sudden death in athletes. Other patients have a history of gradually progressive symptoms. A final stage may be a transition into dilated cardiomyopathy.

3. Restrictive Cardiomyopathy

Restrictive cardiomyopathy is characterized by impaired diastolic filling with preserved contractile function. This condition is relatively uncommon, with the most frequent causes being amyloidosis, radiation, and myocardial fibrosis after open heart surgery. In Africa, endomyocardial fibrosis, a specific entity in which there is severe fibrosis of the endocardium, often with eosinophilia (Löffler's syndrome) is common. Other causes of a restrictive picture are infiltrative cardiomyopathies (eg, sarcoidosis, hemochromatosis, carcinoid syndrome) and connective tissue diseases (eg, scleroderma).

Amyloidosis can affect the heart in several ways. Although it is a frequent cause of restrictive cardiomyopathy, it more often produces dilated cardiomyopathy with congestive heart failure. Almost invariably, conduction disturbances are present. Low voltages on the ECG combined with ventricular hypertrophy by echo are suggestive. Rectal, abdominal fat, or gingival biopsies—as well as myocardial biopsy—can be diagnostic.

The primary diagnostic problem with restrictive cardiomyopathy is differentiation from constrictive pericarditis. The clinical picture often strongly suggests the diagnosis,

but the status of left ventricular function (usually normal with pericarditis, slightly depressed with restrictive cardiomyopathy) can be helpful, as can be evidence of a thickened pericardium. Myocardial biopsies are usually negative with pericarditis but not in restrictive cardiomyopathy. In some cases, only surgical exploration can make the diagnosis.

Unfortunately, little useful therapy is available for either the causative conditions or restrictive cardiomyopathy itself. Diuretics can help, but excessive diuresis can produce worsening symptoms. Steroids may be helpful in sarcoidosis but relieve conduction abnormalities more often than heart failure.

■ ACUTE RHEUMATIC FEVER & RHEUMATIC HEART DISEASE

Essentials of Diagnosis

- Uncommon in United States but may be overlooked.
- Peak incidence ages 5-15 years.
- Diagnosis based on Jones criteria and confirmation of streptococcal infection.
- May involve mitral and other valves acutely, rarely leading to heart failure.

General Considerations

Rheumatic fever is a systemic immune process which is a sequela to beta-hemolytic streptococcal infection of the pharynx. Pyodermic infections are not associated with rheumatic fever. Signs of rheumatic fever usually commence 2-3 weeks after infection but may appear as early as 1 week or as late as 5 weeks. It had become quite uncommon in the United States, except in recent immigrants. However, there have been recent reports of new outbreaks in several regions of the United States. The peak incidence is between ages 5 and 15; rheumatic fever is rare before age 4 and after age 40. Rheumatic carditis and valvulitis may be self-limited or may lead to slowly progressive valvular deformity. The characteristic lesion is a perivascular granulomatous reaction with vasculitis. The mitral valve is attacked in 75-80% of cases, the aortic valve in 30% (but rarely as the sole valve), and the tricuspid and pulmonary valves in under 5%.

Clinical Findings

Diagnostic criteria first described by Jones are still employed. The presence of two major criteria—or one major and two minor criteria—establishes the diagnosis.

A. Major Criteria

1. Carditis—Carditis is most likely to be evident in children and adolescents. Any of the following suggests the presence of carditis: (1) pericarditis; (2) cardiomegaly, detected by physical signs, radiography, or echocardiography; (3) congestive failure, right- or left-sided—the former perhaps more prominent in children, with painful liver engorgement due to tricuspid regurgitation; and (4) mitral or aortic regurgitation murmurs, indicative of dilation of a valve ring with or without associated valvulitis. The Carey-Coombs short middiastolic mitral murmur may be present.

In the absence of any of the above definitive signs, the diagnosis of carditis depends upon the following less specific abnormalities: (1) electrocardiographic changes, including changing contour of P waves or inversion of T waves; (2) changing quality of heart sounds; and (3) sinus tachycardia, arrhythmia, or ectopic beats.

2. Erythema marginatum and subcutaneous nodules—The former begin as rapidly enlarging macules that assume the shape of rings or crescents with clear centers. They may be raised, confluent, and either transient or persistent.

Subcutaneous nodules are uncommon except in children. They are small (= 2 cm in diameter), firm, and nontender and are attached to fascia or tendon sheaths over bony prominences. They persist for days or weeks, are recurrent, and are indistinguishable from rheumatoid nodules.

3. Sydenham's chorea—Sydenham's chorea—involuntary choreoathetoid movements primarily of the face, tongue, and upper extremities—may be the sole manifestation; only half of cases have other overt signs of rheumatic fever. Girls are more frequently affected, and occurrence in adults is rare. This is the least common (3% of cases) but most diagnostic of the manifestations of rheumatic fever.

4. Arthritis—This is a migratory polyarthritis that involves the large joints sequentially. In adults, only a single joint may be affected. The arthritis lasts 1-5 weeks and subsides without residual deformity. Prompt response of arthritis to therapeutic doses of salicylates or nonsteroidal agents is characteristic.

B. Minor Criteria

These include fever, polyarthralgias, reversible prolongation of the PR interval, rapid erythrocyte sedimentation rate, and evidence of an antecedent beta-hemolytic streptococcal infection or a history of rheumatic fever.

C. Laboratory Findings BR>There is nonspecific evidence of inflammatory disease, as shown by a rapid sedimentation rate. High or increasing titers of antistreptococcal antibodies (antistreptolysin O and anti-DNase B) are used to confirm recent infection; 10% of cases lack this serologic evidence.

Differential Diagnosis

Rheumatic fever may be confused with the following: rheumatoid arthritis, osteomyelitis, endocarditis, chronic meningococcemia, systemic lupus erythematosus, Lyme disease, sickle cell anemia, "surgical abdomen," and many other diseases.

Complications

Congestive heart failure occurs in severe cases. In the longer term, the development of rheumatic heart disease is the major problem. Other complications include arrhythmias, pericarditis with effusion, and rheumatic pneumonitis.

Treatment

A. General Measures

The patient should be kept at strict bed rest until the temperature returns to normal without medications, the sedimentation rate is normal, the resting pulse rate is normal (< 100/min in adults), and the ECG has returned to baseline.

B. Medical Measures

1. Salicylates—The salicylates markedly reduce fever and relieve joint pain and swelling. They have no effect on the natural course of the disease. Adults may require aspirin, 0.6-0.9 g every 4 hours; children are treated with lower doses. Toxicity includes tinnitus, vomiting, and gastrointestinal bleeding.

2. Penicillin—Penicillin (benzathine penicillin, 1.2 million units intramuscularly once, or procaine penicillin, 600,000 units intramuscularly daily for 10 days) is employed to eradicate streptococcal infection if present. Erythromycin may be substituted.

3. Corticosteroids—There is no proof that cardiac damage is prevented or minimized by corticosteroids. A short course of corticosteroids (prednisone, 40-60 mg orally daily, with tapering over 2 weeks) usually causes rapid improvement of the joint symptoms and is indicated when response to salicylates has been inadequate.

Prevention of Recurrent Rheumatic Fever

The initial episode of rheumatic fever can usually be prevented by early treatment of streptococcal pharyngitis. (See [Chapter 33](#).) Prevention of recurrent episodes is critical. Recurrences of rheumatic fever are most common in patients who have had carditis during their initial episode and in children, 20% of whom will have a second

episode within 5 years. Recurrences are uncommon after 5 years and in patients over 25 years of age. Prophylaxis is usually discontinued after these times except in groups with a high risk of streptococcal infection—parents or teachers of young children, nurses, military recruits, etc.

A. Penicillin

The preferred method of prophylaxis is with benzathine penicillin G, 1.2 million units intramuscularly every 4 weeks. Oral penicillin (200,000-250,000 units twice daily) is less reliable.

B. Sulfonamides or Erythromycin

If the patient is allergic to penicillin, sulfadiazine (or sulfisoxazole), 1 g daily, or erythromycin, 250 mg orally twice daily, may be substituted.

Prognosis

Initial episodes of rheumatic fever may last months in children and weeks in adults. The immediate mortality rate is 1-2%. Persistent rheumatic carditis with cardiomegaly, heart failure, and pericarditis imply a poor prognosis; 30% of children thus affected die within 10 years after the initial attack. After 10 years, two-thirds of patients will have detectable valvular abnormalities (usually thickened valves with limited mobility), but significant symptomatic valvular heart disease or persistent cardiomyopathy occurs in less than 10% of patients with a single episode. In developing countries, acute rheumatic fever occurs earlier in life, recurs more frequently, and the evolution to chronic valvular disease is both accelerated and more severe.

Rheumatic Heart Disease

Chronic rheumatic heart disease results from single or repeated attacks of rheumatic fever that produce rigidity and deformity of valve cusps, fusion of the commissures, or shortening and fusion of the chordae tendineae. Stenosis or insufficiency results, and the two often coexist. The mitral valve alone is affected in 50-60% of cases, and combined lesions of the aortic and mitral valves occur in 20%; pure aortic lesions are less common. Tricuspid involvement occurs only in association with mitral or aortic disease in about 10% of cases. The pulmonary valve is rarely affected. A history of rheumatic fever is obtainable in only 60% of patients with rheumatic heart disease.

The first clue to organic valvular disease is a murmur. Physical examination permits accurate diagnosis in many cases, but echocardiography will reveal valve cusp thickening with decreased opening in stenosis, estimate the magnitude of regurgitation, and demonstrate the earliest stages of specific chamber enlargement.

Recurrences of acute rheumatic fever can be prevented (see above). The patient should also receive prophylactic antibiotics preceding dental extraction, urologic and surgical procedures, etc, to prevent endocarditis ([Table 33-4](#)). With mitral valve disease, it is important to identify the onset of atrial fibrillation in order to institute anticoagulation. The important findings in each of the major valve lesions are summarized in [Table 10-1](#). The hemodynamic changes, symptoms, associated findings, and course have been discussed previously.

■ DISEASES OF THE PERICARDIUM

ACUTE PERICARDITIS

The pericardium consists of two layers: an inner visceral layer, which is attached to the epicardium, and an outer parietal layer. The pericardium stabilizes the heart in anatomic position and reduces contact between the heart and surrounding structures. It is composed of fibrous tissue, and while it will permit moderate changes in cardiac size, it cannot stretch rapidly enough to accommodate rapid dilation of the heart or accumulation of fluid without increasing intrapericardial (and, therefore, intracardiac) pressure.

The pericardium is often involved by processes that affect the heart, but it may also be affected by diseases of adjacent tissues and may itself be a primary site of disease.

INFLAMMATORY PERICARDITIS

Acute inflammation of the pericardium may be infectious in origin or may be due to systemic diseases (autoimmune syndromes, uremia), neoplasm, radiation, drug toxicity, hemopericardium, or contiguous inflammatory processes in the myocardium or lung. In many of these conditions, the pathologic process involves both the pericardium and the myocardium.

The presentation and course of inflammatory pericarditis depend on its cause, but all syndromes are often (not always) associated with chest pain, which is usually pleuritic and postural (relieved by sitting). The pain is substernal but may radiate to the neck, shoulders, back, or epigastrium. Dyspnea may also be present. A pericardial friction rub is characteristic, with or without evidence of fluid accumulation or constriction (see below). Fever and leukocytosis are often present. The ECG usually shows generalized ST and T wave changes and may manifest a characteristic progression beginning with diffuse ST elevation, followed by a return to baseline and then to T wave inversion. The chest x-ray may show cardiac enlargement if fluid has collected, as well as signs of related pulmonary disease. The echocardiogram may disclose pericardial effusions and indicate their hemodynamic significance, but it is often normal in inflammatory pericarditis.

Several of the specific pericarditis syndromes are discussed below.

Viral Pericarditis

Viral infections (especially infections with coxsackieviruses and echoviruses but also influenza, Epstein-Barr, varicella, hepatitis, mumps, and HIV viruses) are the commonest cause of acute pericarditis and probably are responsible for many cases classified as idiopathic. Males—usually under age 50—are most commonly affected. Pericardial involvement often follows upper respiratory infection. The diagnosis is usually clinical, but rising viral titers in paired sera may be obtained for confirmation. Cardiac enzymes may be slightly elevated, reflecting a myocarditic component. The differential diagnosis is primarily with myocardial infarction.

Treatment is generally symptomatic. Aspirin (650 mg every 3-4 hours) or other nonsteroidal agents (eg, indomethacin, 100-150 mg daily in divided doses) are usually effective. Corticosteroids may be beneficial in unresponsive cases. In general, symptoms subside in several days to weeks. The major early complication is tamponade, which occurs in fewer than 5% of patients. There may be recurrences in the first few weeks or months. Rare patients will continue to experience recurrences chronically, sometimes leading to constrictive pericarditis, when pericardial resection may be required.

Tuberculous Pericarditis

Tuberculous pericarditis has become rare in developed countries but remains common in other areas. It results from direct lymphatic or hematogenous spread; clinical pulmonary involvement may be absent or minor, although associated pleural effusions are common. The presentation tends to be subacute, but nonspecific symptoms (fever, night sweats, fatigue) may be present for days to months. Pericardial effusions are usually small or moderate but may be large. The diagnosis can be inferred if acid-fast bacilli are found elsewhere. The yield of organisms by pericardiocentesis is low; pericardial biopsy has a higher yield but may also be negative, and pericardiectomy may be required. Standard antituberculous drug therapy is usually successful (see [Chapter 9](#)), but constrictive pericarditis can occur.

Other Infectious Pericarditides

Bacterial pericarditis has become rare and usually results from direct extension from pulmonary infections. Symptoms and signs are similar to those of other types of inflammatory pericarditides, but patients appear toxic and are often critically ill. *Borrelia burgdorferi*, the organism responsible for Lyme disease, can also cause myopericarditis.

Uremic Pericarditis

This syndrome is a common complication of renal failure. The pathogenesis is uncertain; it occurs both with untreated uremia and in otherwise stable dialysis patients. The pericardium is characteristically "shaggy," and the effusion is hemorrhagic and exudative. Uremic pericarditis can present with or without symptoms; fever is absent. The pericarditis usually resolves with the institution of—or with more aggressive—dialysis. Tamponade is fairly common, and partial pericardiectomy (pericardial window) may be necessary. While anti-inflammatory agents may relieve the pain and fever associated with uremic pericarditis, indomethacin and systemic glucocorticoids do not affect the natural history of uremic pericarditis.

Neoplastic Pericarditis

Spread of adjacent lung cancer as well as invasion by breast cancer, renal cell carcinoma, Hodgkin's disease, and lymphomas are the commonest neoplastic processes involving the pericardium and have become the most frequent cause of pericardial tamponade in many countries. Often the process is painless, and the presenting symptoms relate to hemodynamic compromise or the primary disease. The diagnosis can usually be made by cytologic examination of the effusion or by biopsy, but it may be difficult to establish clinically if the patient has received mediastinal radiation within the previous year. MRI and CT scan can visualize neighboring tumor when present. The prognosis with neoplastic effusion is dismal, with only a small minority surviving 1 year. If it is compromising the patient, the effusion is initially drained. Instillation of chemotherapeutic agents or tetracycline may also prevent recurrence. Pericardial windows are rarely effective, but partial pericardiectomy from a subxiphoid incision may be successful; patients may be too ill to tolerate this.

Postmyocardial Infarction or Postcardiotomy Pericarditis (Dressler's Syndrome)

Pericarditis may occur 2-5 days after infarction due to an inflammatory reaction to transmural myocardial necrosis. It usually presents as a recurrence of pain with pleural-pericardial features. A rub is often audible, and repolarization changes may be confused with ischemia. Large effusions are uncommon, and spontaneous resolution usually occurs in a few days. Aspirin or nonsteroidal agents in the dosages given in the section on viral pericarditis provide symptomatic relief.

Dressler's syndrome occurs weeks to several months after myocardial infarction or open heart surgery, may be recurrent, and probably represents an autoimmune syndrome. Patients present with typical pain, fever, malaise, and leukocytosis. The sedimentation rate is usually high. Large pericardial effusions and accompanying pleural effusions are frequent. Tamponade is rare with Dressler's syndrome after infarction but not when it occurs postoperatively. Nonsteroidal agents may be given, but recurrences are common; corticosteroids are effective but may be difficult to withdraw without relapse.

Radiation Pericarditis

Radiation can initiate a fibrinous and fibrotic process in the pericardium, presenting as subacute pericarditis or constriction. The clinical onset is usually within the first year but may be delayed for many years. Radiation pericarditis usually follows treatments of more than 4000 cGy delivered to ports including more than 30% of the heart. Symptomatic therapy is the initial approach, but recurrent effusions and constriction often require surgery.

Other Causes of Pericarditis

These include connective tissue diseases, such as lupus erythematosus and rheumatoid arthritis, drug-induced pericarditis (minoxidil, penicillins), and myxedema.

Wood JE et al: Pericarditis associated with renal failure: evolution and management. Semin Dial 2001;14:61. [PMID: 11208042]

PERICARDIAL EFFUSION

Pericardial effusion can develop during any of the processes discussed in the preceding paragraphs. The speed of accumulation determines the physiologic importance of the effusion. Because the pericardium stretches, large effusions (> 1000 mL) that develop slowly may produce no hemodynamic effects. Smaller effusions that appear rapidly can cause tamponade. Tamponade is characterized by elevated intrapericardial pressure (> 15 mm Hg), which restricts venous return and ventricular filling. As a result, the stroke volume and pulse pressure fall, and the heart rate and venous pressure rise. Shock and death may result.

Clinical Findings

A. Symptoms and Signs

Pericardial effusions may be associated with pain if they occur as part of an acute inflammatory process or may be painless, as is often the case with neoplastic or uremic effusion. Dyspnea and cough are common, especially with tamponade. Other symptoms may result from the primary disease.

A pericardial friction rub may be present even with large effusions. In cardiac tamponade, tachycardia, tachypnea, a narrow pulse pressure, and a relatively preserved systolic pressure are characteristic. Pulsus paradoxus—a greater than 10 mm Hg decline in systolic pressure during inspiration due to further impairment of left ventricular filling—is the classic finding, but it may also occur with obstructive lung disease. Central venous pressure is elevated, and edema or ascites may be present; these signs favor a more chronic process.

B. Laboratory Findings

Laboratory tests tend to reflect the underlying processes.

C. Diagnostic Studies

Chest x-ray can suggest effusion by an enlarged cardiac silhouette with a globular configuration but may appear normal. The ECG often reveals nonspecific T wave changes and low QRS voltage. Electrical alternans is present uncommonly but is pathognomonic. Echocardiography is the primary method for demonstrating pericardial effusion. Tamponade presents a characteristic picture of inadequate ventricular filling (diastolic collapse of the right ventricle or right atrium). The echocardiogram readily discriminates pericardial effusion from congestive heart failure. MRI also demonstrates pericardial fluid and lesions. Diagnostic pericardiocentesis or biopsy is often indicated for microbiologic and cytologic studies; a pericardial biopsy may be performed relatively simply through a small subxiphoid incision.

Treatment

Small effusions can be followed clinically and with the aid of echocardiograms. When tamponade is present, urgent pericardiocentesis is required. Removal of a small amount of fluid often produces immediate hemodynamic benefit, but complete drainage with a catheter is preferable. Continued drainage may be indicated.

Additional therapy is determined by the nature of the primary process. Recurrent effusion in neoplastic disease and uremia, in particular, may require partial pericardiectomy.

CONSTRICTIVE PERICARDITIS

Inflammation can lead to a thickened, fibrotic, adherent pericardium that restricts diastolic filling and produces chronically elevated venous pressures. In the past, tuberculosis was the most common cause of constrictive pericarditis, but the process now more often occurs after radiation therapy, cardiac surgery, or viral pericarditis; histoplasmosis is another uncommon cause.

The principal symptoms are slowly progressive dyspnea, fatigue, and weakness. Chronic edema, hepatic congestion, and ascites are usually present. The examination reveals these signs and a characteristically elevated jugular venous pressure with a rapid y descent. Kussmaul's sign—an increase in jugular venous pressure during inspiration—occurs in constrictive pericarditis and restrictive cardiomyopathy. Pulsus paradoxus is unusual. Atrial fibrillation is common.

The chest x-ray may show normal heart size or cardiomegaly. Pericardial calcification is best seen on the lateral view and is common. Echocardiography can demonstrate a thick pericardium and small chambers. CT scans and MRI are helpful in revealing pericardial thickening and may be more sensitive than echocardiography.

The primary differential diagnoses are restrictive cardiomyopathy and tamponade. The former distinction can be difficult and is best made by evaluating left ventricular

function (more consistently depressed in cardiomyopathy), measuring hemodynamics (which show more complete equalization of diastolic pressures in all four chambers in constrictive pericarditis), and demonstrating pericardial thickening and calcification.

Initial treatment consists of gentle diuresis. Surgical removal of the pericardium, which should be complete, is usually required in symptomatic patients but is associated with a relatively high mortality rate.

■ PULMONARY HYPERTENSION & HEART DISEASE

PRIMARY PULMONARY HYPERTENSION

Primary pulmonary hypertension is defined as pulmonary hypertension and elevated pulmonary vascular resistance in the absence of other disease of the lungs or heart. Pathologically, it is characterized by diffuse narrowing of the pulmonary arterioles. Circumstantial evidence suggests that unrecognized recurrent pulmonary emboli or in situ thrombosis may play a role in some cases. However, the latter may well be an exacerbating factor (precipitated by local endothelial injury) rather than a cause of the syndrome. Primary pulmonary hypertension must be distinguished from chronic pulmonary heart disease (cor pulmonale), recurrent pulmonary emboli, mitral stenosis, and congenital heart disease; cirrhosis of the liver is another cause. The diet pills fenfluramine, dexfenfluramine, and phentermine may cause a picture indistinguishable from that of primary pulmonary hypertension, which is frequently irreversible. Exclusion of secondary causes by echocardiography and lung scanning—and, if necessary, pulmonary angiography—is essential.

The clinical picture is similar to that of pulmonary hypertension from other causes. Patients—characteristically young women—present with evidence of right heart failure that is usually progressive, leading to death in 2-8 years. Patients have manifestations of low cardiac output, with weakness and fatigue, as well as edema and ascites as right heart failure advances. Peripheral cyanosis is present, and syncope on effort may occur.

The chest x-ray shows enlarged main pulmonary arteries with reduced peripheral branches. The right ventricle is enlarged. The ECG shows right ventricular and atrial hypertrophy.

Some authorities advocate chronic oral anticoagulation. The efficacy of vasodilator drugs is controversial. They may lower systemic arterial pressure more than pulmonary arterial pressure, resulting in hypotension that may be life-threatening. The calcium channel blockers nifedipine and diltiazem may be effective early in the course of the disease but offer little in advanced stages. More advanced disease has been managed successfully with chronic infusions of prostacyclin, a potent pulmonary vasodilator. This agent often improves symptoms, sometimes dramatically, in patients who have not responded to other vasodilators. An oral endothelin antagonist, bosentan, has proved very effective in treating moderate to severe primary pulmonary hypertension and may become the treatment of choice for all stages of the disease. Inhaled nitric oxide has been used in patients who do not respond to prostacyclin.

Even with prostacyclin therapy, the symptoms usually progress, and most patients will ultimately require heart-lung transplantation.

PULMONARY HEART DISEASE (COR PULMONALE)

Essentials of Diagnosis

- Symptoms and signs of chronic bronchitis and pulmonary emphysema.
- Elevated jugular venous pressure, parasternal lift, edema, hepatomegaly, ascites.
- ECG shows tall, peaked P waves (P pulmonale), right axis deviation, and right ventricular hypertrophy.
- Chest x-ray: Enlarged right ventricle and pulmonary artery.
- Echocardiogram or radionuclide angiography excludes primary left ventricular dysfunction.

General Considerations

The term "cor pulmonale" denotes right ventricular hypertrophy and eventual failure resulting from pulmonary disease and attendant hypoxia or from pulmonary vascular disease. Its clinical features depend upon both the primary underlying disease and its effects on the heart.

Cor pulmonale is most commonly caused by chronic obstructive pulmonary disease. Less frequent causes include pneumoconiosis, pulmonary fibrosis, kyphoscoliosis, primary pulmonary hypertension, repeated episodes of subclinical or clinical pulmonary embolization, Pickwickian syndrome, schistosomiasis, and obliterative pulmonary capillary or lymphangitic infiltration from metastatic carcinoma.

Clinical Findings

A. Symptoms and Signs

The predominant symptoms of compensated cor pulmonale are related to the pulmonary disorder and include chronic productive cough, exertional dyspnea, wheezing respirations, easy fatigability, and weakness. When the pulmonary disease causes right ventricular failure, these symptoms may be intensified. Dependent edema and right upper quadrant pain may also appear. The signs of cor pulmonale include cyanosis, clubbing, distended neck veins, right ventricular heave or gallop (or both), prominent lower sternal or epigastric pulsations, an enlarged and tender liver, and dependent edema.

B. Laboratory Findings

Polycythemia is often present in cor pulmonale secondary to COPD. The arterial oxygen saturation is often below 85%; PCO₂ may or may not be elevated.

C. Electrocardiography and Chest X-Ray

The ECG may show right axis deviation and peaked P waves. Deep S waves are present in lead V₆. Right axis deviation and low voltage may be noted in patients with pulmonary emphysema. Frank right ventricular hypertrophy is uncommon except in primary pulmonary hypertension. The ECG often mimics myocardial infarction; Q waves may be present in leads II, III, and aVF because of the vertically placed heart, but they are rarely deep or wide, as in inferior myocardial infarction. Supraventricular arrhythmias are frequent and nonspecific.

The chest radiograph discloses the presence or absence of parenchymal disease and a prominent or enlarged right ventricle and pulmonary artery.

D. Diagnostic Studies

Pulmonary function tests usually confirm the underlying lung disease. The echocardiogram should show normal left ventricular size and function but right ventricular dilation. Perfusion lung scans are rarely of value, but, if negative, they help to exclude pulmonary emboli, an occasional cause of cor pulmonale. Pulmonary angiography is the most specific method of diagnosis for the pulmonary emboli, but it carries increased risk when performed in patients with pulmonary hypertension.

Differential Diagnosis

In its early stages, cor pulmonale can be diagnosed on the basis of radiologic, echocardiographic, or electrocardiographic evidence. Catheterization of the right heart will establish a definitive diagnosis but is usually performed to exclude left-sided heart failure, which may in some patients be an inapparent cause of right-sided failure. Differential diagnostic considerations relate chiefly to the specific pulmonary disease that has produced right ventricular failure (see above).

Treatment

The details of the treatment of chronic pulmonary disease (chronic respiratory failure) are discussed in [Chapter 9](#). Otherwise, therapy is directed at the pulmonary process responsible for right heart failure. Oxygen, salt, and fluid restriction and diuretics are mainstays; digitalis has no place in right heart failure unless atrial fibrillation is present.

Prognosis

Compensated cor pulmonale has the same prognosis as the underlying pulmonary disease. Once congestive signs appear, the average life expectancy is 2-5 years, but survival is significantly longer when uncomplicated emphysema is the cause.

Vizza CD et al: Right and left ventricular dysfunction in patients with severe pulmonary disease. *Chest* 1998;113:576. [\[PMID: 9515827\]](#)

■ NEOPLASTIC DISEASES OF THE HEART

Primary cardiac tumors are rare and constitute only a small fraction of all tumors that involve the heart or pericardium. Metastases from malignant tumors elsewhere are more frequent. Tumors involving the heart are bronchogenic carcinoma, carcinoma of the breast, malignant melanoma, lymphoma, renal cell carcinoma, and, in patients with AIDS, Kaposi's sarcoma. These are often clinically silent but may lead to pericardial tamponade, arrhythmias and conduction disturbances, heart failure, and peripheral emboli. The diagnosis is often made by echocardiography, but MRI and CT scanning are also helpful. Electrocardiography may reveal regional Q waves. The prognosis is dismal; effective treatment is not available.

The commonest primary tumors of the heart are atrial myxomas. These tend to occur in middle age, more often in women than in men. They usually originate in the intraventricular septum, with over 80% growing into the left atrium. Myxomas are benign tumors but can embolize systemically.

Patients with myxoma can present with a picture of a systemic illness, obstruction of blood flow through the heart, or signs of peripheral embolization. The characteristic picture includes fever, malaise, weight loss, leukocytosis, elevated sedimentation rate, and emboli (peripheral or pulmonary, depending on the location of the tumor). This picture is often confused with infective endocarditis, lymphoma, other cancers, or autoimmune diseases. In other cases, the tumor may grow to considerable size and produce symptoms by obstructing mitral flow. Episodic pulmonary edema (classically occurring when an upright posture is assumed) and signs of low output may result. Physical examination may reveal a diastolic sound related to motion of the tumor ("tumor plop") or a diastolic murmur similar to that of mitral stenosis. Right-sided myxomas may cause symptoms of right-sided failure. The diagnosis is established by echocardiography or by pathologic study of embolic material. MRI is also useful. Contrast angiography is usually not necessary. Surgical excision is usually curative.

Other primary cardiac tumors include rhabdomyomas, fibrous histiocytomas, hemangiomas, and a variety of unusual sarcomas. The diagnosis may be supported by an abnormal cardiac contour on x-ray. Echocardiography is usually helpful but may miss tumors infiltrating the ventricular wall. It is likely that MRI will be useful as well.

■ CARDIAC INVOLVEMENT IN MISCELLANEOUS SYSTEMIC DISEASES
