The heart may be involved in a number of systemic syndromes. Many of these have been mentioned briefly in prior subsections of this chapter. The pericardium, myocardium, heart valves, and coronary arteries may be involved either singly or in various combinations. In most cases the cardiac manifestations are not the dominant feature, but in some it is the primary cause of symptoms and may be fatal.

The most common type of myocardial involvement is an infiltrative cardiomyopathy, such as systemic amyloidosis, sarcoidosis, hemochromatosis, or glycogen storage disease. Cardiac calcinosis can occur in hyperparathyroidism (usually the secondary form) and in primary oxalosis. A number of muscular dystrophies can cause a cardiomyopathic picture (particularly Duchenne's, less frequently myotonic dystrophy, and several rarer forms). In addition to left ventricular dysfunction and heart failure, all of these conditions frequently cause conduction abnormalities, which may be the presenting or only feature. The myocardium may also be involved in inflammatory and autoimmune diseases. It is commonly affected in polymyositis and dermatomyositis, but usually this is subclinical. Systemic lupus erythematosus, scleroderma, and mixed connective tissue disease may cause myocarditis, but these commonly also involve the pericardium, coronary arteries, or valves. Several endocrinopathies, including acromegaly, thyrotoxicosis, myxedema, and pheochromocytoma, can produce cardiomyopathies, though again they are usually not isolated features.

Pericardial involvement is quite common in many of the connective tissue diseases. Systemic lupus erythematosus may present with pericarditis, and pericardial involvement is not uncommon (but is less frequently symptomatic) in active rheumatoid arthritis, systemic sclerosis, and mixed connective tissue disease. Endocardial involvement takes the form of patchy fibrous—predominantly on the right side—or inflammatory or sclerotic changes of the heart valves. Carcinoid heart disease typically is manifested as tricuspid regurgitation, and the same may be the case in systemic lupus erythematosus. The hypereosinophilic syndromes involve the endocardium, leading to restrictive cardiomyopathy. A variety of arthritic syndromes are associated with aortic valvulitis or aortitis, including ankylosing spondylitis, rheumatoid arthritis, and Reiter's syndrome, as is tertiary syphilis also. Disorders of elastic tissue (Marfan's syndrome is the most frequent) often affect the ascending aorta, with resulting aneurysmal dilation and aortic regurgitation.

Virtually any vasculitic syndrome can involve the coronary arteries, leading to myocardial infarction. This is most common with polyarteritis nodosa and systemic lupus erythematosus. Two vasculitic syndromes have a particular predilection for the coronary arteries—Kawasaki's disease and Takayasu's disease. In these, myocardial infarction may be the presenting symptom.

■ TRAUMATIC HEART DISEASE

Penetrating wounds to the heart are, of course, usually lethal unless surgically repaired. Stab wounds to the right ventricle occasionally lead to hemopericardium without progressing to tamponade. The clinical result may be constrictive pericarditis, so surgery is recommended even if the patient presents in a stable condition.

Blunt trauma is a more frequent cause of cardiac injuries, particularly outside of the emergency room setting. This type of injury is quite frequent in motor vehicle accidents and may occur with any form of chest trauma. The most common injuries are myocardial contusions or hematomas. These may be asymptomatic (particularly in the setting of more severe injuries) or may present with chest pains of a nonspecific nature or, not uncommonly, with a pericardial component. A minority of patients will develop left or, less commonly, right ventricular aneurysm. Elevations of cardiac enzymes are frequent, and echocardiography may reveal an akinetic segment. Heart failure is uncommon if there are no associated cardiac or pericardial injuries, and conservative management is usually sufficient.

Severe trauma may also cause cardiac or valvular rupture. Cardiac rupture may involve any chamber, but survival is most likely if injury is to one of the atria or the right ventricle. Hemopericardium or pericardial tamponade is the usual clinical presentation, and surgery is almost always necessary. Mitral and aortic valve rupture may occur during severe blunt trauma—the former presumably if the impact occurs during systole and the latter if during diastole. Patients reach the hospital in shock or severe heart failure. Immediate surgical repair is essential. The same types of injuries may result in transection of the aorta, either at the level of the arch or distal to the takeoff of the left subclavian artery. Transthoracic and transesophageal echocardiography are the most helpful and immediately available diagnostic techniques.

Blunt trauma may also result in damage to the coronary arteries. Acute or subacute coronary thrombosis is the most common presentation. The clinical syndrome is one of acute myocardial infarction with attendant electrocardiographic, enzymatic, and contractile abnormalities. Emergent revascularization is sometimes feasible, either by the percutaneous route or by coronary artery bypass surgery. Left ventricular aneurysms are common outcomes of traumatic coronary occlusions. Coronary artery dissection or rupture may also occur in the setting of blunt cardiac trauma.

■ THE CARDIAC PATIENT & SURGERY

Patients with known or suspected cardiac disease undergoing general surgery present a common management problem. Anesthesia and surgery are often associated with marked fluctuations of heart rate and blood pressure, changes in intravascular volume, myocardial ischemia or depression, arrhythmias, decreased oxygenation, increased sympathetic nervous system activity, and alterations in medical regimens and pharmacokinetics. Even with careful monitoring and management, the perioperative period can be very stressful to cardiac patients.

The risk of surgery in patients with heart disease depends primarily on three factors: the type of operation, the nature of the heart disease, and the degree of preoperative stability. The type of anesthesia is less important, though halothane, enflurane, and barbiturates are more severe myocardial depressants, while narcotics have little depressive effect. Spinal and epidural anesthesia were previously thought to be preferable in patients with heart disease, but this has not proved to be the case.

The highest-risk procedures are surgery of the aorta and vascular procedures, in part because these patients often have associated severe coronary disease but also because marked blood pressure and volume changes are common. Major abdominal and thoracic surgery are also associated with substantial cardiovascular risk, especially in older patients with associated cardiovascular disease.

Numerous studies have evaluated the excess risk of surgery in patients with various cardiac diseases. Recent (within 3 months) myocardial infarction, unstable angina, congestive heart failure, and significant aortic stenosis are associated with substantial increases in operative morbidity and mortality rates. Any degree of instability in these conditions magnifies the potential risk. Stable angina, especially in an inactive individual, is also associated with a higher operative risk. Although less common, cyanotic congenital heart disease and severe primary or secondary pulmonary hypertension pose great risks during major surgery. In patients with any of these problems, the risk-to-benefit ratio of the planned surgery should be carefully examined. If the procedure is necessary but elective, consideration should be given to delaying it until full recovery postinfarction and correction or optimal stabilization of the other conditions are achieved. Hypertension should be at least moderately controlled. Patients with severe angina should have increased medical therapy or be considered for revascularization before noncardiac surgery. Symptomatic arrhythmias, nonsustained ventricular tachycardia, or high-grade atrioventricular block and cardiac failure should be treated optimally.

Clinical assessment provides the most useful guidance in determining the risk of noncardiac surgery. Important indicators of high risk have been discussed above. A multifactorial cardiac risk index is included in [Chapter 3 \(Table 3-4\)](#). Patients with known but clinically stable heart disease, such as angina pectoris or prior myocardial infarction, are at intermediate risk, particularly for major operations such as vascular surgery. If a history or symptoms of heart failure are present, assessment of left ventricular function can be very helpful in perioperative management. Although frequently advocated, further noninvasive testing for myocardial ischemia for the purpose of risk stratification is probably overutilized. Tests such as stress myocardial perfusion scintigraphy or dobutamine echocardiography should be reserved for situations in which the results may alter patient management. There is no evidence that prophylactic revascularization by either PTCA or coronary artery bypass surgery alters long-term outcome in patients undergoing noncardiac surgical procedures without the usual indications for PTCA or CABG. Only in the case of major vascular operations is perioperative mortality and morbidity high enough that prophylactic PTCA or CABG should be considered.

However, it should be noted that many patients undergoing surgery have not had recent medical follow-up, and this may be an appropriate opportunity to perform a more complete evaluation. Thus, stress testing may be indicated for selected patients with symptomatic angina or prior myocardial infarction with a view to instituting more comprehensive medical management or performing coronary revascularization to reduce long-term (rather than perioperative) mortality and morbidity. At the least, such patients should not be discharged without a plan for an appropriate follow-up and institution of antihyperlipidemic, aspirin, and beta-blocker therapy as indicated.

Once the decision to operate is made, careful management is essential. Most cardiac medications should be continued preoperatively and postoperatively. In patients judged to be at high risk or medium risk, beta-blockers should be initiated preoperatively unless contraindicated. If practical, oral therapy with atenolol or metoprolol should be started several days prior to surgery and gradually increased to 100 mg in single or divided doses. Otherwise, 15 mg of metoprolol or 10 mg of atenolol may be administered intravenously in 5 mg increments separated by 5-10 minutes prior to induction. These doses should be repeated every 12 hours—or more frequently if excessive tachycardia occurs—until oral therapy can be commenced. Monitoring is an important prophylactic measure in high-risk individuals; hemodynamic monitoring can facilitate early intervention in patients with heart failure, severe valve disease, or easily induced myocardial ischemia. Excessive hypertension, hypotension, and myocardial ischemia should be identified and appropriately treated using rapidly acting agents. Transesophageal echocardiography can also be used for intraoperative monitoring of ischemia, but its value has never been established in well-designed studies. Ischemic events, whether symptomatic or silent, should be vigorously treated.

■ THE CARDIAC PATIENT & PREGNANCY

The management of cardiac disease in pregnancy is discussed in detail in the references listed below. Only a few major points can be covered in this brief section.

CARDIOVASCULAR CHANGES DURING PREGNANCY

Normal physiologic changes during pregnancy can exacerbate symptoms of underlying cardiac disease even in previously asymptomatic individuals. Maternal blood volume rises progressively until the end of the sixth or seventh month. Stroke volume increases over the same time course as a result of the volume change and an increase in ejection fraction. The latter reflects predominantly a decline in peripheral resistance due to vasodilation and the low-resistance shunting through the placenta. The heart rate tends to rise in the third trimester. Overall, cardiac output increases by 30-50%; systolic blood pressure tends to rise slightly or remain unchanged, but diastolic pressure falls significantly.

High cardiac output causes alterations in the cardiac examination. A third heart sound is prominent and normal, and a pulmonary flow murmur is common. Electrocardiographic changes include rate-related decreases in PR and QT intervals, a leftward axis shift, inferior Q waves due to the more horizontal position of the heart, and nonspecific ST-T wave changes.

MANAGEMENT OF PREEXISTING CONDITIONS

The physiologic changes imposed by pregnancy can cause cardiac decompensation in patients with any significant cardiac abnormality, but the most severe problems are encountered in patients with valvular stenosis (especially mitral and aortic stenosis), congenital or acquired abnormalities associated with pulmonary hypertension or right-to-left shunting, congestive heart failure due to any cause, coronary heart disease, and hypertension. Valvular insufficiency or left-to-right shunting often diminishes because of the fall in peripheral resistance and is better tolerated.

Mitral stenosis becomes more hemodynamically severe owing to the increase in diastolic flow and the rate-related shortening of diastole. Left atrial pressures rise, and dyspnea or pulmonary edema can occur in previously asymptomatic individuals. The onset of atrial fibrillation often leads to acute decompensation. Patients with moderate to severe stenosis should have the condition corrected prior to becoming pregnant if possible. Patients who become symptomatic can undergo successful surgery, preferably in the third trimester. Balloon valvuloplasty is an attractive alternative, though radiation exposure to the fetus is unavoidable. Coarctation is usually well tolerated, but patients with symptoms should have corrective surgery before pregnancy. Patients with severe pulmonary hypertension and cyanotic congenital heart disease and those with severe aortic stenosis are at extremely high risk and should attempt to avoid pregnancy.

Asymptomatic arrhythmias should be closely observed unless underlying heart disease is present, in which case they should be treated with drugs. Paroxysmal supraventricular arrhythmias are quite common. Patients with Wolff-Parkinson-White syndrome may have more problems during pregnancy. Therapy is similar to that required for nonpregnant women.

Preexisting systemic hypertension is usually well tolerated and controllable, though the fetal morbidity rate is slightly increased. The incidence of preeclampsia and eclampsia (see [Chapter 18](#)) is increased.

Hydralazine and methyldopa are the antihypertensive agents for which there has been the greatest experience during pregnancy. Diuretics have also been used

frequently, but concern has been raised that intravascular hypovolemia might impair uterine blood flow. Nonetheless, these agents are relatively safe. More recently, there has been considerable use of the combined alpha-beta-blocker labetalol and of calcium channel blockers, which have been proved effective and safe to both the mother and fetus. On the other hand, atenolol has been associated with lower fetal weights. ACE inhibitors and angiotensin II blockers are contraindicated in pregnancy because of the risk of fetal injury. Beta-blockers may retard fetal growth, but experience with them has been generally favorable. Little is known about the safety of most other antihypertensive agents.

CARDIOVASCULAR COMPLICATIONS OF PREGNANCY

Pregnancy-related hypertension (eclampsia and preeclampsia) is discussed in [Chapter 18](#).

Cardiomyopathy of Pregnancy (Peripartum Cardiomyopathy)

In approximately one out of 4000-15,000 patients, dilated cardiomyopathy develops in the final month of pregnancy or within 6 months after delivery. The cause is unclear, but immune and viral causes have been postulated. The course of the disease is variable; many cases improve or resolve completely over several months, but others progress to refractory heart failure. Immunosuppressive therapy has been advocated, but few supportive data are available. Recently, beta-blockers have been administered judiciously to these patients, with at least anecdotal success. Recurrence in subsequent pregnancies is common, particularly if cardiac function has not recovered.

Coronary Artery & Other Vascular Abnormalities

There have been a number of reports of myocardial infarction during pregnancy. It is known that pregnancy predisposes to dissection of the aorta and other arteries, perhaps because of the accompanying connective tissue changes. However, coronary artery dissection is responsible for only a minority of the infarctions, with the majority being caused by atherosclerotic coronary artery disease or coronary emboli. Most of the events occur near term or shortly following delivery. Clinical management is essentially similar to that of other patients with acute infarction.

SPECIAL PROBLEMS

Prophylaxis for Infective Endocarditis

Although there is not universal agreement, many authorities recommend antibiotic prophylaxis during labor for patients at risk for endocarditis, especially if forceps delivery is anticipated or episiotomy is employed. Ampicillin (2 g intravenously or intramuscularly) plus gentamicin (1.5 mg/kg intravenously or intramuscularly [up to 80 mg]) followed by amoxicillin, 1.5 g orally every 6 hours, is the recommended regimen.

Management of Labor

While vaginal delivery is usually well tolerated, unstable patients (including patients with severe hypertension and worsening heart failure) should have cesarean section. An increased risk of aortic rupture has been noted during delivery in patients with coarctation of the aorta and severe aortic root dilation with Marfan's syndrome, and vaginal delivery should be avoided in these conditions.

Cardiovascular Drugs During Pregnancy

Experience during pregnancy with many drugs is limited, and the effect on the fetus is often not well defined. Drugs with known potential for teratogenicity or fetal injury include phenytoin and the ACE inhibitors. Warfarin also presents a risk, but—at least in patients with prosthetic heart valves—many recommend that it be continued until the final 2 weeks. Self-injected low-molecular-weight heparin may be a good alternative, but data regarding efficacy and safety are lacking. Other than antihypertensive agents, which have been discussed above, cardiac drugs that appear safe during pregnancy include the digitalis glycosides, quinidine, procainamide, lidocaine, and short-term verapamil.

CARDIOVASCULAR SCREENING OF ATHLETES

The sudden death of a competitive athlete inevitably becomes an occasion for local if not national publicity. On each such occasion, the public and the medical community ask whether such events could be prevented by more careful or complete screening. Although each such event is tragic, it must be appreciated that there are approximately 5 million competitive athletes at the high school level or above in any given year. The number of cardiac deaths occurring during athletic participation is unknown, but estimates at the high school level range from one in 300,000 to one in 100,000 participants. Death rates among more mature athletes increase as the prevalence of coronary artery disease rises. These numbers highlight the problem of how to screen individual participants. Even an inexpensive test such as an ECG would generate an enormous cost if required of all athletes, and it is likely that few at-risk individuals would be detected. Echocardiography, either as a routine test or as a follow-up examination for abnormal ECGs, would be prohibitively expensive.

Thus, the most feasible approach is that of a careful medical history and cardiac examination performed by personnel aware of the conditions responsible for most sudden deaths in competitive athletes. In a series of 158 athletic deaths in the United States between 1985 and 1995, hypertrophic cardiomyopathy (36%) and coronary anomalies (19%) were by far the most frequent underlying conditions. Left ventricular hypertrophy was present in another 10%, ruptured aorta (presumably due to Marfan's syndrome or cystic medial necrosis) in 6%, myocarditis or dilated cardiomyopathy in 6%, aortic stenosis in 4%, and arrhythmogenic right ventricular dysplasia in 3%.

It is likely that a careful family and medical history and cardiovascular examination will identify some individuals at risk. A family history of premature sudden death or cardiovascular disease or of any of these predisposing conditions should mandate further workup, including an echocardiogram and ECG. Symptoms of chest pain, syncope, or near-syncope also warrant further evaluation. A Marfan-like appearance, significant elevation of blood pressure or abnormalities of heart rate or rhythm, and pathologic heart murmurs or heart sounds should also be investigated before clearance for athletic participation is given. Such an evaluation is recommended before participation at the high school and college levels and every 2 years during athletic competition. Selective use of routine electrocardiography and stress testing is recommended in men above age 40 and women above age 50 who continue to participate in vigorous exercise and at earlier ages when there is a positive family history for premature coronary artery disease or multiple risk factors.

Table 10-1. Differential diagnosis of valvular heart disease.

	Mitral Stenosis	Mitral Regurgitation	Aortic Stenosis	Aortic Regurgitation
Inspection	Malar flush, precordial bulge, and diffuse pulsation in young patients.	Usually prominent and hyperdynamic apical impulse to left of MCL.	Sustained PMI, prominent atrial filling wave.	Hyperdynamic PMI to left of MCL and down. Visible carotid pulsations.
Palpation	"Tapping" sensation over area of expected PMI. Mid-diastolic or presystolic thrill at apex. Small pulse. Right ventricular pulsation left third to fifth ICS parasternally when pulmonary hypertension is present.	Forceful, brisk PMI; systolic thrill over PMI. Pulse normal, small, or slightly collapsing.	Powerful, heaving PMI to left and slightly below MCL. Systolic thrill over aortic area, sternal notch, or carotids. Small and slowly rising carotid pulse.	Apical impulse forceful and displaced significantly to left and down. Prominent carotid pulses. Rapidly rising and collapsing pulses.
Heart sounds, rhythm, and blood pressure	Loud snapping M ₁ . Opening snap following S ₂ along left sternal border or at apex. Atrial fibrillation common. Blood pressurenormal.	M ₁ normal or buried in murmur. Prominent third heart sound. Atrial fibrillation common. Blood pressure normal. Midsystolic clicks may be present.	A ₂ normal, soft, or absent. Paradoxical splitting of S ₂ if A ₂ is audible. Prominent S ₄ . Blood pressure normal, or systolic pressure normal with high diastolic.	S ₁ normal or reduced, A ₂ loud. Wide pulse pressure with diastolic pressure < 60 mm Hg.
Murmurs Location and transmission	Localized at or near apex. Rarely, short diastolic (Graham Steell) murmur along lower left sternal border in severe pulmonary hypertension.	Loudest over PMI; transmitted to left axilla, left infrascapular area. With posterior papillary muscle dysfunction, may transmit to base.	Right second ICS parasternally or at apex, heard in carotids and occasionally in upper interscapular area.	Diastolic: louder along left sternal border in third to fourth interspace. Heard over aortic area and apex. May be associated with low-pitched middiastolic murmur at apex (Austin Flint) in nonrheumatic disease.
Timing	Onset at opening snap ("middiastolic") with presystolic accentuation if in sinus rhythm. Graham Steell begins with P ₂ (early diastole).	Pansystolic: begins with M ₁ and ends at or after A ₂ . May be late systolic in papillary muscle dysfunction.	Midsystolic: begins after M ₁ , ends before A ₂ , reaches maximum intensity in mid systole.	Begins immediately after aortic second sound and ends before first sound.
Character	Low-pitched, rumbling; presystolic murmur merges with loud M ₁ and ends at or after A ₂ . May be late systolic in papillary muscle dysfunction.	Blowing, high-pitched; occasionally harsh or musical.	Harsh, rough.	Blowing, often faint.
Optimum ¹ auscultatory conditions	After exercise, left lateral recumbency. Bell chest piece lightly applied.	After exercise; diaphragm chest piece. In prolapse, findings most prominent while standing.	Patient resting, leaning forward, breath held in full expiration.	Patient leaning forward, breath held in expiration.
X-ray	Straight left heart border. Large left atrium sharply indenting esophagus. Elevation of left main stem bronchus. Large right ventricle and pulmonary artery if pulmonary hypertension is present. Calcification occasionally seen in mitral valve.	Enlarged left ventricle and left atrium.	Concentric left ventricular hypertrophy. Prominent ascending aorta, small knob. Calcified valve common.	Moderate to severe left ventricular enlargement. Prominent aortic knob.
Electrocardiography	Broad P waves in standard leads; broad negative phase of diphasic P in V ₁ . If pulmonary hypertension is present, tall peaked P waves, right axis deviation, or right ventricular hypertrophy appears.	Left axis deviation or frank left ventricular hypertrophy. P waves broad, tall, or notched in standard leads. Broad negative phase of diphasic P in V ₁ .	Left ventricular hypertrophy.	Left ventricular hypertrophy.
Echocardiography M mode	Thickened, immobile mitral valve with anterior and posterior leaflets moving together. Slow early diastolic filling slope, left atrial enlargement, normal to small left ventricle.	Thickened mitral valve in rheumatic disease; mitral valve prolapse; flail leaflet or vegetations may be seen. Enlarged left ventricle with above-normal, normal, or decreased function.	Dense persistent echoes from the aortic valve with poor leaflet excursion, left ventricular hypertrophy with preserved contractile function.	Diastolic vibrations of the anterior leaflet of the mitral valve and septum, early closure of the mitral valve when severe, dilated left ventricle with normal or decreased contractility.
Two-dimensional	Maximum diastolic orifice size reduced, subvalvular apparatus foreshortened, variable thickening of other valves.	Same as M mode but more reliable.	Above plus poststenotic dilation of the aorta, restricted opening of the aortic leaflets, bicuspid aortic valve in about 30%.	Above plus may show vegetations in endocarditis, bicuspid valve, root dilation.
Doppler	Prolonged pressure halftime across mitral valve; indirect evidence of pulmonary hypertension.	Regurgitant flow mapped into left atrium; indirect evidence of pulmonary hypertension.	Increased transvalvular flow velocity, yielding calculated gradient. Valve area estimate using continuity equation.	Demonstrates regurgitation and qualitatively estimates severity.
A ₂ = Aortic second sound ICS = Intercostal space M ₁ = Mitral first sound	MCL = Midclavicular line P ₂ = Pulmonary second sound PMI = Point of maximal impulse	S ₂ = Second heart sound S ₄ = Fourth heart sound V ₁ = Chest ECG lead 1

Table 10-5. Antiarrhythmic drugs.

Agent	Intravenous Dosage	Oral Dosage	Therapeutic Plasma Level	Route of Elimination	Side Effects
Class Ia: Action: Sodium channel blockers: Depress phase 0 depolarization; slow conduction; prolong repolarization. Indications: Supraventricular tachycardia, ventricular tachycardia, prevention of ventricular fibrillation, symptomatic ventricular premature beats.					
Quinidine	6-10 mg/kg (IM or IV) over 20 min (rarely used parenterally)	200-400 mg every 4-6 h or every 8 h (long-acting)	2-5 mg/mL	Hepatic	GI, ?LVF, ?Dig
Procainamide	100 mg/1-3 min to 500-1000 mg; maintain at 2-6 mg/min	50 mg/kg/d in divided doses every 3-4 h or every 6 h (long-acting)	4-10 mg/mL; NAPA (active metabolite), 10-20 µg/mL	Renal	SLE, hypersensitivity, ?LVF
Disopyramide		100-200 mg every 6-8 h	2-8 mg/mL	Renal	Urinary retention, dry mouth, markedly ?LVF
Moricizine		200-300 mg every 8 h	Note: Active metabolites	Hepatic	Dizziness, nausea, headache, ?theophylline level, ?LVF
Class Ib: Action: Shorten repolarization. Indications: Ventricular tachycardia, prevention of ventricular fibrillation, symptomatic ventricular beats.					
Lidocaine	1-2 mg/kg at 50 mg/min; maintain at 1-4 mg/min		1-5 mg/mL	Hepatic	CNS, GI
Mexiletine		100-300 mg every 6-12 h. Maximum: 1200 mg/d	0.5-2 mg/mL	Hepatic	CNS, GI, leukopenia
Phenytoin	50 mg/5 min to 1000 mg (12 mg/kg); maintain at 200-400 mg/d	200-400 mg every 12-24 h	5-20 mg/mL	Hepatic	CNS, GI
Class Ic: Action: Depress phase 0 repolarization; slow conduction. <i>Propafenone</i> is a weak calcium channel- and beta-blocker and prolongs action potential and refractoriness. Indications: Life-threatening ventricular tachycardia or fibrillation; refractory supraventricular tachycardia.					
Flecainide		100-200 mg twice daily	0.2-1 mg/mL	Hepatic	CNS, GI, ??LVF, incessant VT, sudden death
Propafenone		150-300 mg every 8-12 h	Note: Active metabolites	Hepatic	CNS, GI, ??LVF, ?Dig
Class II: Action: Beta-blocker, slows AV conduction. Note: Other beta-blockers may also have antiarrhythmic effects but are not yet approved for this indication in the USA. Indications: Supraventricular tachycardia; may prevent ventricular fibrillation.					
500 mg/kg over 1-2 min; maintain at 25-200 mg/kg/min	Other beta-blockers may be used concomitantly	0.15-2 mg/mL	Hepatic	?LVF, bronchospasm	
Propranolol	1-5 mg at 1 mg/min	40-320 mg in 1-4 doses daily (depending on preparation)	Not established	Hepatic	?LVF, bradycardia, AV block, bronchospasm
Metoprolol	2.5-5 mg	50-200 mg daily	Not established	Hepatic	?LVF, bradycardia, AV block
Class III: Action: Prolong action potential. Indications: <i>Amiodarone</i> :refractory ventricular tachycardia, supraventricular tachycardia, prevention of ventricular tachycardia, atrial fibrillation, ventricular fibrillation; <i>dofetilide</i> : atrial fibrillation and flutter; <i>sotalol</i> : ventricular tachycardia; atrial fibrillation; <i>bretylum</i> : ventricular fibrillation, ventricular tachycardia; <i>ibutilide</i> : conversion of atrial fibrillation and flutter.					
Amiodarone	150 mg infused rapidly, followed by 1 mg/min infusion for 6 hours (360 mg) and then 0.5 mg/min. Additional 150 mg as needed	800-1600 mg/d for 7-21 days; maintain at 100-400 mg/d (higher doses may be needed)	1-5 mg/mL	Hepatic	Pulmonary fibrosis, hypothyroidism, hyperthyroidism, corneal and skin deposits, hepatitis, ?Dig, neurotoxicity, G
Sotalol		80-160 mg every 12 h (higher doses may be used for life-threatening arrhythmias)		Renal (dosing interval should be extended if creatinine clearance is < 60 mL/min)	Early incidence of torsade de pointes, ?LVF, bradycardia, fatigue (and other side effects associated with beta-blockers)
Dofetilide		500 mg twice daily		Renal (dose must be reduced with renal dysfunction)	Torsade de pointes in 3%; interaction with cytochrome P450 inhibitors
Ibutilide	1 mg over 10 minutes, followed by a second infusion of 0.5-1 mg over 10 minutes			Hepatic and renal	Torsade de pointes in up to 5% patients within 3 hours after administration. Patients must be monitored with defibrillator near
Bretylum	5-10 mg/kg over 5-10 min; maintain at 0.5-2 mg/min. Maximum: 30 mg/kg		0.5-1.5 mg/mL	Renal	Hypotension, nausea
Class IV: Action: Slow calcium channel blockers. Indications: Supraventricular tachycardia.					
Verapamil	10-20 mg over 2-20 min; maintain at 5 mg/kg/min	80-120 mg every 6-8 h; 240-360 mg once daily with sustained-release preparation	0.1-0.15 mg/mL	Hepatic	?LVF, constipation, ?Dig, hypotension
Diltiazem	0.25 mg/kg over 2 min; second 0.35 mg/kg bolus after 15 min if response is inadequate; infusion rate, 5-15 mg/h	180-360 mg daily in 1-3 doses depending on preparation (oral forms not approved for arrhythmias)		Hepatic metabolism, renal excretion	Hypotension, ?LVF
Class V: Indications: Supraventricular tachycardia.					
Adenosine	6 mg rapidly followed by 12 mg after 1-2 min if needed. Use half these doses if administered via central line.			Adenosine receptor stimulation, metabolized in blood	Transient flushing, dyspnea, chest pain, AV block, sinus bradycardia effect ? by theophylline, ? by dipyridamole
Digoxin	0.5 mg over 20 min followed by increment of 0.25 or 0.125 mg to 1-1.5 mg over 24 hours	1-1.5 mg over 24-36 hours in 3 or 4 doses; maintenance, 0.125-0.5 mg/d	0.7-2 mg/mL	Renal	AV block, arrhythmias, GI, visual changes
Key: AV = atrioventricular; CNS = central nervous system; ?Dig = elevation of serum digoxin level; GI = gastrointestinal (nausea, vomiting, diarrhea); ?LVF = reduced left ventricular function; NAPA = <i>N</i> -acetylprocainamide; SLE = systemic lupus erythematosus; VT = ventricular tachycardia

Table 10-6. Stages of heart failure.¹

Stage	Description	Examples
A	Patients at high risk of developing heart failure because of the presence of conditions that are strongly associated with the development of heart failure. Such patients have no identified structural or functional abnormalities of the pericardium, myocardium, or cardiac valves and have never shown signs or symptoms of heart failure.	Systemic hypertension; coronary artery disease; diabetes mellitus; history of cardiotoxic drug therapy or alcohol abuse; personal history of rheumatic fever; family history of cardiomyopathy.
B	Patients who have developed structural heart disease that is strongly associated with the development of heart failure but who have never shown symptoms or signs of heart failure.	Left ventricular hypertrophy or fibrosis; left ventricular dilatation or hypocontractility; asymptomatic valvular heart disease; previous myocardial infarction.
C	Patients who have current or prior symptoms of heart failure associated with underlying structural heart disease.	Dyspnea or fatigue due to left ventricular systolic dysfunction; asymptomatic patients who are undergoing treatment for prior symptoms of heart failure.
D	Patients with advanced structural heart disease and marked symptoms of heart failure at rest despite maximal medical therapy and who require specialized interventions.	Patients who are frequently hospitalized for heart failure and cannot be safely discharged from the hospital; patients in the hospital awaiting heart transplantation; patients at home receiving continuous intravenous support for symptom release or being supported with a mechanical circulatory assist device; patients in a hospice setting for the management of heart failure.

Table 10-7. Classification of the cardiomyopathies.

	Dilated	Hypertrophic	Restrictive
Frequent causes	Idiopathic, alcoholic, myocarditis, postpartum, doxorubicin, endocrinopathies, genetic diseases	Hereditary syndrome, possibly chronic hypertension	Amyloidosis, post radiation, post open heart surgery, diabetes, endomyocardial fibrosis
Symptoms	Left or biventricular congestive heart failure	Dyspnea, chest pain, syncope	Dyspnea, fatigue, right-sided congestive heart failure
Physical examination	Cardiomegaly, S ₃ , elevated jugular venous pressure, rales	Sustained point of maximal impulse, S ₄ , variable systolic murmur, bisferiens carotid pulse	Elevated jugular venous pressure, Kussmaul's sign
ECG	ST-T changes, conduction abnormalities, ventricular ectopy	Left ventricular hypertrophy, exaggerated septal Q waves	ST-T changes, conduction abnormalities, low voltage
Chest x-ray	Enlarged heart, pulmonary congestion	Mild cardiomegaly	Mild to moderate cardiomegaly
Echocardiogram, nuclear studies	Left ventricular dilation and dysfunction	Left ventricular hypertrophy, asymmetric septal hypertrophy, small left ventricular size, normal or supranormal function, systolic anterior mitral motion, diastolic dysfunction	Small or normal left ventricular size, normal or mildly reduced left ventricular function
Cardiac catheterization	Left ventricular dilation and dysfunction, high diastolic pressures, low cardiac output	Small, hypercontractile left ventricle, dynamic outflow gradient, diastolic dysfunction	High diastolic pressure, "square root" sign, normal or mildly reduced left ventricular function

■ INTRODUCTION

Fifty million Americans have elevated blood pressure (systolic blood pressure = 140 mm Hg or diastolic blood pressure = 90 mm Hg); of these, 70% are aware of their diagnosis, but only 50% are receiving treatment and only 25% are under control using a threshold criterion of 140/90 mm Hg. Hypertension increases with age and is more common in blacks than in whites. The mortality rates for stroke and coronary heart disease, two of the major complications of hypertension, have declined by up to 60% over the past 3 decades but have recently leveled off. The incidence of end-stage renal disease and the incidence of heart failure—two other conditions in which hypertension plays a major causative role—continues to rise.

Cardiovascular morbidity and mortality increase as both systolic and diastolic blood pressures rise, but in individuals over age 50 the systolic pressure and pulse pressure are better predictors of complications than diastolic pressure. As shown in [Table 11-1](#), hypertension is diagnosed based upon elevations of *either* the systolic or diastolic blood pressure, and the objective of management is to achieve normalization of both.

Blood pressure should be measured with a well-calibrated sphygmomanometer with a cuff of proper size (the bladder width within the cuff should encircle at least 80% of the arm circumference) after the patient has been resting comfortably, back supported in the sitting or supine position, for a least 5 minutes and at least 30 minutes after smoking or coffee ingestion. Because blood pressure readings in many individuals are highly variable—especially in the office setting—the diagnosis of hypertension should be made only after elevation is noted on three readings on different occasions, over a period of several months unless the elevations are severe or associated with symptoms (see [Table 11-1](#)). Transient elevation of blood pressure caused by excitement or apprehension does not constitute hypertensive disease but may indicate a propensity toward its evolution. Ambulatory 24-hour blood pressure monitoring may be helpful in evaluating patients with borderline or variable office blood pressure, approximately 20% of whom will have no evidence of hypertension elsewhere, as well as in assessing resistant hypertension and possible treatment-related hypotensive symptoms. This technique is employed only to address specific management problems because of cost (\$200-\$300).

Continued hypertension does not necessarily indicate the need for pharmacologic treatment. Nonpharmacologic approaches and individualized assessment of the benefit-to-risk ratio of drug therapy should precede pharmacologic management in patients with stage I hypertension (diastolic pressure < 95 mm Hg; systolic < 160 mm Hg). The value of pharmacologic therapy in individual patients with pressures in these ranges is unproved in the absence of other conditions that increase their cardiovascular risk—such as diabetes, dyslipidemia, and smoking—or evidence of target organ damage such as left ventricular hypertrophy, heart failure, coronary artery disease, renal dysfunction, and microalbuminuria

Conversely, as a group, patients with high-normal blood pressures are at increased risk for future cardiovascular events. Treatment of high-risk individuals (those with diabetes, chronic renal insufficiency, atherosclerotic vascular disease) who have high-normal pressures is often indicated, particularly when agents that favorably modify risk factors are employed.

■ APPROACH TO HYPERTENSION

ETIOLOGY & CLASSIFICATION

A. Primary (Essential) Hypertension

Essential hypertension is the term applied to the 95% of cases in which no cause can be identified. This occurs in 10-15% of white adults and 20-30% of black adults in the United States. The onset is usually between ages 25 and 55; it is uncommon before age 20. In young people, secondary hypertension resulting from renal insufficiency, renal artery stenosis, or coarctation of the aorta makes up a greater—but still relatively small—proportion of cases.

Elevations in pressure are often intermittent early in the course. Even in established cases, the blood pressure fluctuates widely in response to emotional stress and physical activity. Blood pressures taken by the patient at home or during daily activities using a portable apparatus are often lower than those recorded in the office, clinic, or hospital and may be more reliable in estimating prognosis. Patients with daytime average pressures less than 135/85 mm Hg have a low rate of cardiovascular complications and a low prevalence of left ventricular hypertrophy, suggesting that this is an appropriate ambulatory blood pressure criterion for diagnosing hypertension.

The pathogenesis of essential hypertension is multifactorial. Genetic factors play an important role. Children with one—and more so with two—hypertensive parents have higher blood pressures. Environmental factors also are significant. Increased salt intake and obesity have long been incriminated. These factors alone are probably not sufficient to raise blood pressure to abnormal levels but are synergistic with a genetic predisposition. Other factors that may be involved in the pathogenesis of essential hypertension are the following.

1. Sympathetic nervous system hyperactivity—This is most apparent in younger hypertensives, who may exhibit tachycardia and an elevated cardiac output. However, correlations between plasma catecholamines and blood pressure are poor. Insensitivity of the baroreflexes may play a role in the genesis of adrenergic hyperactivity.

2. Renin-angiotensin system—Renin, a proteolytic enzyme, is secreted by the juxtaglomerular cells surrounding afferent arterioles in response to a number of stimuli, including reduced renal perfusion pressure, diminished intravascular volume, circulating catecholamines, increased sympathetic nervous system activity, increased arteriolar stretch, and hypokalemia. Renin acts on angiotensinogen to cleave off the ten-amino-acid peptide angiotensin I. This peptide is then acted upon by angiotensin-converting enzyme to create the eight-amino-acid peptide angiotensin II, a potent vasoconstrictor and a major stimulant of aldosterone release from the adrenal glands. The incidence of hypertension and its complications may be increased in individuals with the DD genotype of the allele coding for angiotensin-converting enzyme. Despite the role of this system in the regulation of blood pressure, it probably does not play a primary role in the pathogenesis of most essential hypertension. Patients with low plasma renin activity may have higher intravascular volumes. Black hypertensives and older patients tend to have lower plasma renin activity; plasma levels are classified in relation to dietary sodium intake or urinary sodium excretion. Approximately 10% of essential hypertension patients have high levels, 60% normal, and 30% low.

3. Defect in natriuresis—Normal individuals increase their renal sodium excretion in response to elevations in arterial pressure and to a sodium or volume load. Hypertensive patients, particularly when their blood pressure is normal, exhibit a diminished ability to excrete a sodium load. This defect may result in increased plasma volume and hypertension. During chronic hypertension, a sodium load is usually handled normally.

4. Intracellular sodium and calcium—Intracellular Na⁺ is elevated in blood cells and other tissues in essential hypertension. This may result from abnormalities in Na⁺-K⁺ exchange and other Na⁺ transport mechanisms. An increase in intracellular Na⁺ may lead to increased intracellular Ca²⁺ concentrations as a result of facilitated exchange and might explain the increase in vascular smooth muscle tone that is characteristic of established hypertension.

5. Exacerbating factors—A number of conditions elevate blood pressure, especially in predisposed individuals. **Obesity** is associated with an increase in intravascular volume and an elevated cardiac output. Weight reduction lowers blood pressure modestly. The relationship between **sodium intake** and hypertension remains controversial, and some—not all—hypertensives respond to high salt intake with substantial blood pressure increases. Patients with high normal or elevated blood pressures should consume no more than 100 mmol/d of salt (2.4 g of sodium, 6 g of sodium chloride daily).

Excessive use of **alcohol** also raises blood pressure, perhaps by increasing plasma catecholamines. Hypertension can be difficult to control in patients who consume more than 40 g of ethanol (two drinks) daily or drink in "binges." **Cigarette smoking** raises blood pressure, again by increasing plasma norepinephrine. Although the long-term effect of smoking on blood pressure is less clear, the synergistic effects of smoking and high blood pressure on cardiovascular risk are well documented. The relationship of **exercise** to hypertension is variable. Aerobic exercise lowers blood pressure in previously sedentary individuals, but increasingly strenuous exercise in already active subjects has less effect. The relationship between stress and hypertension is not established. **Polycythemia**, whether primary or due to diminished plasma volume, increases blood viscosity and may raise blood pressure. **Nonsteroidal anti-inflammatory agents** produce increases in blood pressure averaging 5

mm Hg, and are best avoided in patients with borderline or elevated blood pressures. Low **potassium intake** is associated with higher blood pressure in some patients; an intake of 90 mmol/d is recommended.

There is a growing recognition that the complex of abnormalities termed the "metabolic syndrome" is associated with both the development of hypertension and an increased risk of adverse cardiovascular outcomes. The metabolic syndrome (sometimes also called syndrome X or the "deadly quartet") consists of upper body obesity, hyperinsulinemia and insulin resistance, hypertriglyceridemia, and hypertension. Affected patients usually also have low HDL cholesterol levels and have been found to have elevated catecholamines and inflammatory markers such as C-reactive protein.

B. Secondary Hypertension

Approximately 5% of patients with hypertension have specific causes. The history, examination, and routine laboratory tests may identify such patients. In particular, patients who develop hypertension at an early age without a positive family history, those who first exhibit hypertension when over age 50, or those previously well-controlled who become refractory to treatment are more likely to have secondary hypertension. Causes include the following.

1. Estrogen use—A small increase in blood pressure occurs in most women taking oral contraceptives, but considerable rises are noted occasionally. This is caused by volume expansion due to increased activity of the renin-angiotensin-aldosterone system. The primary abnormality is an increase in the hepatic synthesis of renin substrate. Five percent of women taking oral contraceptives chronically will exhibit a rise in blood pressure above 140/90 mm Hg, twice the expected prevalence. Contraceptive-related hypertension is more common in women over 35 years of age, in those who have taken contraceptives for more than 5 years, and in obese individuals. It is less common in those taking low-dose estrogen tablets. In most, hypertension is reversible by discontinuing the contraceptive, but it may take several weeks. Postmenopausal estrogen does not cause hypertension. These agents maintain endothelium-mediated vasodilation.

2. Renal disease—Renal parenchymal disease is the most common cause of secondary hypertension. Hypertension may result from glomerular diseases, tubular interstitial disease, and polycystic kidneys. Most cases are related to increased intravascular volume or increased activity of the renin-angiotensin-aldosterone system. Hypertension accelerates progression of renal insufficiency, and rigorous control to target blood pressure of 130/85 or lower will retard this progression. Diabetic nephropathy is another cause of chronic hypertension. This process is exacerbated by intraglomerular hypertension, itself worsened by systemic hypertension. Dilation of the efferent arterioles by angiotensin-converting enzyme inhibition reduces the rate of progression.

3. Renal vascular hypertension—Renal artery stenosis is present in 1-2% of hypertensive patients. Its cause in most younger individuals is fibromuscular hyperplasia, which is most common in women under 50. The remainder of renal vascular disease is due to atherosclerotic stenoses of the proximal renal arteries. The mechanism of hypertension is excessive renin release due to reduction in renal blood flow and perfusion pressure. Renal vascular hypertension may occur when a single branch of the renal artery is stenotic, but in as many as 25% of patients both arteries are obstructed.

Renal vascular hypertension should be suspected in the following circumstances: (1) if the documented onset is below age 20 or after age 50, (2) if there are epigastric or renal artery bruits, (3) if there is atherosclerotic disease of the aorta or peripheral arteries (15-25% of patients with symptomatic lower limb atherosclerotic vascular disease have renal artery stenosis), or (4) if there is abrupt deterioration in renal function after administration of angiotensin-converting enzyme inhibitors. Additional evaluation is indicated in such patients, especially if hypertension is difficult to control.

There is no ideal screening test for renal vascular hypertension. If the suspicion of renal vascular hypertension is sufficiently high, renal arteriography, the definitive diagnostic test, is the best approach. Where suspicion is moderate to low, radioisotope renography, duplex ultrasound, and MR or CT angiography have all been used successfully, but the results vary greatly between institutions. Except when stenosis is critical (> 80-90%) and unifocal, its significance may be assessed by measuring differences in renin activity between the renal veins. If the lesion is not associated with an increase in renin activity, hypertension often persists despite correction.

Young individuals and low-risk patients of any age who have not responded to medical therapy should have the lesion corrected. Percutaneous intervention with stent placement is the preferred approach for fibromuscular hyperplasia and for discrete stenotic arteriosclerotic lesions that do not involve the renal artery ostium. In older individuals with arteriosclerosis, only a minority experience complete normalization without continued drug therapy. Thus, it is reasonable to manage these patients medically if renal function does not deteriorate. Although ACE inhibitors have improved the success rate of medical therapy of hypertension due to renal artery stenosis, they have been associated with marked hypotension and renal dysfunction in individuals with bilateral renal artery stenosis. Thus, renal function and blood pressure should be closely monitored during the first weeks of therapy in patients in whom this is a consideration.

4. Primary hyperaldosteronism and Cushing's syndrome—Patients with excess aldosterone secretion make up less than 0.5% of all cases of hypertension. The usual lesion is an adrenal adenoma, though some patients have bilateral adrenal hyperplasia. The diagnosis should be suspected when patients present with hypokalemia prior to diuretic therapy associated with excessive urinary potassium excretion (usually > 40 meq/L on a spot specimen) and suppressed levels of plasma renin activity; serum sodium usually exceeds 140 meq/L. Aldosterone concentrations in urine and blood are elevated. The lesion can be demonstrated by CT scanning or MRI. Less commonly, patients with Cushing's syndrome (glucocorticoid excess) may present with hypertension (see [Chapter 26](#)).

5. Pheochromocytoma—Although hypertension due to pheochromocytoma may be episodic, most patients have sustained elevations. The majority of patients have orthostatic falls in blood pressure, the converse of essential hypertension; some develop glucose intolerance. The diagnosis and treatment are discussed in [Chapter 26](#).

6. Coarctation of the aorta—This uncommon cause of hypertension is discussed in [Chapter 10](#).

7. Hypertension associated with pregnancy—Hypertension occurring de novo or worsening during pregnancy is one of the commonest causes of maternal and fetal morbidity and mortality (see [Chapter 18](#)).

8. Other causes of secondary hypertension—Hypertension has also been associated with hypercalcemia due to any cause, acromegaly, hyperthyroidism, hypothyroidism, and a variety of neurologic disorders causing increased intracranial pressure. A number of medications may cause or exacerbate hypertension—most importantly cyclosporine and NSAIDs.

Complications of Untreated Hypertension

Complications of hypertension are related either to sustained elevations of blood pressure, with consequent changes in the vasculature and heart, or to atherosclerosis that accompanies and is accelerated by long-standing hypertension. The excess morbidity and mortality related to hypertension are progressive over the whole range of systolic and diastolic blood pressures; the risk approximately doubles for each 6 mm Hg increase in diastolic blood pressure. However, target-organ damage varies markedly between individuals with similar levels of office hypertension. Ambulatory pressures are more closely related to end-organ damage.

A. Hypertensive Cardiovascular Disease

Cardiac complications are the major causes of morbidity and mortality in essential hypertension, and preventing them is a major goal of therapy. Electrocardiographic evidence of left ventricular hypertrophy is found in up to 15% of chronic hypertensives. It is an indication of increased risk for morbidity and mortality; for any level of blood pressure, its presence is associated with incremental risk. Echocardiographic left ventricular hypertrophy is a powerful predictor of prognosis. Left ventricular hypertrophy may cause or facilitate many cardiac complications of hypertension, including congestive heart failure, ventricular arrhythmias, myocardial ischemia, and sudden death.

Left ventricular diastolic dysfunction, which may present with all of the signs and symptoms of congestive heart failure, is common in patients with long-standing hypertension. The occurrence of heart failure is reduced by 50% with antihypertensive therapy. Hypertensive left ventricular hypertrophy regresses with therapy and is most closely related to the degree of systolic blood pressure reduction. Diuretics have produced equal or greater reductions of left ventricular mass when compared with other drug classes.

B. Hypertensive Cerebrovascular Disease and Dementia

Hypertension is the major predisposing cause of stroke, especially intracerebral hemorrhage but also ischemic cerebral infarction. Cerebrovascular complications are more closely correlated with systolic than diastolic blood pressure. The incidence of these complications is markedly reduced by antihypertensive therapy. Preceding hypertension is associated with a higher incidence of subsequent dementia, both the vascular and the Alzheimer types. Effective blood pressure control may modify the risk or rate of progression of cognitive dysfunction.

C. Hypertensive Renal Disease

Chronic hypertension leads to nephrosclerosis, a common cause of renal insufficiency; aggressive blood pressure control attenuates the process. In patients with hypertensive nephropathy, the blood pressure should be 130/85 mm Hg or lower when proteinuria is present. Secondary renal disease is more common in blacks, particularly when accompanying diabetes is present. Hypertension also plays an important role in accelerating the progression of other forms of renal disease, most commonly diabetic nephropathy. Angiotensin-converting enzyme inhibitors are particularly effective in preventing the latter complication, but these agents appear to prevent the progression of other forms of nephropathy.

D. Aortic Dissection

Hypertension is a contributing factor in many patients with dissection of the aorta. Its diagnosis and treatment are discussed in [Chapter 12](#).

E. Atherosclerotic Complications

Most Americans with hypertension die of complications of atherosclerosis, but the linkage between hypertension and atherosclerotic cardiovascular disease is much less close than that with the previously discussed complications. Effective antihypertensive therapy is thus less successful in preventing complications of coronary heart disease.

Clinical Findings

The clinical and laboratory findings are mainly referable to involvement of the target organs: heart, brain, kidneys, eyes, and peripheral arteries.

A. Symptoms

Mild to moderate essential hypertension is asymptomatic for many years, so the typical patient has no reason to be aware of having hypertension. The most frequent symptom, headache, is also very nonspecific. Suboccipital pulsating headaches, characteristically occurring early in the morning and subsiding during the day, are said to be characteristic, but any type of headache may occur. Accelerated hypertension is associated with somnolence, confusion, visual disturbances, and nausea and vomiting (hypertensive encephalopathy).

Patients with pheochromocytomas that secrete predominantly norepinephrine usually have sustained hypertension but may have episodic hypertension. Attacks (lasting minutes to hours) of anxiety, palpitation, profuse perspiration, pallor, tremor, and nausea and vomiting occur; blood pressure is markedly elevated, and angina or acute pulmonary edema may occur. In primary aldosteronism, patients may have muscular weakness, polyuria, and nocturia due to hypokalemia; malignant hypertension is rare. Chronic hypertension often leads to left ventricular hypertrophy, which may be associated with diastolic or, in late stages, systolic dysfunction. Exertional and paroxysmal nocturnal dyspnea may result, and ischemic heart disease is more common (especially when concomitant coronary artery disease is present).

Cerebral involvement causes (1) stroke due to thrombosis or (2) small or large hemorrhage from microaneurysms of small penetrating intracranial arteries, and focal symptoms depend upon which vessels are involved. Hypertensive encephalopathy is probably caused by acute capillary congestion and exudation with cerebral edema. The findings are usually reversible if adequate treatment is given promptly. There is no strict correlation of diastolic blood pressure with hypertensive encephalopathy; it usually exceeds 130 mm Hg.

B. Signs

Like symptoms, physical findings depend upon the cause of hypertension, its duration and severity, and the degree of effect on target organs.

1. Blood pressure—On initial examination, pressure is taken in both arms and, if lower extremity pulses are diminished or delayed, in the legs to exclude coarctation of the aorta. An orthostatic drop is present in pheochromocytoma. Older patients may have falsely elevated readings by sphygmomanometry because of noncompressible vessels. This may be suspected in the presence of Osler's sign—a palpable brachial or radial artery when the cuff is inflated above systolic pressure. Occasionally, it may be necessary to make direct measurements of intra-arterial pressure, especially in patients with apparent severe hypertension who do not tolerate therapy.

2. Retinas—Narrowing of arterial diameter to less than 50% of venous diameter, copper or silver wire appearance, exudates, hemorrhages, or papilledema are associated with a worse prognosis.

3. Heart and arteries—Left ventricular enlargement with a left ventricular heave indicates severe or long-standing hypertrophy. Older patients frequently have systolic ejection murmurs resulting from calcific aortic sclerosis, and these may evolve to significant aortic stenosis in some individuals. Aortic insufficiency may be auscultated in up to 5% of patients, and hemodynamically insignificant aortic insufficiency can be detected by Doppler echocardiography in 10-20%. A presystolic (S₄) gallop due to decreased compliance of the left ventricle is quite common in patients with sinus rhythm.

4. Pulses—The timing of upper and lower extremity pulses should be compared to exclude coarctation of the aorta. All major peripheral pulses should be evaluated to exclude aortic dissection and peripheral atherosclerosis, which may be associated with renal artery involvement.

C. Laboratory Findings

Recommended testing includes the following: hemoglobin; urinalysis and renal function studies, to detect hematuria, proteinuria, and casts, signifying primary renal disease or nephrosclerosis; serum K⁺, to seek mineralocorticoid excess; fasting blood sugar level, since hyperglycemia is noted in diabetes and pheochromocytoma; plasma lipids, as an indicator of atherosclerosis risk and an additional target for therapy; and serum uric acid, since if elevated it is a relative contraindication to diuretic therapy.

D. Electrocardiography and Chest X-Ray

Electrocardiographic criteria are highly specific but not very sensitive for left ventricular hypertrophy. The "strain" pattern of ST-T wave changes is a sign of more advanced disease and is associated with a poor prognosis. A chest x-ray is not necessary in the work-up for uncomplicated hypertension since it usually does not yield additional information.

E. Echocardiography

Although echocardiography has been advocated to determine the need for drug therapy in patients with borderline or mildly elevated pressures, it is unusual to find left ventricular mass readings above the upper 75% confidence limits in the absence of systolic hypertension. The primary role of echocardiography should be to evaluate patients with clinical symptoms or signs of cardiac disease.

F. Diagnostic Studies

Only if the clinical presentation or routine tests suggest secondary or complicated hypertension are additional diagnostic studies indicated. These may include tests for endocrine causes of hypertension, renal ultrasound to diagnose primary renal disease (polycystic kidneys, obstructive uropathy), and testing for renal artery stenosis. Further evaluation may include abdominal imaging studies (ultrasound, CT scan, or MRI) or renal arteriography.

G. Summary

Since most hypertension is "primary," few studies are necessary beyond those listed above. If conventional therapy is unsuccessful or if symptoms suggest a secondary cause, further studies are indicated.

Nonpharmacologic Therapy

Lifestyle modification may have an impact on morbidity and mortality. A diet rich in fruits, vegetables, and low-fat dairy foods and low in saturated and total fats (DASH diet) has been shown to lower blood pressure. Additional measures can prevent or mitigate hypertension or its cardiovascular consequences as shown in [Table 11-2](#).

All patients with high-normal or elevated blood pressures, those who have a family history of cardiovascular complications of hypertension, and those who have multiple coronary risk factors should be counseled about nonpharmacologic approaches to lowering blood pressure. Approaches of proved but modest value include weight reduction, reduced alcohol consumption, and in some patients, reduced salt intake. Gradually increasing activity levels should be encouraged in previously sedentary patients, but strenuous exercise training programs in already active individuals may have less benefit. Calcium and potassium supplements have been advocated, but their ability to lower blood pressure is limited.

Smoking cessation will reduce overall cardiovascular risk.

Who Should Be Treated with Medications? (Tables 11-3 and 11-4)

Many excellent trials have shown that drug therapy of patients with stage II and III hypertension reduces the incidence of stroke by 30-50%, congestive heart failure by 40-50%, and progression to accelerated hypertension syndromes. The decreases in fatal and nonfatal coronary heart disease and cardiovascular and total mortality have been less dramatic, ranging from 10% to 15%. This lesser decrease in coronary heart disease has generated controversy. Some have attributed the lesser benefit to characteristics of the drugs (primarily diuretics and beta-blockers), such as their adverse effect on lipid profiles and electrolyte balance. Others believe it is due to the more chronic and multifactorial nature of coronary artery disease, the generally low-risk populations included in trials, and the large number of crossovers from placebo to active therapy. Several studies in older persons with predominantly systolic hypertension have confirmed that antihypertensive therapy prevents fatal and nonfatal myocardial infarction and overall cardiovascular mortality. These trials have also placed the focus on control of systolic blood pressure—in contrast to the historical emphasis on diastolic blood pressures.

Goals of Treatment

The decision to initiate drug therapy should be based upon the assessment of overall cardiovascular risk rather than the level of blood pressure alone. Table 11-3 lists the major risk factors for cardiovascular morbidity and mortality and the cardiovascular manifestations that predispose to further complications. Table 11-4 sets forth the criteria used to institute therapy. Thus, patients with systolic blood pressure over 160 mm Hg with diastolic blood pressure over 90 mm Hg after repeated measurements should be treated to a goal blood pressure below 140 mm Hg systolic and below 90 mm Hg diastolic. Those with stage I hypertension and at least one additional indicator of increased risk should be treated also. Very high risk groups, such as diabetics, patients with nephropathy, and (most likely) patients with heart failure and coronary disease benefit from antihypertensives even when their blood pressure is in the high-normal range. There has been concern that excessive lowering of diastolic blood pressures may induce myocardial ischemia. On balance, a lower target blood pressure (130/85 mm Hg) is indicated in high-risk individuals, such as patients with diabetes or renal dysfunction, and in selected individuals with clinical cardiovascular disease.

DRUG THERAPY

General Principles

There are now many classes of potentially antihypertensive drugs of which five (diuretics, beta-blockers, angiotensin-converting enzyme [ACE] inhibitors, calcium channel blockers, and angiotensin II receptor blockers [ARBs]) are suitable for initial or single-drug therapy based on efficacy and tolerability. A number of considerations enter into the selection of the initial drug for a given patient. These include the weight of evidence for beneficial effects on clinical outcomes, the safety and tolerability of the drug, its cost, demographic differences in response, concomitant medical conditions, and lifestyle issues. The specific classes of antihypertensive medications are discussed below, and guidelines for the choice of initial medications are offered in subsequent paragraphs.

Current Antihypertensive Agents (See Tables 11-5, 11-6, 11-7, 11-8, 11-9 for dosages.)

A. Diuretics (Table 11-5.)

Diuretics are the antihypertensives that have been most extensively studied and most consistently effective in clinical trials. They lower blood pressure initially by decreasing plasma volume (by suppressing tubular reabsorption of sodium, thus increasing the excretion of sodium and water) and cardiac output, but during chronic therapy their major hemodynamic effect is reduction of peripheral vascular resistance. Most of the antihypertensive effect of these agents is achieved at lower dosages than used previously (typically, 12.5 or 25 mg of hydrochlorothiazide or equivalent), but their biochemical and metabolic effects are dose-related. The thiazide diuretics are the most widely used. During chronic therapy, hydrochlorothiazide may be administered every other day with undiminished efficacy. The loop diuretics (such as furosemide) may lead to electrolyte and volume depletion more readily than the thiazides and have short durations of action; therefore, they should not be used in hypertension except in the presence of renal dysfunction (serum creatinine above 2.5 mg/dL). Relative to the beta-blockers and the ACE inhibitors, diuretics are more potent in blacks, older individuals, the obese, and other subgroups with increased plasma volume or low plasma renin activity. Interestingly, they are relatively more effective in smokers than in nonsmokers. Chronic diuretic administration also mitigates the loss of bone mineral content in older women at risk for osteoporosis.

Overall, diuretics administered alone control blood pressure in 50% of patients with mild to moderate hypertension and can be used effectively in combination with all other agents. They are also useful for lowering isolated or predominantly systolic hypertension. Some observations suggest that the use of thiazide diuretics as initial therapy has been associated with greater reductions in myocardial infarction than beta-blockers.

The adverse effects of diuretics relate chiefly to the metabolic changes listed in Table 11-5. Impotence, skin rashes, and photosensitivity are less frequent. Hypokalemia has been a concern but is uncommon at the recommended dosages (12.5-25 mg hydrochlorothiazide). The risk can be minimized by limiting salt intake or a high-potassium diet; potassium replacement is not usually required to maintain serum K^+ at > 3.5 mmol/L. Higher serum levels are prudent in patients at special risk from intracellular potassium depletion, such as those taking digoxin or who have a history of ventricular arrhythmias. If higher doses of diuretic are required, the drug should be used in combination with a potassium-sparing agent or with an ACE inhibitor or ARB. Diuretics reduce insulin sensitivity and cause modest increases in blood glucose. Compared with ACE inhibitors and ARBs, diuretic therapy is associated with a slightly higher incidence of new-onset diabetes. Diuretics also increase serum uric acid and may precipitate gout. Increases in blood glucose, triglycerides, low-density lipoprotein cholesterol, and plasma insulin may occur but are relatively minor during long-term low-dose therapy.

B. Beta-Adrenergic Blocking Agents (Table 11-6.)

These drugs are effective in hypertension because they decrease the heart rate and cardiac output. Even after continued use of beta-blockers, cardiac output remains lower and systemic vascular resistance higher with agents that do not have intrinsic sympathomimetic or alpha-blocking activity. The beta-blockers also decrease renin release and are more efficacious in populations with elevated plasma renin activity, such as younger white patients. They neutralize the reflex tachycardia caused by vasodilators and are especially useful in patients with associated conditions that benefit from the cardioprotective effects of these agents. These include individuals with angina pectoris, chronic previous myocardial infarction, and stable congestive heart failure as well as those with migraine headaches and somatic manifestations of anxiety. In some clinical trials, beta-blockers have not been as effective as diuretics in preventing first myocardial infarctions.

Although all beta-blockers appear to be similar in antihypertensive potency, controlling approximately 50% of patients, they differ in a number of pharmacologic properties (these differences are summarized in Table 11-6), including those relatively specific to the cardiac β_1 receptors (cardioselectivity) and whether they also block the β_2 receptors in the bronchi and vasculature; at higher dosages, however, all agents are nonselective. The beta-blockers also differ in their pharmacokinetics and lipid solubility—which determines whether they cross the blood-brain barrier and affect the incidence of central nervous system side effects—and route of metabolism. Labetalol and carvedilol are combined alpha- and beta-blockers and, unlike most beta-blockers, decrease peripheral vascular resistance.

The side effects of all beta-blockers include inducing or exacerbating bronchospasm in predisposed patients (asthmatics, some COPD patients), sinus node dysfunction and atrioventricular conduction depression (resulting in bradycardia or AV block), precipitating or worsening clinically important left ventricular failure, nasal congestion, Raynaud's phenomenon, and central nervous system symptoms with nightmares, excitement, depression, and confusion. Fatigue, lethargy, and impotence may occur. All beta-blockers tend to increase plasma triglycerides. The nonselective and, to a lesser extent, the cardioselective (β_1 -selective) beta-blockers tend to depress the protective HDL fraction of plasma cholesterol. As with diuretics, the changes are blunted with time and dietary changes.

Beta-blockers have traditionally been considered contraindicated in patients with congestive heart failure. Evolving experience suggests that they have a propitious effect on the natural history of patients with chronic stable heart failure and reduced ejection fractions (see Chapter 10). Beta-blockers are used cautiously in patients with type 1 diabetes, since they can mask the symptoms of hypoglycemia and prolong these episodes by inhibiting gluconeogenesis. Although they may increase blood glucose levels in type 2 diabetics, the prognosis of these patients on balance is improved. These drugs should also be used with caution in patients with advanced peripheral vascular disease associated with rest pain or nonhealing ulcers, but they are generally well tolerated in patients with mild claudication.

C. Angiotensin-Converting Enzyme (ACE) Inhibitors (Table 11-7.)

These drugs are being increasingly used as the initial medication in mild to moderate hypertension. Their primary mode of action is inhibition of the renin-angiotensin-aldosterone system, but they also inhibit bradykinin degradation, stimulate the synthesis of vasodilating prostaglandins, and, sometimes, reduce sympathetic nervous system activity. These latter actions may explain why they exhibit some effect even in patients with low plasma renin activity. The ACE inhibitors appear to be more effective in younger whites. They are relatively less effective in blacks and older persons and in predominantly systolic hypertension. While as single therapy they achieve adequate antihypertensive control in only about 40-50% of patients, the combination of an ACE inhibitor and a diuretic or calcium channel blocker is potent.

The ACE inhibitors are the agents of choice in type I diabetics with frank proteinuria or evidence of renal dysfunction, because they delay the progression to end-stage renal disease. Many authorities have expanded this indication to include type II diabetics and type I diabetics with microalbuminuria, even when they do not meet the usual criteria for antihypertensive therapy. The Heart Outcomes Prevention Evaluation (HOPE) trial demonstrated that the ACE inhibitor ramipril reduces the number of cardiovascular deaths, nonfatal myocardial infarctions, and nonfatal strokes and reduces also the incidences of new-onset heart failure, renal dysfunction, and new-onset diabetes in a population of patients at high risk for vascular events. Although this was not specifically a hypertensive population, the benefits were associated with a modest reduction in blood pressure and the results inferentially support the use of ACE inhibitors in similar hypertensive patients. ACE inhibitors may also delay the progression of other forms of renal disease. They are a drug of choice (usually in conjunction with a diuretic and a beta-blocker) in patients with congestive heart failure and are indicated also in asymptomatic patients with reduced ejection fractions whether due to myocardial infarction or to other causes.

ACE inhibitors have effects on mortality and most cardiovascular outcomes similar to those achieved with diuretics and beta-blockers. However, compared with calcium channel blockers, ACE inhibitors are associated with lower incidences of coronary events and heart failure.

An advantage of the ACE inhibitors is their relative freedom from troublesome side effects. Severe hypotension can occur in patients with bilateral renal artery stenosis; acute renal failure may ensue. Hyperkalemia may develop in patients with intrinsic renal disease and type IV renal tubular acidosis (commonly seen in diabetics) and in the elderly. A chronic dry cough is common, seen in 10% of patients or more, and may require stopping the drug. Dizziness occurs but may not be related to the degree of blood pressure lowering. Skin rashes are observed with any ACE inhibitor. Taste alterations are seen more often with captopril than with the non-sulphydryl-containing agents (enalapril and lisinopril) but often disappear with continued therapy. Angioedema is an uncommon but potentially dangerous side effect of all agents of this class because of their inhibition of kininase.

D. Angiotensin II Receptor Blockers (ARBs) (Table 11-7.)

Although losartan, the first member of this group, was less potent than high doses of ACE inhibitors in reducing blood pressure, the newer angiotensin II antagonists (valsartan, irbesartan, candesartan, telmisartan, and eprosartan) appear to be equipotent to ACE inhibitors. A growing body of data indicates that ARBs can improve cardiovascular outcomes in hypertensives and patients with related conditions such as heart failure and type 2 diabetes with nephropathy. ARBs have not been compared with ACE inhibitors in randomized controlled trials in patients with hypertension, but two trials comparing losartan with captopril in heart failure and post-myocardial infarction left ventricular dysfunction showed trends toward worse outcomes in the losartan group. Whether this suggestion of less efficacy is specific to losartan or may also be true for other ARBs is as yet unknown. However, the Losartan Intervention for Endpoints (LIFE) trial in nearly 9000 hypertensive patients with electrocardiographic evidence of left ventricular hypertrophy—comparing losartan with the beta-blocker atenolol as initial therapy—demonstrated a significant reduction in stroke with losartan. Of note is that in diabetics, death and myocardial infarction were also reduced, and there was a lower occurrence of new-onset diabetes. In this trial, as in the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) with an ACE inhibitor, blacks exhibited less blood pressure reduction and less benefit with regard to clinical endpoints.

Unlike ACE inhibitors, the angiotensin II receptor blockers do not cause cough and are only infrequently associated with skin rashes, the most common side effects of the ACE inhibitors. However, they still present a risk of hypotension and renal failure in patients with bilateral renal artery stenosis and hyperkalemia, and, rarely—but much less frequently than with ACE inhibitors—angioedema. Because of their higher costs, limited long-term experience, and unproved benefits in heart failure and diabetes, the angiotensin II blockers should be reserved primarily for patients who develop cough when taking ACE inhibitors.

E. Calcium Channel Blocking Agents (Table 11-8.)

These agents act by causing peripheral vasodilation, which is associated with less reflex tachycardia and fluid retention than other vasodilators. They are effective as single-drug therapy in approximately 60% of patients in all demographic groups and all grades of hypertension. As a result, they may be preferable to beta-blockers and ACE inhibitors in blacks and older subjects. Calcium channel blockers and diuretics are less additive when given together than when either is combined with beta-blockers or ACE inhibitors. However, verapamil and diltiazem should be combined cautiously with beta-blockers because of their potential for depressing atrioventricular conduction and sinus node automaticity as well as contractility.

Although concerns have previously been raised about increased risk of myocardial infarction in hypertensive patients and of higher mortality in acute coronary syndromes treated with calcium channel blockers, this was not the case with amlodipine in the ALLHAT trial. Diabetic patients receiving calcium channel blockers may have higher rates of heart failure and myocardial infarction than those receiving ACE inhibitors, and in other studies heart failure has been more common than in patients treated with diuretics or ACE inhibitors. Whether these outcomes reflect beneficial effects of the comparators or specific risks of calcium channel blockers is uncertain. A protective effect against stroke with calcium blockers is well established, and in two trials (ALLHAT and the Systolic Hypertension in Europe trial) these agents appeared to be more effective than diuretic-based therapy.

The most common side effects of calcium channel blockers are headache, peripheral edema, bradycardia, and constipation (especially with verapamil in the elderly). The dihydropyridine agents—nifedipine, nicardipine, isradipine, felodipine, nisoldipine, and amlodipine—are more likely to produce symptoms of vasodilation, such as headache, flushing, palpitations, and peripheral edema. Calcium channel blockers have negative inotropic effects and may cause or exacerbate heart failure in patients with cardiac dysfunction. Amlodipine is the only calcium channel blocker with established safety in patients with severe heart failure. Most calcium blockers are now available in preparations that can be administered once daily.

F. Alpha-Adrenoceptor Antagonists (Table 11-9.)

Prazosin, terazosin, and doxazosin block postsynaptic alpha receptors, relax smooth muscle, and reduce blood pressure by lowering peripheral vascular resistance. These agents are effective as single-drug therapy in some individuals, but tachyphylaxis may appear during long-term therapy and side effects are relatively common. These include marked hypotension and syncope after the first dose, which, therefore, should be small and be given at bedtime. Postdosing palpitations, headache, and nervousness may continue to occur during chronic therapy; they may be less frequent or severe with doxazosin because of its more gradual onset of action.

Unlike the beta-blockers and diuretics, the alpha-blockers have no adverse effect on serum lipid levels—in fact, they increase high-density lipoprotein cholesterol while reducing total cholesterol. Whether this is beneficial in the long term has not been established. In the Antihypertensive Lipid Lowering Heart Attack Trial (ALLHAT), subjects receiving doxazosin as initial therapy had a significant increase in heart failure hospitalizations and a higher incidence of stroke relative to the subjects receiving diuretics and were removed from the study. In sum, alpha-blockers should generally not be used as initial agents to treat hypertension—except perhaps in men with symptomatic prostatism.

G. Drugs With Central Sympatholytic Action (Table 11-9.)

Methyldopa, clonidine, guanabenz, and guanfacine lower blood pressure by stimulating alpha-adrenergic receptors in the central nervous system, thus reducing efferent peripheral sympathetic outflow. These agents are effective as single therapy in some patients, but they are usually employed as second- or third-line agents because of the high frequency of drug intolerance, including sedation, fatigue, dry mouth, postural hypotension, and impotence. An important concern is rebound hypertension following withdrawal. Methyldopa also causes hepatitis and hemolytic anemia and is avoided except in individuals who have already tolerated chronic therapy. There is considerable experience with methyldopa in pregnant women, and it is still used for this population. Clonidine is available in patches and may have particular value in patients in whom compliance is a troublesome issue.

H. Arteriolar Dilators (Table 11-9.)

Hydralazine and minoxidil relax vascular smooth muscle and produce peripheral vasodilation. When given alone, they stimulate reflex tachycardia, increase myocardial contractility, and cause headache, palpitations, and fluid retention. They are usually given in combination with diuretics and beta-blockers in resistant patients. Hydralazine produces frequent gastrointestinal disturbances and may induce a lupus-like syndrome. Minoxidil causes hirsutism and marked fluid retention; this agent is reserved for the most refractory of patients.

I. Peripheral Sympathetic Inhibitors (Table 11-9.)

These agents are now used infrequently and usually in refractory hypertension. Reserpine remains a cost-effective antihypertensive agent. Its reputation for inducing mental depression and its other side effects—sedation, nasal stuffiness, sleep disturbances, and peptic ulcers—has made it unpopular, though these problems are uncommon at low dosages. Guanethidine and guanadrel inhibit catecholamine release from peripheral neurons but frequently cause orthostatic hypotension (especially in the morning or after exercise), diarrhea, and fluid retention.

Developing an Antihypertensive Regimen

A few years ago there were only a few large trials examining the impact of antihypertensive therapy on clinical outcomes; these indicated that diuretic-based—and, to a

lesser extent, beta-blocker-based—"step therapy" prevented stroke, with a lesser impact on mortality and myocardial infarction. [Figure 11-1](#) summarizes the data from a number of these trials and supports the overall conclusion that antihypertensive therapy with diuretics and beta-blockers has a major beneficial effect on a broad spectrum of cardiovascular outcomes. Similar placebo-controlled data pertaining to the newer agents are generally lacking except for stroke reduction with the calcium channel blocker nitrendipine in the Systolic Hypertension in Europe trial, although there is substantial evidence that ACE inhibitors and to a lesser extent ARBs reduce adverse cardiovascular outcomes in other related populations (patients with diabetic nephropathy, heart failure, or post-myocardial infarction, and individuals at high risk for cardiovascular events).

Therefore, all of these agents have been recommended and utilized as first-line therapy in some populations, but until recently there were few trials that compared different antihypertensive agents with clinical outcome endpoints. Now such comparative data are abundantly available. Most large clinical trials that have compared outcomes in relatively unselected patients have failed to show a difference between newer agents—such as ACE inhibitors, calcium channel blockers, and angiotensin receptor blockers—and the older diuretics and beta-blockers with regard to survival, myocardial infarction, and stroke. The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), completed in 2002, found that treatment initiated with the thiazide-like diuretic chlorthalidone, the ACE inhibitor lisinopril, and the calcium antagonist amlodipine was associated with similar incidences of the primary outcomes of death and myocardial infarction. There were somewhat fewer strokes with amlodipine and more with lisinopril, though the latter trend was seen only in blacks, who had a lesser blood pressure response with this agent. The development or worsening of heart failure was a common outcome in this trial and was more frequent in patients randomized to amlodipine and lisinopril than to chlorthalidone. A similar difference in the incidence of heart failure in ACE inhibitor patients has not been observed in other comparative antihypertensive trials, and, as with the difference in stroke, appears to occur mainly in blacks. Of note is a 6073-patient Australian trial published in 2003 comparing ACE inhibitor-based therapy with diuretic-based therapy. It found an 11% reduction in its primary outcomes—death from any cause or all cardiovascular events—and no difference in stroke events in the ACE inhibitor group.

The lack of superiority of other antihypertensive agents has led experts to recommend diuretics as the first-line treatment of most older patients with hypertension because these agents are at least as effective and less expensive. Specific exceptions are appropriate for individuals who have specific indications for another class of agent, such as post-myocardial infarction patients (beta-blockers, ACE inhibitors), patients with diabetic nephropathy (ACE inhibitors, ARBs), or other comorbid conditions. [Table 11-10](#) provides suggestions for individualizing first-line treatment.

However, in trials that include patients with systolic hypertension, the large majority of patients require two or more medications and even then a substantial proportion of patients do not achieve the goal systolic blood pressure of < 140 mm Hg (130 mm Hg in diabetics). In diabetic patients, three or four drugs are usually required to reduce systolic blood pressure to < 140 mm Hg, and many patients cannot be maintained at the recommended goal of < 130 mm Hg with any combination. As a result, debating the appropriate first-line agent is less relevant than determining the most appropriate combinations of agents. This has led many experts and practitioners to reconsider the use of fixed-dose combination antihypertensive agents as first-line therapy in patients with substantially elevated systolic pressures (> 160 mm Hg) or difficult-to-control hypertension (associated diabetes or renal dysfunction). Based both on antihypertensive efficacy and complementarity, combinations of a diuretic and an ACE inhibitor (or an ARB if ACE-intolerant) or a diuretic and a beta-blocker are recommended. The initial use of low-dose combinations allows faster blood pressure reduction without substantially higher intolerance rates and is likely to be better accepted by patients.

When an initial agent is selected, the patient should be informed of common side effects and the need for diligent compliance. Treatment should start at a low dose, and unless the initial blood pressure is very high (> 180/110 mm Hg), follow-up visits should usually be at 4- to 6-week intervals to allow for full medication effects to be established (especially with diuretics) before further titration or adjustment. If, after titration to usual doses, the patient has shown a discernible but incomplete response and a good tolerance of the initial drug, a second medication should be added. If the initial medication was a diuretic or a calcium channel blocker, the second agent should be a beta-blocker, ACE inhibitor, or angiotensin II blocker, since these combinations are generally complementary. If the initial drug was a beta-blocker, ACE inhibitor, or angiotensin II blocker, the second drug should be a diuretic. On the other hand, if the first agent showed no effect, another should be substituted. Again, if the first drug was a diuretic or a calcium channel blocker, the substituted drug should be a beta-blocker, ACE inhibitor, or angiotensin II blocker; if a beta-blocker, ACE inhibitor, or angiotensin II blocker, the substituted agent should be a diuretic or a calcium channel blocker. If therapy was initiated with a combination of a diuretic and an ACE inhibitor, ARB, or beta-blocker and the patient remains below goal, addition of a calcium blocker is the recommended approach.

Most patients with hypertension can be controlled with one-drug or two-drug regimens that combine complementary agents. A minority of patients require three, four, or even more medications in combination. As discussed above, multidrug regimens are more frequently needed in patients with high systolic pressures and in diabetics. Unless absolutely contraindicated, one of these components should be a diuretic. Particularly useful multidrug regimens are (1) a diuretic plus an ACE inhibitor (or ARB if ACE-intolerant) plus a calcium channel blocker (or other vasodilator), (2) a diuretic plus a beta-blocker plus either a calcium channel blocker or a sympatholytic (or both), and (3) a calcium channel blocker (in patients in whom a diuretic is not tolerated) plus an ACE inhibitor plus either a sympatholytic or a beta-blocker (or both). Patients who are compliant with their medications and who do not respond to these combinations should usually be evaluated for secondary hypertension before proceeding to more complex regimens.

Special Considerations in the Treatment of Diabetic Hypertensive Patients

Hypertensive patients with diabetes are at particularly high risk for cardiovascular events. More aggressive treatment of hypertension in these patients prevents progressive nephropathy, myocardial infarction, and stroke. Treatment recommendations suggest a target of < 130/85 mm Hg. Because of their beneficial effects in diabetic nephropathy, ACE inhibitors (and angiotensin II receptor blockers in intolerant patients) should be part of the initial treatment regimen. However, most diabetics require combinations of three to five agents to achieve these goals, usually including a diuretic and a calcium channel blocker or beta-blocker. In addition to rigorous blood pressure control, management of diabetics should include aggressive treatment of other risk factors and early intervention for coronary disease and left ventricular dysfunction.

Hypertension Management in Blacks

Substantial evidence indicates that blacks are not only more likely to become hypertensive and more susceptible to the cardiovascular complications of hypertension—they also respond differently to many antihypertensive medications. This may reflect genetic differences in the cause of hypertension or the subsequent responses to it, differences in occurrence of comorbid conditions such as diabetes or obesity, or environmental factors such as diet, activity, stress, or access to health care services. In any case, as in all hypertensives, a multifaceted program of education and life-style modification is warranted. Because it appears that ACE inhibitors and ARBs—in the absence of concomitant diuretics—are less effective in blacks than in whites, initial therapy should generally be a diuretic or a diuretic combination, with the use of additional agents as discussed above. Some experts have recommended a goal blood pressure of 130/80 mm Hg for blacks at high risk for cardiovascular events or with diabetes.

Treatment of Additional Cardiovascular Risk Factors

Since the goal is to reduce cardiovascular morbidity and mortality, attention must be paid to the management of other risk factors. Aggressive reduction of elevated LDL-cholesterol levels reduces the risk of myocardial infarction and death in patients with multiple risk factors. Thus, if LDL-cholesterol levels remain over 130 mg/dL following an attempt at dietary intervention, drug therapy is indicated in most hypertensives. Levels under 100 mg/dL should be achieved in patients with coronary artery disease, cerebrovascular disease, peripheral arterial disease, or diabetes. Smoking cessation, regular exercise, and weight loss when indicated are other important features of hypertension management.

Follow-Up of the Treated Hypertensive

Once blood pressure is controlled on a well-tolerated regimen, follow-up visits can be infrequent and laboratory testing limited to tests appropriate for the patient and the medications utilized. Yearly monitoring of blood lipids is recommended, and an ECG should be repeated at 2- to 4-year intervals depending on whether initial abnormalities are present, the presence of coronary risk factors, and age.

Patients who have had excellent blood pressure control for several years, especially if they have lost weight and initiated favorable lifestyle modifications, should be considered for "step-down" of therapy to determine if lower doses or discontinuing of medications is feasible.

HYPERTENSIVE URGENCIES & EMERGENCIES

Hypertensive emergencies have become less frequent in recent years but still require prompt recognition and aggressive but careful management. A spectrum of acute presentations exists, and the appropriate therapeutic approach varies accordingly.

Hypertensive urgencies are situations in which blood pressure must be reduced within a few hours. These include patients with asymptomatic severe hypertension (systolic blood pressure > 220 mm Hg or diastolic pressure > 125 mm Hg that persist after a period of observation) and with optic disk edema, progressive target organ complications, and severe perioperative hypertension. Elevated blood pressure levels alone—in the absence of symptoms or new or progressive target organ damage—rarely require emergency therapy. Parenteral drug therapy is not usually required, and partial reduction of blood pressure with relief of symptoms is the goal.

Hypertensive emergencies require substantial reduction of blood pressure within 1 hour to avoid the risk of serious morbidity or death. Although blood pressure is usually strikingly elevated (diastolic pressure > 130 mm Hg), the correlation between pressure and end-organ damage is often poor. It is the latter that determines the seriousness of the emergency and the approach to treatment. Emergencies include hypertensive encephalopathy (headache, irritability, confusion, and altered mental status due to cerebrovascular spasm), hypertensive nephropathy (hematuria, proteinuria, and progressive renal dysfunction due to arteriolar necrosis and intimal hyperplasia of the interlobular arteries), intracranial hemorrhage, aortic dissection, preeclampsia-eclampsia, pulmonary edema, unstable angina, or myocardial infarction. **Malignant hypertension** is by historical definition characterized by encephalopathy or nephropathy with accompanying papilledema. Progressive renal failure usually ensues if treatment is not provided. The therapeutic approach is identical to that employed with other antihypertensive emergencies.

Parenteral therapy is indicated in most hypertensive emergencies, especially if encephalopathy is present. The initial goal in hypertensive emergencies is to reduce the pressure by no more than 25% (within minutes to 1 or 2 hours) and then toward a level of 160/100 mm Hg within 2-6 hours. Excessive reductions in pressure may precipitate coronary, cerebral, or renal ischemia. To avoid such declines, the use of agents that have a predictable, dose-dependent, transient, and not precipitous antihypertensive effect is preferable. In that regard, the use of sublingual or oral fast-acting nifedipine preparations is best avoided.

Pharmacologic Management

A. Parenteral Agents

A growing number of agents are available for management of acute hypertensive problems. (Table 11-11 lists drugs, dosages, and adverse effects.) Sodium nitroprusside is the agent of choice for the most serious emergencies because of its rapid and easily controllable action, but continuous monitoring is essential when this agent is used. In the presence of myocardial ischemia, intravenous nitroglycerin or an intravenous beta-blocker, such as labetalol or esmolol, is preferable.

1. Nitroprusside sodium—This agent is given by controlled intravenous infusion gradually titrated to the desired effect. It lowers the blood pressure within seconds by direct arteriolar and venous dilatation. Monitoring with an intra-arterial line avoids hypotension. Nitroprusside—in combination with a beta-blocker—is especially useful in patients with aortic dissection.

2. Nitroglycerin, intravenous—This agent is a less potent antihypertensive than nitroprusside and should be reserved for patients with accompanying acute ischemic syndromes.

3. Labetalol—This combined beta- and alpha-blocking agent is the most potent adrenergic blocker for rapid blood pressure reduction. Other beta-blockers are far less potent. Excessive blood pressure drops are unusual. Experience with this agent in hypertensive syndromes associated with pregnancy has been favorable.

4. Esmolol—This rapidly acting beta-blocker is approved only for treatment of supraventricular tachycardia but is often used for lowering blood pressure. It is less potent than labetalol and should be reserved for patients in whom there is particular concern about serious adverse events related to beta-blockers.

5. Nicardipine—Intravenous nicardipine is the most potent antihypertensive agent and the longest-acting of the parenteral calcium channel blockers. As a primarily arterial vasodilator, it has the potential to precipitate reflex tachycardia, and for that reason it should not be used without a beta-blocker in patients with coronary artery disease.

6. Fenoldopam—Fenoldopam is a new peripheral dopamine-1 (DA₁) receptor agonist that causes a dose-dependent reduction in arterial pressure without evidence of tolerance, rebound, or withdrawal or deterioration of renal function. In higher dosage ranges, tachycardia may occur.

7. Enalaprilat—This is the active form of the oral ACE inhibitor enalapril. The onset of action is usually within 15 minutes, but the peak effect may be delayed for up to 6 hours. Thus, enalaprilat is used primarily as an adjunctive agent.

8. Diazoxide—Diazoxide acts promptly as a vasodilator without decreasing renal blood flow. To avoid hypotension, it should be given in small boluses or as an infusion rather than as the previously recommended large bolus. One use of diazoxide has been in preeclampsia-eclampsia. Hyperglycemia and sodium and water retention may occur. The drug should be used only for short periods and is best combined with a loop diuretic.

9. Hydralazine—Hydralazine can be given intravenously or intramuscularly, but its effect is less predictable than that of other drugs in this group. It produces reflex tachycardia and should not be given without beta-blockers in patients with possible coronary disease or aortic dissection. Hydralazine is now used primarily in pregnancy and in children, but even in these situations, newer agents are supplanting it.

10. Trimethaphan—The ganglionic blocking agent trimethaphan is titrated with the patient sitting; its activity depends upon this. The patient can be placed supine if the hypotensive effect is excessive. The effect occurs within a few minutes and persists for the duration of the infusion. This agent has largely been replaced by nitroprusside and newer medications.

11. Diuretics—Intravenous loop diuretics can be very helpful when the patient has signs of heart failure or fluid retention, but the onset of their hypotensive response is slow, making them an adjunct rather than a primary agent for hypertensive emergencies. Low dosages should be used initially (furosemide, 20 mg, or bumetanide, 0.5 mg). They facilitate the response to vasodilators, which often stimulate fluid retention.

B. Oral Agents

Patients with less severe acute hypertensive syndromes can often be treated with oral therapy. Abrupt blood pressure lowering is not usually necessary in asymptomatic individuals, and the use of agents such as rapid-acting nifedipine probably causes more adverse effects than benefits.

1. Clonidine—Clonidine, 0.2 mg orally initially, followed by 0.1 mg every hour to a total of 0.8 mg, will usually lower blood pressure over a period of several hours. Sedation is frequent, and rebound hypertension may occur if the drug is stopped.

2. Captopril—Captopril, 12.5-25 mg orally, will also lower blood pressure in 15-30 minutes. The response is variable and may be excessive.

3. Nifedipine—Fast-acting nifedipine capsules are commonly employed in the emergency room or urgent care setting because they usually provide a rapid reduction in blood pressure. However, the nifedipine effect is unpredictable and may be excessive, resulting in hypotension and reflex tachycardia. Because myocardial infarction and stroke have been reported in this setting, the use of nifedipine without concomitant beta-blocker therapy is not advised.

C. Subsequent Therapy

When the blood pressure has been brought under control, combinations of oral antihypertensive agents can be added as parenteral drugs are tapered off over a period of 2-3 days. Most subsequent regimens should include a diuretic.

Table 11-1. Classification and follow-up of blood pressure measurements.¹

Category ²	Systolic Blood Pressure (mm Hg)	Diastolic Blood Pressure (mm Hg)	Follow-Up Recommended
Optional	< 120	< 80	Recheck in 2 years
Normal	< 130	< 85	Recheck in 2 years
High normal	130-139	85-90	Recheck in 1 year ³
Hypertension ⁴			
Stage 1 (mild)	140-159	90-99	Confirm within 2 months
Stage 2 (moderate)	160-179	100-109	Evaluate or refer within 1 month
Stage 3 (severe)	> 180	> 110	Evaluate or refer within 1 week

¹From: The sixth report of the Joint National Committee on detection, education, and treatment of high blood pressure (JNC VI). Arch Intern Med 1997;157:2413.

²When systolic and diastolic pressures fall into different categories, the higher category should be selected to classify the individual's blood pressure. Isolated systolic hypertension is defined as a systolic blood pressure of 140 mm Hg or more and a diastolic blood pressure of less than 90 mm Hg.

³Consider offering counseling about lifestyle modifications (Table 11-2).

⁴In individuals aged 18 years or older not taking antihypertensive drugs and not acutely ill. Based on the average of two or more readings on two or more occasions after initial screening.

Table 11-2. Lifestyle modifications for hypertension prevention and management.¹

- Lose weight if overweight
- Limit alcohol intake to no more than 1 oz (30 mL) of ethanol (eg, 24 oz [720 mL] of beer, 10 oz [300 mL] of wine, or 2 oz [60 mL] of 100-proof whiskey) per day for men or 0.5 oz (15 mL) of ethanol per day for women and lighter-weight men
- Increase aerobic physical activity (30-45 minutes most days of the week)
- Reduce sodium intake to no more than 100 mmol/d (2.4 g of sodium or 6 g of sodium chloride)
- Maintain adequate intake of dietary potassium (approximately 90 mmol/d)
- Maintain adequate intake of dietary calcium and magnesium for general health
- Stop smoking and reduce intake of dietary saturated fat and cholesterol for overall cardiovascular health

Stage 1 (140-159/80-99)	Lifestyle modification (up to 12 mo)	Lifestyle modification ⁵ (up to 6 mo)	Drug therapy
Stages 2 and 3 (≥ 160/ = 100)	Drug therapy	Drug therapy	Drug therapy

¹From: The sixth report of the Joint National Committee on detection, education, and treatment of high blood pressure (JNC VI). Arch Intern Med 1997;157:2413.

²**Note:** For example, a patient with diabetes and blood pressure of 142/94 mm Hg plus left ventricular hypertrophy should be classified as having stage 1 hypertension with target organ disease (left ventricular hypertrophy) and with another major risk factor (diabetes). This patient would be categorized as "Stage 1, Risk Group C," and recommended for immediate initiation of pharmacologic treatment. Lifestyle modification should be adjunctive therapy for all patients recommended for pharmacologic therapy.

³TOD/CCD indicates target organ disease/clinical cardiovascular disease (see Table 11-3).

⁴For those with heart failure, renal insufficiency, or diabetes.

⁵For patients with multiple risk factors, clinicians should consider drugs as initial therapy plus lifestyle modifications.

Indication	Drug Therapy
COMPELLING INDICATIONS UNLESS CONTRAINDICATED	
Diabetes mellitus (type 1) with proteinuria	ACE I
Heart failure	ACE I, diuretics, β-blockers
Post-myocardial infarction	β-Blockers (non-ISA), ACE I (with systolic dysfunction)
Isolated systolic hypertension (older patients)	Diuretics (preferred), calcium antagonists
MAY HAVE FAVORABLE EFFECTS ON COMORBID CONDITIONS ²	
Angina	β-Blockers, calcium antagonists
Atherosclerotic vascular disease	ACE inhibitors
Atrial tachycardia, fibrillation	β-Blockers, calcium antagonists (nondihydropyridine)
Cyclosporine-induced hypertension (caution with the dose of cyclosporine)	Calcium antagonists
Diabetes mellitus (types 1 and 2) with proteinuria	ACE I
Diabetes mellitus (type 2)	Low-dose diuretics
Essential tremor	β-Blockers (noncardioselective)
Hyperthyroidism	β-Blockers
Migraine	β-Blockers (noncardioselective), calcium antagonists (nondihydropyridine)
Osteoporosis	Thiazides
Preoperative hypertension	β-Blockers
Prostatism (benign prostatic hyperplasia)	α-Blockers
Renal insufficiency (caution in renovascular hypertension and creatinine level = 3 mg/dL [265.2 μmol/L])	ACE I
MAY HAVE UNFAVORABLE EFFECTS ON COMORBID CONDITIONS ^{2,3}	
Bronchospastic disease	β-Blockers ⁴
Depression	β-Blockers, central α-agonists, reserpine ⁴
Diabetes mellitus (types 1 and 2)	β-Blockers, high-dose diuretics
Dyslipidemia	β-Blockers (non-ISA), diuretics (high-dose)
Gout	Diuretics
Heart block, (2nd or 3rd degree)	β-Blockers, ⁴ calcium antagonists
Heart failure	(nondihydropyridine) ⁴
Liver disease	Calcium antagonists (except amlodipine), α-blockers, β-blockers ⁵
Peripheral vascular disease	β-blockers ⁵
Pregnancy	Labetalol hydrochloride, methyldopa ⁴
Renal insufficiency	β-Blockers
Renovascular disease	ACE I, ⁴ angiotensin II receptor blockers ⁴
	Potassium-sparing agents
	ACE I, angiotensin II receptor blockers

ACE I, angiotensin-converting enzyme inhibitors; ISA, intrinsic sympathomimetic activity.

Table 11-11. Drugs for hypertensive emergencies and urgencies.

Agent	Action	Dosage	Onset	Duration	Adverse Effects	Comments
PARENTERAL AGENTS (INTRAVENOUSLY UNLESS NOTED)						
Nitroprusside (Nipride)	Vasodilator	0.25-10 µg/kg/min	Seconds	3-5 minutes	GI, CNS; thiocyanate and cyanide toxicity, especially with renal and hepatic insufficiency; hypotension.	Most effective and rapid treatment. Use with caution in aortic dissection.
Nitroglycerin	Vasodilator	0.25-5 µg/kg/min	2-5 minutes	3-5 minutes	Headache, nausea, hypotension, bradycardia.	Tolerance may develop with prolonged use, primarily with myocardial ischemia.
Labetalol (Normodyne, Trandate)	Beta- and alpha-blocker	20-40 mg every 10 minutes to 300 mg; 2 mg/min infusion	5-10 minutes	3-6 hours	GI, hypotension, bronchospasm, bradycardia, heart block.	Avoid in congestive heart failure and asthma. May be useful in aortic dissection.
Esmolol (Brevibloc)	Beta-blocker	Loading dose 500 µg/kg over 1 minute; maintenance, 25-200 µg/kg/min	1-2 minutes	10-30 minutes	Bradycardia, nausea.	Avoid in congestive heart failure and asthma. Weak anesthetic agent.
Nicardipine (Cardene)	Calcium channel blocker	5 mg/h; may increase by 1-2.5 mg/h every 15 minutes to 15 mg/h	1-5 minutes	3-6 hours	Hypotension, tachycardia, headache.	May precipitate myocardial infarction in patients with severe atherosclerosis.
Enalaprilat (Vasotec)	ACE inhibitor	1.25 mg every 6 hours	15 minutes	6 hours or more	Excessive hypotension.	Additive with diuretics. May be continued orally.
Furosemide (Lasix)	Diuretic	10-80 mg	15 minutes	4 hours	Hypokalemia, hypotension.	Adjunct to vasodilators.
Hydralazine (Apresoline)	Vasodilator	5-20 mg IV or IM (less desirable); may repeat after 20 minutes	10-30 minutes	2-6 hours	Tachycardia, headache, GI.	Avoid in coronary artery disease and pregnancy.
Diazoxide (Hyperstat)	Vasodilator	50-150 mg repeated at intervals of 5-15 minutes, or 15-30 mg/min by IV infusion to a maximum of 600 mg	1-2 minutes	4-24 hours	Excessive hypotension, tachycardia, myocardial ischemia, headache, nausea, vomiting, hyperglycemia. Necrosis with extravasation.	Avoid in coronary artery disease and dissection. Use of beta-blocker and diuretics is obsolete.
Trimethaphan (Arfonad)	Ganglionic blocker	0.5-5 mg/min	1-3 minutes	10 minutes	Hypotension, ileus, urinary retention, respiratory arrest. Liberates histamine; use caution in allergic individuals.	Useful in aortic dissection. Otherwise rarely used.
ORAL AGENTS						
Nifedipine (Adalat, Procardia)	Calcium channel blocker	10 mg initially; may be repeated after 30 minutes	15 minutes	2-6 hours	Excessive hypotension, tachycardia, headache, angina, myocardial infarction, stroke.	Response unpredictable.
Clonidine (Catapres)	Central sympatholytic	0.1-0.2 mg initially; then 0.1 mg every hour to 0.8 mg	30-60 minutes	6-8 hours	Sedation.	Rebound may occur if discontinued abruptly.
Captopril (Capoten)	ACE inhibitor	12.5-25 mg	15-30 minutes	4-6 hours	Excessive hypotension.	
Fenoldopam (Corlopam)	Dopamine receptor agonist	0.1-1.6 µg/kg/min	4-5 minutes	< 10 minutes	Reflex tachycardia, hypotension, ? intraocular pressure.	May protect renal function.

■ INTRODUCTION

Most arterial occlusive disease is produced by atherosclerosis. Atherosclerosis is a generalized response of the artery wall to injury. Atherosclerotic plaques are characterized by smooth muscle migration into the intima and subsequent proliferation and extracellular lipid deposition. Complex lesions are composed of a fibrous cap containing smooth muscle and inflammatory cells overlying a central core of lipid-rich necrotic debris. Clinical symptoms are produced by progressive stenosis, calcification, intraplaque hemorrhage, distal embolization, and luminal thrombosis after cap rupture. Atherosclerosis is a systemic disease, associated with some degree of involvement of all major arteries, but its most common clinical manifestations involve a limited number of arteries at areas of turbulent flow and low shear stress: the carotid bifurcation, the infrarenal aorta and the iliac, superficial femoral, and tibial arteries, and the ostia of the renal and visceral arteries.

Most arterial aneurysms are classified as atherosclerotic or degenerative, because atheromas are found in the aneurysm wall and many patients have typical atherosclerotic risk factors. Both occlusive disease and aneurysms may be present in the same individual. However, the exact role of atherosclerosis in the causation of aneurysms is poorly defined. An imbalance of tissue metalloproteinases and metalloproteinase inhibitors is responsible for elastin and collagen degradation. Genetic predisposition, inflammation, and hemodynamic factors may also play a permissive role in aneurysm formation.

Atherosclerosis has been associated with increasing age, hypercholesterolemia, diabetes mellitus, smoking, a positive family history, hypertension, elevated levels of lipoprotein(a) and C-reactive protein, sedentary lifestyle, obesity, and homocystinuria. Control of risk factors by use of antihypertensive and lipid-lowering medications, regulation of blood sugar, tobacco cessation, and regular exercise remain the mainstays of treatment. Aspirin and clopidogrel (and potentially glycoprotein IIb/IIIa inhibitors) may prevent microemboli by impairing platelet aggregation; clopidogrel reduces the relative risk of stroke, myocardial infarction, and vascular death by 24% over aspirin alone in at-risk patients. Preliminary studies suggest that antioxidants, particularly dietary vitamin E, may also be beneficial in slowing the progression of disease. More recently, research has focused on the use of macrolide antibiotics in atherosclerotic disease, based on the finding of *Chlamydia pneumoniae* in symptomatic atheromas. Gene transfer of vascular endothelial growth factor (VEGF) and endothelial nitric oxide synthetase (eNOS), as well as specifically targeted gene therapy for risk factor management, represent active area of investigation.

■ ARTERIAL ANEURYSMS

ANEURYSMS OF THE ABDOMINAL AORTA

Essentials of Diagnosis

- Most aortic aneurysms are asymptomatic, detected during a routine physical examination or sonography.
- Severe back or abdominal pain and hypotension indicate rupture.
- Concomitant atherosclerotic occlusive disease of lower extremities is present in 25%.

General Considerations

Over 90% of abdominal aneurysms originate below the renal arteries, and many extend into the common iliac arteries. The infrarenal aorta is normally 2 cm in diameter; an aneurysm is defined as an aortic diameter exceeding 3 cm. An aortic aneurysm is present in 5-8% of the male population over the age of 65. The reported incidence has tripled over the last 30 years. Routine ultrasound screening of high-risk groups is associated with a reduction in aneurysm-related deaths of 53%. Half of all newly detected aneurysms are under 5 cm in diameter, and nearly two-thirds of these will increase sufficiently in size to require repair. Beta-blockers and, more recently, oral roxithromycin (300 mg daily for 30 days) have been shown to decrease the expansion rate of small aneurysms. Patients with chronic obstructive pulmonary disease appear more likely to rupture smaller aneurysms.

Clinical Findings

A. Symptoms and Signs

1. Asymptomatic aneurysms—An aneurysm may be suspected on routine physical examination by detection of a prominent aortic pulsation. More often, asymptomatic aneurysms are discovered as incidental findings on abdominal ultrasound or CT scan. Peripheral pulses are often normal, but coexisting renal or lower extremity arterial occlusive disease is present in 25%. Popliteal artery aneurysms are present in 15% of patients with aneurysms of the abdominal aorta, and, conversely, more than one-third of patients with popliteal aneurysms have abdominal aortic aneurysms.

2. Symptomatic aneurysms—Midabdominal or lower back pain (or both) in the presence of a prominent aortic pulsation may indicate rapid aneurysmal growth, rupture, or inflammatory aortic aneurysm. Inflammatory aneurysms account for fewer than 5% of aortic aneurysms and are characterized by extensive periaortic and retroperitoneal inflammation of unknown cause. These patients may have low-grade fever, elevated sedimentation rate, and a history of recent upper respiratory tract infection; they are often active smokers. Infected aortic aneurysms (either caused by septic emboli to a normal aorta or bacterial colonization of an existing aneurysm) are rare but should be suspected in patients with saccular aneurysms or aneurysms in conjunction with fever of unknown origin, particularly if blood cultures are positive for salmonella. Peripheral emboli can also be a symptom of aneurysmal disease.

3. Ruptured aneurysms—Patients with ruptured aortic aneurysms present with severe back, abdominal, or flank pain and hypotension. Posterior rupture confined to the retroperitoneum carries a better prognosis than anterior rupture into the peritoneal cavity. As many as 90% of patients die either before they reach the hospital or in the immediate perioperative period. The only chance for survival is emergent surgical repair.

B. Laboratory Findings

Electrocardiogram, serum creatinine, hematocrit and hemoglobin, and type and crossmatch should be obtained routinely in all patients.

C. Imaging

Abdominal ultrasonography is the screening study of choice and is valuable also for following aneurysm growth in patients with small (< 5 cm) aneurysms. Aneurysms typically grow by about 10% of their diameter per year; annual ultrasound examinations are recommended for aneurysms greater than 3.5 cm. In about three-fourths of patients, size can be estimated by measurement of curvilinear calcifications in the aneurysm wall on an abdominal radiograph, but this is much less accurate than ultrasonography.

Contrast-enhanced CT scanning not only precisely sizes the aneurysm but also defines its relationship to the renal arteries. MRI is as sensitive and specific as CT and is useful if renal insufficiency precludes contrast-enhanced CT. Aortography is indicated prior to elective aneurysm repair when arterial occlusive disease of the visceral or lower extremity arteries is suspected or when endograft repair is being considered.

Treatment

A. Standard Therapy

Surgical excision and synthetic graft replacement is the treatment of choice for most aneurysms of the infrarenal abdominal aorta greater than 5 cm. The maximum diameter of the aneurysm correlates best with the risk of rupture. Yearly rupture risk is 2% for 4- 5.9-cm aneurysms, 7% for 6-6.9-cm aneurysms, and 25% for 7-cm

aneurysms. Recommendation of an elective repair must be balanced with the risk of rupture. In asymptomatic good-risk patients, surgery is advised when the aneurysm exceeds 5 cm, while poor-risk patients may not be considered for repair until the aneurysm exceeds 6 cm. Urgent repair is indicated for symptomatic patients irrespective of aneurysm size.

Preoperative evaluation must include a detailed assessment of cardiac risk and examination of the carotid arteries since acute myocardial infarction, arrhythmia, and stroke remain among the most frequent perioperative complications. In patients with asymptomatic aneurysms and a history of angina or of carotid stenosis greater than 80%, coronary angioplasty, coronary bypass grafting, or carotid endarterectomy may be indicated before repair of the aneurysm.

B. Endovascular Repair

Endovascular stent grafts, or "covered stents," have evolved over the last decade for treatment of aortic aneurysms. Aortic stent grafts are configured to be uni-iliac or bifurcated depending on the particular anatomy of the aneurysm. Uni-iliac grafts are combined with endovascular occlusion of the contralateral common iliac artery and femoral-femoral bypass grafting. Both types of grafts are deployed via the common femoral arteries; in most cases, this involves bilateral inguinal incisions. The operation can be performed under epidural anesthesia, often in less than 2 hours and with minimal blood loss, which has made repair of aortic aneurysms feasible in high-risk patients previously deemed inoperable. Additional advantages include reduced incisional pain, fewer cardiopulmonary complications, and avoidance of postoperative ileus; most patients are discharged from the hospital on the second postoperative day. Endografts have been used successfully for repair of ruptured aneurysms, using balloon catheter control of the supraceliac aorta to facilitate intraoperative angiography and stent deployment.

Not all patients are candidates for standard endovascular repair. The proximal neck of the aneurysm must be adequate (at least 1.5 cm in length and less than 3 cm in width) to allow fixation and sufficient tissue apposition below the renal arteries. Iliac artery aneurysms, iliac stenoses, and iliac tortuosity or calcification all increase the complexity of stent deployment. The newest technology includes use of smaller introducer sheaths intended for eventual percutaneous deployment. Long-term durability of endovascular grafts needs to be established before comparison can be made with open repair for use in the good-risk patient with asymptomatic aortic aneurysm. Objective comparison with open surgical repair has been complicated by the multiplicity of continually evolving stent graft designs.

Complications

Complications after aneurysm resection include myocardial infarction, bleeding, respiratory insufficiency, ischemic colitis, limb ischemia, renal insufficiency, and stroke. Bowel infarction, liver dysfunction, acalculous cholecystitis, and renal failure are more common with emergent aneurysm repair or when repair of the aneurysm requires supraceliac or suprarenal cross-clamping. However, renal insufficiency can occur even when the clamp is infrarenal and there is no reported intraoperative hypotension, presumably because of renal artery vasoconstriction, atheroemboli, preoperative contrast administration for CT scan, and dehydration from fasting or bowel preparation. For this reason, mannitol (25-g intravenous bolus) is given as a diuretic and free-radical scavenger prior to cross-clamping, and dopamine (3 ug/kg/min) or fenoldopam (0.05-0.1 ug/kg/min) continued in the immediate postoperative period to increase renal perfusion and glomerular filtration rate. Rarely (0.1% of cases), lower extremity paralysis complicates repair of abdominal aortic aneurysm because of occlusion of the spinal artery from atheroemboli, shock, or aortic cross-clamping. Graft infection and graft-enteric fistulas are well described as fatal late complications, occurring more often after emergent aneurysm repair. One complication specific to endovascular repair is persistent filling of the aneurysm (endoleak). Endoleaks are classified as type 1 (leak around the top or bottom of the stent graft), type 2 (leak from a back-bleeding patent lumbar artery or inferior mesenteric artery), and type 3 (leak through the graft material). They are detected by contrast CT obtained routinely on postoperative days 2 and 30, and at 6-month or yearly intervals thereafter. Type 1 endoleaks are restented to allow adequate proximal or distal fixation. Type 2 endoleaks are not uncommon (20-30% of patients) in the immediate postoperative period but usually disappear by the 1-month CT scan. Persistent type 2 endoleaks occur in 5% of patients and are correlated with the use of warfarin and the presence of a patent inferior mesenteric artery preoperatively. They can be eliminated by endovascular coil embolization of the feeding arteries.

Renal failure from contrast nephropathy, intraoperative atheroemboli, or graft impingement on the main or accessory renal arteries is another possible complication of endovascular repair. Conversion to open repair because of aortic or iliac rupture, inability to gain access, error in positioning, inadequate fixation, or stent malfunction is rare (1-3%) if patients are properly screened preoperatively.

Prognosis

Mortality following elective open or endovascular repair is 1-5%. In general, a patient with an aortic aneurysm greater than 5 cm has a threefold greater chance of dying as a consequence of rupture of the aneurysm than of dying from surgical resection. Five-year survival after surgical repair is 60-80%. Five to 10 percent of patients will develop another aortic aneurysm adjacent to the graft or in the thoracic aorta.

ANEURYSMS OF THE THORACIC AORTA

Aneurysms of the thoracic aorta account for fewer than 10% of aortic aneurysms. Medial degeneration, chronic dissection, vasculitis, and collagen-vascular disease (Marfan's syndrome or Ehlers-Danlos syndrome) are common causes; syphilis is now a rare cause of thoracic aneurysm. Traumatic aneurysms occur at the ligamentum arteriosus just beyond the left subclavian artery and result from shearing injury during rapid-deceleration automobile accidents.

Thoracoabdominal aneurysms are categorized by the Crawford classification: Type 1 extends from left subclavian artery to the renal arteries, type 2 from the left subclavian artery to the iliac bifurcation, type 3 from the midthoracic to the infrarenal region, and type 4 from the diaphragmatic hiatus to the infrarenal region. The prevalence of each type of thoracoabdominal aneurysm is roughly equal, but type 4 aneurysms have the lowest operative mortality (2-5%) and the lowest risk of postoperative neurologic deficits (2-10%).

Clinical Findings

A. Symptoms and Signs

Clinical manifestations depend largely on the size and position of the aneurysm and its rate of growth. Most are asymptomatic and are discovered during a diagnostic procedure undertaken for other reasons. Some patients present with substernal, back, or neck pain. Others develop dyspnea, stridor, or a brassy cough from pressure on the trachea, dysphagia from pressure on the esophagus, hoarseness from pressure on the left recurrent laryngeal nerve, or neck and arm edema from external compression of the superior vena cava. Aortic regurgitation due to distortion of the aortic valve annulus may occur with aneurysms of the ascending aorta.

B. Imaging

An aneurysm suspected on chest radiography must be differentiated from other anterior mediastinal masses, including lung neoplasm, thymoma, cyst, and substernal goiter. CT scan and MRI are the most sensitive and accurate means of imaging thoracic aneurysms. Aortography may be necessary to assess involvement of the arch vessels. The coronary vessels and the aortic valve should also be studied if aortic root replacement is anticipated.

Treatment

Control of hypertension and use of beta-blockers may slow aneurysmal growth. Indications for surgical treatment include the presence of symptoms, rapid expansion, or size greater than 5 cm. Operative risk from comorbid medical conditions must be considered when recommending repair of asymptomatic aneurysms. Morbidity and mortality are higher than with abdominal aortic aneurysms; the 30-day operative mortality is 8-20% with repair of type 1 and type 2 thoracoabdominal aneurysms. The thoracotomy incision is associated with a higher risk of pulmonary complications and more challenging postoperative pain management. Proximity to the recurrent laryngeal nerve, the phrenic nerve, and the carotid and subclavian arteries makes injury to these structures possible. The great radicular artery (artery of Adamkiewicz) arises from an intercostal artery between T8 and L1 and is the dominant artery to the spinal cord in 80% of patients, imposing a 5-30% risk of paraplegia during thoracic aneurysm repair. Use of left heart bypass or femoral bypass to preserve retrograde perfusion below the level of the cross-clamp or antegrade perfusion by direct cannulation of selected arteries reduces end-organ ischemia. Lumbar drains, spinal cord cooling, naloxone infusion, and administration of corticosteroids are also described as techniques for spinal cord protection.

Endovascular repair of thoracic aortic aneurysms reduces cardiopulmonary risk, but the location of the aneurysm may preclude endovascular repair by current methods. Recent investigations involve development of branched stent grafts for repair of arch and thoracoabdominal aneurysms.

Prognosis

Five-year survival for patients with unrepaired thoracic aneurysms greater than 6 cm is 20-25%. Most deaths are due to rupture or to the complications of generalized atherosclerosis.

PERIPHERAL ARTERY ANEURYSMS (POPLITEAL & FEMORAL)

Most lower extremity aneurysms occur in men over age 50. Half are bilateral. One-third of patients with popliteal aneurysms and one-half of those with femoral aneurysms have an associated aortoiliac aneurysm.

Popliteal Aneurysms

Popliteal aneurysms account for approximately 85% of all peripheral artery aneurysms. Symptoms are rarely due to rupture but result rather from arterial thrombosis, peripheral embolization, or compression of adjacent structures with resultant venous thrombosis or neuropathy. Arterial thrombosis can be limb-threatening if all outflow vessels are occluded, leading to amputation in up to 30% of patients.

Ultrasound is the diagnostic study of choice to measure the diameter of the aneurysm as well as to search for other arterial aneurysms. MRA or conventional arteriography is required to define the anatomy of the outflow arteries in preparation for operative repair.

Surgery is recommended for all asymptomatic aneurysms larger than 2 cm and for all symptomatic aneurysms regardless of size. If preoperative angiography reveals no patent distal vessels for bypass, catheter-directed thrombolysis can be attempted. If a patent outflow vessel is identified or is recanalized with thrombolytic therapy, a saphenous vein bypass graft with proximal and distal ligation of the aneurysm is performed. In large aneurysms producing popliteal vein or nerve compression, resection of the aneurysm in addition to grafting is required.

Femoral Aneurysms

Femoral aneurysms present as pulsatile groin masses. They have the potential for the same complications as popliteal aneurysms. Because the incidence of complications is lower than with popliteal aneurysms, patients with combined disease undergo repair of aortoiliac and popliteal aneurysms before repair of the femoral aneurysm.

Femoral pseudoaneurysms may result from injury produced by intravenous drug abuse, femoral artery puncture for angiography, or femoral line insertion. Mycotic aneurysms must be widely debrided with proximal and distal ligation or interposition grafting using autologous vein. Uninfected, small (< 5 cm) traumatic pseudoaneurysms can often be treated by ultrasound-guided compression of the neck of the aneurysm or by thrombin injection, which has a reported success rate of 90%. If these techniques are not successful, open repair is required. Pseudoaneurysms may also develop at the distal anastomosis of an aortofemoral bypass graft. They should be repaired if graft infection is suspected or if their diameter exceeds 2 cm.

VISCERAL ANEURYSMS

Mesenteric, Hepatic, & Splenic Artery Aneurysms

Historically, mesenteric aneurysms had a high mortality rate because of failures of diagnosis. High-resolution CT scanning has increased the capability to detect incidental mesenteric aneurysms and has broadened our understanding of the disease. In the last decade, hepatic artery aneurysms have become the most common of the visceral artery aneurysms, superseding splenic artery aneurysms, which now comprise less than 40% of the total. Superior mesenteric, celiac, gastric, and gastroepiploic artery aneurysms each represent about 5% of visceral aneurysms. Aneurysms of mesenteric branch vessels are rare and often associated with connective tissue disease or vasculitis.

Medial degeneration is the most commonly cited cause of hepatic aneurysms. Increasingly, however, injury during cholangiography, hepatic biopsy, or blunt abdominal trauma is implicated—particularly in intrahepatic aneurysms, which account for about half of all hepatic aneurysms. Splenic artery aneurysms are most commonly related to medial fibroplasia, though portal hypertension, splenomegaly, pregnancy, amphetamine use, and local inflammation (eg, pancreatitis) have all been implicated as possible risk factors. These aneurysms occur four times more frequently in women than in men, underscoring possible hormonal influences. Most superior mesenteric artery aneurysms are associated with infective endocarditis and suspected septic emboli. Atherosclerosis may play a role in the pathogenesis of celiac artery aneurysms—and a secondary role in development of other mesenteric aneurysms.

Surgical (aneurysmectomy or aneurysmorrhaphy with ligation of branches) or endovascular (embolization) management is warranted for symptomatic aneurysms and aneurysms over 2 cm in circumference. Asymptomatic splenic aneurysms less than 2 cm in diameter rarely rupture, and treatment is not generally advised unless the patient is pregnant since the highest risk of rupture is in young women during pregnancy.

Stone WM et al: Superior mesenteric artery aneurysms: is presence an indication for intervention? J Vasc Surg 2002; 36:234. [\[PMID: 12170202\]](#)

Renal Artery Aneurysms

Renal artery aneurysms have a reported incidence of about 1% in the adult population. Many are asymptomatic and diagnosed as an incidental finding on CT scan or angiography performed for another purpose. Others are found during evaluation for hematuria, renal infarct, flank pain, or suspected renovascular hypertension. Five percent present with rupture. Fibromuscular dysplasia is present in about 40% of patients; another 25% have atherosclerosis. Medial degeneration, trauma, and injury after renal biopsy or percutaneous nephrolithostomy are other potential causes. Indications for treatment include size greater than 2 cm, local symptoms, renovascular hypertension, distal embolization, growth on serial imaging, or aneurysms in women of childbearing age.

The standard surgical approach for renal artery aneurysms is excision with interposition grafting; infrequently, the aneurysm extends into the branch vessels, and ex vivo reconstruction may be required. Autologous and prosthetic materials have been equally effective for interposition grafting of main renal arteries greater than 5 mm in diameter, with a 5-year primary patency rate approaching 70%. Recently, polytetrafluoroethylene-covered stent grafts have been used for treatment of saccular aneurysms of the main renal artery. Interlobar aneurysms can be treated by endovascular embolization with microcoils.

AORTIC DISSECTION

Essentials of Diagnosis

- A history of hypertension or Marfan's syndrome is often present.
- Sudden severe chest pain with radiation to the back, occasionally migrating to the abdomen and hips.
- Patient appears to be in shock, but blood pressure is normal or elevated; pulse discrepancy in many patients.
- Acute aortic regurgitation may develop.

General Considerations

Aortic dissection is the most common aortic catastrophe requiring admission to a hospital. It is caused by an intimal tear, which allows creation of a false lumen between the media and adventitia. Over 95% of intimal tears occur either in the ascending aorta just distal to the aortic valve (Stanford type A) or just distal to the left subclavian artery (Stanford type B). These are points where the aorta is fixed and allow for intimal injury during shear stress. The false lumen can rupture into the left pleural space, retroperitoneum, or abdominal cavity. More commonly, the dissection propagates distally to involve aortic branch vessels, producing acute spinal cord (3%), visceral (9%), renal (12%), or lower extremity (9%) ischemia. Antegrade extension of a type B dissection can stretch the aortic annulus or occlude a coronary artery orifice, producing acute aortic regurgitation, myocardial infarction, and intrapericardial rupture with tamponade. Both blood pressure and the rate of acceleration of pulsatile flow (dP/dt) are important in propagation of dissection; 80% of patients with acute dissection are hypertensive. Other risk factors for dissection are Marfan's syndrome, pregnancy, bicuspid aortic valve, and coarctation of the aorta.

When not appropriately diagnosed and treated, aortic dissection is a lethal disease. Untreated type A dissections are associated with 50% mortality at 48 hours and 90% mortality at 1 month—due to free rupture, tamponade, or acute left ventricular failure. Mortality with untreated type B dissection is 10-20%, usually secondary to free rupture into the pleural space, acute mesenteric ischemia, or renal failure.

Clinical Findings

A. Symptoms and Signs

Eighty-five percent of patients report sudden excruciating ("ripping") pain in the chest or upper back. The pain may radiate into the abdomen, neck, or groin. Most patients are hypertensive at presentation. Some present with syncope, hemiplegia, or lower extremity paralysis. On physical examination, peripheral pulses and blood pressures may be diminished or unequal. A diastolic murmur of aortic insufficiency may be heard.

B. Laboratory Findings

The ECG may be normal but often reveals left ventricular hypertrophy from long-standing hypertension. Acute ischemic changes suggest coronary artery involvement. Because dissections preferentially extend into the right coronary ostium, inferior wall abnormalities predominate.

C. Imaging

Chest radiographs often reveal—in comparison with previous films—an abnormal aortic contour or a widened superior mediastinum. Pleural or pericardial effusion may be present. Dynamic CT scanning, angiography, MRI, and transesophageal echocardiography (TEE) have all been used to diagnose acute dissection. TEE is favored because of its high sensitivity (98%) and specificity (99%) and because it can be performed rapidly and at the bedside. The best initial study is the one most readily available that can be interpreted accurately in a given hospital setting. MRI has not played a major role in the initial diagnosis but is useful for serial follow-up.

Differential Diagnosis

Acute myocardial infarction, pulmonary embolus, esophageal disruption, strangulated paraesophageal hernia, mesenteric ischemia, and symptomatic aortic aneurysm may all be considered in the differential diagnosis of the patient presenting with acute aortic dissection.

Treatment

A. Medical Treatment

Aggressive blood pressure control should be initiated immediately. The patient is placed at bed rest and given opioids for pain relief. An arterial line is placed for continuous blood pressure monitoring. Treatment is targeted to reductions in aortic pressure and pulsatile flow (dP/dt). This is accomplished by lowering systemic vascular resistance and cardiac output (primarily heart rate).

Systemic vascular resistance is reduced by means of a rapid-acting antihypertensive agent titrated by intravenous infusion to maintain a systolic blood pressure of 100-120 mm Hg. Possible medications include nitroprusside (0.3-10 ug/kg/min), which causes direct vasodilation by its action on smooth muscle nitric oxide receptors, or fenoldopam (0.1-1.6 ug/kg/min), which acts as an agonist of D₁-dopamine receptors. When nitroprusside is continued for 48 hours or more, thiocyanate levels should be checked and the infusion stopped if the level is over 10 mg/dL (to avoid toxicity).

The heart rate is decreased by administering the selective β_1 -adrenergic antagonist esmolol (50-300 ug/kg/min intravenously) and by intermittent administration of metoprolol (5-10 mg intravenously every 15 minutes) or the α_1 - and nonselective β -antagonist labetalol (20-80 mg intravenously every 10 minutes or 1-2 mg/min).

Chronic medical management of aortic dissections involves use of a β -antagonist (eg, metoprolol, 25-100 mg orally twice daily; atenolol, 50-100 mg orally daily), often in combination with another antihypertensive agent such as the centrally acting α_2 -agonist clonidine (0.1-0.3 mg orally twice daily or 0.1-0.3 mg transdermal patch topically every 24 hours) or the direct vasodilator hydralazine (10-50 mg orally four times daily), the calcium channel blocker amlodipine (2.5-10 mg orally daily), or the angiotensin-converting enzyme inhibitor enalapril (2.5-20 mg orally daily).

B. Surgical Treatment

All patients with type A dissection should undergo emergent surgical repair. Most patients with type B dissection can be managed initially with aggressive drug therapy. Indications for surgical treatment of type B dissections are aortic rupture; severe intractable pain; mesenteric, renal, or limb ischemia; and progression of the dissection. For type A dissection, the ascending aorta and, if necessary, the aortic valve and arch are replaced with reimplantation of the coronary and brachiocephalic vessels. The mortality rate for such operations approaches 20%. Type B dissection with ischemic complications is treated by obliteration of the false lumen and secondary arterial bypass if this fails to restore blood flow to the ischemic organs. Several different techniques have been described for obliteration of the false lumen: resection of the entry point of the dissection and prosthetic tube graft interposition, open or endovascular fenestration of the dissection flap, or stent graft deployment to cover the entry point. Use of felt strips or instillation of tissue glue into the false lumen during open repair are described as methods for strengthening the dissected aortic wall.

Surgical indications and risks for chronic type B dissections are the same as for degenerative thoracoabdominal aneurysms. Repair is considered in symptomatic patients or patients with aneurysms larger than 5 cm. Reported surgical mortality is 5-30%. For this reason, long-term medical management may be the preferred treatment for patients with significant comorbidities.

Prognosis

Because of comorbid illnesses, operative mortality of patients with type B dissection is twice that of patients with type A dissection. After hospital discharge, 5-year survival is 70-80% for repaired type A and 50-70% for repaired type B dissections. In some medically treated type B dissections, the false lumen thromboses and eventually heals with minimal dilation. In others, a chronic dissection results in a progressively enlarging aneurysm requiring eventual repair in up to 30% of patients. For this reason, all unoperated patients should be followed with annual CT scan or MRI.

■ LOWER EXTREMITY OCCLUSIVE DISEASE

Occlusive disease of the lower extremities is a common cause of disability. It is also a predictor of cardiovascular morbidity and mortality; patients with intermittent claudication have a 2.5 times higher risk of cardiac events than that of an age-matched population. Severe triple-vessel coronary artery disease is found in almost 30% of patients undergoing routine coronary catheterization prior to peripheral bypass. Vascular endothelial dysfunction may be a systemic phenomenon and a marker for atherosclerosis; impairment of flow-mediated dilation in the peripheral arteries has been shown to correlate with the presence of coronary artery disease. It is essential for the primary care clinician to emphasize prevention of disease, particularly in light of what is known about etiologic factors.

DeBakey first characterized the distribution of atherosclerotic disease in the lower extremity. Plaque formation predominates at the aortic bifurcation, at the tibial trifurcation, and in the superficial femoral artery at the adductor hiatus. Interestingly, occlusive disease often spares the internal iliac, profunda, and peroneal arteries. Three distinct patterns of disease have since been described. Type 1 disease affects about 10-15% of patients and is limited to the aorta and common iliac arteries. It is most commonly found in younger men and women (ages 40-55) who are heavy smokers or who have hyperlipidemia. Type 2 disease (25% of patients) involves the aorta, the common iliac artery, and the external iliac artery. Type 3 disease is the most common (60-70% of patients) and is multilevel disease, affecting the aorta and the iliac, femoral, popliteal, and tibial arteries. Patients with type 2 and type 3 patterns of disease have typical risk factors for atherosclerosis: older age, male gender, diabetes, and hypertension. They also have a high incidence of coexisting cerebrovascular and coronary artery disease.

Clinical Findings

A. Symptoms and Signs

Lower extremity occlusive disease is manifested by several different clinical presentations: impotence, claudication, rest pain, and gangrene. The symptoms and physical examination predict the location and severity of disease. Occlusive disease of the iliac arteries can produce male erectile dysfunction. The triad of bilateral hip and buttock claudication, erectile dysfunction, and absent femoral pulses is known as Leriche's syndrome.

Claudication is characterized by pain, numbness, or weakness in the calves, thighs, or buttocks brought on by walking and completely relieved after a few minutes of rest. These reproducible symptoms help to differentiate claudication from other causes of leg pain such as radiculopathy and musculoskeletal disorders. Ischemic rest pain, defined as pain in the absence of exertion, is usually described as a nocturnal pain located across the dorsum of the foot at the metatarsal heads. It is ameliorated by placing the legs in the dependent position, usually by hanging them over the side of the bed. Rest pain implies impending gangrene.

Examination of the pulses indicates the level of disease. Absent or weak femoral pulses or the presence of an iliac or femoral bruit suggests inflow disease. Similarly, normal femoral pulses but a diminished or absent popliteal pulse is indicative of superficial femoral artery stenosis, and normal femoral and popliteal pulses and nonpalpable dorsalis pedis or posterior tibial pulse indicate tibial disease. An ankle-brachial index (ABI) is useful in gauging the degree of arterial insufficiency. A normal ratio of ankle to brachial systolic blood pressures is 1.0; less than 0.8 is consistent with claudication. Exercise, which lowers the ABI by exaggerating the difference in brachial and ankle blood pressures, can sometimes aid in detection of occlusive disease. Rest pain and nonhealing ulcers are common with an ABI less than 0.4. A toe-brachial index (TBI) can be used in diabetic or renal failure patients when an ABI cannot be obtained because the tibial arteries are calcified and noncompressible. A penile-brachial index (PBI) is obtained when vasogenic impotence is suspected. A PBI less than 0.6 suggests significant arterial disease. These measurements can also be used to monitor progression of disease and to assess the effect of therapeutic intervention.

Other findings on physical examination include atrophy of the skin, subcutaneous tissues, and muscles of the calf. Dependent rubor, hair loss, and coolness of the skin are signs of advanced ischemia. Ulcers from arterial occlusive disease are painful, well-circumscribed lesions generally located over pressure points, such as the first metatarsal head or heel. Ulcers that have failed to heal with 3 months of appropriate local wound care and ulcers associated with an ABI less than 0.3 are unlikely to heal without treatment to improve arterial blood flow and tissue perfusion.

B. Imaging

Angiography demonstrates the extent of the disease and the condition of the distal target vessels for potential bypass operation. The standard study images the infrarenal aorta and iliacs (including oblique views of the pelvis and groin to visualize the origins of the hypogastric and profunda arteries), the runoff vessels, and the foot in a lateral position. Angiography is undertaken only for percutaneous treatment or in preparation for surgical intervention. Gadolinium-enhanced MRA and duplex ultrasound are noninvasive imaging modalities occasionally used in evaluation of lower extremity occlusive disease, particularly in workup of popliteal occlusion and in identification of tibial target vessels poorly visualized by conventional angiography. Ultrasound is also used in routine follow-up of infrainguinal bypass grafts to screen for graft stenoses amenable to prophylactic angioplasty. Radiographs of the lower leg and foot are often obtained to rule out osteomyelitis underlying an infected ulcer or to identify calcification of potential runoff vessels.

Treatment

A. Conservative Measures

Treatment of claudication begins with identification and control of risk factors and initiation of an exercise program. Tobacco cessation slows the rate of progression of arterial occlusive disease and reduces cardiovascular mortality. Lipid-lowering medications have been shown to produce a 40% risk reduction for new-onset claudication or worsening of claudication. A supervised, dedicated walking program sustained over 3-6 months has been shown to increase pain-free walking distance by as much as 150%. Exercise improves symptoms by increasing muscle anaerobic metabolism rather than by increasing collateral flow as previously thought; the ABI does not change appreciably. A standard program is structured as a 30-minute daily session: walking along flat ground until discomfort occurs, resting until it subsides, and then resuming walking.

Some medications are available for use in the treatment of claudication. Pentoxifylline (400 mg orally three times daily), which theoretically works by causing deformation of red blood cells, has been used with variable therapeutic success. More recently, the phosphodiesterase inhibitor cilostazol (100 mg orally twice daily), which impairs platelet aggregation and increases calcium-mediated vasodilation, has been shown to increase walking distance by 34% more than placebo. It is contraindicated in patients with heart failure and is not well tolerated in about 20% of patients due to side effects of headache, dizziness, and diarrhea. Propionyl-L-carnitine (1000 mg orally twice daily) has also been correlated with increased walking distance in patients with claudication. Its mechanism of action is unknown; it may improve skeletal muscle metabolism. Ginkgo biloba extract (120 mg/d) is a herbal medication with some reported benefit in claudication (see [Chapter 44](#)). It has been correlated with an increased risk of bleeding and so should be used with caution in patients on anticoagulation. Aspirin (325 mg orally daily) is routinely prescribed for all patients who do not have drug allergy or intolerance. It is continued indefinitely after angioplasty or surgery in order to decrease thrombotic complications and impede progression of intimal hyperplasia. Clopidogrel (75 mg orally daily) or warfarin (dosed to maintain an INR of 2.0-3.0) may be selected for postoperative patients perceived to have a higher risk of graft thrombosis due to a hypercoagulable state, suboptimal conduit, or poor distal runoff.

Treatment of male erectile dysfunction requires evaluation of its possible causes (medications, diabetes mellitus, psychogenic factors, and arterial occlusive disease). Iliac artery revascularization can be beneficial in some cases of vasculogenic impotence. Other patients may respond to sildenafil, 25-50 mg 30 minutes to 4 hours prior to sexual activity. It is contraindicated in patients taking nitroglycerin because of the risk of myocardial ischemia due to hypotension (see [Chapter 23](#)).

B. Surgery

Percutaneous or open operation is considered for good-risk patients with short-distance (less than two blocks) claudication that impairs their ability to work or perform activities of daily living. Development of rest pain or tissue loss indicates progression of disease and also warrants evaluation for possible surgery.

Because many of these patients have coexisting ischemic heart disease, medical management should be optimized preoperatively. The roles of exercise testing and coronary angiography are discussed in [Chapter 3](#) and [Chapter 10](#). The carotid arteries should be imaged by ultrasound; endarterectomy may be indicated to minimize perioperative stroke risk.

1. Endovascular techniques—Common iliac artery stenoses are often amenable to percutaneous treatment. Stent angioplasty has been shown to decrease recurrence rates seen with angioplasty alone; most recent studies report a 70-80% 3-year patency rate with self-expanding (Wall) stents or balloon-expandable (Palmaz) stents. Stenting of distal lesions (external iliac or infrainguinal arteries) is not as successful, with reported 3-year primary patency rates of 55-60%. Stents do not appear to confer added benefits over angioplasty alone for femoral-popliteal lesions except in cases of postangioplasty arterial dissection or successfully recanalized short-segment arterial occlusion. Ideal lesions for angioplasty are discrete, short-segment (< 5 cm in length), concentric lesions in noncalcified large-diameter vessels. Often, endovascular techniques are used in conjunction with surgery for treatment of multifocal lower extremity occlusive disease such as an iliac stent being placed at the time of an ipsilateral femoral popliteal bypass. Some surgeons are evaluating long-segment closed superficial femoral artery endarterectomy combined with distal stenting as an alternative to femoral popliteal bypass in high-risk surgical patients with suboptimal vein available for bypass conduit. Few groups have achieved favorable results with percutaneous atherectomy devices or laser probes.

2. Open surgery—Aortobifemoral bypass grafting using a synthetic prosthesis is the standard treatment for complex aortoiliac occlusive disease. In general, a bifurcated polytetrafluoroethylene or Dacron graft is anastomosed end-to-end with the infrarenal abdominal aorta and end-to-side to each common femoral artery. If both external iliac arteries are occluded, an end-to-side aortic anastomosis preserves inflow into the internal iliac arteries. For high-risk patients, an axillary-femoral or femoral-femoral bypass graft can be considered, though such extra-anatomic grafts have lower long-term patency than bypass grafting (50% versus 80% at 10 years).

For infrainguinal occlusive disease, the bypass conduit of choice is autogenous greater saphenous vein. Five-year patency rates of 75-80% can be achieved with vein bypasses to the dorsalis pedis artery or the posterior tibial artery at the ankle. By contrast, the 5-year patency of femoral-tibial bypasses performed with synthetic conduit is less than 40%. Some surgeons prefer prosthetic graft for femoral-to-above-knee-popliteal artery bypasses, as the reported long-term patency in this position is almost equivalent to that of vein graft. Others maintain an "all autogenous" policy for all infrainguinal bypass grafts. In as many as 30% of patients, the greater saphenous vein is inadequate because it is sclerotic, thrombosed, or less than 3 mm in diameter or because the patient has undergone varicose vein stripping or saphenous vein harvesting for coronary artery bypass or previous leg bypass. Alternative conduits in these patients include lesser saphenous vein, arm vein, cryopreserved homologous vein, or prosthetic graft with a distal vein cuff.

Other determinants of long-term graft patency include quality of arterial inflow, patency of runoff arteries, and length of the bypass conduit. It is imperative to address any flow-limiting aortoiliac disease before performing any infrainguinal bypass.

Thomboendarterectomy involves resecting the thickened intima and media from the diseased vessel and is an alternative to bypass for short-segment lesions in larger arteries. It can be used in type 1 disease to obviate the need for prosthetic graft. Common femoral or profunda femoral thomboendarterectomy is combined with distal bypass to improve inflow.

Lumbar sympathectomy, once a common procedure, is now reserved for symptomatic patients with unreconstructable disease. Hyperbaric oxygen has also achieved successful healing of ischemic ulcers in selected patients who are not candidates for revascularization.

Operative mortality is 2-5% for open aortic surgery and 1-3% for infrainguinal bypass, largely attributable to cardiac complications. Risks specific to aortic surgery include renal insufficiency, bowel ischemia, impotence or retrograde ejaculation, and blue toe syndrome secondary to distal emboli. Late complications include graft thrombosis, graft infection, and aortoduodenal fistula. Particular concerns of percutaneous techniques include puncture site complications (hematoma, pseudoaneurysm, arteriovenous fistula, retroperitoneal hemorrhage, occlusion), dissection or rupture of the vessel during angioplasty, distal emboli from catheter manipulation, and contrast nephropathy. Patients with chronic renal insufficiency (serum creatinine > 1.5 mg/dL) undergoing angiography may be pretreated with intravenous hydration and acetylcysteine, 400 mg orally twice daily for 48 hours before and after contrast administration.

Prognosis

Twenty-five percent of patients with claudication will eventually develop ischemic rest pain or ulceration, though fewer than 10% will require amputation. In part, the high rate of limb salvage reflects a high mortality rate from comorbid disease. Because of coronary artery disease, patients with claudication have a 5-year survival of 50%. For this reason, operation is generally deferred until failure of medical management, impairment of activities of daily living, or clear progression of disease is documented. Almost 80% of patients with mild to moderate claudication will have relatively stable symptoms and will go for years without much progression. Some may improve as collateral circulation develops.

The overall 5-year patency rate for infrainguinal saphenous vein grafts is 60-80%. Higher graft patency and limb salvage rates are achieved with supragenicular bypasses and with patients presenting with claudication rather than rest pain or gangrene. Graft occlusion may convert a patient with claudication to one with limb-threatening ischemia because of loss of collateral flow. Conversely, a diabetic with sensory deficit from peripheral neuropathy who undergoes bypass for distal gangrene may have a clinically silent graft occlusion after the ulcer heals. Surveillance duplex ultrasound is advised at 6-month intervals to detect stenotic, or "threatened," grafts before they progress to occlusion.

UNUSUAL CAUSES OF POPLITEAL ARTERY OCCLUSION

The most common cause of popliteal artery occlusion is athero-occlusive disease. Thrombosis of a popliteal aneurysm can also cause popliteal occlusion and acute leg ischemia. Claudication in a young, athletic individual with no risk factors for atherosclerosis and normal pulses on the unaffected leg suggests popliteal entrapment syndrome, popliteal adventitial cystic disease, trauma, or extrinsic compression by a Baker cyst.

Popliteal entrapment syndrome is a group of anatomic anomalies that lead to arterial compression in the popliteal space. Type 1 (20% of patients) is produced by an abnormal course of the popliteal artery, passing medial to the medial head of the gastrocnemius muscle. Type 2 (25%) is caused by medial insertion of the medial head of the gastrocnemius muscle. The popliteal artery is compressed by an abnormal accessory slip of gastrocnemius muscle in type 3 (30%) or popliteus muscle in type 4 (8%). Almost 30% of patients have bilateral disease. Claudication symptoms may be atypical, such as pain with walking but not with running. Diagnosis is made by MRA or by positional angiography; the patent artery becomes impinged with passive dorsiflexion or active plantar flexion of the ankle. Treatment is surgical and involves transection of the abnormal muscle; if the artery is occluded, short-segment bypass with greater or lesser saphenous vein is also required.

Popliteal adventitial disease is a rare disorder of unknown cause characterized by formation of cysts within the wall of the popliteal artery. The cysts compress the arterial lumen, causing stenosis or occlusion. Their contents resemble synovial fluid, and some may be in continuity with the joint space. The disease most often affects healthy men 40-50 years of age. Larger cysts are amenable to ultrasound-guided aspiration, but most are small and appear only as a thickening of the popliteal artery wall on MRA. In these cases, bypass or interposition grafting is curative.

OCCLUSIVE CEREBROVASCULAR DISEASE

Every year, half a million people in the United States suffer a stroke. Fifteen to 30 percent of these episodes are fatal, making stroke the third leading cause of death in this country. Initially, hypoperfusion of the brain secondary to high-grade carotid stenosis or occlusion was thought to be the cause of stroke. However, carotid thomboendarterectomy (TEA) performed in awake patients revealed that only 10-15% of patients become symptomatic during carotid occlusion by cross-clamping. Most neurologic events are in fact caused by emboli occluding small cerebral arteries. Emboli from the carotid bifurcation may consist of platelet aggregates that form on irregular or ulcerated surfaces or plaque debris liberated by turbulent flow and intraplaque hemorrhage. Less commonly (fewer than 10% of cases), emboli arise from the heart (eg, mural thrombus or atrial myxoma) or from the aortic arch. Stroke can also be caused by intracerebral hemorrhage (from trauma or a ruptured cerebral aneurysm) or by small vessel occlusive disease in the pons, basal ganglia, and internal capsule of the brain (lacunar infarcts).

A transient ischemic attack (TIA) is defined as the sudden onset of a neurologic deficit that resolves completely within 24 hours. A stroke is a neurologic deficit that persists beyond 24 hours. A single TIA is associated with a 30% risk of subsequent stroke.

Risk of neurologic events increases with the degree of carotid artery stenosis. For stenoses less than 60%, risk of stroke is 1.6% per year; this doubles for stenoses over 60%. At 80% stenosis, the annual ipsilateral stroke risk is 5-10%. Increased stroke risk is also associated with rapid progression of carotid disease and with plaque heterogeneity or ulceration. Risk factors for carotid disease include hypertension, diabetes mellitus, hypercholesterolemia, advanced age, smoking, and coronary artery disease.

Clinical Findings

A. Symptoms

Typical manifestations of carotid artery occlusive disease include contralateral weakness or sensory loss, expressive aphasia, and amaurosis fugax (transient partial or complete loss of vision in the ipsilateral eye). Vertebrobasilar TIAs are characterized by brain stem and cerebellar symptoms, including dysarthria, diplopia, vertigo, ataxia, and hemiparesis or quadriparesis.

Dizziness and unsteadiness, particularly when associated with a quick change in position, are nonspecific symptoms and more often the result of postural hypotension than of vertebrobasilar insufficiency. Atypical neurologic symptoms, personality changes, and dementia are not typical symptoms of carotid disease.

B. Signs

Occlusive disease of the brachiocephalic arteries may be accompanied by cervical bruits, diminished or absent pulses in the neck or arms, Hollenhorst plaques (bright, refractile cholesterol emboli) in the retinal arteries, or a blood pressure difference between the two arms of more than 10 mm Hg. The common carotid pulsation can be examined qualitatively by palpation at the base of the neck. The presence of superficial temporal artery pulsation confirms patency of the ipsilateral external carotid artery. A carotid bruit is a high-pitched, blowing noise sharply localized high in the lateral neck close to the angle of the mandible. Heart sounds must be auscultated to make certain that the bruit is not caused by a referred murmur of aortic stenosis. Only 30% of patients with cervical bruits have carotid stenosis greater than 60%. The absence of a bruit also does not preclude the possibility of a hemodynamically significant lesion—thus, bruits are neither sensitive nor specific for carotid occlusive disease. In fact, asymptomatic carotid bruits are stronger predictors of death from coronary artery disease than of death from stroke.

Imaging Studies

Duplex ultrasonography has become the study of choice for evaluation of carotid occlusive disease. It provides both physiologic and anatomic information. Percent stenosis is derived from measurement of blood flow velocities, with sensitivity and specificity greater than 90%. Ultrasound also provides some characterization of the plaque itself, including its location and the presence of calcification, ulceration, and intraplaque hemorrhage. Patients with adequate ultrasound studies may be offered surgery without further imaging. Patients with suboptimal ultrasound studies or in whom intracranial tandem lesions are suspected are referred for gadolinium-enhanced magnetic resonance angiography, which provides more detailed information about plaque composition and characterizes the intracranial circulation and the brain parenchyma. When compared with en bloc resected specimens, correlation of percent stenosis is better with ultrasound and MRA than with conventional angiography. This can be explained by the fact that MRA and ultrasound both produce cross-sectional imaging of vessels whose stenotic regions may be eccentric. Symptomatic patients with ipsilateral carotid occlusion by ultrasound should be referred for conventional or CT angiography before electing nonoperative management because a small percentage of these patients will have an internal carotid artery "string sign" and should be revascularized. Catheter angiography carries a 1% risk of procedure-related stroke and is reserved for patients with greatly disparate ultrasound and MRA findings, those suspected of vertebrobasilar insufficiency or intracranial lesions unable to undergo MRA, and those potentially requiring endovascular intervention. As ultrasound is highly operator-dependent, MRA is highly equipment-dependent; selection of the most accurate imaging modality may vary by institution.

Treatment

A. Medical Measures

Acute or evolving strokes and strokes associated with major neurologic deficits are initially managed medically, delaying surgery for 5-8 weeks until the deficit is stable, as discussed in the section on cerebrovascular accidents in [Chapter 24](#). Patients with transient ischemic attacks may be treated with an oral antiplatelet medication (aspirin, 325 mg daily, ticlopidine, 250 mg twice daily, or clopidogrel, 75 mg twice daily) to reduce the likelihood of thrombosis and microemboli. However, if the attacks are of increasing frequency, the patient is admitted and placed on a heparin drip while being evaluated for surgery. Postoperatively, most patients are maintained on aspirin indefinitely to reduce the incidence of thrombosis or recurrent disease in the newly endarterectomized vessel.

For patients in whom neurologic symptoms are thought to be secondary to intracerebral disease not amenable to surgical reconstruction, warfarin or clopidogrel may be indicated.

B. Surgery

1. Transient ischemic attacks and stroke—Carotid endarterectomy plus optimal drug therapy and risk factor modification are highly effective in preventing stroke and death in symptomatic patients with carotid stenosis greater than 70—as demonstrated by the North American Symptomatic Carotid Endarterectomy Trial (NASCET). A more modest risk-benefit ratio has been demonstrated for carotid endarterectomy in symptomatic 50-69% stenoses. Surgical success is maximized when preoperative symptoms are related to ischemia of the ipsilateral hemisphere and when the surgery is done by a vascular surgeon who performs carotid endarterectomies regularly with a mortality-complication rate less than 5%. Placement of a temporary carotid shunt during surgery allows cerebral perfusion during cross-clamping; however, the shunt may increase the technical complexity of the operation. Indications for intraoperative shunting vary by surgeon. Most surgeons shunt patients with previous stroke; some selectively shunt for a measured stump pressure (internal carotid back pressure) under 50 mm Hg or for patients with EEG changes, and others shunt all patients.

2. Asymptomatic carotid stenosis—Approximately 5% of patients per year with asymptomatic carotid stenosis greater than 80% suffer a stroke. This statistic helps form the basis for the American Heart Association's recommendation of upper limits of acceptable combined morbidity and mortality for carotid endarterectomy: 3% for asymptomatic patients, 5-7% for those with TIAs or stroke, and 10% for those with recurrent carotid stenosis. The Asymptomatic Carotid Artery Stenosis (ACAS) trial demonstrated that in good-risk asymptomatic patients with greater than 60% stenosis, surgery afforded an overall risk reduction of 53% over aspirin alone. These findings are supported by a smaller Veterans Administration Hospital study of patients with asymptomatic carotid artery stenosis. Most vascular surgeons offer surgery to asymptomatic patients with greater than 80% stenosis in the ipsilateral carotid artery.

3. Percutaneous techniques—Patients who are not good candidates for surgery because of medical comorbidities can be considered for carotid angioplasty and stenting. This option is also explored in patients with a history of previous neck surgery or irradiation, in whom there is a higher risk of cranial nerve injury because of fibrosis and scarring. Stenting has also recently been shown to be safe and effective treatment for immediate postoperative stroke, particularly when the neurologic event is due to dissection of the vessel. Carotid stenting is associated with a 5-18% risk of periprocedural stroke or transient ischemic attack, which is not significantly improved with various cerebral protection devices, and an 8-14% per year incidence of recurrent stenosis (compared with less than 4% per year with surgery). This makes it a seldom-favored approach for most carotid disease.

Prognosis

Prognosis is related to the difficulty of surgery and the collateral flow in the circle of Willis. Surgery carries a reported average 1-2% mortality rate and a 1-4% risk of neurologic complication, though wide institutional variation exists. In symptomatic patients, endarterectomy reduces stroke risk fivefold to tenfold at 5 years. The 5-15% incidence of late stroke after uncomplicated endarterectomy is often related to contralateral carotid or intracranial disease.

Restenosis occurring less than 2 years after carotid endarterectomy is usually not symptomatic because it is due to intimal hyperplasia, which produces a smooth, nonfriable luminal surface. These lesions respond well to angioplasty and stenting, and the risk of procedural neurologic events is lower than for atherosclerotic lesions. After 2 years, restenosis is more often related to progression of atherosclerotic disease. These lesions can be friable and prone to intraplaque hemorrhage, just like the original plaque. In general, repeat surgery or stenting is advised for symptomatic restenoses or stenoses greater than 80%.

OTHER DISEASES OF THE CAROTID ARTERY

Carotid Dissection

Carotid dissection is a false channel in the wall of the carotid artery produced by a tear in the intima. The classic triad of symptoms is unilateral neck pain or headache, stroke or transient ischemic attack, and an incomplete Horner syndrome (miosis and ptosis without anhidrosis). Dissections can be spontaneous or traumatic, caused by shearing of the internal carotid artery between the C2 and C3 transverse processes during deceleration injuries such as car accidents, wrestling, chiropractic maneuvers, and "head-banging" dancing. The primary treatment of dissection is medical. With warfarin anticoagulation (to an INR of 2.0-3.0), 60-85% of carotid

dissections will heal in 3-6 months with complete or near-complete neurologic recovery. Recurrent dissection is estimated at 3% at 3 years and 12% at 10 years and most often involves a different cervical vessel, which justifies the use of long-term aspirin. Surgery (usually carotid interposition) or carotid stenting is indicated for ongoing symptoms with residual stenosis or aneurysm.

Carotid Body Tumors

The carotid body is a chemoreceptor derived from embryonic neural crest cells located at the carotid bifurcation. Carotid body tumors (also called paraganglionomas or chemodectomas) are rare and usually present as painless neck masses. Most of these tumors are slow-growing and benign, but lymph node metastases have been reported. If untreated, they are locally invasive; a large tumor may cause vagus or hypoglossal nerve deficit from mass effect or may encircle the internal carotid artery to the skull base. The tumor is hypervascular and splays the internal and external carotid arteries, giving it a classic angiographic appearance of a tumor blush in the center of a widened carotid bifurcation. Biopsy is contraindicated; diagnosis is made by angiography or MRA. Preoperative angiography for tumor embolization and test occlusion of the internal carotid artery are advised for tumors over 4 cm in diameter. Using the same approach as for carotid endarterectomy, the tumor is resected off the carotid artery, with care to preserve the artery wall adventitia. Many small arteries arising from the external and internal carotid arteries supply the tumor and must be individually ligated. The incidence of cranial nerve injury with resection of large tumors approaches 40%. Prognosis after complete resection is excellent, with survival equal to that of age-matched controls and long-term recurrence of 6%.

Carotid Artery Aneurysms

Carotid aneurysms are much more common in the intracerebral than in the cervical portion of the carotid arteries. Most often, cervical aneurysms arise in the common carotid artery and are fusiform; these are associated with atherosclerosis. Traumatic aneurysms can be related to healing of an internal carotid dissection or to penetrating trauma. Mycotic aneurysms can be caused by staphylococcal, *Escherichia coli*, or tuberculous infections. Many other vasculitides are associated with carotid aneurysms, such as Behcet's disease, Takayasu's disease, fibromuscular dysplasia, and segmental arterial mediolysis. Anytime a mass in the neck is pulsatile, an aneurysm should be considered and diagnosis confirmed by angiography. Other symptoms include neck pain, cranial nerve dysfunction, and transient ischemic attack or stroke. Surgery should be considered for aneurysms resulting from penetrating trauma, aneurysms associated with neurologic deficit, mycotic aneurysms, and aneurysms over 2 cm in diameter. Primary repair of the artery may be accomplished for most penetrating injuries. Carotid resection and interposition grafting or simple carotid ligation is performed for most other aneurysms.

VISCERAL ARTERY INSUFFICIENCY

Chronic intestinal ischemia results from atherosclerotic occlusive lesions at the origins of the superior mesenteric, celiac, and inferior mesenteric arteries. Because of collateral flow via the marginal artery of Drummond, the pancreaticoduodenal arteries, and the hemorrhoidal arteries, bowel ischemia does not occur until two of the three main visceral arteries are severely diseased. In fact, almost 30% of patients with peripheral vascular disease have asymptomatic occlusive disease of the mesenteric arteries. Symptoms consist of epigastric or periumbilical postprandial pain, often accompanied by bloating or diarrhea and, at later stages, food avoidance (sitophobia), resulting in weight loss. Chronic intestinal ischemia is usually a diagnosis of exclusion, derived after a negative workup for peptic ulcer disease, gastroesophageal reflux, pancreatitis, irritable bowel syndrome, and malignancy. A suggestive history in a person over 45 years of age who appears chronically ill, has risk factors for arterial occlusive disease, and has no other identifiable cause for abdominal symptoms is an indication for arteriography. Intravenous hydration must be provided to avoid acute bowel ischemia from catheter-induced or contrast-associated arterial spasm. Surgical or endovascular management is directed toward restoration of antegrade visceral arterial flow. Transaortic endarterectomy and mesenteric artery bypass are associated with a 5-9% mortality rate and a 10-25% recurrence rate at long-term follow-up. A higher recurrence rate is observed with stenting of short-segment lesions; these patients require routine angiographic follow-up. Perioperative nutritional supplementation is essential to the successful management of these patients.

Celiac axis compression syndrome (stenosis of the celiac artery caused by external compression of the arcuate ligament) has been described as a variant of chronic mesenteric ischemia. As an isolated entity, it is occasionally associated with cramping abdominal pain, nausea, vomiting, and diarrhea. Division of the arcuate ligament may be combined with mesenteric reconstruction for multivessel occlusive disease, but it is seldom performed as an isolated procedure, because of poorly defined symptoms and variable postoperative result.

Acute intestinal ischemia may result from (1) embolic occlusion of a visceral branch of the abdominal aorta, generally in patients with mitral valvular disease, atrial fibrillation, or left ventricular mural thrombus; (2) thrombosis of an atherosclerotic mesenteric vessel; (3) low-flow or shock state due to cardiac failure or arterial spasm induced by ergot or cocaine intoxication; or (4) postcoarctectomy syndrome, producing nonocclusive mesenteric vascular insufficiency. Emboli are responsible for almost half of all cases. Symptoms include sudden onset of severe epigastric and periumbilical abdominal pain with minimal appreciable findings on abdominal examination ("pain out of proportion to physical findings") and a high leukocyte count. Lactic acidosis, hypotension, and abdominal distention indicate bowel infarction. Mortality approaches 80% despite aggressive surgical management.

Visceral angiography can be performed in the stable patient; duplex ultrasound is of less diagnostic value in this setting. Mesenteric thrombosis causes occlusion at the origin of the vessel, while emboli most often lodge within the superior mesenteric artery at the first jejunal branch. In hypoperfusion-related mesenteric ischemia, the vessels are pruned but patent. Angiography also allows delivery of catheter-directed therapy: thrombolytics (alteplase, 0.5-1 mg/h) for thrombotic disease or vasodilators (papaverine, 30-60 mg/h) for nonocclusive disease. Broad-spectrum antibiotics are administered to all patients. Embolic disease, acidosis, hemodynamic instability, or severe or progressive abdominal pain mandate emergent laparotomy. Mesenteric flow is first reestablished with thomboembolectomy or bypass, and the bowel resection margins are then determined by gross inspection or examination with fluorescein. A second-look operation is planned if any bowel is of questionable viability at the close of the case.

Mesenteric vein occlusion is responsible for 5-15% of cases of acute mesenteric ischemia. Risk factors include hypercoagulable state (malignancy; protein C, protein S, or antithrombin III deficiency; presence of anticardiolipin or antiphospholipid antibody; polycythemia vera), intra-abdominal sepsis, previous splenectomy or portal angiography or sclerotherapy, portal hypertension, and cirrhosis. Diagnosis is made by contrast-enhanced abdominal CT scan or arterial portography. Patients should be treated with long-term anticoagulation. Surgery is reserved for those suspected of having bowel infarction and consists of bowel resection and occasionally venous thrombectomy. In some cases, percutaneous transhepatic administration of thrombolytics has been successful.

Ischemic colitis can develop as a result of acute or chronic colonic ischemia and is characterized by bouts of crampy lower abdominal pain and mild—often bloody—diarrhea. This picture may be indistinguishable from inflammatory bowel disease. Colonoscopy reveals segmental inflammatory changes, most prominent in the watershed areas of the rectosigmoid junction and splenic flexure. Conservative management is usually adequate. Surgery may be indicated for progressive symptoms or stricture formation.

RENAL ARTERY STENOSIS

Renal artery stenosis is produced predominantly by atherosclerotic occlusive disease (80-90% of patients) or fibromuscular dysplasia (10-15% of patients). Characteristically, patients with occlusive disease have common risk factors for atherosclerosis, and their lesions are focal proximal or ostial calcific plaques, often described as "spillover" aortic disease. Patients with fibromuscular dysplasia tend to be women 30-50 years of age with distal renal artery disease that often extends into the branch vessels in a classic "string of beads" pattern of alternating stenoses and dilations.

Renal artery stenosis has two important clinical manifestations: renovascular hypertension and ischemic nephropathy. Renovascular hypertension accounts for only about 5% of all cases of hypertension. In certain subsets of patients, the incidence is much higher. Seventy percent of patients over 60 years of age with diastolic blood pressure greater than 105 mm Hg and serum creatinine greater than 2 mg/dL have renovascular hypertension. In hypertensive children under 5 years of age, the incidence of this disease approaches 80%. Evaluation should be considered in patients with poorly controlled or acutely worsening hypertension on a seemingly adequate medical regimen (three or more antihypertensive medications), particularly when presenting in conjunction with renal insufficiency, lateral abdominal bruit, or noncardiogenic "flash" pulmonary edema. A history of acute renal failure when starting an angiotensin-converting enzyme inhibitor is highly suggestive.

An incidental finding of renal artery stenosis greater than 50% is noted in as many as 45% of patients undergoing angiography for aortoiliac occlusive disease. Infrequently, it is associated with progressive renal insufficiency. High-grade (over 70%) bilateral stenoses or stenosis in a solitary kidney warrant close follow-up. Renal artery occlusive disease is suspected in patients with rapidly progressive renal insufficiency and no evidence of obstructive uropathy or intrinsic renal disease (no proteinuria on urinalysis, no polycystic disease on ultrasound).

Initial screening tests include duplex ultrasound, captopril renal scintigraphy, and MRA. Sensitivity and specificity of detecting renal artery stenosis greater than 60% are over 90% for each of these modalities, but the tests are highly operator-dependent and equipment-dependent—the most reliable examination varies by institution. An assessment should also be made of the kidney parenchyma: renal size, cortical thickness, and presence of infarcts. One pitfall of these modalities is failure to identify small accessory renal arteries, which when diseased can contribute to renovascular hypertension.

Indications for treatment include renovascular hypertension refractory to aggressive medical management or renal artery stenosis with progressive renal failure or sudden-onset noncardiogenic pulmonary edema. Percutaneous endovascular or open surgical procedures do not confer added benefit over medical therapy alone in patients with well-controlled hypertension and no ischemic nephropathy.

Angiography is generally required for planning an operative strategy and in many cases discloses a lesion amenable to angioplasty and stenting. Ideal lesions for endovascular treatment are focal, proximal, nonostial plaques that do not extend into the branch vessels. Primary stenting is advised for stenoses in renal arteries greater than 6 mm in diameter because of improved patency over angioplasty alone. One exception to this rule is fibromuscular dysplasia, in which a durable clinical effect is often produced by angioplasty alone. In patients with renal insufficiency, use of nonionized contrast, preprocedure intravenous hydration, and administration of the antioxidant acetylcysteine, 600 mg orally twice daily for 2 days before and 2 days after examination, is advised. The long-term patency of renal artery stents is yet undefined, but a 20-44% restenosis rate from intimal hyperplasia is noted at 6-36 months. Overall, 3-13% of initially stented patients ultimately require surgery.

Surgery is indicated for threatened loss of total renal mass (bilateral renal artery stenosis greater than 75%), for treatment of progressive renal failure or uncontrolled renovascular hypertension in patients with lesions refractory to angioplasty, for complex lesions extending into the branch vessels, or for concomitant aortic disease requiring surgical reconstruction. Because of superior long-term patency, surgery may be preferred over angioplasty for primary treatment of renal artery occlusive disease in good-risk surgical candidates. Surgical options include transaortic renal endarterectomy, renal artery bypass, or extra-anatomic (hepatorenal, splenorenal, or iliorenal) bypass. Mannitol (25 g intravenously) and fenoldopam (0.5-1 ug/kg/min) have been beneficial in the perioperative management of these patients. Nephrectomy is considered for patients with renovascular hypertension and irreversible renal atrophy (kidney length less than 5 cm, severe cortical thinning, less than 10% of total renal function by split function testing). Endarterectomy and aortorenal bypass have 5-year patency greater than 80%, with beneficial blood pressure response in 70-90% of patients and improvement or stabilization in renal function in 70-80%.

ACUTE LIMB ISCHEMIA

Acute limb ischemia can be embolic, thrombotic, or traumatic. Symptoms and signs are related to the location of the occlusion, the duration of ischemia, and the degree of development of collateral circulation. Baseline pulse examination and assessment of motor and sensory function are imperative. Characteristically, acute ischemia is described by the six Ps: pain, pallor, pulselessness, paresthesias, poikilothermia, and paralysis. Pain and paresthesias are the most common early symptoms.

The following differential points should be considered: (1) Are there manifestations of advanced occlusive arterial disease in other areas, especially the opposite extremity (bruit, absent pulses, secondary skin changes), and is there a history of intermittent claudication? These findings suggest primary arterial thrombosis. (2) Is there a history of rheumatic heart disease, atrial fibrillation, or myocardial infarction? These findings suggest embolism.

1. Arterial Embolism

Eighty to 90 percent of arterial emboli arise from the heart. Atrial fibrillation is present in 60-70% of patients with arterial emboli and is associated with formation of thrombus in the left atrial appendage. Thrombus within a postinfarct ventricular aneurysm may also be a potential embolic source. Emboli arising from rheumatic heart disease are decreasing in incidence and now comprise less than 20% of arterial emboli. Cardiac valvular prostheses and cardiac tumors (myxomas) can also produce emboli. Noncardiac emboli arise from atherosclerotic lesions in proximal vessels, tumors, and foreign bodies. Paradoxical emboli deriving from deep venous thrombosis in the leg can also occur.

Emboli tend to lodge at the bifurcation of major arteries, with 40% going to the aortic bifurcation or the infrainguinal vessels. Thirty percent lodge in the cerebrovascular vessels, 10% in the visceral vessels, and 15% in the upper extremity vessels. Noncardiac emboli from arterial ulcerations are usually small, giving rise to peripheral ulceration and digital ischemia or occasionally to a systemic illness resembling vasculitis.

Treatment

Heparin sodium should be given as soon as the diagnosis of acute arterial occlusion is made and continued intraoperatively in order to prevent distal thrombosis. Emergent embolectomy is performed by introducing a balloon catheter through a small arteriotomy. An embolus at the aortic bifurcation or in the iliac artery can often be removed under local anesthesia through unilateral or bilateral common femoral arteriotomies. Smaller balloon catheters passed distally from the femoral artery can be used to extract popliteal or tibial emboli, though these often require popliteal arteriotomy. Percutaneous catheter techniques (aspiration, mechanical thrombolysis, or thrombolytic therapy) have some reported success in treatment of peripheral embolic disease. Lifelong anticoagulation is recommended because of the high frequency of recurrent emboli. Surface or transesophageal echocardiography should be performed to exclude the possibility of atrial thrombus, valvular disease, or cardiac tumor.

Embolectomy performed more than 6 hours following onset of symptoms is often accompanied by development of a compartment syndrome. In mild cases, fasciotomy performed at the time of embolectomy can result in full functional recovery of the limb. The most common persistent major neurologic deficit is foot drop secondary to peroneal nerve ischemia. Myoglobinuria and renal failure can result from rhabdomyolysis and can be minimized with aggressive hydration, forced diuresis, and alkalization of the urine. These measures decrease the risk of myoglobin precipitation in the renal tubules. One regimen involves initial infusion of 250 mL/h of crystalloid, half as 0.45 normal saline and the rest as D₅W with two ampules of sodium bicarbonate and 12.5 g of mannitol per liter of fluid. Severe cases of compartment syndrome may result in anuric renal failure and systemic inflammatory response syndrome. In these patients, primary amputation may be life-saving.

Prognosis

Arterial embolism is associated with a 5-25% risk of limb loss and a 25-30% in-hospital mortality. Heart disease is responsible for over half of these deaths.

In patients with atrial fibrillation, mechanical or pharmacologic cardioversion or long-term anticoagulant therapy may decrease the risk of further emboli.

If no heart disease exists, prognosis is dependent on identification and exclusion of the embolic source. Cholesterol emboli from proximal arterial aneurysm or ulceration may occlude small distal vessels, producing digital ischemia or "trash foot." One common scenario is "blue toes" after aortography or aortic cross-clamping for coronary artery bypass or aneurysm repair. However, atheroemboli can also produce transient ischemic attacks, acute renal insufficiency, or bowel ischemia depending on their location. Microhematuria, eosinophilia, and an elevated sedimentation rate are detectable transiently on laboratory testing. Biopsy of the infarcted tissue reveals cholesterol clefts in the small vessels under polarized light. These lesions are not treatable by embolectomy because the vessels involved are so small, and heparinization may worsen the problem by liberating more fragments from an ulcerated atherosclerotic plaque. Aortic or iliac lesions can be treated by endarterectomy, by resection and interposition graft, or by placement of a covered stent.

2. Acute Arterial Thrombosis

Acute arterial thrombosis is most commonly a complication of chronic atherosclerotic occlusive disease but can also occur as a consequence of trauma, low-flow states such as hypovolemic or cardiogenic shock, or an inflammatory arteritis. Polycythemia, dehydration, and hypercoagulable states also increase the risk of thrombosis. Generally, thrombus starts at the point of greatest stenosis and propagates distally to the next open branch point, such as a patent collateral vessel.

Treatment

Nonoperative treatment is the initial approach for many patients with acute arterial thrombosis. Because thrombosis develops in the setting of chronic occlusive disease, there are usually well-developed collaterals and little arterial spasm. The extremity is able to tolerate the longer periods of ischemia required for catheter-directed thrombolysis. Instillation of alteplase (0.5-1 mg/h) directly into the thrombus through a multi-side-holed catheter may allow recanalization of distal

vessels that are less amenable to surgical thrombectomy. It also helps to disclose the underlying stenotic lesion, which can then be treated with angioplasty, endarterectomy, or bypass grafting. Thrombolysis is successful in 50-80% of cases, with a limb salvage rate approaching 90%.

Less commonly, arterial thrombosis follows penetrating trauma, such as arterial transection and foreign body embolization, or blunt trauma, such as posterior knee dislocation and crush injury. These patients require surgical treatment. The vessel involved may be previously undiseased, with only a few small collaterals. Thrombolysis is generally not indicated because of the more advanced state of limb ischemia on presentation and the high incidence of bleeding complications.

Prognosis

Limb salvage is usually possible with acute thrombosis of the iliac or superficial femoral arteries but is less likely with popliteal thrombosis because of the paucity of available collaterals. Acute thrombosis of a popliteal aneurysm is associated with a 10-25% risk of amputation.

■ OTHER ARTERIOPATHIES

THROMBOANGIITIS OBLITERANS (BUERGER'S DISEASE)

Buerger's disease is an episodic and segmental inflammatory and thrombotic process of the peripheral arteries and veins. The cause is not known. It is seen most commonly in men under 40 who smoke, and particularly in those of Eastern European or Asian background. It is characterized by occlusion of distal arteries, producing claudication, rest pain, and tissue necrosis. The inflammatory process is intermittent, with quiescent periods lasting weeks, months, or years. Different arterial segments may become occluded in successive episodes; recanalization can occur during periods of disease remission.

There are no pathognomonic signs, but several findings are characteristic of Buerger's disease. (1) The typical patient is a man under 40 who smokes. Fewer than 20% of patients are women. (2) There is a history of migratory superficial segmental thrombophlebitis, eg, red, tender nodules in the branches of the saphenous vein. Biopsy of the affected vein may show inflammatory infiltrate in the vessel wall, microabscesses, and thrombus or recanalization with perivascular fibrosis, depending on the stage of disease. (3) Intermittent claudication typically begins in the arch of the foot and progresses to the calf; instep claudication is not typical of atherosclerotic occlusive disease. Rest pain and diminished sensation from ischemic neuropathy are present in over 70% of patients at presentation. (4) Proximal pulses are normal, while distal pulses are diminished or absent. Digital disease is often asymmetric: Not all of the toes are affected to the same degree. The affected digits may be pale or cyanotic or erythematous. (5) Ulcers are present in 75% of patients and are typically located at the nail margins. (6) The disease is never confined to one limb. Although not all limbs may be symptomatic, an abnormal Allen test or distal pulse examination can usually be demonstrated. (7) There is often a history of cold sensitivity or Raynaud's phenomenon. (8) The clinical course is usually episodic, with acute exacerbations followed by rather definite remissions. By contrast, steadily progressive symptoms are typical in atherosclerotic occlusive disease.

Atherosclerotic occlusive disease, emboli, and autoimmune disorders are included in the differential diagnosis. Several angiographic findings can be helpful in making these distinctions. Buerger's disease involves the distal arteries and spares the proximal arteries; it is segmental in appearance, with skip areas of disease; there is no vascular calcification; and extensive collateralization via tortuous "corkscrew" vessels is typical. Peripheral ultrasound or angiography and echocardiography are helpful in excluding an embolic source. Blood tests (complete blood count, coagulation studies, sedimentation rate, antinuclear antibody, lupus anticoagulant, rheumatoid factor, anticentromere antibody, and antiphospholipid antibody) are obtained to rule out vasculitis, lupus erythematosus, scleroderma, rheumatoid vascular disease, or a hypercoagulable state due to antiphospholipid antibody syndrome. A careful history is generally sufficient to exclude other rare disorders that may mimic Buerger's disease, such as ergotamine intoxication, cannabis arteritis, or small vessel occlusive disease secondary to the use of vibratory tools (hypothernar hammer syndrome).

Smoking cessation is imperative. The disease can remain active with as little as a single cigarette a day; chewing tobacco, marijuana, nicotine patches, nicotine gum, and exposure to second-hand smoke must all be eliminated to arrest the disease process. Local wound care of ulcers consists of limited debridement, appropriate dressings, and intravenous antibiotics for cellulitis. Nonulcerated skin should be kept moisturized. Lamb's wool between the toes and heel protectors or sheepskin-lined boots (Rooke boots) help to reduce further trauma to the skin. Warming pads must be used judiciously, as burns are possible in patients with diminished sensation from peripheral neuropathy. Supplementary oxygen by nasal cannula is often used to increase oxygen supply to the wound. Some ulcers may respond to hyperbaric oxygen.

Nonsteroidal anti-inflammatory medications and opioids are used for pain control. Aspirin (325 mg daily) or another antiplatelet agent is generally prescribed to reduce thrombotic complications. Calcium channel blockers are often used to promote vasodilation. Preliminary trials have shown intravenous infusion of the prostaglandin analog iloprost to be efficacious in healing of ischemic ulcers, but the drug is not yet available in the United States. Vascular endothelial growth factor (VEGF) is also being investigated for use in Buerger's disease.

Rarely do distal target vessels exist for arterial bypass. Sympathectomy may at least transiently reduce the vasospastic manifestations of the disease and aid in the establishment of collateral circulation to the skin. It is indicated for relief of intractable rest pain and healing of ulcers refractory to other treatment. Sympathectomy is often performed in conjunction with digital amputation. Amputation is reserved for patients with wet gangrene or severe rest pain.

Prognosis is dependent on the success of smoking cessation. Over 90% of patients who quit smoking avoid further amputation.

IDIOPATHIC ARTERITIS OF TAKAYASU ("PULSELESS DISEASE")

Takayasu's disease is a rare polyarteritis of unknown cause with a special predilection for the branches of the aortic arch. It results in segmental stenoses, occlusions, and aneurysms. It predominantly affects Asian women under the age of 40. There are a myriad of clinical presentations depending on the stage of disease (early "inflammatory" or late "occlusive") and the vessels involved. Early stages of disease are often accompanied by fever, myalgias, arthralgias, and pain over the involved artery as well as leukocytosis and elevated sedimentation rate. Other symptoms are related to arterial insufficiency: syncope, dizziness, amaurosis fugax, stroke, angina, pulmonary hypertension, and claudication. Hypertension related to proximal renal artery stenosis or aortic coarctation is present in over one-quarter of patients. Vascular bruits, diminished peripheral pulses, or asymmetric blood pressure measurements are common findings on physical examination.

Angiography is essential for diagnosis and most often will reveal combined occlusive and aneurysmal disease. The most commonly involved vessels are the subclavian artery, descending thoracic aorta, renal artery, carotid artery, and mesenteric arteries, although the ascending and abdominal aorta and the vertebral, coronary, pulmonary, iliac, and brachial arteries can also be affected. In cases of upper extremity stenoses, aortic root pressure should be measured by manometry at the time of angiography to assess for essential hypertension. MRA can also be used for routine surveillance of patients with suspected Takayasu's disease.

Pulseless disease must be differentiated from vascular lesions of the aortic arch due to atherosclerosis, though in the latter instance concomitant lower extremity disease is invariably present. Histologically, the arterial lesions are indistinguishable from those of giant cell arteritis. In the early, active stage, corticosteroids (prednisone, 1 mg/kg/d) are used to control symptoms and limit the progression of disease; cytotoxic agents may be added if steroids are ineffectual. Surgical or percutaneous intervention is not advised until the disease becomes indolent. Bypass of the occluded or aneurysmal segments is the usual surgical approach. Histologic examination of the resected artery may show nonspecific transmural inflammation or chronic fibrosis. Percutaneous angioplasty or stenting is possible for short-segment stenoses, but there is a high recurrence rate in these usually noncompliant vessels.

Johnston SL et al: Takayasu arteritis: a review. J Clin Pathol 2002;55:481. [\[PMID: 12101189\]](#)

FIBROMUSCULAR DYSPLASIA

Fibromuscular dysplasia is a nonatherosclerotic, noninflammatory disease of unknown cause characterized by segmental irregularity of small and medium-sized muscular arteries. Typically, it affects white women 30-50 years of age; a family history of disease is not unusual. The most frequently involved vessels (in descending order) are the renal, carotid, and common iliac arteries. Patients present with renovascular hypertension and, less often, with renal insufficiency, transient ischemic attacks or claudication. Angiography reveals a "string of beads" pattern of disease. There are four recognized histologic types of fibromuscular dysplasia: medial fibrodysplasia, intimal fibroplasia, medial hyperplasia, and perimedial dysplasia, though the first type is responsible for over 80% of all cases. Aspirin is advised for most patients. Percutaneous or surgical intervention is reserved for symptomatic patients. Most lesions respond well to percutaneous angioplasty; stents do not appear to offer any advantage over angioplasty alone. More complex lesions extending into branch vessels may require interposition grafting. It is important to recognize that intracranial aneurysms are present in as many as half of patients with internal carotid fibromuscular dysplasia.

Birrer M: Treatment of renal artery fibromuscular dysplasia with balloon angioplasty: a prospective follow-up study. Eur J Vasc Endovasc Surg 2002;23:146. [\[PMID: 11863332\]](#)

VASCULITIS

The term vasculitis describes a diverse group of inflammatory disorders characterized by multi-organ system vascular involvement, systemic markers of disease (fever, malaise, weight loss, elevated white blood cell count and sedimentation rate), and suspected immunologic origin. Often there are accompanying rheumatologic or cutaneous manifestations such as arthralgias, conjunctivitis, or erythema nodosum. Drugs (amphetamines, cocaine, hydralazine, procainamide), infections (hepatitis B, gonococcus, streptococcus), chronic inflammatory diseases, and cancer are cited as inciting causes for vasculitis. These diseases can be grouped into disorders that affect medium and large blood vessels (polyarteritis nodosa, scleroderma, systemic lupus erythematosus, temporal arteritis, Behcet's disease, Kawasaki syndrome, rheumatoid arteritis, relapsing polychondritis) and those that affect smaller vessels (Churg-Strauss syndrome, Wegener's granulomatosis, Henoch-Schonlein purpura, essential mixed cryoglobulinemia). These are discussed in detail in [Chapter 20](#). In general, the vascular lesions are treated with anti-inflammatory medications. Surgery is indicated for acute complications (bowel infarction, gangrene, or aneurysm rupture) and for chronic ischemic symptoms or large aneurysms in patients with quiescent disease.

■ VASOMOTOR DISORDERS

RAYNAUD'S DISEASE & RAYNAUD'S PHENOMENON

Essentials of Diagnosis

- Episodic bilateral digital pallor, cyanosis, and rubor.
- Precipitated by cold or emotional stress; relieved by warmth.
- Seventy to 80 percent of patients are women.

General Considerations

Raynaud's syndrome is an episodic vasospastic disorder characterized by digital color change (white-blue-red) with exposure to cold environment or emotional stress. If idiopathic, it is called Raynaud's disease. If associated with a possible precipitating systemic or regional disorder (autoimmune diseases, myeloproliferative disorders, multiple myeloma, cryoglobulinemia, myxedema, macroglobulinemia, or arterial occlusive disease), it is called Raynaud's phenomenon. The incidence of disease is estimated to be as high as 10% in the general population. Other vasospastic disorders, such as variant angina and migraine headache, are common in patients with Raynaud's syndrome. An abnormality of the sympathetic nervous system has long been implicated in the etiology of Raynaud's disease; recently, research has focused on the theory of up-regulation of vascular smooth muscle α_2 -adrenergic receptors.

Clinical Findings

Classically, Raynaud's disease and Raynaud's phenomenon are characterized by intermittent attacks of pallor of the hands or fingers brought on by cold or emotional stress, progressing to cyanosis and then rubor on rewarming. Mild discomfort, paresthesias, numbness, and trace edema often accompany the color changes. In Raynaud's disease, the disease is symmetric, by rule; in Raynaud's phenomenon, the changes may be most noticeable in one hand or even in one or two fingers only. Infrequently, the feet and toes are involved. Between attacks, the affected extremities may be entirely normal.

The distinction between Raynaud's disease and Raynaud's phenomenon is meant to reflect a difference in prognosis. While Raynaud's disease is benign and entirely reversible, Raynaud's phenomenon may progress to atrophy of the terminal fat pads and development of fingertip gangrene. However, because many inciting diseases may not be clinically suspected at the time the diagnosis of Raynaud's disease is made, there is a large degree of crossover between groups. The diagnosis is based on clinical criteria. Raynaud's disease appears first between ages 15 and 45, almost always in women. A patient with suggestive symptoms that persist for over 3 years without evidence of an associated disease is given the diagnosis of Raynaud's disease.

Differential Diagnosis

A patient with Raynaud's syndrome must be evaluated for possible inciting systemic disorders. Directed history and physical examination and serologic testing may be helpful in excluding the collagen-vascular disorders, which include scleroderma, systemic lupus erythematosus, dermatomyositis, and rheumatoid arthritis. It is estimated that 80% of patients with scleroderma ultimately develop Raynaud's phenomenon. Likewise, cryoglobulinemia can be excluded by appropriate testing. Raynaud's phenomenon is also occasionally seen in patients with neurogenic thoracic outlet syndrome or carpal tunnel syndrome; nerve conduction studies can be obtained if warranted by examination. Frostbite, ergotamine toxicity, and use of chemotherapeutic agents, which can also be associated with Raynaud's phenomenon, can usually be excluded by a careful history; up to one-third of patients receiving combined bleomycin and vincristine (such as for testicular cancer) develop symptomatic vasospastic disease. An abnormal or asymmetric pulse examination, differential blood pressure cuff measurements, gangrene, or a positive Allen test—any of these are suggestive of arterial occlusive disease and should prompt upper extremity angiography to exclude stenosis or occlusion from atherosclerosis, Buerger's disease, arterial thoracic outlet syndrome, embolic disease, or repetitive motion injury of the small vessels of the hand. Even undiseased upper extremity vessels often show intense vasospasm with contrast injection, so the arm is wrapped for warmth and prophylactic use of a vasodilator (papaverine or nitroglycerin, 30 mg, injected through the angiography catheter) is advised; both arms are imaged for side-by-side comparison.

Other vasospastic disorders that should be included in the differential but are usually easily distinguishable by physical examination are acrocyanosis and livedo reticularis.

Treatment

A. General Measures

Warmth and protection of the hands are the basic tenets of therapy. In Raynaud's phenomenon, wounds heal slowly, and infections are consequently hard to control. Gloves should be worn in cold environments and during activities that may cause trauma to the skin, such as dishwashing, gardening, woodworking, or office filing. Moisturizing lotion should be applied frequently to avoid fissured dry skin. Smoking cessation is imperative, as nicotine is a known vasoconstrictor. Stress management should be addressed. Oral contraceptives, beta-blockers, and ergotamines are associated with exacerbation of symptoms and ideally should be discontinued. Aspirin is prescribed to decrease the risk of thrombotic complications.

B. Vasodilators

Vasodilator drugs may be of some benefit in patients whose symptoms are not adequately controlled with simpler measures. Low-dose nifedipine (sustained-release, 30 mg/d) or diltiazem (sustained-release, 30 mg/d) has superseded topical or oral nitroglycerin for treatment of vasospasm. Use of prostaglandins has been disappointing, but the serotonin reuptake inhibitor and antidepressant fluoxetine (20 mg daily) shows some promise in reduction of the frequency and severity of attacks.

C. Surgery

Bypass should be considered for severe Raynaud's phenomenon associated with reconstructible arterial occlusive disease. Sympathectomy is indicated for unreconstructible occlusive disease or pure vasospastic disease refractory to medical management. In the lower extremity, sympathectomy may produce complete and permanent relief of symptoms; however, for unclear reasons, the beneficial effects are often transient in the upper extremity. Limited improvement is seen in advanced ischemia, particularly if significant digital artery obstructive disease is present.

Prognosis

Raynaud's disease is usually benign, causing mild discomfort on exposure to cold and progressing very slightly over the years. The prognosis of Raynaud's phenomenon is that of the associated disease.

LIVEDO RETICULARIS

Livedo reticularis is an uncommon vasospastic disorder of unknown cause that results in a painless, mottled discoloration on large areas of the extremities, generally in a fishnet pattern with reticulated cyanotic areas surrounding a paler central core. It occurs in men and women of all ages. In most instances, livedo reticularis is entirely benign; infrequently, it is associated with an occult malignancy, polyarteritis nodosa, atherosclerotic microemboli, or antiphospholipid antibody syndrome. The disorder is characterized by arteriolar vasoconstriction with capillary and venous dilation; the particular pattern is believed to represent arborization of capillaries surrounding the feeding arteriole.

Livedo reticularis is most apparent on the thighs but can occur on the forearms or lower abdomen and is most pronounced in cold weather. In warm environments, the reticular pattern may fade but does not entirely disappear. A few patients report paresthesias, coldness, or numbness in the involved areas. Peripheral pulses are normal. The affected regions may be cool. Skin ulceration is rare. Treatment consists of protection from exposure to cold; use of vasodilators is seldom indicated. In the rare patient who develops ulcerations or gangrene, an underlying systemic disease should be excluded.

ACROCYANOSIS

Acrocyanosis is an uncommon vasospastic disorder characterized by persistent cyanosis of the hands and feet and, to a lesser degree, the forearms and legs. It is associated with arteriolar vasoconstriction combined with dilation of the subcapillary venous plexus of the skin, through which deoxygenated blood slowly circulates. It is worse in cold weather but does not completely disappear during the warm season. It occurs primarily in women, is most common in the teens and twenties, and may improve with advancing age or during pregnancy. It is characterized by symmetric coldness, sweating, slight edema, and cyanotic discoloration of the hands or feet. Peripheral pulses are normal, and pain, trophic lesions, and disability do not occur.

ERYTHROMELALGIA

Erythromelalgia is a paroxysmal bilateral vasodilatory disorder of unknown cause. Idiopathic (primary) erythromelalgia occurs in otherwise healthy persons and affects men and women equally. A secondary type is occasionally seen in patients with polycythemia vera, hypertension, gout, and neurologic diseases.

The chief symptoms are erythema, warmth, and bilateral burning pain that lasts minutes to hours, at first involving circumscribed areas on the balls of the feet or palms and often progressing to involve the entire extremity. Symptoms occur in response to vasodilation produced by exercise or heat and can be prominent at night when the extremities are warmed under bedclothes. Relief may be obtained by cooling and elevating the affected extremity.

No findings are generally present between attacks. With onset of an attack, skin temperature and arterial pulsations are increased and the involved areas are warm, erythematous, and sweaty.

In primary erythromelalgia, aspirin (650 mg every 4-6 hours) often provides excellent relief and may in fact be diagnostic. Warm environments are avoided. Beta-blockers, epidural corticosteroid injections, and lidocaine patches have reported anecdotal success. Secondary erythromelalgia may improve with treatment of the primary disease process.

COMPLEX REGIONAL PAIN SYNDROME TYPE 1 (REFLEX SYMPATHETIC DYSTROPHY)

Essentials of Diagnosis

- Burning or aching pain of greater severity and longer duration than expected following trauma to an extremity.
- Manifestations of localized vasomotor instability are generally present.

General Considerations

The syndrome is characterized by burning or aching pain in an injured extremity which is more severe than would be expected given the inciting trauma. It occurs in all age groups and equally in both sexes and can involve either the arms or the legs. The degree of trauma is in some cases surprisingly minor (phlebotomy), but most cases follow crushing injuries with lacerations and soft tissue destruction. Closed fractures, simple lacerations, burns (especially electric burns), elective operative procedures, and myocardial infarction with referred left arm pain are other reported causes.

Clinical Findings

In the early stages, the pain, tenderness, and hyperesthesia are localized to the injured area and the extremity is warm, dry, swollen, and red or slightly cyanotic. With time, muscle spasm and joint stiffness limit mobility, and the nails may become ridged. In advanced stages, the pain is more diffuse, and nocturnal pain may become extreme; the extremity becomes cool and clammy and intolerant of temperature changes (particularly cold); and the skin becomes glossy and atrophic. The patient's dominant concern is to avoid external stimuli, particularly in trigger point areas. Pain and disuse lead to loss of function. Radiographs reveal asymmetric osteopenia more severe than anticipated from immobility alone.

Prevention

Trauma to peripheral nerves during surgery is avoided by knowledge of their anatomy and careful mobilization by handling of the perineural tissue only. Splinting and adequate analgesia followed by early mobilization of an injured extremity minimizes the occurrence of reflex sympathetic dystrophy.

BR>**Treatment & Prognosis**

A. Conservative Measures

Early recognition and treatment are essential to preserve function of the limb. In the early stages, when major secondary changes have not yet developed, physical therapy involving active and passive exercises combined with a mild anxiolytic (diazepam, 2 mg twice daily, or alprazolam, 0.125-0.25 mg twice daily) may relieve symptoms. Opioids have been a mainstay of treatment; recently, however, gabapentin (beginning at 200 mg twice daily) has been used with success. Sympathetic blocks (stellate ganglion or lumbar) can be combined with intensive physical therapy for cases refractory to more conservative treatment. Protection from further injury and avoidance of irritating stimuli are imperative.

B. Surgery

Patients who achieve significant temporary relief of symptoms after sympathetic blocks may be cured by sympathectomy. With advanced disease and in cases with significant psychologic overlay, however, the prognosis for improvement with sympathectomy is poor. Implantable spinal cord biostimulator devices have had limited success.

Wasner G et al: Vascular abnormalities in reflex sympathetic dystrophy (CPRS 1): mechanisms and diagnostic value. Brain 2001;124:587. [\[PMID: 11222458\]](#)

THORACIC OUTLET SYNDROME

Thoracic outlet syndrome can be subdivided into neurogenic, venous, and arterial types depending on which structures are compressed in the interscalene triangle or costoclavicular space.

Neurogenic thoracic outlet syndrome is the most common (over 90% of patients) and often the most difficult to diagnose and treat effectively. Patients most often

present with supraclavicular and anterior chest wall burning pain and with segmental pain and paresthesias of the arm in an ulnar nerve distribution. Weakness of the intrinsic muscles of the hand is not uncommon. Thenar or hypothenar muscle wasting is rare. There is usually a history of whiplash trauma (motor vehicle accident, fall, assault) or repetitive activity of the upper extremity (word processing, filing), particularly overhead activities (lifting). Physical examination will often disclose supraclavicular tenderness and positive brachial plexus tension testing. A positive Adson test (obliteration of the radial pulse on inspiration while turning the head away from the affected side), a positive Roos test (reproduction of symptoms with rapid opening and closing of the hand with the arm 90 degrees abducted at the shoulder and 90 degrees flexed at the elbow), or a positive Tinel sign (tingling in the distribution of the nerve produced by tapping in the supraclavicular interscalene region) may also be elicited. Presence of a cervical rib or other bony anomalies should be excluded by chest film. Electrophysiologic testing is usually negative. The cornerstone of treatment is specific physical therapy treatment such as the Edgelow Neurovascular Entrapment Self-Treatment (ENVEST) program, beginning with breathing exercises and attention to posture. Transcutaneous electrical nerve stimulation (TENS) is often helpful. Surgery may be indicated in severe refractory cases and involves resection of the hypertrophied anterior and middle scalene muscles, brachial plexus neurolysis, and resection of bony abnormalities. Although in carefully selected patients the initial surgical outcome is excellent, symptoms return within a year in as many as 25%, presumably due to late postoperative scarring around the nerve roots.

Venous thoracic outlet syndrome involves external compression of the subclavian vein by the first rib, anterior scalene muscle, clavicle, and costocoracoid ligament. A history of repetitive upper arm exercises or clavicular fracture is common. Positional venography is essential in the diagnosis of venous thoracic outlet syndrome; external compression of the vein and filling of venous collaterals are demonstrated by abduction of the arm. Thrombosis of the involved vein segment is known as Paget-Schroetter syndrome, or effort thrombosis, and often presents as acute unilateral arm edema, axillary fullness, hand cyanosis, and enlarged shoulder and chest wall collateral veins in an otherwise healthy patient. Evaluation for hypercoagulable state, including plasma levels of antithrombin III, factor V Leiden, cardiolipin antibody, and proteins C and S, is recommended, as an abnormality is detected in 56% of patients presenting with acute axillary-subclavian vein thrombosis. Treatment for symptomatic venous thoracic outlet syndrome involves anterior and middle scalenectomy and first rib resection with venolysis, which can be performed through a supraclavicular, a combined supra- and infraclavicular, or a transaxillary approach. If the vein is thrombosed, multimodality therapy is employed: preoperative thrombolysis followed immediately by surgery with intraoperative angioplasty of any residual venous stenosis. If the vein cannot be recannulated preoperatively, surgical thrombectomy may be required. The prognosis is excellent with appropriate treatment.

Arterial thoracic outlet syndrome is the least common of these disorders and involves compression of the subclavian artery between the anterior and middle scalene muscles. It most often produces subclavian artery aneurysms, which result in digital ischemia due to atheroemboli. These aneurysms can be subtle, often requiring magnified multiplanar views in order to be shown angiographically. Arm claudication is a less common presentation. The Wylie-Allen test (performed by exsanguinating the arm with elevation, occluding the radial and ulnar arteries at the wrist, and observing capillary refill of the hand when these arteries are released) may reveal occult digital artery occlusions that can be confirmed by angiography. Treatment involves removal of anterior and middle scalene muscles and resection of the aneurysm with polytetrafluoroethylene interposition graft.

■ VENOUS DISEASES

VARICOSE VEINS

Essentials of Diagnosis

- Dilated, tortuous superficial veins in the lower extremities.
- May be asymptomatic or associated with fatigue, aching discomfort, bleeding, or localized pain.
- Edema, pigmentation, and ulceration suggest concomitant venous stasis disease.
- Increased frequency after pregnancy.

General Considerations

Abnormally dilated veins develop in several locations, giving rise to varicoceles, esophageal varices, and hemorrhoids. However, varicose veins are most commonly found in the legs as abnormally dilated, elongated, and tortuous alterations in the saphenous veins and their tributaries. Fifteen percent of adults develop saphenous vein varicosities. Risk factors include female gender, pregnancy, family history, prolonged standing, and history of phlebitis.

The long saphenous vein and its tributaries are most commonly involved, but the short saphenous vein may also be affected. These vessels lie immediately beneath the skin and superficial to the deep fascia.

An inherited vein wall or valvular defect appears to play a role in the development of most primary varicosities. Secondary varicosities may result from valve damage following thrombophlebitis, trauma, deep venous thrombosis, arteriovenous fistula, or nontraumatic proximal venous obstruction (pregnancy, pelvic tumor). Venous reflux caused by valvular incompetence is characteristic of both primary and secondary varicose veins. At the saphenofemoral junction and the perforating veins of the medial calf and thigh, the superficial and deep veins of the leg communicate; valve incompetence in these segments permits blood flow to be bidirectional. Thus, high venous pressures (> 300 mm Hg) from within the deep system that occur during calf compression associated with walking are transmitted to these superficial veins, which dilate. With long-standing disease, the surrounding tissue and skin may develop secondary changes such as fibrosis, chronic edema, and skin pigmentation and atrophy.

Clinical Findings

A. Symptoms

The severity of the symptoms is not necessarily correlated with the number and size of the varicosities. Dull, aching heaviness or a feeling of fatigue brought on by periods of standing is the most common complaint. Itching from an associated eczematoid dermatitis may occur above the ankle.

B. Signs

Dilated, tortuous, elongated veins on the medial aspect of the thigh and leg are usually readily visible with the patient standing, though in very obese patients palpation may be necessary to detect their presence and location. Smaller, flat, blue-green reticular veins, telangiectasias, and spider veins may accompany varicose veins and are further evidence of venous dysfunction. Secondary tissue changes may be absent even in the presence of extensive large varicosities; however, with deep venous insufficiency and long-standing varicose veins signs of chronic venous insufficiency appear. These may include brownish pigmentation and thinning of the skin above the ankle, edema, fibrosis, scaling dermatitis, and venous ulceration. Duplex ultrasonography is used to detect the precise location of incompetent valves. The Brodie-Trendelenburg test is less accurate but can help differentiate saphenofemoral valve incompetence from perforator vein incompetence. With the patient lying supine, the leg is elevated until all varicosities collapse. A tourniquet is placed at the mid thigh to exclude reflux secondary to incompetence at the saphenofemoral junction. With the tourniquet in place, the patient is asked to stand. If the varicosities stay collapsed, this implies valvular insufficiency at the saphenofemoral junction. However, if the varicosities rapidly refill, perforator vein incompetence is implicated. The tourniquet can then be moved more distally to identify the location of the incompetent perforator.

Differential Diagnosis

Primary varicose veins should be differentiated from secondary varicose veins in order to exclude the possibility of chronic venous insufficiency of the deep system of veins, obstruction of the pelvic veins, arteriovenous fistula (congenital or acquired), or congenital venous malformation. If extensive varicose veins are encountered in a young patient—especially if unilateral and in an atypical distribution (lateral leg)—Klippel-Trenaunay syndrome must be considered. The classic triad of Klippel-Trenaunay syndrome is varicose veins, limb hypertrophy, and a cutaneous birthmark (port wine stain or venous malformation). Because the deep veins are often anomalous or absent, saphenous vein stripping can be hazardous. Standard treatment for patients with Klippel-Trenaunay syndrome is graduated support stockings, surgery for correction of leg length discrepancy, and limited stab avulsion (excision through 1-cm-long incisions) of symptomatic varices after thorough duplex ultrasound vein mapping.

Pain or discomfort secondary to arthritis, radiculopathy, or arterial insufficiency should be distinguished from symptoms associated with coexistent varicose veins.

Complications

Complications of varicose veins include secondary ulceration, bleeding, chronic stasis dermatitis, superficial venous thrombosis, and thrombophlebitis.

Treatment

A. Nonsurgical Measures

Knee-high or thigh-high elastic graduated compression stockings give external support to the superficial veins. For most patients, a gradient of compression of 20-30 mm Hg is appropriate. The stockings are worn all day to reduce venous hypertension due to pooling of blood and are removed at night. Periodic leg elevation and regular exercise are encouraged. In many patients, this program may provide relief of symptoms and discourage progression of disease sufficient to avoid surgery.

Small venous ulcers generally heal with leg elevation and compression bandages (Ace wrap or Unna boot). Varicose vein excision should be postponed until infection and edema are controlled.

B. Surgical Measures

Indications for surgical treatment include persistent or disabling pain, recurrent superficial thrombophlebitis, erosion of the overlying skin with bleeding, and manifestations of chronic venous insufficiency (particularly ulceration).

The operative plan is dependent on determination of the competency of the deep and perforating veins and the location of sites of venous reflux. Preoperative duplex ultrasound is essential in identification of incompetent perforating veins and in assessment of the saphenofemoral junction. Surgery can then be tailored to the pattern of disease. Stab avulsion surgery is combined with prevention of reflux by high ligation of the saphenofemoral junction or ligation of perforator branches. Stripping of the entire saphenous system is rarely required and may be complicated by hematoma formation, infection, and saphenous nerve irritation.

C. Compression Sclerotherapy

Compression sclerotherapy can be used for telangiectasias, spider veins, and small (< 4 mm) varicosities that persist after vein stripping. With patients in supine position, small volumes of a sclerosing solution (23.4% hypertonic saline or 2.5% sodium morrhuate) are injected and direct pressure is then maintained with compression stockings. The goal is to obliterate the abnormal vein by inducing localized endothelial destruction and fibrosis. More than one treatment is often required. Complications—including allergic reactions, thrombophlebitis, neoangiogenesis, skin necrosis, or hyperpigmentation—are rare.

Prognosis

With careful patient selection and properly selected operative techniques, most patients experience relief of symptoms and the recurrence rate is about 10%. Patients should be informed that this is a chronic disease and that prevention of new varicosities is dependent on continued use of the compression stockings, leg elevation, and exercise. If extensive varicosities reappear after surgery, the completeness of the high ligation should be questioned, and reexploration of the saphenofemoral area may be necessary. Even after adequate treatment, secondary tissue changes may not regress.

1. Thrombophlebitis of the Deep Veins

Essentials of Diagnosis

- Pain in the calf or thigh, often associated with edema. Fifty percent of patients are asymptomatic.
- History of congestive heart failure, recent surgery, trauma, neoplasia, oral contraceptive use, or prolonged inactivity.
- Physical signs unreliable.
- Duplex ultrasound is diagnostic.

General Considerations

Acute deep venous thrombosis (DVT) affects as many as 800,000 new patients per year. Treatment of this disease is estimated to cost \$1-2.5 billion per year, not including costs associated with long-term sequelae.

Although the cause is often multifactorial, Virchow's triad (stasis, vascular injury, and hypercoagulability) defines the events that predispose a vein to the development of thrombophlebitis. Trauma to the endothelium of the vein wall results in exposure of subendothelial tissues to platelets. With venous stasis, platelet aggregates form on the vein wall and deposition of fibrin, leukocytes, and erythrocytes results in a free-floating thrombus. Within 7-10 days, this thrombus becomes adherent to the vein wall and secondary inflammatory changes develop, though a free-floating tail may persist. The thrombus is ultimately invaded by fibroblasts, resulting in neovascularization and scarring of the vein wall and destruction of the valves. Central recanalization usually follows, with restoration of flow through the vein; however, because the valves are damaged irreparably, chronic venous insufficiency with postphlebitis syndrome occurs in approximately 35% of patients. In 80% of cases, the thrombosis begins in the deep veins of the calf. Propagation into the popliteal and femoral veins takes place in approximately 25% of these cases.

About 3% of patients undergoing major general surgical procedures will develop clinical manifestations of thrombophlebitis, and up to 30% develop asymptomatic deep vein thrombosis. Certain operations, such as total hip replacement, are associated with appreciably higher incidences of thromboembolic complications. Prolonged bed rest or immobility caused by cardiac failure, stroke, ventilatory support, pelvic bone or limb fracture, paralysis, extended air travel, or a lengthy operative procedure is one contributing factor. A hypercoagulable state resulting from malignancy, nephrotic syndrome, inherited deficiency in protein C or S or antithrombin III, homocystinuria, factor V Leiden mutation, or paroxysmal nocturnal hemoglobinuria may also play a role. An estimated 20% of patients with new deep venous thrombosis have an underlying occult or known malignancy. One-fourth of these are lung cancer, though cancers of the pancreas, prostate, breast, and ovary are not uncommon. Most are associated with increased fibrinogen or thrombocytosis. Other risk factors for deep venous thrombosis include advanced age, type A blood group, obesity, previous thrombosis, multiparity, use of oral contraceptives, inflammatory bowel disease, and lupus erythematosus. Oral contraceptives should be avoided in women who smoke or who have a history of phlebitis because of the high associated risk of thrombotic disease.

Clinical Findings

A. Symptoms and Signs

Fifty percent of patients with thrombophlebitis and 60-70% with acute pulmonary embolism have no symptoms or signs in the involved extremity. Symptomatic patients with deep venous thrombosis may complain of a dull ache, tightness, or pain in the calf or leg, especially when walking. Physical examination may disclose slight edema of the involved calf, a palpable cord, distention of the superficial venous collaterals, or low-grade fever and tachycardia. Homans' sign (pain on passive dorsiflexion of the ankle) is positive in only 50% of cases. Iliofemoral venous thrombosis can result in cyanosis of the skin (phlegmasia cerulea dolens) or a pale, cool extremity if reflex arterial spasm is superimposed (phlegmasia alba dolens).

B. Diagnostic Techniques

Because of the difficulty in making a precise diagnosis by history and physical examination and because of the morbidity associated with treatment, diagnostic studies are essential.

1. Duplex ultrasonography—Duplex ultrasonography, because of its high sensitivity, specificity, and reproducibility, has supplanted venography as the most widely used diagnostic test in the initial evaluation of patients suspected of having this disorder. The examination includes both a B mode image and Doppler flow analysis. Each venous segment is assessed for the presence of thrombosis, indicated by venous dilation and incompressibility during light probe pressure. Doppler findings suggestive of acute thrombosis are absence of spontaneous flow, loss of flow variation with respiration, and failure to increase flow velocity with distal augmentation. The criteria for the presence of chronic venous thrombosis are less well established. The chronically occluded vein is often narrowed, and there are prominent nearby collaterals. Chronic thrombi are highly echogenic, while acute thrombi are anechoic (and therefore not visible) on the B mode image. Duplex ultrasound is less accurate in detection of calf DVTs and is highly operator-dependent.

2. Ascending contrast venography—This study is rarely used because it is invasive and exposes the patient to ionizing radiation and the risks of contrast allergy, contrast-induced nephropathy, and phlebitis. Patients in whom deep venous thrombosis is strongly suspected but ultrasound is equivocal are now being referred for gadolinium-enhanced magnetic resonance venography. In experienced hands, this examination has a sensitivity of 100% and a specificity of 96% and may provide some information about the age of the thrombus.

Differential Diagnosis

Localized muscle strain or contusion or Achilles tendon rupture can often mimic thrombophlebitis. Cellulitis can have a similar clinical presentation: edema, localized pain, and erythema. Other causes of unilateral leg edema (lymphedema, rupture of a Baker cyst, obstruction of the popliteal vein by a Baker cyst, obstruction of the iliac vein by tumor or fibrosis, or external compression of the left iliac vein by the right common iliac artery, known as May-Thurner syndrome) and bilateral leg edema (heart, liver, or kidney failure, or vena caval obstruction by tumor, retroperitoneal fibrosis, or pregnancy) must be excluded.

Complications

Complications of deep venous thrombosis include pulmonary embolism (see [Chapter 9](#)), varicose veins, and chronic venous insufficiency.

Prevention

Prophylactic measures may diminish the incidence of venous thrombosis in hospitalized patients. Choice of therapy is dependent on stratification of individual patient risk factors.

A. Nonpharmacologic Measures

Venous stasis can be minimized by several simple maneuvers. Elevation of the foot of the bed 15-20 degrees encourages venous outflow. Slight flexion of the knees is desirable. A footboard enables the patient to perform leg exercises (ankle flexion and extension) while in bed. Sitting in a chair for long periods in the early postoperative period should be avoided. Early ambulation is ideal. Graduated compression stockings and sequential compression devices have proven efficacy in reducing risk of calf vein thrombosis and are particularly useful in moderate-risk and high-risk patients in whom anticoagulation is contraindicated. They function by increasing venous flow, decreasing venous stasis, and increasing the release of endothelial fibrinolytic factors and are safe for use on almost all patients. They have not been shown to decrease the incidence of pulmonary emboli.

B. Anticoagulation

Low-dose unfractionated heparin, 5000 units subcutaneously twice daily, and low-molecular-weight heparin (LMWH), eg, with enoxaparin, 30 mg subcutaneously twice daily, have both been shown to reduce significantly the incidence of postoperative deep venous thrombosis and pulmonary embolus. LMWH appears to be more effective in the orthopedic surgery patient and is associated also with a lower risk of bleeding complications (1-5% with enoxaparin versus 2-12% with unfractionated heparin). Use of heparin products is contraindicated in patients with recent craniotomy, intracranial bleeding, or severe gastrointestinal bleeding. Either medication must be withheld 12 hours prior to placement or removal of an epidural catheter to avoid epidural hematoma. Coagulation studies are unaffected with prophylactic dosing, but the platelet count must be monitored for early detection of heparin-induced thrombocytopenia, which occurs with peak incidence at 5-10 days of treatment. Warfarin is seldom used for perioperative deep venous thrombosis prophylaxis but may be indicated for long-term management of minimally ambulatory patients. Lifetime anticoagulation with low-dose warfarin or prophylactic vena caval filter placement is considered in patients with hypercoagulable state or paralysis.

Treatment

The standard treatment of deep venous thrombosis is systemic anticoagulation with heparin (initial bolus 100 units/kg followed by 10 units/kg/h, dosed to a goal partial thromboplastin time of 1.5-2 times normal). This reduces the risk of pulmonary embolism and decreases the rate of thrombophlebitis recurrence by 80%. Systemic anticoagulation does not directly lyse thrombi but stops propagation and allows natural fibrinolysis to occur.

Warfarin is started after therapeutic heparinization. The two therapies should overlap to diminish the possibility of a hypercoagulable state, which can occur during the first few days of warfarin administration because warfarin also inhibits synthesis of the natural anticoagulant proteins C and S. The recommended treatment for the first episode of uncomplicated deep venous thrombosis is 3-6 months of warfarin to maintain a goal INR of 2.0-3.0. After a second episode, warfarin is continued indefinitely. The risk for recurrent venous thrombosis is increased markedly in the presence of factor V Leiden mutations, homozygous activated protein C resistance, antiphospholipid antibody, and deficiencies of antithrombin III and of protein C or protein S, so lifelong anticoagulation is also recommended for these conditions.

Recently, enoxaparin at therapeutic dosing (1 mg/kg subcutaneously twice daily) has been shown to be equally safe and effective for treatment of deep venous thrombosis. Enoxaparin does not require monitoring of its anticoagulant effect because of its predictable dose-response relationship, so it has been promoted for use in outpatient treatment. Unfractionated heparin inhibits thrombin by complexing thrombin and antithrombin III. The enoxaparin molecule is too small to inhibit thrombin in this manner; its main therapeutic effect comes from inhibition of factor Xa activity, which accounts for its lower risk of bleeding complications and thrombocytopenia. It has also demonstrated less protein C and S inhibition, less complement activation, and a lower risk of osteoporosis.

Current research efforts are directed toward creation of an oral thrombin inhibitor. This is expected to have a more favorable dose-response curve and side-effect profile than warfarin.

Many studies have evaluated the efficacy of fibrinolytic agents in the treatment of acute deep venous thrombosis. Although faster clot lysis and increased venous patency are observed with alteplase versus heparin, this has not translated to a decreased incidence of postphlebitis syndrome. Risk of bleeding complications is higher with alteplase and does not appear to be reduced by selective catheterization for local administration. To be effective, it is felt that alteplase should be instituted within 1 week after clot formation, before extensive fibrin cross-linking can occur. One possible application for alteplase is acute iliofemoral venous thrombosis complicated by massive extremity edema and cyanosis. In this setting, iliofemoral thrombectomy is unsuccessful in as many as 50% of patients, often because of inability to effectively treat distal thrombosis.

Treatment of isolated calf vein thrombosis is controversial, as it is associated with a low risk of pulmonary emboli. However, if untreated, 25% progress to the proximal deep veins, where the incidence of chronic venous insufficiency is 25% and that of fatal pulmonary embolism is 10%. Patients with symptomatic calf vein thrombosis should be anticoagulated; asymptomatic patients may be followed expectantly with serial ultrasound examination.

Prognosis

With early and effective treatment, prognosis in most cases is good. Mortality is related to pulmonary embolus, which occurs in 60% of patients with inadequately treated proximal lower extremity thrombosis.

2. Thrombophlebitis of the Superficial Veins

Essentials of Diagnosis

- Induration, redness, and tenderness along a superficial vein.
- Often a history of recent intravenous line or trauma. No significant swelling of the extremity.

General Considerations

Superficial thrombophlebitis may occur spontaneously in patients with varicose veins, in pregnant or postpartum women, or in patients with thromboangiitis obliterans or Behcet's disease. It can also occur after trauma, such as a blow to the leg, or after intravenous infusion. A migratory thrombophlebitis may be a manifestation of

abdominal cancer such as carcinoma of the pancreas (Trousseau's syndrome). The long saphenous vein and its tributaries are most often involved. Superficial thrombophlebitis is associated with occult deep vein thrombosis in about 20% of cases. Pulmonary emboli are rare unless extension into the deep venous system occurs.

Clinical Findings

The patient usually experiences a dull pain in the region of the involved vein. Induration, redness, and tenderness correspond to dilated, thrombosed superficial veins. Edema of the extremity and deep calf tenderness are absent unless the deep veins are involved. Chills and high fever suggest septic or suppurative phlebitis, which is most often encountered as a complication of an indwelling intravenous catheter. Plastic intravenous catheters should be observed daily for signs of local inflammation and removed if a local reaction develops to avoid serious thrombotic or septic complications.

Differential Diagnosis

The linear rather than circular nature of the lesion and the distribution along the course of a superficial vein help to differentiate superficial phlebitis from cellulitis, erythema nodosum, erythema induratum, panniculitis, and fibrositis. Lymphangitis and deep thrombophlebitis must also be considered.

Treatment

The primary treatment of superficial venous thrombophlebitis is the administration of nonsteroidal anti-inflammatory drugs, local heat, and elevation. Ambulation is encouraged. In the majority of circumstances, symptoms will resolve within 7 to 10 days. Excision of the involved vein is recommended for symptoms that persist over 2 weeks on treatment, or for recurrent phlebitis in the same vein segment. If there is progressive proximal extension to the saphenofemoral junction or cephalic-subclavian junction, ligation and resection of the vein at the junction should be performed. Anticoagulation is reserved for rapidly progressing disease or extension into the deep system.

Septic thrombophlebitis requires treatment with intravenous antibiotics. As the causative organism is often staphylococcus or a gram-negative rod, broad-spectrum antibiotic coverage should be instituted until blood culture results become available. If rapid resolution of the phlebitis occurs, no treatment beyond a 7- to 10-day course of antibiotics is required. However, if the patient becomes septic, immediate excision of the infected vein is required.

Prognosis

The course is generally benign and brief, and the prognosis depends on the underlying pathologic process. Phlebitis of a saphenous vein occasionally extends to the deep veins, in which case pulmonary emboli may occur.

Belcaro G et al: Superficial thrombophlebitis of the legs: a randomized, controlled, follow-up study. *Angiology* 1999; 50:523. [\[PMID: 10431991\]](#)

CHRONIC VENOUS INSUFFICIENCY

Essentials of Diagnosis

- History of phlebitis or leg injury.
- Ankle edema is the earliest sign.
- Late signs are stasis pigmentation, dermatitis, subcutaneous induration, varicosities, and ulceration.

General Considerations

Chronic venous insufficiency is most often secondary to deep venous thrombosis, although a history of phlebitis is not obtainable in about 25% of patients. Other possible causes are leg trauma, varicose veins, neoplastic obstruction of the pelvic veins, or congenital or acquired arteriovenous fistula.

The basic physiologic abnormality in patients with chronic venous insufficiency is chronic elevation in venous pressure. The normal venous capacitance can accommodate large-volume changes that occur during exercise with only minimal changes in venous pressure. However, when valves in the deep and perforating veins are destroyed by thrombophlebitis, valvular reflux and bidirectional blood flow result in abnormally high ambulatory venous pressures. Proximal venous obstruction also results in venous hypertension. High ambulatory venous pressure transmitted through perforating veins of the calf and ankle results in superficial varicosities, edema and fibrosis of the subcutaneous tissue and skin, hyperpigmentation, and, later, dermatitis and ulceration.

Clinical Findings

Chronic venous insufficiency is characterized by progressive edema of the leg that begins at the ankle and calf and is accompanied by a dull aching discomfort. Typically, the edema is worst at the end of the day and improves with leg elevation. Varicosities are often present. Stasis dermatitis, brownish pigmentation, brawny induration, and ulceration develop with long-standing disease. The skin is usually thin, shiny, atrophic, and cyanotic. Cellulitis may appear in scaly, dry, itchy regions with skin breakdown; in other areas, a weeping dermatitis may develop. Venous stasis ulcers are large, painless, and irregular in outline. They have a shallow, moist granulation bed and occur in the gaiter area on the medial or lateral aspects of the ankle. Healing of these ulcers results in a thin scar on a fibrotic base that often breaks down with minor trauma.

Differential Diagnosis

Congestive heart failure and chronic renal disease may result in bilateral edema of the lower extremities. Lymphedema is associated with a brawny thickening in the subcutaneous tissue that does not respond readily to elevation; edema is particularly prominent on the dorsum of the feet and in the toes; varicosities are absent, and there is often a history of recurrent cellulitis.

Primary varicose veins or acute deep venous thrombosis may be difficult to differentiate from chronic venous insufficiency without diagnostic tests.

Other conditions associated with chronic ulcers of the leg include autoimmune diseases (eg, Felty's syndrome), arterial insufficiency (often painful, well circumscribed, and located over pressure points), sickle cell anemia, erythema induratum (bilateral and usually on the posterior aspect of the lower part of the leg), and fungal infections (cultures specific; no chronic swelling or varicosities).

Prevention

The irreversible tissue changes that accompany chronic venous stasis disease can be minimized by early and aggressive management of conditions associated with deep venous reflux such as acute deep venous thrombosis and varicose veins.

Treatment

A. General Measures

The key to successful management of chronic venous stasis disease is the realization that it is an incurable but manageable problem. Most patients respond to a conservative treatment program. The causes of complications of chronic venous insufficiency are largely mechanical, and so the solutions are mechanical. Bed rest with leg elevation is fundamental in the treatment of the acute complications. Similarly, chronic care of the leg includes (1) intermittent elevation of the legs during the day and elevation of the legs at night (kept above the level of the heart with pillows under the mattress), (2) avoidance of long periods of sitting or standing, (3) the daily use of fitted knee-high or thigh-high graduated compression stockings (20-30 mm Hg), and (4) regular exercise.

B. Management of Stasis Dermatitis

Eczematous eruption may be acute or chronic; treatment varies accordingly. The simplest treatment for acute weeping dermatitis is strict bed rest, leg elevation, and wet saline compresses. Antiseptic solutions containing peroxide, boric acid, or buffered aluminum acetate (Burow's solution) are not recommended because they impede wound healing. Cadexomer iodine is an iodine-containing starch powder dressing that has been shown to speed healing of weepy ulcers. Alginate dressings are also effective in this setting. In general, however, no definitive advantage has emerged of occlusive over semioclusive dressings or of topical antibiotics, growth factors, or free radical scavengers over simple inert dressings.

Systemic antibiotics and topical antifungal agents (1% clotrimazole or 2% miconazole cream) are indicated only if active infection is suspected. With reduction of the acute edema, 0.5% hydrocortisone cream is applied to the area for 1-2 weeks or until no further improvement is noted. Cordran tape, a plastic tape impregnated with

flurandrenolide, is a convenient way to apply both medication and dressing. Zinc oxide ointment with ichthammol, 3%, applied once or twice daily, is an alternative treatment for chronic dermatitis.

C. Ulceration

Venous ulcerations can be treated by wet-to-dry normal saline dressings and Ace wrap compression, or with an Unna boot. The Unna boot is a layered dressing composed of a medicated bandage (such as the original Dome paste composed of calamine, zinc oxide, glycerin, sorbitol, gelatin, and magnesium aluminum silicate), followed by a gauze dressing, followed by an elastic wrap. It must be kept dry and is usually changed weekly. Occasionally, the ulcer is so large and chronic that wide debridement and skin grafting is the best approach. This can be combined with open or endoscopic ligation of incompetent perforating veins contributing to elevated venous pressure in the ulcer bed. Venous reconstructive surgery is performed in some centers for intractable chronic venous stasis disease. The goal of the surgery is to increase venous outflow and decrease venous hypertension in the limb by repairing or replacing incompetent valves in the deep system. Valvuloplasty, venous segment transposition, and valvular transplantation have been performed with variable reported success rates.

Prognosis

Recurrent venous stasis ulcers and progressive venous stasis changes of the skin are not uncommon, particularly if patients do not adhere to a lifelong routine of intermittent leg elevation, regular exercise, and use of graduated compression stockings.

Mohr DN et al: The venous stasis syndrome after deep venous thrombosis or pulmonary embolism: A population-based study. Mayo Clin Proc 2000;75:1249. [\[PMID: 11126832\]](#)

SUPERIOR VENA CAVA OBSTRUCTION

Superior vena cava syndrome is a rare disorder caused by partial or complete obstruction of the superior vena cava. The most frequent causes are (1) superior mediastinal tumors (responsible for over 80% of cases), such as adenocarcinoma of the lung, lymphoma, thyroid carcinoma, thymoma, teratoma, synovial cell carcinoma, or angiosarcoma; (2) chronic fibrotic mediastinitis, either idiopathic or secondary to tuberculosis, histoplasmosis, pyogenic infections, or drugs (such as methysergide); (3) thrombophlebitis secondary to indwelling central venous catheters or pacemaker wires; (4) aneurysm of the aortic arch; and (5) constrictive pericarditis.

Clinical Findings

A. Symptoms and Signs

Symptoms include swelling of the neck and face, headache, dizziness, visual disturbances, stupor, and syncope related to progressive obstruction of the venous drainage of the head, neck, and upper extremities. Bending over or lying down accentuates the symptoms; sitting quietly is generally preferred. The severity of symptoms is dependent on the degree and duration of stenosis and the development of venous collateral circulation. Dilated anterior chest wall veins and facial flushing ultimately can progress to brawny edema and cyanosis of the face and arms. Cerebral and laryngeal edema result in impaired mental status and respiratory insufficiency.

B. Diagnosis

Diagnosis is usually suggested by the history and physical examination. Duplex ultrasound can be suggestive, but more specific anatomic information is obtained with CT scan or MRA, which can also disclose etiologic causes. Contrast venography is reserved for cases in which surgical or endoscopic treatment is anticipated.

Treatment

Therapy is dictated by the cause of the disease and the severity of symptoms. Benign thrombosis is treated with central venous catheter removal, head elevation, and short-course warfarin anticoagulation or thrombolysis and venous angioplasty. Venous bypass (left atrial appendage to internal jugular or innominate vein) has good patency rates in selected patients refractory to more conservative measures. Surgical excision of the fibrous tissue encasing the great vessels may reestablish flow in patients with mediastinal fibrosis or pericardial constriction. Unless concomitant tumor resection is planned, superior vena cava syndrome secondary to malignant disease is preferentially treated by endovascular stenting. Chemotherapy or external beam radiation may also achieve symptomatic improvement in patients with malignancy.

Lanciego C et al: Stenting as first option for endovascular treatment of malignant superior vena cava syndrome. AJR Am J Roentgenol 2001;177:585. [\[PMID: 11517051\]](#)

■ DISEASES OF THE LYMPHATIC CHANNELS

LYMPHANGITIS & LYMPHADENITIS

Essentials of Diagnosis

- Red streak extending from an infected area toward enlarged, tender regional lymph nodes.
- Chills, fever, and malaise may be present.

General Considerations

Lymphangitis and lymphadenitis frequently accompany a streptococcal or staphylococcal infection in the distal arm or leg. The inciting wound may be a superficial scratch with cellulitis, an insect bite, or an established abscess. A prominent red streak extending toward tender, enlarged regional lymph nodes is diagnostic. Systemic manifestations include fever, chills, tachycardia, and malaise. If untreated, the infection can progress rapidly, often in a matter of hours.

Clinical Findings

A. Symptoms and Signs

Throbbing pain at the site of the inciting wound is usually present. Malaise, anorexia, sweating, chills, and fever of 37.8-40°C develop rapidly. The red streak may be faint initially and easily missed, especially in dark-skinned patients. The involved regional lymph nodes may be significantly enlarged and tender.

B. Laboratory Findings

Leukocytosis with a left shift is usually present. Blood cultures are often positive for staphylococcal or streptococcal species. Wound cultures may be helpful in treatment of the more severe or refractory infections but are often difficult to interpret because of skin contaminants.

Differential Diagnosis

Superficial thrombophlebitis is distinguished from lymphangitis by the pattern of erythema (localized to an indurated thrombosed vein) and the lack of lymphadenitis. Cat-scratch disease caused by *Bartonella henselae* typically presents with enlarged but nontender lymph nodes. Lymphangitis must also be differentiated from cellulitis and from severe soft tissue infections such as acute streptococcal hemolytic gangrene and necrotizing fasciitis requiring emergent debridement. These infections are nonlinear and are characterized by induration and subcutaneous crepitus.

Treatment

The extremity is elevated, and warm compresses are applied to the involved area. Analgesics and intravenous antibiotics (penicillin G, 4 million units every 6 hours, or cefazolin, 1 g every 8 hours) should be instituted immediately. Examination of the wound will determine the need for debridement or incision and drainage of an abscess.

Prognosis

Early institution of appropriate antibiotic therapy and wound care will usually control the infection in 48-72 hours. Delayed or inadequate therapy can result in rapidly progressive infection, septicemia, and death.

LYMPHEDEMA

Essentials of Diagnosis

- Painless edema of upper or lower extremities.
- Involves the dorsal surfaces of the hands and fingers or the feet and toes.
- Developmental or acquired, unilateral or bilateral.
- Edema is pitting initially and becomes brawny and nonpitting with time.
- Ulceration, varicosities, and stasis pigmentation do not occur. There may be episodes of lymphangitis and cellulitis.

General Considerations

The underlying mechanism in lymphedema is impairment of the flow of lymph from an extremity. When due to congenital developmental abnormalities consisting of hypo- or hyperplastic changes of the proximal or distal lymphatics, it is referred to as primary lymphedema. Familial lymphedema developing before 1 year of age is called Milroy's disease; it is usually bilateral and affects boys more often than girls. More often, lymphedema develops during adolescence (lymphedema praecox) and is unilateral; there is a 3.5:1 female predominance. Lymphedema occurring after age 35 is referred to as lymphedema tarda. The secondary form of lymphedema results from an inflammatory or mechanical obstruction of the lymphatics following trauma, regional lymph node resection, irradiation, bacterial or fungal infections, lymphoproliferative diseases, or filariasis.

Lymphatic obstruction results in stasis of a protein-rich fluid, with slowly progressive, painless edema and secondary fibrosis that may be exacerbated by superimposed episodes of acute infection. The edema is usually centered around the ankle and involves the toes and the dorsum of the foot. Hypertrophy of the limb results, with markedly thickened skin and subcutaneous tissue. Rarely, lymphangiosarcoma or angiosarcoma may develop as a complication of chronic lymphedema. This neoplastic transformation of blood vessels and lymphatics is called the Stewart-Treves syndrome.

Diagnosis is usually made on the basis of clinical findings. Venous duplex ultrasonography is performed to exclude venous insufficiency or vascular malformations. Lymphangiography and radioactive isotope studies are indicated only if surgical reconstruction is anticipated.

Treatment

Lymphedema is a chronic disease for which there is no complete cure. However, a variety of conservative measures can substantially reduce the risk of further complications and disability. No drug therapy is effective. Use of benzopyrones (eg, dicumarol) and corticosteroid injections to increase lymphatic transport has not shown consistent benefit. Diuretics can be useful for acute exacerbation of edema secondary to infection or for coexisting venous stasis disease but are not recommended for long-term use.

The mainstay of treatment is external compression and meticulous skin care. Mechanical reduction of lymphedema can best be achieved with a program of frequent leg elevation, manual lymphatic drainage massage, and external compression. Sequential pneumatic compression devices are traditionally the first line of treatment for limb reduction. Many different devices are available for use on the leg, and Reid sleeves can be custom fit for patients with postmastectomy arm lymphedema. Graduated compression stockings (20-30 mm Hg) maintain the limb after reduction by pneumatic compression.

Good skin care is imperative in order to prevent infection. Moisturizing lotions should be applied regularly, especially after showering or bathing. Drying and cracking of the skin can create portals of entry for bacteria. Infection is difficult to eradicate because of disordered lymphatic drainage and can be a threat to limb survival.

In carefully selected cases, surgery may improve limb function. The goal is to reduce limb bulk, either by ablative techniques (excision of excess tissue) or by physiologic techniques (lymphatic reconstruction). Microsurgical lymphaticovenous anastomosis has yielded some satisfactory cosmetic and functional results, though long-term efficacy is as yet unknown.

■ HYPOTENSION & SHOCK

Essentials of Diagnosis

- Hypotension, tachycardia, oliguria, altered mental status.
- Peripheral hypoperfusion and hypoxia.

General Considerations

Shock occurs when the rate of arterial blood flow is inadequate to meet tissue metabolic needs. Tissue oxygen delivery is dependent on cardiac output, hemoglobin saturation, and peripheral microcirculation—some or all of these factors are altered in the shock state. The physiologic response to shock is mediated by the neuroendocrine system through release of catecholamines, renin, antidiuretic hormone, glucagon, cortisol, and growth hormone. These hormones are responsible for many of the clinical manifestations of shock: tachycardia, oliguria, delayed capillary refill, increasing agitation, and insulin resistance. Treatment must be directed both at the manifestations of shock and at its cause.

Classification (Table 12-1)

A. Hypovolemic Shock

Decreased intravascular volume resulting from loss of blood, plasma, or fluids and electrolytes may be obvious (eg, external hemorrhage) or subtle (eg, sequestration in a "third space"). Compensatory vasoconstriction temporarily reduces the size of the vascular bed and may transiently maintain the blood pressure, but unreplaced ongoing losses of over 15% of the blood volume result in hypotension, increased peripheral resistance, collapse of capillary and venous beds, and progressive tissue hypoxia. Even a moderate sudden loss of circulating fluids can result in severe damage to vital organs.

B. Cardiogenic Shock

Pump failure can be related to myocardial infarction, cardiomyopathy, myocardial contusion, valvular incompetence or stenosis, or arrhythmias. See discussion in [Chapter 10](#).

C. Obstructive Shock

Cardiac tamponade, tension pneumothorax, and massive pulmonary embolism can cause acute decrease in cardiac output resulting in shock. These are medical emergencies requiring prompt diagnosis and treatment. Pericardiocentesis or pericardial window, chest tube placement, or catheter-directed thrombolytic therapy can be lifesaving.

D. Distributive Shock

Reduction in systemic vascular resistance from sepsis, anaphylaxis, systemic inflammatory response syndrome (SIRS) produced by severe pancreatitis or burns, or acute adrenal insufficiency may result in inadequate cardiac output despite normal circulatory volume. Elevated nitric oxide levels may explain many of the physiologic aspects of the disease.

1. Septic shock—Sepsis is the most common cause of distributive shock and carries a mortality of 40-80%. Typically, patients present with fever, chills, hypotension, hyperglycemia, and altered mental status due to gram-negative bacteremia (*Escherichia coli*, klebsiella, proteus, and pseudomonas). Gram-positive cocci and gram-negative anaerobes (bacteroides) are less often implicated. Risk factors include extremes of age, diabetes, immunosuppression, and recent urinary, biliary, or gynecologic manipulation, such as placement of a percutaneous nephrostomy or biliary drain in an obstructed system.

2. Neurogenic shock—Neurogenic shock is caused by traumatic spinal cord injury or effects of an epidural or spinal anesthetic. Reflex vagal parasympathetic stimulation evoked by pain, gastric dilation, or fright may simulate neurogenic shock, producing hypotension, bradycardia, and syncope.

Diagnosis of Shock & Impending Shock

The different types of shock are characterized by the same clinical signs.

A. Hypotension

Hypotension in adults is traditionally defined as a systolic blood pressure of 90 mm Hg or less but must be evaluated relative to the patient's normal blood pressure. While a systolic blood pressure of 90 mm Hg may be normal in a healthy, athletic adult, a pressure of 100 mm Hg may indicate shock in a patient who is normally hypertensive. A drop in systolic pressure of more than 10-20 mm Hg and an increase in pulse of more than 15 with positional change suggests depleted intravascular volume. Orthostatic hypotension resulting from peripheral neuropathy or use of beta-blockers is usually not associated with an increase in pulse rate.

B. End-Organ Hypoperfusion

Patients in shock often have cool or mottled extremities and weak or absent peripheral pulses. Splanchnic vasoconstriction leads to oliguria, bowel ischemia, and hepatic dysfunction, which can ultimately result in multiorgan failure.

C. Altered Mental Status

Patients may demonstrate normal mental status or may be restless, agitated, confused, lethargic, or comatose as a result of inadequate perfusion of the brain.

Treatment

A. General Measures

Treatment depends upon prompt diagnosis and an accurate appraisal of inciting conditions. Initial therapy consists of basic life support: airway maintenance, oxygen, cardiopulmonary resuscitation, intravenous access and fluid resuscitation. Cardiac monitoring can detect myocardial ischemia requiring cardiac catheterization and thrombolytic therapy or malignant arrhythmias treated by standard advanced cardiac life support (ACLS) protocols. A thorough history and physical examination, including stool guaiac testing, is helpful in locating potential sources of sepsis or hemorrhage and excluding immediately reversible causes such as tamponade or tension pneumothorax. Unresponsive or minimally responsive patients are immediately given 50% dextrose (one ampule intravenously) and naloxone (2 mg intravenously or intramuscularly) followed by neurologic assessment (Glasgow Coma Scale) and are then intubated for airway protection. Specimens should be sent for complete blood count, electrolytes, glucose, arterial blood gas determinations, coagulation parameters, and typing and cross-matching. An arterial line is placed for continuous blood pressure measurement and a Foley catheter for assessment of urine volume. Urine output should be maintained at > 0.5 mL/kg/h.

Early consideration is given to placement of a pulmonary artery catheter for hemodynamic pressure measurements. This is helpful in distinguishing cardiogenic and septic shock and in monitoring the effects of volume resuscitation or pressor medications. Because of the attendant risks associated with pulmonary artery catheters (infection, arrhythmias, vein thrombosis, pulmonary artery rupture), the value of the information they might provide must be carefully weighed in each patient. They are useful in management of patients with cardiogenic shock; in other types of shock, a central venous line may be adequate. Central lines may also be useful in the administration of medications and in measurement of central venous oxygen saturation. In general, a central venous pressure (CVP) or pulmonary capillary wedge pressure (PCWP) under 5 mm Hg suggests hypovolemia and over 18 mm Hg suggests volume overload, cardiac failure, tamponade, or pulmonary hypertension. A cardiac index < 2 L/min/m² indicates a need for pharmacologic or mechanical pressor support. A high cardiac index (> 4 L/min/m²) in a hypotensive patient is consistent with early septic shock. The systemic vascular resistance (SVR) is a derived value and is low (< 800 dyne·s/cm⁵) in early sepsis and neurogenic shock and high (> 1500 dyne·s/cm⁵) in hypovolemic and cardiogenic shock. Treatment is directed at maintaining a central venous pressure of 8-12 mm Hg, a mean arterial pressure of 65-90 mm Hg, a cardiac index of 2-4 L/min/m², and central venous oxygen saturation of greater than 70%.

B. Volume Replacement

Hypovolemic shock is treated with fluid resuscitation. Initial response is gauged after bolus administration of 2 L of crystalloid, and additional fluid requirements are then estimated from measurement of ongoing losses, CVP or PCWP, and urine output.

Selection of the proper fluid for restoration and maintenance of hemodynamic stability is controversial. Blood products are indicated in hemorrhagic shock; type-specific or type O negative packed red blood cells (PRBC) are given to maintain the hematocrit above 30%. Whole blood provides extra volume and clotting factors. Each unit of PRBC or whole blood is expected to raise the hematocrit by 3%. With abnormal coagulation studies, platelet count less than 10,000/uL, or transfusion of over six units of PRBC, fresh frozen plasma and platelets should be administered. When hematocrit is greater than 30% and CVP is less than 8 mm Hg, crystalloid solutions are generally the preferred resuscitation fluid. Isotonic (0.9%) sodium chloride or lactated Ringer's solution (which contains potassium, calcium, and bicarbonate as well as sodium chloride) is given in boluses of 500 or 1000 mL. Dextrose-containing solutions are generally not needed initially except in the treatment of hypoglycemic shock. Hypertonic (7.5%) saline is being investigated for use in the prehospital setting and in the hypotensive patient with closed head injury.

Plasma expanders—or colloids such as albumin, dextran, and hetastarch—are high-molecular-weight substances that increase plasma oncotic pressure. Increased capillary permeability in the lung accompanying septic shock or SIRS may result in increased pulmonary edema in patients administered colloids, so use of these agents warrants careful consideration. Side effects include coagulopathy and anaphylaxis. Oxygen-carrying synthetic plasma expanders ("artificial blood") have been used with success in some trauma centers for treatment of hypovolemic shock.

Large-volume resuscitation with unwarmed fluids produces hypothermia, which must be treated to avoid hypothermia-induced coagulopathy.

C. Medications

Calcium should be administered to maintain an ionized calcium level greater than 1.15 mmol/L. Sodium bicarbonate may be considered in patients with arterial pH less than 7.20.

Pressors are administered only after adequate fluid resuscitation. Dopamine hydrochloride has variable effects according to dosage. At low doses (2-3 ug/kg/min), stimulation of dopaminergic and beta-agonist receptors produces increased glomerular filtration rate, heart rate, and contractility. At higher doses (> 5 ug/kg/min), alpha-adrenergic effects predominate, resulting in peripheral vasoconstriction.

Dobutamine (2-20 ug/kg/min), a synthetic catecholamine with greater inotropic effect and afterload reduction than dopamine, is the first-line drug for cardiogenic shock. Because tachyphylaxis can occur after 48 hours, the phosphodiesterase inhibitor amrinone (5-15 ug/kg/min) is often substituted. Diuretics, thrombolytics, morphine, nitroglycerin, antiarrhythmics, and antiplatelet agents may be part of a multimodality approach to treatment of cardiogenic shock secondary to acute myocardial infarction.

Distributive shock or neurogenic shock may require peripheral vasoconstrictors such as epinephrine (2-10 ug/min) or norepinephrine (0.5-30 ug/min). Phenylephrine is avoided in neurogenic shock because of the potential for reflex bradycardia.

Vasopressin (antidiuretic hormone [ADH]) is gaining widespread acceptance in treatment of distributive shock and has been added to the ACLS algorithm for ventricular fibrillation cardiac arrest. Shock due to sepsis or SIRS is associated with low levels of endogenous vasopressin; in hemorrhagic shock, vasopressin is initially elevated and then drops to subnormal levels. Vasopressin has multiple therapeutic effects: peripheral vasoconstriction, decreased heart rate, hemostasis, increased serum cortisol, and coronary, cerebral, and pulmonary vasodilation. It is shown also to potentiate the effects of other peripheral vasoconstrictors. Paradoxically, at low doses (0.01-0.04 units/min), it acts as a diuretic. The dose is regulated to maintain normal physiologic serum levels of 20-30 pg/mL. The effect on mortality rate in septic shock is as yet unknown. Vasopressin-induced vasoconstriction may be mediated by effects on nitric oxide synthesis.

Methylene blue is another inhibitor of the nitric oxide pathway being investigated for use in distributive shock.

Broad-spectrum antibiotics are administered in septic shock until blood cultures and sensitivities become available. Sedation, anxiolytics, and pain medications are tailored for each individual case. Corticosteroids are lifesaving in the treatment of shock associated with acute adrenal insufficiency (see [Chapter 26](#)) and decrease inflammation associated with acute spinal shock, but they are of no benefit in other types of shock. Research has focused on regulation of specific inhibitors of the inflammatory response. Protein C levels are diminished in septic shock, and recombinant protein C (drotrecogin alfa) is now in phase 3 trials. It has been shown to significantly decrease 28-day mortality in septic shock when given as a continuous infusion of 24 ug/kg/h for 96 hours. Its mechanism of action is reduction of systemic inflammation by inhibition of thrombosis. Administration of recombinant protein C has been correlated with lower D-dimer and interleukin-6 levels in this setting.

Other Treatment Modalities

Cardiac failure may require use of transcutaneous or transvenous pacing or placement of an intra-arterial balloon pump. Emergent revascularization by stent angioplasty or coronary artery bypass appears to improve long-term outcome. Urgent hemodialysis or continuous venovenous hemofiltration may be indicated for maintenance of fluid and electrolyte balance during acute renal insufficiency resulting from shock.

■ ANEMIAS

General Approach to Anemias

Anemia is present in adults if the hematocrit is less than 41% (hemoglobin < 13.5 g/dL) in males or 37% (hemoglobin < 12 g/dL) in females. Congenital anemia is suggested by the patient's personal and family history. Poor diet results in folic acid deficiency and contributes to iron deficiency. Bleeding is present universally in iron deficiency in adults. Physical examination includes attention to signs of primary hematologic diseases (lymphadenopathy, hepatosplenomegaly, or bone tenderness). Mucosal changes such as a smooth tongue suggest megaloblastic anemia.

Anemias are classified according to their pathophysiologic basis, ie, whether related to diminished production or accelerated loss of red blood cells ([Table 13-1](#)), or according to cell size ([Table 13-2](#)). The diagnostic possibilities in microcytic anemia are iron deficiency, thalassemia, and anemia of chronic disease. A severely microcytic anemia (MCV < 70 fL) is due either to iron deficiency or thalassemia. Macrocytic anemia may be due to megaloblastic (folate or vitamin B₁₂ deficiency) or nonmegaloblastic causes, especially antiretrovirals. A severely macrocytic anemia (MCV > 125 fL) is almost always megaloblastic; exceptions are the myelodysplastic syndromes.

IRON DEFICIENCY ANEMIA

Essentials of Diagnosis

- Both pathognomonic: absent bone marrow iron stores or serum ferritin < 12 ug/L.
- Caused by bleeding in adults unless proved otherwise.
- Response to iron therapy.

General Considerations

Iron deficiency is the most common cause of anemia worldwide. The causes are listed in [Table 13-3](#). Iron is necessary for the formation of heme and other enzymes. Total body iron ranges between 2 and 4 g: approximately 50 mg/kg in men and 35 mg/kg in women. Most (70-95%) of iron is present in hemoglobin in circulating red blood cells. One milliliter of packed red blood cells (not whole blood) contains approximately 1 mg of iron. In men, red blood cell volume is approximately 30 mL/kg. A 70-kg man will therefore have approximately 2100 mL of packed red blood cells and consequently 2100 mg of iron in his circulating blood. In women, the red cell volume is about 27 mL/kg; a 50-kg woman will thus have 1350 mg of iron circulating in her red blood cells. Only 200-400 mg of iron is present in myoglobin and nonheme enzymes. Aside from circulating red blood cells, the major location of iron in the body is the storage pool, as ferritin or as hemosiderin and in macrophages. The range for storage iron is wide (0.5-2 g); approximately 25% of women in the United States have none.

The average American diet contains 10-15 mg of iron per day. About 10% of this amount is absorbed. Absorption occurs in the stomach, duodenum, and upper jejunum. Dietary iron present as heme is efficiently absorbed (10-20%) but nonheme iron less so (1-5%), largely because of interference by phosphates, tannins, and other food constituents. Small amounts of iron—approximately 1 mg/d—are normally lost though exfoliation of skin and mucosal cells. There is no physiologic mechanism for increasing normal body iron losses.

Menstrual blood loss in women plays a major role in iron metabolism. The average monthly menstrual blood loss is approximately 50 mL, or about 0.7 mg/d. However, menstrual blood loss may be five times the average. In order to maintain adequate iron stores, women with heavy menstrual losses must absorb 3-4 mg of iron from the diet each day. This strains the upper limit of what may reasonably be absorbed, and women with menorrhagia of this degree will almost always become iron-deficient.

In general, iron metabolism is balanced between absorption of 1 mg/d and loss of 1 mg/d. Pregnancy may also upset the iron balance, since requirements increase to 2-5 mg of iron per day during pregnancy and lactation. Normal dietary iron cannot supply these requirements, and medicinal iron is needed during pregnancy and lactation. Repeated pregnancy (especially with breast feeding) may cause iron deficiency if increased requirements are not met with supplemental medicinal iron. Decreased iron absorption can on very rare occasions cause iron deficiency and usually occurs after gastric surgery, though concomitant bleeding is frequent.

By far the most important cause of iron deficiency anemia is blood loss, especially gastrointestinal blood loss. Chronic aspirin use may cause it even without a documented structural lesion. Iron deficiency demands a search for a source of gastrointestinal bleeding if other sites of blood loss (menorrhagia, other uterine bleeding, and repeated blood donations) are excluded.

Chronic hemoglobinuria may lead to iron deficiency since iron is lost in the urine; traumatic hemolysis due to a prosthetic cardiac valve and other causes of intravascular hemolysis (eg, paroxysmal nocturnal hemoglobinuria) should also be considered.

Clinical Findings

A. Symptoms and Signs

As a rule, the only symptoms of iron deficiency anemia are those of the anemia itself (easy fatigability, tachycardia, palpitations and tachypnea on exertion). Severe deficiency causes skin and mucosal changes, including a smooth tongue, brittle nails, and cheilosis. Dysphagia because of the formation of esophageal webs (Plummer-Vinson syndrome) also occurs. Many iron-deficient patients develop pica, craving for specific foods (ice chips, lettuce, etc) often not rich in iron.

B. Laboratory Findings

Iron deficiency develops in stages. The first is depletion of iron stores. At this point, there is anemia and no changes in red blood cell size. The serum ferritin will become abnormally low. A ferritin value less than 30 ug/L is a highly reliable indicator of iron deficiency. The serum total iron-binding capacity (TIBC) rises.

After iron stores have been depleted, red blood cell formation will continue with deficient supplies of iron. Serum iron values decline to less than 30 ug/dL and transferrin saturation to less than 15%.

In the early stages, the MCV remains normal. Subsequently, the MCV falls and the blood smear shows hypochromic microcytic cells. With further progression, anisocytosis (variations in red blood cell size) and poikilocytosis (variation in shape of red cells) develop. Severe iron deficiency will produce a bizarre peripheral blood smear, with severely hypochromic cells, target cells, hypochromic pencil-shaped cells, and occasionally small numbers of nucleated red blood cells. The platelet count is commonly increased.

Differential Diagnosis

Other causes of microcytic anemia include anemia of chronic disease, thalassemia, and sideroblastic anemia. Anemia of chronic disease is characterized by normal or increased iron stores in the bone marrow and a normal or elevated ferritin level; the serum iron is low, often drastically so, and the TIBC is either normal or low. Thalassemia produces a greater degree of microcytosis for any given level of anemia than does iron deficiency. Red blood cell morphology on the peripheral smear is abnormal earlier in the course of thalassemia.

Treatment

To make the diagnosis of iron deficiency anemia, one can either demonstrate an iron-deficient state or evaluate the response to a therapeutic trial of iron replacement.

Since the anemia itself is rarely life-threatening, the most important part of treatment is identification of the cause—especially a source of occult blood loss.

A. Oral Iron

Ferrous sulfate, 325 mg three times daily, which provides 180 mg of iron daily of which up to 10 mg is absorbed (though absorption may exceed this amount in cases of severe deficiency), is the preferred therapy. Compliance is improved by introducing the medicine more slowly in a gradually escalating dose with food. An appropriate response is a return of the hematocrit level halfway toward normal within 3 weeks with full return to baseline after 2 months. Iron therapy should continue for 3-6 months after restoration of normal hematologic values in order to replenish iron stores. Failure of response to iron therapy is usually due to noncompliance, although occasional patients may absorb iron poorly. Other reasons for failure to respond include incorrect diagnosis (anemia of chronic disease, thalassemia) and ongoing

gastrointestinal blood loss that exceeds the rate of new erythropoiesis.

B. Parenteral Iron

The indications are intolerance to oral iron, refractoriness to oral iron, gastrointestinal disease (usually inflammatory bowel disease) precluding the use of oral iron, and continued blood loss that cannot be corrected. Because of the possibility of anaphylactic reactions, parenteral iron therapy should be used only in cases of persistent anemia after a reasonable course of oral therapy.

The dose (total 1.5-2 g) may be calculated by estimating the decrease in volume of red blood cell mass and then supplying 1 mg of iron for each milliliter of volume of red blood cells below normal. One should then add approximately 1 g for storage iron. The entire dose may be given as an intravenous infusion over 4-6 hours. A test dose of a dilute solution is given first, and the patient should be observed during the entire infusion for anaphylaxis.

Goddard AF et al: Guidelines for the management of iron deficiency anaemia. British Society of Gastroenterology. Gut 2000;46(Suppl 3-4):IV1. [\[PMID: 10862605\]](#)

Goodnough LT et al: Erythropoietin, iron, and erythropoiesis. Blood 2000;96:823. [\[PMID: 10910892\]](#)

ANEMIA OF CHRONIC DISEASE

Many chronic systemic diseases are associated with mild or moderate anemia. Common causes include chronic infection or inflammation, cancer, and liver disease. The anemia of chronic renal failure is somewhat different in pathophysiology and is usually more severe.

Red blood cell survival is modestly reduced, and the bone marrow fails to compensate adequately by increasing red blood cell production. Failure to increase red cell production is largely due to sequestration of iron within the reticuloendothelial system. Decrease in erythropoietin is rarely an important cause of underproduction of red cells except in renal failure.

Clinical Findings

A. Symptoms and Signs

The clinical features are those of the causative condition. The diagnosis should be suspected in patients with known chronic diseases; it is confirmed by the findings of low serum iron, low TIBC, and normal or increased serum ferritin (or normal or increased bone marrow iron stores). In cases of significant anemia, coexistent iron deficiency or folic acid deficiency should be suspected. Decreased dietary intake of folate or iron is common in these ill patients, and many will also have ongoing gastrointestinal blood losses. Patients undergoing hemodialysis regularly lose both iron and folate during dialysis.

B. Laboratory Findings

The hematocrit rarely falls below 60% of baseline (except in renal failure). The MCV is usually normal or slightly reduced. Red blood cell morphology is nondiagnostic, and the reticulocyte count is neither strikingly reduced nor increased. Serum iron values may be unmeasurable, and transferrin saturation may be extremely low, leading to an erroneous diagnosis of iron deficiency. In contrast to iron deficiency, serum ferritin values should be normal or increased. A serum ferritin value of less than 30 ug/L should suggest coexistent iron deficiency.

Treatment

In most cases no treatment is necessary. Purified recombinant erythropoietin (epoetin alfa) is effective for treatment of the anemia of renal failure and other secondary anemias such as anemia related to cancer or inflammatory disorders (eg, rheumatoid arthritis). In renal failure, optimal response to epoetin alfa requires adequate intensity of dialysis. Epoetin alfa must be injected subcutaneously and is very expensive. One effective schedule is 30,000 units once weekly. This agent is used only when the patient is transfusion-dependent or when the quality of life is clearly improved by the hematologic response.

Goodnough LT et al: Erythropoietin, iron, and erythropoiesis. Blood 2000;96:823. [\[PMID: 10910892\]](#)

THE THALASSEMIAS

Essentials of Diagnosis

- Microcytosis out of proportion to the degree of anemia.
- Positive family history or lifelong personal history of microcytic anemia.
- Abnormal red blood cell morphology with microcytes, acanthocytes, and target cells.
- In beta thalassemia, elevated levels of hemoglobin A₂ or F.

General Considerations

The thalassemias are hereditary disorders characterized by reduction in the synthesis of globin chains (alpha or beta). Reduced globin chain synthesis causes reduced hemoglobin synthesis and eventually produces a hypochromic microcytic anemia because of defective hemoglobinization of red blood cells. Thalassemias can be considered among the hypoproliferative anemias, the hemolytic anemias, and the anemias related to abnormal hemoglobin, since all of these factors may play a role in pathogenesis.

Normal adult hemoglobin is primarily hemoglobin A, which represents approximately 98% of circulating hemoglobin. Hemoglobin A is formed from a tetramer—two alpha chains and two beta chains—and can be designated α₂β₂. Two copies of the α-globin gene are located on chromosome 16, and there is no substitute for α-globin in the formation of hemoglobin. The β-globin gene resides on chromosome 11 adjacent to genes encoding the beta-like globin chains, delta and gamma. The tetramer of α₂δ₂ forms hemoglobin A₂, which normally comprises 1-2% of adult hemoglobin. The tetramer α₂?₂ forms hemoglobin F, which is the major hemoglobin of fetal life but which comprises less than 1% of normal adult hemoglobin.

Alpha thalassemia is due primarily to gene deletion causing reduced α-globin chain synthesis ([Table 13-4](#)). Since all adult hemoglobins are alpha-containing, alpha thalassemia produces no change in the percentage distribution of hemoglobins A, A₂, and F. In severe forms of alpha thalassemia, excess beta chains may form a β₄ tetramer called hemoglobin H.

Beta thalassemias are usually caused by point mutations rather than deletions ([Table 13-5](#)). These mutations result in premature chain termination or in problems with transcription of RNA and ultimately result in reduced or absent β-globin chain synthesis. The molecular defects leading to beta thalassemia are numerous and heterogeneous. Defects that result in absent globin chain expression are termed β⁰, whereas those causing reduced synthesis are termed β⁺. The reduced β-globin chain synthesis in beta thalassemia results in a relative increase in the percentages of hemoglobins A₂ and F compared to hemoglobin A, as the beta-like globins (gamma and delta) substitute for the missing beta chains. In the presence of reduced beta chains, the excess alpha chains are unstable and precipitate, leading to damage of red blood cell membranes. This leads to intramedullary and peripheral hemolysis. The bone marrow becomes hyperplastic under the drive of anemia and ineffective erythropoiesis resulting from destruction of the developing erythroid cells. This marked expansion of the erythroid element in the bone marrow causes severe bony deformities, osteopenia, and pathologic fractures.

Clinical Findings

A. Symptoms and Signs

The alpha thalassemia syndromes are seen primarily in persons from southeast Asia and China, and, less commonly, in blacks. Normally, adults have four copies of the α-globin chain. When three α-globin genes are present, the patient is hematologically normal and is called a silent carrier. When two α-globin genes are present, the patient is said to have alpha thalassemia trait, one form of thalassemia minor. These patients are clinically normal and have normal life expectancy and performance status, with a mild microcytic anemia. When only one α-globin chain is present, the patient has hemoglobin H disease. This is a chronic hemolytic anemia of variable severity (thalassemia minor or intermedia). Physical examination will reveal pallor and splenomegaly. Although affected individuals do not usually require transfusions, they may do so during periods of hemolytic exacerbation caused by infection or other stresses. When all four α-globin genes are deleted, the affected fetus is stillborn as a result of hydrops fetalis.

Beta thalassemia affects persons of Mediterranean origin (Italian, Greek) and to a lesser extent Chinese, other Asians, and blacks. Patients homozygous for beta thalassemia have thalassemia major. Affected children are normal at birth but after 6 months, when hemoglobin synthesis switches from hemoglobin F to hemoglobin A, develop severe anemia requiring transfusion. Numerous clinical problems ensue, including growth failure, bony deformities (abnormal facial structure, pathologic

fractures), hepatosplenomegaly, and jaundice. The clinical course is modified significantly by transfusion therapy, but the transfusional iron overload (hemosiderosis) results in a clinical picture similar to hemochromatosis, with heart failure, cirrhosis, and endocrinopathies, usually after more than 100 units. These problems develop because of the body's inability to excrete the iron (see above) from transfused red cells. Death from cardiac failure usually occurs between ages 20 and 30.

Patients homozygous for a milder form of beta thalassemia (allowing a higher rate of globin gene synthesis) have thalassemia intermedia. These patients have chronic hemolytic anemia but do not require transfusions except under periods of stress. They also may develop iron overload because of periodic transfusion. They survive into adult life but with hepatosplenomegaly and bony deformities. Patients heterozygous for beta thalassemia have thalassemia minor and a clinically insignificant microcytic anemia.

Prenatal diagnosis is available, and genetic counseling should be offered and the opportunity for prenatal diagnosis discussed.

B. Laboratory Findings

1. Alpha thalassemia trait—Patients with two α -globin genes have mild anemia, with hematocrits between 28% and 40%. The MCV is strikingly low (60-75 fL) despite the modest anemia, and the red blood count is normal or increased. The peripheral blood smear shows microcytes, hypochromia, occasional target cells, and acanthocytes (cells with irregularly spaced bulbous projections). The reticulocyte count and iron parameters are normal. Hemoglobin electrophoresis will show no increase in the percentage of hemoglobins A_2 or F and no hemoglobin H. Alpha thalassemia trait is thus usually diagnosed by exclusion.

2. Hemoglobin H disease—These patients have a more marked hemolytic anemia, with hematocrits between 22% and 32%. The MCV is remarkably low (60-70 fL) and the peripheral blood smear markedly abnormal, with hypochromia, microcytosis, target cells, and poikilocytosis. The reticulocyte count is elevated. Hemoglobin electrophoresis will show the presence of a fast migrating hemoglobin (hemoglobin H), which comprises 10-40% of the hemoglobin. A peripheral blood smear can be stained with supravital dyes to demonstrate the presence of hemoglobin H.

3. Beta thalassemia minor—As in alpha thalassemia trait, these patients have a modest anemia with hematocrit between 28% and 40%. The MCV ranges from 55 to 75 fL, and the red blood cell count is normal or increased. The peripheral blood smear is mildly abnormal, with hypochromia, microcytosis, and target cells. In contrast to alpha thalassemia, basophilic stippling may be present. The reticulocyte count is normal or slightly elevated. Hemoglobin electrophoresis (using quantitative techniques) may show an elevation of hemoglobin A_2 to 4-8% and occasional elevations of hemoglobin F to 1-5%.

4. Beta thalassemia major—Beta thalassemia major produces severe anemia, and without transfusion the hematocrit may fall to less than 10%. The peripheral blood smear is bizarre, showing severe poikilocytosis, hypochromia, microcytosis, target cells, basophilic stippling, and nucleated red blood cells. Little or no hemoglobin A is present. Variable amounts of hemoglobin A_2 are seen, and the major hemoglobin present is hemoglobin F.

Differential Diagnosis

Mild forms of thalassemia must be differentiated from iron deficiency. Compared to iron deficiency anemia, patients with thalassemia have a lower MCV, a more normal red blood count, and a more abnormal peripheral blood smear at modest levels of anemia. Iron studies are normal. Severe forms of thalassemia may be confused with other hemoglobinopathies. The diagnosis is made by hemoglobin electrophoresis.

Treatment

Patients with mild thalassemia (alpha thalassemia trait or beta thalassemia minor) require no treatment and should be identified so that they will not be subjected to repeated evaluations and treatment for iron deficiency. Patients with hemoglobin H disease should take folate supplementation and avoid medicinal iron and oxidative drugs such as sulfonamides. Patients with severe thalassemia are maintained on a regular transfusion schedule and receive folate supplementation. Splenectomy is performed if hypersplenism causes a marked increase in the transfusion requirement. Deferoxamine is routinely given as an iron-chelating agent to avoid or postpone hemosiderosis. A diet low in iron may help in all of these patients.

Allogeneic bone marrow transplantation has been introduced as treatment for beta thalassemia major. Children who have not yet experienced iron overload and chronic organ toxicity do well, with long-term survival in more than 80% of cases.

SIDEROBLASTIC ANEMIA

The sideroblastic anemias are a heterogeneous group of disorders in which hemoglobin synthesis is reduced because of failure to incorporate heme into protoporphyrin to form hemoglobin. Iron accumulates, particularly in the mitochondria. A Prussian blue stain of the bone marrow will reveal ringed sideroblasts, cells with iron deposits encircling the red cell nucleus. The disorder is usually acquired. Sometimes it represents a stage in evolution of a generalized bone marrow disorder (myelodysplasia) that may ultimately terminate in acute leukemia. Other causes include chronic alcoholism and lead poisoning.

Patients have no specific clinical features other than those related to anemia. The anemia is usually moderate, with hematocrits of 20-30%, but transfusions may occasionally be required. Although the MCV is usually normal or slightly increased, it may occasionally be low, leading to confusion with iron deficiency. The peripheral blood smear characteristically shows a dimorphic population of red blood cells, one normal and one hypochromic. In cases of lead poisoning, coarse basophilic stippling of the red cells is seen.

The diagnosis is made by examination of the bone marrow. Characteristically, there is marked erythroid hyperplasia, a sign of ineffective erythropoiesis (expansion of the erythroid compartment of the bone marrow that does not result in the production of reticulocytes in the peripheral blood). The iron stain of the bone marrow shows a generalized increase in iron stores and the presence of ringed sideroblasts. Other characteristic laboratory features include a high serum iron and a high transferrin saturation. In lead poisoning, serum lead levels will be elevated.

Occasionally, the anemia is so severe that support with transfusion is required. These patients usually do not respond to erythropoietin therapy.

VITAMIN B₁₂ DEFICIENCY

Essentials of Diagnosis

- Macrocytic anemia.
- Macro-ovalocytes and hypersegmented neutrophils on peripheral blood smear.
- Serum vitamin B₁₂ level less than 100 pg/mL.

General Considerations

Vitamin B₁₂ belongs to the family of cobalamins and serves as a cofactor for two important reactions in humans. As methylcobalamin, it is a cofactor for methionine synthetase in the conversion of homocysteine to methionine and as adenosylcobalamin for the conversion of methylmalonyl-CoA to succinyl-CoA. All vitamin B₁₂ comes from the diet and is present in all foods of animal origin. The daily absorption of vitamin B₁₂ is 5 ug.

After being ingested, vitamin B₁₂ is bound to intrinsic factor, a protein secreted by gastric parietal cells. Other cobalamin-binding proteins (called R factors) compete with intrinsic factor for vitamin B₁₂. Vitamin B₁₂ bind to R factors cannot be absorbed. The vitamin B₁₂-intrinsic factor complex travels through the intestine and is absorbed in the terminal ileum by cells with specific receptors for the complex. It is then transported through plasma and stored in the liver. Three plasma transport proteins have been identified. Transcobalamins I and III (differing only in carbohydrate structure) are secreted by white blood cells. Although approximately 90% of plasma vitamin B₁₂ circulates bind to these proteins, only transcobalamin II is capable of transporting vitamin B₁₂ into cells. The liver contains 2000-5000 ug of stored vitamin B₁₂. Since daily losses are 3-5 ug/d, the body usually has sufficient stores of vitamin B₁₂ so that vitamin B₁₂ deficiency develops more than 3 years after vitamin B₁₂ absorption ceases.

Since vitamin B₁₂ is present in all foods of animal origin, dietary vitamin B₁₂ deficiency is extremely rare and seen only in vegans—strict vegetarians who avoid all dairy products as well as meat and fish ([Table 13-6](#)). Abdominal surgery may lead to vitamin B₁₂ deficiency in several ways. Gastrectomy will eliminate that site of intrinsic factor production; blind loop syndrome will cause competition for vitamin B₁₂ by bacterial overgrowth in the lumen of the intestine; and surgical resection of the ileum will eliminate the site of vitamin B₁₂ absorption. Rare causes of vitamin B₁₂ deficiency include fish tapeworm (*Diphyllobothrium latum*) infection, in which the parasite uses luminal vitamin B₁₂, pancreatic insufficiency (with failure to inactivate competing cobalamin-binding proteins), and severe Crohn's disease, causing sufficient destruction of the ileum to impair vitamin B₁₂ absorption.

The most common cause of vitamin B₁₂ deficiency is that associated with **pernicious anemia**. Although the disease is hereditary, it is rare clinically before age 35. Pernicious anemia produces a number of clinical findings in addition to vitamin B₁₂ deficiency. Atrophic gastritis is invariably present and results in histamine-fast achlorhydria. These patients may also have a number of other autoimmune diseases, including IgA deficiency, as well as polyglandular endocrine insufficiency. The atrophic gastritis is associated with an increased risk of gastric carcinoma.

Clinical Findings

A. Symptoms and Signs

The hallmark of vitamin B₁₂ deficiency is megaloblastic anemia. The anemia may be severe, with hematocrits as low as 10-15%. The megaloblastic state also produces changes in mucosal cells, leading to glossitis, as well as other vague gastrointestinal disturbances such as anorexia and diarrhea. Vitamin B₁₂ deficiency also leads to a complex neurologic syndrome. Peripheral nerves are usually affected first, and patients complain initially of paresthesias. The posterior columns next become impaired, and patients complain of difficulty with balance. In more advanced cases, cerebral function may be altered as well, and on occasion dementia and other neuropsychiatric changes may precede hematologic changes.

Patients are usually pale and may be mildly icteric. Neurologic examination may reveal decreased vibration and position sense but is more commonly normal in early stages of the disease.

B. Laboratory Findings

The megaloblastic state produces an anemia of variable severity that on occasion may be very severe. The MCV is usually strikingly elevated, between 110 and 140 fL. However, it is possible to have vitamin B₁₂ deficiency with a normal MCV. Occasionally, the normal MCV may be explained by coexistent thalassemia or iron deficiency, but in other cases the reason is obscure. Patients with neurologic symptoms and signs that suggest possible vitamin B₁₂ deficiency should be evaluated for that deficiency despite a normal MCV and the absence of anemia. The peripheral blood smear is usually strikingly abnormal, with anisocytosis and poikilocytosis. A characteristic finding is the macro-ovalocyte, but numerous other abnormal shapes are usually seen. The neutrophils are hypersegmented. Typical features include a mean lobe count greater than four or the finding of six-lobed neutrophils. The reticulocyte count is reduced. Because vitamin B₁₂ deficiency affects all hematopoietic cell lines, in severe cases the white blood cell count and the platelet count are reduced, and pancytopenia is present.

Bone marrow morphology is characteristically abnormal. Marked erythroid hyperplasia is present as a response to defective red blood cell production (ineffective erythropoiesis). Megaloblastic changes in the erythroid series include abnormally large cell size and asynchronous maturation of the nucleus and cytoplasm—ie, cytoplasmic maturation continues while impaired DNA synthesis causes retarded nuclear development. In the myeloid series, giant metamyelocytes are characteristically seen.

Other laboratory abnormalities include elevated serum LDH and a modest increase in indirect bilirubin. These two findings are a reflection of intramedullary destruction of developing abnormal erythroid cells and are similar to those observed in peripheral hemolytic anemias.

The diagnosis of vitamin B₁₂ deficiency is made by finding an abnormally low vitamin B₁₂ serum level. Whereas the normal vitamin B₁₂ level is 150-350 pg/mL, most patients with overt vitamin B₁₂ deficiency will have serum levels less than 100 pg/mL. When the serum level of vitamin B₁₂ is borderline, the diagnosis can be confirmed by an elevated serum level of methylmalonic acid or homocysteine. The Schilling test has been used to document the decreased absorption of oral vitamin B₁₂ characteristic of pernicious anemia. A large intramuscular dose of vitamin B₁₂ is given to saturate plasma transport proteins. Thereafter, radiolabeled vitamin B₁₂ is administered orally, and a 24-hour urine collection is performed to determine how much vitamin B₁₂ is absorbed and subsequently excreted. Normally, more than 7% of a dose is present in the urine; most patients with impaired absorption will have less than 3% present in the urine. The second stage of the Schilling test is to give radiolabeled vitamin B₁₂ together with intrinsic factor. If pernicious anemia (a lack of intrinsic factor) is the cause of vitamin B₁₂ deficiency, the combined use of vitamin B₁₂ and intrinsic factor should correct the abnormally low absorption. However, the full-blown megaloblastic state causes abnormalities in intestinal epithelium that may lead to generalized malabsorption. In these cases, the second stage of the Schilling test will remain abnormal until the intestinal mucosal defect is first corrected by vitamin B₁₂ replacement (in approximately 2 months). The repeat evaluation should thus be deferred until there has been time for correction. If the deficiency is caused by bacterial overgrowth in a blind loop (eg, jejunal diverticula), a course of antibiotics will reverse the abnormal second stage of the Schilling test. If the deficiency has been produced by pancreatic insufficiency, a course of pancreatic enzymes will reverse the abnormality. If a fish tapeworm is responsible, an anthelmintic agent is indicated (see [Chapter 35](#)).

Differential Diagnosis

Vitamin B₁₂ deficiency should be differentiated from folic acid deficiency, the other common cause of megaloblastic anemia, in which red blood cell folate is low while vitamin B₁₂ levels are normal. The distinction between vitamin B₁₂ deficiency and myelodysplasia (the other common cause of macrocytic anemia with abnormal morphology) is based on the characteristic morphology and the low vitamin B₁₂ level. Peripheral neuropathy and dementia of other cause may be similar clinically to nonhematologic pernicious anemia.

Treatment

Patients with pernicious anemia are often treated with parenteral therapy. Intramuscular injections of 100 ug of vitamin B₁₂ are adequate for each dose. Replacement is usually given daily for the first week, weekly for the first month, and then monthly for life. It is a lifelong disorder, and if patients discontinue their monthly therapy the vitamin deficiency will recur. Oral cobalamin may be used instead of parenteral therapy in a dose of 1000 ug/d and must be continued indefinitely.

Patients respond to therapy with an immediate improvement in their sense of well-being. Hypokalemia may complicate the first several days of therapy, particularly if the anemia is severe. A brisk reticulocytosis occurs in 5-7 days, and the hematologic picture normalizes in 2 months. Central nervous system symptoms and signs are reversible if they are of relatively short duration (less than 6 months) but become permanent if treatment is not initiated promptly.

Kaptan K et al: *Helicobacter pylori*—is it a novel causative agent in vitamin B₁₂ deficiency? Arch Intern Med 2000;160:1349. [[PMID: 10809040](#)]

FOLIC ACID DEFICIENCY

Essentials of Diagnosis

- Macrocytic anemia.
- Macro-ovalocytes and hypersegmented neutrophils on peripheral blood smear.
- Normal serum vitamin B₁₂ levels.
- Reduced folate levels in red blood cells or serum.

General Considerations

Folic acid is the term commonly used for pteroylmonoglutamic acid. In its reduced form of tetrahydrofolate, it serves as an important mediator of many reactions involving one-carbon transfers. Important reactions include the conversion of homocysteine to methionine and of deoxyuridylate to thymidylate, an important step in DNA synthesis.

Folic acid is present in most fruits and vegetables (especially citrus fruits and green leafy vegetables) and daily requirements of 50-100 ug/d are usually met in the diet. Total body stores of folate are approximately 5000 ug, enough to supply requirements for 2-3 months.

By far the most common cause of folate deficiency is inadequate dietary intake ([Table 13-7](#)). Alcoholics, anorectic patients, persons who do not eat fresh fruits and vegetables, and those who overcook their food are candidates for folate deficiency. Reduced folate absorption is rarely seen, since absorption occurs from the entire gastrointestinal tract. However, drugs such as phenytoin, trimethoprim-sulfamethoxazole, or sulfasalazine may interfere with folate absorption. Folic acid requirements are increased in pregnancy, hemolytic anemia, and exfoliative skin disease, and in these cases the increased requirements (five to ten times normal) may not be met by a normal diet. Patients with increased folate requirements should receive supplementation with 1 mg/d of folic acid.

Clinical Findings

A. Symptoms and Signs

The features are similar to those of vitamin B₁₂ deficiency, with megaloblastic anemia and megaloblastic changes in mucosa. However, there are none of the neurologic abnormalities associated with vitamin B₁₂ deficiency.

B. Laboratory Findings

The megaloblastic anemia is identical to that resulting from vitamin B₁₂ deficiency (see above). However, the serum vitamin B₁₂ level is normal. A red blood cell folate level of less than 150 ng/mL is diagnostic of folate deficiency.

Differential Diagnosis

The megaloblastic anemia of folate deficiency should be differentiated from vitamin B₁₂ deficiency by the finding of a normal vitamin B₁₂ level and a reduced red blood cell folate or serum folate level. Alcoholics, who often have folate deficiency, may also have anemia of liver disease. This latter macrocytic anemia does not cause megaloblastic morphologic changes but rather produces target cells in the peripheral blood. Hypothyroidism is associated with mild macrocytosis but also with pernicious anemia.

Treatment

Folic acid deficiency is treated with folic acid, 1 mg/d orally. The response is similar to that seen in the treatment of vitamin B₁₂ deficiency, with rapid improvement and a sense of well-being, reticulocytosis in 5-7 days, and total correction of hematologic abnormalities within 2 months. Large doses of folic acid may produce hematologic responses in cases of vitamin B₁₂ deficiency but will allow neurologic damage to progress.

PURE RED CELL APLASIA

Adult acquired pure red cell aplasia is rare. It appears to be an autoimmune disease mediated either by T lymphocytes or (rarely) by an IgG antibody against erythroid precursors. In adults, the disease is usually idiopathic. However, cases have been seen in association with systemic lupus erythematosus, chronic lymphocytic leukemia, lymphomas, or thymoma. Some drugs (phenytoin, chloramphenicol) may cause red cell aplasia. Transient episodes of red cell aplasia are probably common in response to viral infections, especially parvovirus infections. However, these acute episodes will go unrecognized unless the patient has a chronic hemolytic disorder, in which case the hematocrit may fall precipitously.

The only signs are those of anemia unless the patient has an associated autoimmune or lymphoproliferative disorder. The anemia is often severe and normochromic, with low or absent reticulocytes. Red blood cell morphology is normal, and the myeloid and platelet lines are unaffected. The bone marrow is normocellular. All elements present are normal, but erythroid precursors are markedly reduced or absent. In some cases, chest imaging studies will reveal a thymoma.

The disorder is distinguished from aplastic anemia (in which the marrow is hypocellular and cell lines affected) and from myelodysplasia. This latter disorder is recognized by the presence of morphologic abnormalities that should not be present in pure red cell aplasia.

Possible offending drugs should be stopped. With thymoma, resection results in amelioration of anemia in some instances. High-dose intravenous immune globulin has produced excellent responses in a small number of cases, especially in parvovirus-related cases. For most cases, the treatment of choice is immunosuppressive therapy with a combination of antithymocyte globulin and cyclosporine—similar to therapy of aplastic anemia. Anti-CD20 monoclonal antibody has also enjoyed some success.

HEMOLYTIC ANEMIAS

The hemolytic anemias are a group of disorders in which red blood cell survival is reduced, either episodically or continuously. The bone marrow has the ability to increase erythroid production up to eightfold in response to reduced red cell survival, so anemia will be present only when the ability of the bone marrow to compensate is outstripped. This will occur when red cell survival is extremely short or when the ability of the bone marrow to compensate is impaired for some second reason.

Since red blood cell survival is normally 120 days, in the absence of red cell production the hematocrit will fall at the rate of approximately 1/100 of the hematocrit per day, which translates to a decrease in the hematocrit reading of approximately 3% per week. For example, a fall of hematocrit from 45% to 36% over 3 weeks' time need not indicate hemolysis, since this rate of fall would result simply from cessation of red blood cell production. If the hematocrit is falling at a faster rate than that due to decreased production, blood loss or hemolysis is the cause.

Reticulocytosis is an important clue to the presence of hemolysis, since in most hemolytic disorders the bone marrow will respond with increased red blood cell production. However, hemolysis can be present without reticulocytosis when a second disorder (infection, folate deficiency) is superimposed on hemolysis; in these circumstances, the hematocrit will fall rapidly. However, reticulocytosis also occurs during recovery from hypoproliferative anemia or bleeding. Hemolysis is correctly diagnosed (when bleeding is excluded) if the hematocrit is either falling or stable despite reticulocytosis.

Hemolytic disorders are generally classified according to whether the defect is intrinsic to the red cell or due to some external factor ([Table 13-8](#)). Intrinsic defects have been described in all components of the red blood cell, including the membrane, enzyme systems, and hemoglobin; most of these disorders are hereditary. Hemolytic anemias due to external factors are the immune and microangiopathic hemolytic anemias.

Certain laboratory features are common to all the hemolytic anemias. Haptoglobin, a normal plasma protein that binds and clears hemoglobin released into plasma, may be depressed in hemolytic disorders. However, haptoglobin levels are influenced by many factors and, by themselves, are not a reliable indicator of hemolysis. When intravascular hemolysis occurs, transient hemoglobinemia occurs. Hemoglobin is filtered through the glomerulus and usually reabsorbed by tubular cells. Hemoglobinuria will be present only when the capacity for reabsorption of hemoglobin by these cells is exceeded. In its absence, evidence for prior intravascular hemolysis is the presence of hemosiderin in shed renal tubular cells (positive urine hemosiderin). With severe intravascular hemolysis, hemoglobinemia and methemalbuminemia may be present. Hemolysis increases the indirect bilirubin, and the total bilirubin may rise to 4 mg/dL. Bilirubin levels higher than this may indicate some degree of hepatic dysfunction. Serum LDH levels are strikingly elevated in cases of microangiopathic hemolysis (thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome) and may be elevated in other hemolytic anemias.

HEREDITARY SPHEROCYTOSIS

Essentials of Diagnosis

- Positive family history.
- Splenomegaly.
- Spherocytes and increased reticulocytes on peripheral blood smear.
- Microcytic, hyperchromic indices.

General Considerations

Hereditary spherocytosis is a disorder of the red blood cell membrane, leading to chronic hemolytic anemia. Normally, the red blood cell is a biconcave disk with a diameter of 7-8 μm . The red blood cells must be both strong and deformable—strong to withstand the stress of circulating for 120 days and deformable so as to pass through capillaries 3 μm in diameter and splenic fenestrations in the cords of the red pulp of approximately 2 μm . The red blood cell skeleton, made up primarily of the proteins spectrin and actin, gives the red cells these characteristics of strength and deformability.

The membrane defect in hereditary spherocytosis is an abnormality in spectrin, the protein providing most of the scaffolding for the red blood cell membranes. The result is a decrease in surface-to-volume ratio that results in a spherical shape of the cell. These spherical cells are less deformable and unable to pass through 2- μm fenestrations in the splenic red pulp. Hemolysis takes place because of trapping of red blood cells within the spleen.

Clinical Findings

A. Symptoms and Signs

Hereditary spherocytosis is an autosomal dominant disease of variable severity. It is often diagnosed during childhood, but milder cases may be discovered incidentally late in adult life. Anemia may or may not be present, since the bone marrow may be able to compensate for shortened red cell survival. Severe anemia (aplastic crisis) may occur in folic acid deficiency or when bone marrow compensation is temporarily impaired by infection. Chronic hemolysis causes jaundice and pigment (calcium bilirubinate) gallstones, leading to attacks of cholecystitis. Examination may reveal icterus and a palpable spleen.

B. Laboratory Findings

The anemia is of variable severity, and the hematocrit may be normal. Reticulocytosis is always present. The peripheral blood smear shows the presence of spherocytes, small cells that have lost their central pallor. Spherocytes usually make up only a small percentage of red blood cells on the peripheral smear. Hereditary spherocytosis is the only important disorder associated with microcytosis and an increased MCHC, often greater than 36 g/dL. As with other hemolytic disorders, there may be an increase in indirect bilirubin. The Coombs test is negative.

Because spherocytes are red cells that have lost some membrane surface, they are abnormally vulnerable to swelling induced by hypotonic media. Increased osmotic fragility merely reflects the presence of spherocytes and does not distinguish hereditary spherocytosis from other spherocytic hemolytic disorders such as autoimmune hemolytic anemia.

Treatment

These patients should receive uninterrupted supplementation with folic acid, 1 mg/d. The treatment of choice is splenectomy, which will not correct the membrane defect or correct the spherocytosis but will eliminate the site of hemolysis. In very mild cases discovered late in adult life, splenectomy may not be necessary.

Bolton-Maggs PH: The diagnosis and management of hereditary spherocytosis. *Baillieres Best Pract Res Clin Haematol* 2000;13:327. [PMID: [11030038](#)]

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

Paroxysmal nocturnal hemoglobinuria is an acquired clonal stem cell disorder that results in abnormal sensitivity of the red blood cell membrane to lysis by complement. The defect involves both increased binding of C3b and increased vulnerability to lysis by complement, and is expressed as a deficiency in proteins normally linked to the cell by phosphoinositol. Paroxysmal nocturnal hemoglobinuria should be suspected in confusing cases of hemolytic anemia or pancytopenia. The best screening test is the sucrose hemolysis test.

Clinical Findings

A. Symptoms and Signs

Classically, patients report episodic hemoglobinuria resulting in reddish brown urine. Hemoglobinuria may be present in the first morning urine, since the mild respiratory acidosis of sleep leads to enhanced complement activity. In addition to anemia, these patients are prone to thrombosis, especially mesenteric and hepatic vein thromboses. This hypercoagulopathy may be related to platelet activation by complement. As this is a stem cell disorder, paroxysmal nocturnal hemoglobinuria may progress either to aplastic anemia, to myelodysplasia, or to acute myelogenous leukemia.

B. Laboratory Findings

Anemia is of variable severity, and reticulocytosis may or may not be present. Abnormalities on the blood smear are nondiagnostic and may include macro-ovalocytes. Since the episodic hemolysis in paroxysmal nocturnal hemoglobinuria is intravascular, the finding of urine hemosiderin is a useful test. Serum LDH is characteristically elevated. Iron deficiency is commonly present and is related to chronic iron loss from hemoglobinuria, since hemolysis is primarily intravascular.

The white blood cell count and platelet count may be decreased. A decreased leukocyte alkaline phosphatase—evidence for qualitative abnormality in the myeloid series—may be seen. Bone marrow morphology is variable and may show either generalized hypoplasia or erythroid hyperplasia. Flow cytometric assays may confirm the diagnosis by demonstrating the absence of CD59.

Treatment

Iron replacement is often indicated for treatment of iron deficiency. This may improve the anemia but may also cause a transient increase in hemolysis. For unclear reasons, prednisone is effective in decreasing hemolysis, and some patients can be managed effectively with alternate-day steroids. In severe cases and cases of transformation to myelodysplasia, allogeneic bone marrow transplantation has been used to treat the disorder.

GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

Essentials of Diagnosis

- X-linked recessive disorder seen commonly in American black men.
- Episodic hemolysis in response to oxidant drugs or infection.
- Minimally abnormal peripheral blood smear.
- Reduced levels of G6PD between hemolytic episodes.

General Considerations

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is a hereditary enzyme defect that causes episodic hemolytic anemia because of decreased ability of red blood cells to deal with oxidative stresses. The hexose monophosphate shunt is not an important source of energy in red cells but is important in generating reduced glutathione, which protects hemoglobin from oxidative denaturation. The first step in this pathway is the production of NADPH by the action of G6PD on glucose 6-phosphate. NADPH serves as a cofactor for glutathione reductase in generating reduced glutathione, which detoxifies hydrogen peroxide. In the absence of reduced glutathione, hemoglobin may become oxidized. Oxidized hemoglobin denatures and forms precipitants called Heinz bodies. These Heinz bodies cause membrane damage, which leads to removal of these cells by the spleen.

Numerous types of G6PD enzymes have been described. The normal type found in whites is designated G6PD-B. Most American blacks have G6PD-A, which is normal in function. Ten to 15 percent of American blacks have the variant G6PD designated A⁻, in which there is only 15% of normal enzyme activity, and enzyme activity declines rapidly as the red blood cell ages past 40 days, a fact that explains many of the clinical findings in this disorder. Many other G6PD variants have been described, including some Mediterranean variants with extremely low enzyme activity.

Clinical Findings

G6PD deficiency is an X-linked recessive disorder affecting 10-15% of American black males. Female carriers are rarely affected—only when an unusually high percentage of cells producing the normal enzyme are inactivated.

A. Symptoms and Signs

Patients are usually healthy, without chronic hemolytic anemia or splenomegaly. Hemolysis occurs as a result of oxidative stress on the red blood cells, generated either by infection or exposure to certain drugs. Common drugs initiating hemolysis include dapsone, primaquine, quinidine, quinine, sulfonamides, and nitrofurantoin. Even with continuous use of the offending drug, the hemolytic episode is self-limited because older red blood cells (with low enzyme activity) are removed and replaced with a population of young red blood cells with adequate functional levels of G6PD. Severe G6PD deficiency (as in Mediterranean variants) may produce a chronic hemolytic anemia.

B. Laboratory Findings

Between hemolytic episodes, the blood is normal. During episodes of hemolysis, there is reticulocytosis and increased serum indirect bilirubin. The red blood cell smear is not diagnostic but may reveal a small number of "bite" cells—cells that appear to have had a bite taken out of their periphery. This indicates pitting of hemoglobin aggregates by the spleen. Heinz bodies may be demonstrated by staining a peripheral blood smear with crystal violet; they are not visible on the usual Wright-stained blood smear. Specific enzyme assays for G6PD may reveal a low level but may be misleading if they are performed shortly after a hemolytic episode when the enzyme-deficient cohort of cells has been removed. In these cases, the enzyme assays should be repeated weeks after hemolysis has resolved. In severe cases of G6PD deficiency, enzyme levels are always low.

Treatment

No treatment is necessary except to avoid known oxidant drugs.

Mehta A et al: Glucose-6-phosphate dehydrogenase deficiency. Baillieres Best Pract Res Clin Haematol 2000;13:21. [\[PMID: 10916676\]](#)

SICKLE CELL ANEMIA & RELATED SYNDROMES

Essentials of Diagnosis

- Irreversibly sickled cells on peripheral blood smear.
- Positive family history and lifelong history of hemolytic anemia.
- Recurrent painful episodes.
- Hemoglobin S is the major hemoglobin seen on electrophoresis.

General Considerations

Sickle cell anemia is an autosomal recessive disorder in which an abnormal hemoglobin leads to chronic hemolytic anemia with numerous clinical consequences. A single DNA base change leads to an amino acid substitution of valine for glutamine in the sixth position on the β -globin chain. The abnormal beta chain is designated β^S and the tetramer of $\alpha_2\beta^S_2$ is designated hemoglobin S.

When in the deoxy form, hemoglobin S forms polymers that damage the red blood cell membrane. Both polymer formation and early membrane damage are reversible. However, red blood cells that have undergone repeated sickling are damaged beyond repair and become irreversibly sickled.

The rate of sickling is influenced by a number of factors, most importantly by the concentration of hemoglobin S in the individual red blood cell. Red cell dehydration makes the cell quite vulnerable to sickling. Sickling is also strongly influenced by the presence of other hemoglobins within the cell. Hemoglobin F cannot participate in polymer formation, and its presence markedly retards sickling. Other factors that increase sickling are those which lead to formation of deoxyhemoglobin S, eg, acidosis and hypoxemia, either systemic or locally in tissues.

Prenatal diagnosis is now available for couples at risk of producing a child with sickle cell anemia. DNA from fetal cells can be directly examined, and the presence of the sickle cell mutation can be accurately and definitively diagnosed. Genetic counseling should be made available to such couples.

Clinical Findings

A. Symptoms and Signs

The hemoglobin S gene is carried in 8% of American blacks, and one birth out of 400 in American blacks will produce a child with sickle cell anemia. The disorder has its onset during the first year of life, when hemoglobin F levels fall as a signal is sent to switch from γ -globin to β -globin production.

Chronic hemolytic anemia produces jaundice, pigment (calcium bilirubinate) gallstones, splenomegaly, and poorly healing ulcers over the lower tibia. The chronic anemia may become life-threatening when severe anemia is produced by hemolytic or aplastic crises. The latter occur when the ability of the bone marrow to compensate is reduced by viral or other infection or by folate deficiency. Hemolytic crises may be related to splenic sequestration of sickled cells (primarily in childhood, before the spleen has been infarcted as a result of repeated sickling) or with coexistent disorders such as G6PD deficiency.

Acute painful episodes due to acute vaso-occlusion may occur spontaneously or be provoked by infection, dehydration, or hypoxia. Clusters of sickled red cells occlude the microvasculature of the organs involved. These episodes last hours to days and produce acute pain and low-grade fever. Common sites of acute painful episodes include the bones (especially the back and long bones) and the chest. Acute vaso-occlusion may also cause strokes due to sinus thrombosis and priapism. Vaso-occlusive episodes are not associated with increased hemolysis.

Repeated episodes of vascular occlusion affect a large number of organs, especially the heart and liver. Ischemic necrosis of bone occurs, rendering the bone susceptible to osteomyelitis due to staphylococci or (less commonly) salmonellae. Infarction of the papillae of the renal medulla causes renal tubular concentrating defects and gross hematuria, more often encountered in sickle cell trait than in sickle cell anemia. Retinopathy similar to that noted in diabetes is often present and may lead to blindness.

These patients are prone to delayed puberty. An increased incidence of infection is related to hyposplenism as well as to defects in the alternative pathway of complement.

On examination, patients are often chronically ill and jaundiced. There is hepatomegaly, but the spleen is not palpable in adult life. The heart is enlarged, with a hyperdynamic precordium and systolic murmurs. Nonhealing ulcers of the lower leg and retinopathy may be present.

Sickle cell anemia becomes a chronic multisystem disease, with death from organ failure. With improved supportive care, average life expectancy is now between ages 40 and 50.

B. Laboratory Findings

Chronic hemolytic anemia is present. The hematocrit is usually 20-30%. The peripheral blood smear is characteristically abnormal, with irreversibly sickled cells comprising 5-50% of red cells. Other findings include reticulocytosis (10-25%), nucleated red blood cells, and hallmarks of hyposplenism such as Howell-Jolly bodies and target cells. The white blood cell count is characteristically elevated to 12,000-15,000/uL, and thrombocytosis may occur. Indirect bilirubin levels are high.

Most clinical laboratories offer a screening test for sickle cell hemoglobin, and the diagnosis of sickle cell anemia is then confirmed by hemoglobin electrophoresis ([Table 13-9](#)). Hemoglobin S has an abnormal migration pattern on electrophoresis and will usually comprise 85-98% of hemoglobin. In homozygous S disease, no hemoglobin A will be present. Hemoglobin F levels are variably increased, and high hemoglobin F levels are associated with a more benign clinical course.

Treatment

No specific treatment is available for the primary disease. Patients are maintained on folic acid supplementation and given transfusions for aplastic or hemolytic crises. Pneumococcal vaccination reduces the incidence of infections with this pathogen.

When acute painful episodes occur, precipitating factors should be identified and infections treated if present. The patient should be kept well hydrated, and oxygen should be given if the patient is hypoxic.

Acute vaso-occlusive crises can be treated with exchange transfusion. These are primarily indicated for the treatment of intractable pain crises, priapism, and stroke.

Cytotoxic agents increase hemoglobin F levels by stimulating erythropoiesis in more primitive erythroid precursors. Hydroxyurea (500-750 mg/d) reduces the frequency of painful crises in patients whose quality of life is disrupted by frequent pain crises. Long-term safety is uncertain, and concern remains about the potential of secondary malignancies. Allogeneic bone marrow transplantation is being studied as a possible curative option for severely affected young patients.

Vichinsky EP et al: Causes and outcomes of the acute chest syndrome in sickle cell disease. National Acute Chest Syndrome Study Group. N Engl J Med 2000;342:1855. [\[PMID: 10861320\]](#)

Walters MC et al: Impact of bone marrow transplantation for symptomatic sickle cell disease: an interim report. Blood 2000;95:1918. [\[PMID: 10706855\]](#)

SICKLE CELL TRAIT

Patients with the heterozygous genotype (AS) have sickle cell trait. These persons are clinically normal and have acute painful episodes only under extreme conditions such as vigorous exertion at high altitudes (or in unpressurized aircraft). The patients are hematologically normal, with no anemia and normal red blood cells on peripheral blood smear. They may, however, have a defect in renal tubular function, causing an inability to concentrate the urine, and experience episodes of gross hematuria. This appears to be caused by many years of sickling in the sluggish circulation of the renal medulla. A screening test for sickle hemoglobin will be positive, and hemoglobin electrophoresis will reveal that approximately 40% of hemoglobin is hemoglobin S ([Table 13-9](#)).

No treatment is necessary. Genetic counseling is a reasonable strategy.

SICKLE THALASSEMIA

Patients with homozygous sickle cell anemia and alpha thalassemia have a somewhat milder form of hemolysis because of a slower rate of sickling related to reduced hemoglobin concentration (MCHC) within the red blood cell.

Patients who are double heterozygotes for sickle cell anemia and beta thalassemia are clinically affected with sickle cell syndromes. Sickle β^0 thalassemia is clinically very similar to homozygous SS disease. Vaso-occlusive crises may be somewhat less severe, and the spleen is usually not infarcted. Hematologically, the MCV is usually low, in contrast to the normal MCV of sickle cell anemia. Hemoglobin electrophoresis ([Table 13-9](#)) reveals no hemoglobin A but will show an increase in hemoglobin A₂ which is not present in sickle cell anemia.

Sickle β^+ thalassemia is a milder disorder than homozygous SS disease, with fewer crises. The spleen is usually palpable. The hemolytic anemia is less severe, and the hematocrit is usually 30-38%, with reticulocytes of 5-10%. Hemoglobin electrophoresis shows the presence of some hemoglobin A.

HEMOGLOBIN C DISORDERS

Hemoglobin C is formed by a single amino acid substitution at the same site of substitution as in sickle hemoglobin but with lysine instead of valine substituted for glutamine at the β_6 position. Hemoglobin C is nonsickling but may participate in polymer formation in association with hemoglobin S. Homozygous hemoglobin C disease produces a mild hemolytic anemia with splenomegaly, mild jaundice, and pigment (calcium bilirubinate) gallstones. The peripheral blood smear shows generalized red cell targeting and occasional cells with rectangular crystals of hemoglobin C. Persons heterozygous for hemoglobin C are clinically normal.

Patients with hemoglobin SC disease are double heterozygotes for beta S and beta C. These patients, like those with sickle β^+ thalassemia, have a milder hemolytic anemia and milder clinical course than those with homozygous SS disease. There are fewer vaso-occlusive events, and the spleen remains palpable in adult life. However, persons with hemoglobin SC disease have more retinopathy and more ischemic necrosis of bone than those with SS disease. The hematocrit is usually 30-38%, with 5-10% reticulocytes and few irreversibly sickled cells on the blood smear. Target cells are more numerous than in SS disease. Hemoglobin electrophoresis will show approximately 50% hemoglobin C, 50% hemoglobin S, and no increase in hemoglobin F levels.

UNSTABLE HEMOGLOBINS

Unstable hemoglobins are prone to oxidative denaturation even in the presence of a normal G6PD system. The disorder is autosomal dominant and of variable severity. Most patients have a mild chronic hemolytic anemia with splenomegaly, mild jaundice, and pigment (calcium bilirubinate) gallstones. Less severely affected patients are not anemic except under conditions of oxidative stress.

The diagnosis is made by the finding of Heinz bodies and a normal G6PD level. Hemoglobin electrophoresis is usually normal, since these hemoglobins characteristically do not have a change in their migration pattern. These hemoglobins precipitate in isopropanol. Usually no treatment is necessary. Patients with chronic hemolytic anemia should receive folate supplementation and avoid known oxidative drugs. In rare cases, splenectomy may be required.

AUTOIMMUNE HEMOLYTIC ANEMIA

Essentials of Diagnosis

- Acquired anemia caused by IgG autoantibody.
- Spherocytes and reticulocytosis on peripheral blood smear.
- Positive Coombs test.

General Considerations

Autoimmune hemolytic anemia is an acquired disorder in which an IgG autoantibody is formed that binds to the red blood cell membrane. The antibody is most commonly directed against a basic component of the Rh system present on virtually all human red blood cells. When IgG antibodies coat the red blood cell, the Fc portion of the antibody is recognized by macrophages present in the spleen and other portions of the reticuloendothelial system. The interaction between splenic macrophage and the antibody-coated red blood cell results in removal of red blood cell membrane and the formation of a spherocyte because of the decrease in surface-to-volume ratio of the red blood cell. These spherocytic cells have decreased deformability and become trapped in the red pulp of the spleen because of their inability to squeeze through the 2-um fenestrations. When large amounts of IgG are present on red blood cells, complement may be fixed. Direct lysis of cells is rare, but the presence of C3b on the surface of red blood cells allows Kupffer cells in the liver to participate in the hemolytic process because of the presence of C3b receptors on Kupffer cells.

Approximately half of all cases of autoimmune hemolytic anemia are idiopathic. The disorder may also be seen in association with systemic lupus erythematosus, chronic lymphocytic leukemia, or lymphomas. It must be distinguished from drug-induced hemolytic anemia. Penicillin (and other drugs) coat the red blood cell membrane, and the antibody is directed against the membrane-drug complex.

The Coombs antiglobulin test forms the basis for diagnosis of these immune hemolytic disorders. The Coombs reagent is a rabbit IgM antibody raised against human IgG or human complement. The direct Coombs test is performed by mixing the patient's red blood cells with the Coombs reagent and looking for agglutination, which indicates the presence of antibody on the red blood cell surface. The indirect Coombs test is performed by mixing the patient's serum with a panel of type O red blood cells. After incubation of the test serum and panel red blood cells, the Coombs reagent is added. Agglutination in this system indicates the presence of free antibody in the patient's serum. Because the traditional Coombs test relies on visible agglutination as an end point, the test is not very sensitive and will not detect immune hemolytic anemias in which only a small amount of IgG is present on red blood cells. More sensitive tests (micro-Coombs) are now available.

Clinical Findings

A. Symptoms and Signs

Autoimmune hemolytic anemia typically produces an anemia of rapid onset that may be life-threatening in severity. Patients complain of fatigue and may present with angina or congestive heart failure. On examination, jaundice and splenomegaly are usually present.

B. Laboratory Findings

The anemia is of variable severity but may be severe, with hematocrit of less than 10%. Reticulocytosis is usually present, and spherocytes are seen on the peripheral blood smear. In cases of severe hemolysis, the stressed bone marrow may also release nucleated red blood cells. As with other hemolytic disorders, indirect bilirubin is increased. Approximately 10% of patients with autoimmune hemolytic anemia have coincident immune thrombocytopenia (Evans syndrome).

The direct Coombs test is positive, and the indirect Coombs test may or may not be positive. A positive indirect Coombs test indicates the presence of a large amount of autoantibody that has saturated binding sites in the red blood cell and consequently appears in the serum. A patient with acquired spherocytic hemolytic anemia that may be of the autoimmune variety who has a negative Coombs test should be tested with a micro-Coombs test (which is necessary to make the diagnosis in approximately 10% of cases). Because the patient's serum usually contains the autoantibody, it may be difficult to obtain a compatible cross-match with donor's cells.

Treatment

Initial treatment consists of prednisone, 1-2 mg/kg/d in divided doses. Most transfused blood will survive similarly to the patient's own red blood cells. Because of difficulty in performing the cross-match, incompatible blood may be given. Decisions regarding transfusions should be made in consultation with a hematologist. If prednisone is ineffective or if the disease recurs on tapering the dose, splenectomy should be performed. Patients with autoimmune hemolytic anemia refractory to prednisone and splenectomy may be treated with a variety of agents. Treatment with rituximab, a monoclonal antibody against the B cell antigen CD20, is effective in some cases. The suggested dose is 375 mg/m² intravenously weekly for 4 weeks. Danazol, 600-800 mg/d, is less often effective than in immune thrombocytopenia but is well suited for long-term use because of its low toxicity. Immunosuppressive agents, including cyclophosphamide, azathioprine, or cyclosporine, may also be used. High-dose intravenous immune globulin (1 g daily for 1 or 2 days) may be highly effective in controlling hemolysis. The benefit is short-lived (1-3 weeks), and the drug is very expensive. The long-term prognosis for patients with this disorder is good, especially if there is no underlying autoimmune disorder or lymphoma. Splenectomy is often successful in controlling the disorder.

COLD AGGLUTININ DISEASE

Essentials of Diagnosis

- Increased reticulocytes and spherocytes on peripheral blood smear.
- Coombs test positive only for complement.
- Positive cold agglutinin test.

General Considerations

Cold agglutinin disease is an acquired hemolytic anemia due to an IgM autoantibody usually directed against the I antigen on red blood cells. These IgM autoantibodies characteristically will not react with cells at 37°C but only at lower temperatures. Since the blood temperature (even in the most peripheral parts of the body) rarely goes lower than 20°C, only antibodies active at higher temperatures than this will produce clinical effects. Hemolysis results indirectly from attachment of IgM, which in the cooler parts of the circulation (fingers, nose, ears) binds and fixes complement. When the red blood cell returns to a warmer temperature, the IgM antibody dissociates, leaving complement on the cell. Lysis of cells rarely occurs. Rather, C3b present on the red cells is recognized by Kupffer cells (which have receptors for C3b), and red blood cell sequestration ensues.

Most cases of chronic cold agglutinin disease are idiopathic. Others occur in association with Waldenstrom's macroglobulinemia, in which a monoclonal IgM paraprotein is produced. Acute postinfectious cold agglutinin disease occurs following mycoplasmal pneumonia or infectious mononucleosis (with antibody directed against antigen i rather than I).

Clinical Findings

A. Symptoms and Signs

In chronic cold agglutinin disease, symptoms related to red blood cell agglutination occur on exposure to cold, and patients may complain of mottled or numb fingers or toes. Hemolytic anemia is rarely severe, but episodic hemoglobinuria may occur on exposure to cold. The hemolytic anemia in acute postinfectious syndromes is rarely severe.

B. Laboratory Findings

Mild anemia is present with reticulocytosis and spherocytes. The direct Coombs test will be positive for complement only. Occasionally, a micro-Coombs test is necessary to reveal bound complement (low-titer cold agglutinin disease). A bedside cold agglutinin test may be performed by placing a glass slide in ice and then putting a few drops of heparinized blood on it. Inspection may reveal small clumps of agglutinated blood.

Treatment

Treatment is largely symptomatic, based on avoiding exposure to cold. Patients with severe involvement may be treated with alkylating agents such as cyclophosphamide or with immunosuppressive agents such as cyclosporine. Splenectomy and prednisone are usually ineffective since hemolysis takes place in the liver. High-dose intravenous immunoglobulin (2 g/kg) may be effective temporarily.

Rituximab, a monoclonal antibody directed against B lymphocytes, may be effective. The dose is 375 mg/m² intravenously weekly for 4 weeks.

MICROANGIOPATHIC HEMOLYTIC ANEMIAS

The microangiopathic hemolytic anemias are a group of disorders in which red blood cell fragmentation takes place. The anemia is intravascular, producing hemoglobinemia, hemoglobinuria, and, in severe cases, methemalbuminemia. The hallmark of the disorder is the finding of fragmented red blood cells (schistocytes, helmet cells) on the peripheral blood smear.

These fragmentation syndromes can be caused by a variety of disorders ([Table 13-8](#)). Thrombotic thrombocytopenic purpura is the most important of these and is discussed below. Clinical features are variable and depend on the underlying disorder. Coagulopathy and thrombocytopenia are variably present.

Chronic microangiopathic hemolytic anemia (such as is present with a malfunctioning cardiac valve prosthesis) may cause iron deficiency anemia because of continuous low-grade hemoglobinuria.

APLASTIC ANEMIA

Essentials of Diagnosis

- Pancytopenia.
- No abnormal cells seen.
- Hypocellular bone marrow.

General Considerations

All hematopoietic cells are derived from a pluripotent stem cell that gives rise to precursors of erythroid, myeloid, and platelet forms. Injury to or suppression of this hematopoietic stem cell will result in pancytopenia. Aplastic anemia is a condition of bone marrow failure that arises from injury to or abnormal expression of the stem cell. The bone marrow becomes hypoplastic, and pancytopenia develops.

There are a number of causes of aplastic anemia ([Table 13-10](#)). Direct stem cell injury may be caused by radiation, chemotherapy, toxins, or pharmacologic agents.

Systemic lupus erythematosus may rarely cause suppression of the hematopoietic stem cell by an IgG autoantibody directed against the stem cell. However, the most common pathogenesis of aplastic anemia appears to be autoimmune suppression of hematopoiesis by a T cell-mediated cellular mechanism.

Clinical Findings

A. Symptoms and Signs

Patients come to medical attention because of the consequences of bone marrow failure. Anemia leads to symptoms of weakness and fatigue, neutropenia causes vulnerability to bacterial infections, and thrombocytopenia results in mucosal and skin bleeding. Physical examination may reveal signs of pallor, purpura, and petechiae. Other abnormalities such as hepatosplenomegaly, lymphadenopathy, or bone tenderness should *not* be present, and their presence should lead one to question the diagnosis.

B. Laboratory Findings

The hallmark of aplastic anemia is pancytopenia. However, early in the evolution of aplastic anemia, only one or two cell lines may be reduced.

Anemia may be severe and is always associated with decreased reticulocytes. Red blood cell morphology is unremarkable. The MCV is usually normal but occasionally may be increased. Neutrophils and platelets are reduced in number, and no immature or abnormal forms are seen. The bone marrow aspirate and the bone marrow biopsy appear hypocellular, with only scant amounts of normal hematopoietic progenitors. No abnormal cells are seen.

Differential Diagnosis

The diagnosis of aplastic anemia is made in cases of pancytopenia with a hypocellular marrow biopsy containing no abnormal cells. Aplastic anemia must be differentiated from other causes of pancytopenia ([Table 13-11](#)). Myelodysplastic disorders or acute leukemia may occasionally be confused with aplastic anemia. These are differentiated by the presence of morphologic abnormalities or increased blasts. Hairy cell leukemia has been misdiagnosed as aplastic anemia and should be recognized by the presence of splenomegaly and by abnormal lymphoid cells on the bone marrow biopsy. Pancytopenia with a normocellular bone marrow is usually due to systemic lupus erythematosus, disseminated infection, or hypersplenism. Isolated thrombocytopenia may occur early as aplastic anemia develops and be confused with immune thrombocytopenia.

Treatment

Mild cases of aplastic anemia may be treated with supportive care. Red blood cell transfusions and platelet transfusions are given as necessary, and antibiotics are used to treat infections.

Severe aplastic anemia is defined by a neutrophil count of less than 500/uL, platelets less than 20,000/uL, reticulocytes less than 1%, and bone marrow cellularity less than 20%. When this constellation of features is present (or three of the four), the median survival without treatment is approximately 3 months, and only 20% of patients survive for 1 year. The treatment of choice for young adults (under age 50) who have HLA-matched siblings is allogeneic bone marrow transplantation. Children or very young adults (under age 30) may benefit from allogeneic transplantation using an unrelated donor. Because of the increased risks associated with unrelated-donor transplantation, this treatment is usually reserved for patients who have not benefited from immunosuppressive therapy.

For adults over age 50 or those without HLA-matched siblings, the treatment of choice for severe aplastic anemia is immunosuppression with antithymocyte globulin (ATG) plus cyclosporine. ATG is given in the hospital in conjunction with transfusion and antibiotic support. A useful regimen is 40 mg/kg/d for 4 days in combination with cyclosporine, 6 mg/kg orally twice daily. ATG must be used in combination with corticosteroids (prednisone 1-2 mg/kg/d initially, followed by a rapid taper) to avoid complications of serum sickness. Responses usually occur in 4-12 weeks and are usually only partial, but the blood counts rise high enough to give patients a safe and transfusion-free life.

High-dose immunosuppression with cyclophosphamide, 200 mg/kg, has produced remissions in refractory cases and should be considered for patients without suitable bone marrow donors. Results employing this as primary therapy are promising, but prolonged pancytopenia (median 7 weeks of neutropenia) requiring antibiotic and transfusion support is a major concern.

Androgens have been widely used in the past, with a low response rate. However, a few patients can be maintained successfully with this form of treatment. One regimen is oxymetholone, 2-3 mg/kg orally daily.

Course & Prognosis

Patients with severe aplastic anemia have a rapidly fatal illness if left untreated. Allogeneic bone marrow transplantation is highly successful in children and young adults with HLA-matched siblings. For this group of patients, the durable complete response rate exceeds 80%. ATG treatment leads to partial response in approximately 60% of adults, and the long-term prognosis of responders appears to be good. There is increasing evidence that some fraction (as many as 25%) of these nontransplanted patients may develop clonal hematologic disorders such as paroxysmal nocturnal hemoglobinuria or myelodysplasia after many years of follow-up.

■ NEUTROPENIA

Neutropenia is present when the count is below 1500/uL, though blacks and other specific population groups may normally have neutrophil counts as low as 1200/uL. The neutropenic patient is increasingly vulnerable to infection by gram-positive and gram-negative bacteria and by fungi. The risk of infection is related to the severity of neutropenia. Patients with "chronic benign neutropenia" are free of infection for years despite very low neutrophil levels.

A variety of bone marrow disorders and nonmarrow conditions may cause neutropenia ([Table 13-12](#)). All the causes of aplastic anemia ([Table 13-10](#)) and pancytopenia ([Table 13-11](#)) may cause neutropenia. Isolated neutropenia is often due to an idiosyncratic reaction to a drug, and agranulocytosis (complete absence of neutrophils in the peripheral blood) is almost always due to a drug reaction. In these cases, examination of the bone marrow shows virtual absence of myeloid precursors, with other cell lines undisturbed. **Felty's syndrome**—immune neutropenia associated with seropositive nodular rheumatoid arthritis and splenomegaly—is another cause. Neutropenia in the presence of a normal bone marrow may be due to immunologic peripheral destruction, sepsis, or hypersplenism. Severe neutropenia may be associated with clonal disorders of T lymphocytes, often with the morphology of large granular lymphocytes.

Clinical Findings

Neutropenia results in stomatitis and in infections due to gram-positive or gram-negative aerobic bacteria or to fungi such as candida or aspergillus. The most common infections are septicemia, cellulitis, and pneumonia. In the presence of severe neutropenia, the usual signs of inflammatory response to infection may be absent. Nevertheless, fever in the neutropenic patient should always be assumed to be of infectious origin.

Treatment

Potential causative drugs are discontinued. Infections are treated with broad-spectrum antibiotics, but particular attention should be paid to enteric gram-negative bacteria. Effective antibiotics include the quinolones such as levofloxacin, 500 mg orally or intravenously daily, or new cephalosporins such as cefepime, 2 g intravenously every 8 hours.

Many cases of idiopathic or autoimmune neutropenia respond to myeloid growth factors such as G-CSF. Once-weekly or twice-weekly dosage will often be sufficient to produce a protective neutrophil count.

When Felty's syndrome leads to repeated bacterial infections, splenectomy is the treatment of choice. It usually leads to healing of leg ulcers and to reduction in the rate of infection whether or not the neutrophil count rises.

The prognosis of patients with neutropenia depends on the underlying cause. Most patients with drug-induced agranulocytosis can be supported with broad-spectrum antibiotics and will recover completely. The myeloid growth factors G-CSF (filgrastim) and GM-CSF (sargramostim) may be useful in shortening the duration of neutropenia associated with chemotherapy. The neutropenia associated with large granular lymphocytes responds to cyclosporine therapy.

Klastersky J et al: The multi-national association for supportive care in cancer risk index. A multinational scoring system for identifying low-risk, febrile neutropenic cancer patients. J Clin Oncol 2000;18:3038. [PMID: 10944139]

■ LEUKEMIAS & OTHER MYELOPROLIFERATIVE DISORDERS

Myeloproliferative disorders are due to acquired clonal abnormalities of the hematopoietic stem cell. Since the stem cell gives rise to myeloid, erythroid, and platelet cells, one sees qualitative and quantitative changes in all these cell lines. In some disorders (chronic myelogenous leukemia), specific characteristic chromosomal changes are seen. In others, no characteristic cytogenetic abnormalities are seen.

Classically, the myeloproliferative disorders produce characteristic syndromes with well-defined clinical and laboratory features (Tables 13-13 and 13-14). However, these disorders are grouped together because the disease may evolve from one form into another and because hybrid disorders are commonly seen. All of the myeloproliferative disorders may progress to acute myelogenous leukemia.

POLYCYTHEMIA VERA

Essentials of Diagnosis

- Increased red blood cell mass.
- Splenomegaly.
- Normal arterial oxygen saturation.
- Usually elevated white blood count and platelet count.

General Considerations

Polycythemia vera is an acquired myeloproliferative disorder that causes overproduction of all three hematopoietic cell lines, most prominently the red blood cells. The hematocrit is elevated (at sea level) when values exceed 54% in males or 51% in females (Table 13-15).

When the hematocrit is elevated, the red blood cell mass should be measured to determine whether true polycythemia or relative polycythemia exists. Normal values for red blood cell mass are 26-34 mL/kg in men and 21-29 mL/kg in women. Relative ("spurious") polycythemia presents in middle-aged men who are overweight and hypertensive (often on diuretic therapy); the hematocrit is almost always less than 60%, and they have a high-normal red cell mass and a low-normal plasma volume.

If the red blood cell mass is increased, one must determine whether the increase is primary or secondary. Primary polycythemia (polycythemia vera) is a bone marrow disorder characterized by autonomous overproduction of erythroid cells. Erythroid production is independent of erythropoietin, and the serum erythropoietin level is low. In vitro, erythroid progenitor cells grow without added erythropoietin, a finding not seen in normal individuals.

Clinical Findings

A. Symptoms and Signs

Most patients present with symptoms related to expanded blood volume and increased blood viscosity. Common complaints include headache, dizziness, tinnitus, blurred vision, and fatigue. Generalized pruritus, especially that occurring following a warm shower or bath, may be a striking symptom and is related to histamine release from the increased number of basophils present. Patients may also initially complain of epistaxis. This is probably related to engorgement of mucosal blood vessels in combination with abnormal hemostasis due to qualitative abnormalities in platelet function. Sixty percent of patients are men, and the median age at presentation is 60 years. Polycythemia rarely occurs in persons under age 40.

Physical examination reveals plethora and engorged retinal veins. The spleen is palpable in 75% of cases but nearly always enlarged when imaged.

Thrombosis is the most common complication of polycythemia vera and the major cause of morbidity and death in this disorder. Thrombosis appears to be related to increased blood viscosity and abnormal platelet function. Uncontrolled polycythemia leads to a very high incidence of thrombotic complications of surgery, and elective surgery should be deferred until the condition has been treated. Paradoxically, in addition to thrombosis, increased bleeding also occurs. There is a high incidence of peptic ulcer disease.

B. Laboratory Findings

The hallmark of polycythemia vera is a hematocrit above normal, at times greater than 60%. Red blood cell morphology is normal. By definition, the red blood cell mass is elevated. The white blood count is elevated to 10,000-20,000/uL and the platelet count is variably increased, sometimes to counts exceeding 1,000,000/uL. Platelet morphology is usually normal. White blood cells are usually normal, but basophilia and eosinophilia are frequently present.

The bone marrow is hypercellular, with panhyperplasia of all hematopoietic elements. Iron stores are usually absent from the bone marrow, having been transferred to the increased circulating red blood cell mass. Iron deficiency may also result from chronic gastrointestinal blood loss. Bleeding may lower the hematocrit to the normal range (or lower), creating diagnostic confusion.

Vitamin B₁₂ levels are strikingly elevated because of increased levels of transcobalamin III (secreted by white blood cells). Overproduction of uric acid may lead to hyperuricemia.

Although red blood cell morphology is usually normal at presentation, microcytosis, hypochromia, and poikilocytosis may result from iron deficiency following treatment by phlebotomy (see below). Progressive hypersplenism may also lead to elliptocytosis.

Differential Diagnosis

Spurious polycythemia, in which an elevated hematocrit is due to contracted plasma volume rather than increased red cell mass, may be related to diuretic use or may occur without obvious cause.

A secondary cause of polycythemia should be suspected if splenomegaly is absent and the high hematocrit is not accompanied by increases in other cell lines. Arterial oxygen saturation should be measured to determine if hypoxia is the cause. A smoking history should be taken; carboxyhemoglobin levels may be elevated in smokers. A renal sonogram may be considered to look for an erythropoietin-secreting cyst or tumor. A positive family history should lead to investigation for congenital high-oxygen-affinity hemoglobin.

Polycythemia vera should be differentiated from other myeloproliferative disorders (Table 13-14). Marked elevation of the white blood count (above 30,000/uL) suggests chronic myelogenous leukemia. This disorder is confirmed by the presence of the Philadelphia chromosome. Abnormal red blood cell morphology and nucleated red blood cells in the peripheral blood are seen in myelofibrosis. This condition is diagnosed by bone marrow biopsy showing fibrosis of the marrow. Essential thrombocytosis is diagnosed when the platelet count is strikingly elevated and the red blood cell mass is normal.

Treatment

The treatment of choice is phlebotomy. One unit of blood (approximately 500 mL) is removed weekly until the hematocrit is less than 45%; the hematocrit is maintained at less than 45% by repeated phlebotomy as necessary. Because repeated phlebotomy worsens iron deficiency, the requirement for phlebotomy should gradually decrease. It is important to avoid medicinal iron supplementation, as this can thwart the goals of a phlebotomy program. Maintaining the hematocrit at normal levels has been shown to decrease the incidence of thrombotic complications. A diet low in iron may also increase the intervals between phlebotomies.

Occasionally, myelosuppressive therapy is indicated. Indications include a high phlebotomy requirement, thrombocytosis, and intractable pruritus. There is evidence that reduction of the platelet count to less than 600,000/uL will reduce the risk of thrombotic complications. Alkylating agents have been shown to increase the risk of conversion of this disease to acute leukemia and should be avoided. Hydroxyurea is now being widely used when myelosuppressive therapy is indicated because of the established leukemogenic potential of alkylating agents. The usual dose is 500-1500 mg/d orally, adjusted to keep platelets < 500,000/uL without reducing the neutrophil count to < 2000/uL. Anagrelide is used in treatment of thrombocytosis and may prove valuable.

The role of antiplatelet agents such as aspirin in preventing thrombotic complications is controversial. High doses of aspirin (325 mg three times daily) plus dipyridamole (25 mg three times daily) cause a marked increase in gastrointestinal bleeding and should be avoided. Low-dose aspirin (81-325 mg daily) may reduce the risk of thrombosis without excessive bleeding risk.

Allopurinol may be indicated for hyperuricemia. Antihistamine therapy with diphenhydramine or other H₁ blockers may be helpful for control of pruritus.

Prognosis

Polycythemia is an indolent disease with median survival of 11-15 years. The major cause of morbidity and mortality is arterial thrombosis. Over time, polycythemia vera may convert to myelofibrosis or to chronic myelogenous leukemia. In approximately 5% of cases, the disorder progresses to acute myelogenous leukemia, which is usually refractory to therapy.

ESSENTIAL THROMBOCYTOSIS

Essentials of Diagnosis

- Elevated platelet count in absence of other causes.
- Normal red blood cell mass.
- Absence of Philadelphia chromosome.

General Considerations

Essential thrombocythemia is an uncommon myeloproliferative disorder of unknown cause in which marked proliferation of the megakaryocytes in the bone marrow leads to elevation of the platelet count.

Clinical Findings

A. Symptoms and Signs

The median age at presentation is 50-60 years, and there is a slightly increased incidence in women. The disorder is commonly suspected because of the finding of an elevated platelet count. Less commonly, the first sign is thrombosis.

The most common clinical problem is thrombosis. The risk of thrombosis rises with age. Venous thromboses may occur in unusual sites such as the mesenteric, hepatic, or portal vein. Some patients experience erythromelalgia, painful burning of the hands accompanied by erythema; this symptom is reliably relieved by aspirin. Bleeding, typically mucosal, is less common and is related to a concomitant qualitative platelet defect. Splenomegaly is present in at least 25% of patients.

B. Laboratory Findings

An elevated platelet count is the hallmark of this disorder, and the count may be markedly elevated to over 2,000,000/uL. The white blood cell count is often mildly elevated, usually not above 30,000/uL, but with some immature myeloid forms. The hematocrit is normal. The peripheral blood smear reveals large platelets, but giant degranulated forms seen in myelofibrosis are not observed. Red blood cell morphology is normal. The bleeding time is prolonged in 20% of patients.

The bone marrow shows increased numbers of megakaryocytes but no other morphologic abnormalities. The Philadelphia chromosome is absent but should be assayed by molecular testing of peripheral blood for the *bcr/abl* fusion gene in all suspected cases to differentiate the disorder from chronic myeloid leukemia.

Differential Diagnosis

Essential thrombocythemia must be distinguished from secondary causes of an elevated platelet count. In reactive thrombocythemia, the platelet count seldom exceeds 1,000,000/uL. Inflammatory disorders such as rheumatoid arthritis and ulcerative colitis cause significant elevations of the platelet count, as may chronic infection. The thrombocythemia of iron deficiency is observed only when anemia is significant. The platelet count is temporarily elevated after splenectomy.

Regarding other myeloproliferative disorders, the lack of elevated hematocrit and red blood cell mass distinguishes it from polycythemia vera. Unlike myelofibrosis, red blood cell morphology is normal, nucleated red blood cells are absent, and giant degranulated platelets are not seen. In chronic myeloid leukemia, the Philadelphia chromosome or *bcr/abl* by molecular testing establishes the diagnosis.

Treatment

The risk of thrombosis can be reduced by control of the platelet count, and one should aim to keep it less than 500,000/uL. Standard therapy has consisted of hydroxyurea in a dose of 0.5-2 g/d. In some cases this is not effective because of dose-limiting neutropenia. Anagrelide is highly effective in a dose of 2-4 mg/d but may cause headache, mild anemia, and peripheral edema, and in high doses congestive heart failure.

Vasomotor symptoms such as erythromelalgia and paresthesias respond rapidly to aspirin and eventually to control of the platelet count. The role of chronic low-dose aspirin therapy to reduce the risk of thrombosis remains unsettled. In the unusual event of severe bleeding, the platelet count can be lowered rapidly with plateletpheresis.

Course & Prognosis

Essential thrombocythemia is an indolent disorder and allows long-term survival. Average survival is longer than 15 years from diagnosis. The major source of morbidity—thrombosis—can be reduced by appropriate platelet control. Late in the course of the disease, the bone marrow may become fibrotic, and massive splenomegaly may occur, sometimes with splenic infarction. There is a 5% risk of transformation to acute leukemia over 20 years.

MYELOFIBROSIS

Essentials of Diagnosis

- Striking splenomegaly.
- Teardrop poikilocytosis on peripheral smear.
- Leukoerythroblastic blood picture; giant abnormal platelets.
- Hypercellular bone marrow with reticulin or collagen fibrosis.

General Considerations

Myelofibrosis (myelofibrosis with myeloid metaplasia, agnogenic myeloid metaplasia) is a myeloproliferative disorder characterized by fibrosis of the bone marrow, splenomegaly, and a leukoerythroblastic peripheral blood picture with teardrop poikilocytosis. It is widely believed that fibrosis occurs in response to increased secretion of platelet-derived growth factor (PDGF) and possibly other cytokines. In response to bone marrow fibrosis, extramedullary hematopoiesis takes place in the

liver, spleen, and lymph nodes. In these sites, mesenchymal cells responsible for fetal hematopoiesis can be reactivated.

Clinical Findings

A. Symptoms and Signs

Myelofibrosis develops in adults over age 50 and is usually insidious in onset. Patients most commonly present with fatigue due to anemia or abdominal fullness related to splenomegaly. Uncommon presentations include bleeding and bone pain. On examination, splenomegaly is almost invariably present and is commonly massive. The liver is enlarged in more than half of cases.

Later in the course of the disease, progressive bone marrow failure takes place as it becomes progressively more fibrotic. Anemia becomes severe, requiring transfusion. Progressive thrombocytopenia leads to bleeding. The spleen continues to enlarge, which leads to early satiety. Painful episodes of splenic infarction may occur. Late in the course, the patient becomes cachectic and may experience severe bone pain, especially in the upper legs. Hematopoiesis in the liver leads to portal hypertension with ascites, esophageal varices, and occasionally transverse myelitis caused by myelopoiesis in the epidural space.

B. Laboratory Findings

Patients are almost invariably anemic at presentation. The white blood count is variable—either low, normal, or elevated—and may be increased to 50,000/uL. The platelet count is variable. The peripheral blood smear is dramatic, with significant poikilocytosis and numerous teardrop forms in the red cell line. Nucleated red blood cells are present and the myeloid series is shifted, with immature forms including a small percentage of promyelocytes or myeloblasts. Platelet morphology may be bizarre, and giant degranulated platelet forms (megakaryocyte fragments) may be seen. The triad of teardrop poikilocytosis, leukoerythroblastic blood, and giant abnormal platelets is highly suggestive of myelofibrosis.

The bone marrow usually cannot be aspirated (dry tap), though early in the course of the disease it is hypercellular, with a marked increase in megakaryocytes. Fibrosis at this stage is detected by a silver stain demonstrating increased reticulin fibers. Later, biopsy reveals more severe fibrosis, with eventual replacement of hematopoietic precursors by collagen. There is no characteristic chromosomal abnormality.

Differential Diagnosis

A leukoerythroblastic blood picture from other causes may be seen in response to severe infection, inflammation, or infiltrative bone marrow processes. However, teardrop poikilocytosis and giant abnormal platelet forms will not be present. Bone marrow fibrosis may be seen in metastatic carcinoma, Hodgkin's disease, and hairy cell leukemia. These disorders are diagnosed by characteristic morphology of involved tissues.

Concerning other myeloproliferative disorders, chronic myelogenous leukemia is diagnosed when there is marked leukocytosis, normal red blood cell morphology, and the presence of the Philadelphia chromosome. Polycythemia vera is characterized by an elevated red blood cell mass. Essential thrombocytosis shows predominant and consistent platelet count elevations.

Treatment

There is no specific treatment for this disorder. Anemic patients are supported with transfusion. Androgens such as oxymetholone, 200 mg orally daily, or testosterone reduce the transfusion requirement in one-third of cases but are poorly tolerated by women. Splenectomy is not routinely performed but is indicated for splenic enlargement causing recurrent painful episodes, severe thrombocytopenia, or an unacceptable transfusion requirement. Allogeneic bone marrow transplantation has been performed successfully with 50% long-term survival and should be considered in younger patients. The use of less toxic, non-myeloablative regimens for allogeneic transplantation has produced encouraging results.

Course & Prognosis

It is difficult to date the onset of myelofibrosis, but the median survival from time of diagnosis is approximately 5 years. End-stage myelofibrosis is characterized by generalized debility, liver failure, and bleeding from thrombocytopenia, with some cases terminating in acute myelogenous leukemia.

CHRONIC MYELOGENOUS LEUKEMIA

Essentials of Diagnosis

- Strikingly elevated white blood count.
- Markedly left-shifted myeloid series but with a low percentage of promyelocytes and blasts.
- Presence of Philadelphia chromosome or bcr-abl gene.

General Considerations

Chronic myelogenous leukemia is a myeloproliferative disorder characterized by overproduction of myeloid cells. These myeloid cells retain the capacity for differentiation, and normal bone marrow function is retained during the early phases. The disease usually remains stable for years and then transforms to a more overtly malignant disease.

Chronic myelogenous leukemia is associated with a characteristic chromosomal abnormality, the Philadelphia chromosome, a reciprocal translocation between the long arms of chromosomes 9 and 22. A large portion of 22q is translocated to 9q, and a smaller piece of 9q is moved to 22q. The portion of 9q that is translocated contains *abl*, a proto-oncogene that is the cellular homolog of the Ableson murine leukemia virus. The *abl* gene is received at a specific site on 22q, the break point cluster (bcr). The fusion gene *bcr/abl* produces a novel protein that differs from the normal transcript of the *abl* gene in that it possesses tyrosine kinase activity (a characteristic activity of transforming genes). Evidence that the *bcr/abl* fusion gene is pathogenic is provided by transgenic mouse models in which introduction of the gene almost invariably leads to leukemia.

Usually at the time of diagnosis, the Philadelphia chromosome-positive clone dominates and may be the only one detected. However, a normal clone is present and may express itself either in vivo, after certain forms of therapy, or in vitro, in long-term bone marrow cultures. Approximately 5% of cases of chronic myelogenous leukemia are Philadelphia chromosome-negative at the level of light microscope cytogenetics, though molecular studies demonstrate the *bcr/abl* fusion gene. The entity formerly known as Philadelphia chromosome-negative CML is now recognized as chronic myelomonocytic leukemia (CMML), a subtype of myelodysplasia.

Early chronic myelogenous leukemia ("chronic phase") does not behave like a malignant disease. Normal bone marrow function is retained, white blood cells differentiate, and, despite some qualitative abnormalities (low leukocyte alkaline phosphatase), the neutrophils combat infection normally. However, chronic myelogenous leukemia is inherently unstable, and the disease progresses to accelerated phase and finally after several years, to blast crisis. This progression of the disease is often associated with added chromosomal defects superimposed on the Philadelphia chromosome. Blast crisis chronic myelogenous leukemia is morphologically indistinguishable from acute leukemia.

Clinical Findings

A. Symptoms and Signs

Chronic myelogenous leukemia is a disorder of middle age (median age at presentation is 42 years). Patients usually present with fatigue, night sweats, and low-grade fever related to the hypermetabolic state caused by overproduction of white blood cells. At other times, the patient complains of abdominal fullness related to splenomegaly, or an elevated white blood count is discovered incidentally. Rarely, the patient will present with a clinical syndrome related to leukostasis with blurred vision, respiratory distress, or priapism. The white blood count in these cases is usually greater than 500,000/uL.

On examination, the spleen is enlarged (often markedly so), and sternal tenderness may be present as a sign of marrow overexpansion.

Acceleration of the disease is often associated with fever in the absence of infection, bone pain, and splenomegaly. In blast crisis, patients may experience bleeding and infection related to bone marrow failure.

B. Laboratory Findings

The hallmark of chronic myelogenous leukemia is an elevated white blood count; the median white blood count at diagnosis is 150,000/uL. The peripheral blood is characteristic. The myeloid series is left-shifted, with mature forms dominating and with cells usually present in proportion to their degree of maturation. Blasts are usually less than 5%. Basophilia and eosinophilia of granulocytes may be present. At presentation, the patient is usually not anemic. Red blood cell morphology is normal, and nucleated red blood cells are rarely seen. The platelet count may be normal or elevated (sometimes to strikingly high levels). Platelet morphology is usually normal, but abnormally large forms may be seen.

The bone marrow is hypercellular, with left-shifted myelopoiesis. Myeloblasts comprise less than 5% of marrow cells.

The leukocyte alkaline phosphatase score is invariably low and is a sign of qualitative abnormalities in neutrophils. The vitamin B₁₂ level is usually elevated because of increased secretion of transcobalamin III, and uric acid levels may be high. The Philadelphia chromosome may be detected in either the peripheral blood or the bone marrow. The *bcr/abl* gene may be reliably found in peripheral blood by molecular techniques.

With progression to the accelerated and blast phases, progressive anemia and thrombocytopenia occur, and the percentage of blasts in the blood and bone marrow increases. Blast phase chronic myelogenous leukemia is diagnosed when blasts comprise more than 30% of bone marrow cells.

Differential Diagnosis

Early chronic myelogenous leukemia must be differentiated from the reactive leukocytosis associated with infection. In such cases, the white blood count is usually less than 50,000/uL, splenomegaly is absent, the leukocyte alkaline phosphatase is increased, and the Philadelphia chromosome is not present.

Chronic myelogenous leukemia must be distinguished from other myeloproliferative disease ([Table 13-14](#)). The hematocrit should not be elevated, the red blood cell morphology is normal, and nucleated red blood cells are rare or absent. Definitive diagnosis is made by finding the Philadelphia chromosome or *bcr/abl*.

Treatment

Treatment is usually not emergent even with white blood counts over 200,000/uL, since the majority of circulating cells are mature myeloid cells that are smaller and more deformable than primitive leukemic blasts. In the rare instances in which symptoms result from extreme hyperleukocytosis (priapism, respiratory distress, visual blurring, altered mental status), emergent leukapheresis is performed in conjunction with myelosuppressive therapy.

The treatment of CML has changed with the introduction of imatinib mesylate. This drug is a specifically designed inhibitor of the tyrosine kinase activity of the *bcr/abl* oncogene. It is well tolerated and results in nearly universal (98%) hematologic control of chronic phase disease. It has now replaced both interferon and hydroxyurea as standard therapy. For patients with the chronic phase of CML, the dose is 400 mg orally daily. The most common toxicities are nausea, periorbital swelling, rash, and myalgia, but most of these are modest. The best outcomes are seen in patients in whom the drug produces both hematologic and cytogenetic remission. The latter is assessed by testing bone marrow cytogenetics after 6 months of treatment. Patients with major (< 35% abnormal metaphases) or complete cytogenetic response appear to have an excellent prognosis, with over 95% remaining in control for longer than 2 years. Since almost all clinical experience with imatinib began in early 2000, long-term outcome is uncertain.

Hydroxyurea was formerly the standard treatment for this disease and can be used for patients who do not tolerate imatinib. Hydroxyurea is oral and very well tolerated. The usual dose is 0.5-2.5 g/d, adjusted to keep the white blood cell count ideally near 5000/uL but in any case above 2000/uL. It is given without interruption because of rapid white blood count rebound.

Alpha interferon has been a useful agent in the treatment of CML, but its role is now modest largely because of toxicities that make long-term use difficult.

The only available curative therapy for CML is allogeneic bone marrow transplantation. This treatment is indicated for adults under 60 who have HLA-matched siblings. Sixty percent of patients have long-term disease-free survival following transplantation. The best results (80% success rate) are obtained in patients who are under 40 and transplanted within 1 year after diagnosis. The introduction of imatinib has changed the approach to allogeneic transplant for CML. Patients with the best transplant outcomes (under 40 with matched sibling donors) may be offered allogeneic transplant. An alternative approach is to initiate imatinib and to recommend transplant if there is no major cytogenetic response after 6 months. These recommendations are in flux and may change as long-term experience with imatinib accumulates. For young patients without sibling donors whose disease is not controlled by imatinib, HLA-matched unrelated donors may be located through registries such as the National Marrow Donors Program. Results are inferior to those achieved with matched sibling transplants but offer a cure rate of 40-60% in an otherwise invariably fatal disease.

Allogeneic transplantation cures chronic myeloid leukemia by initial cytoreduction followed by long-term immunologic control mediated by the donor's immune system. This alloimmune phenomenon has been called the "graft-versus-leukemia" effect. The most compelling evidence for its importance is that chronic phase disease which has recurred after allogeneic transplantation can usually be reversed without additional chemotherapy by the infusion of T lymphocytes from the initial bone marrow donor. This donor lymphocyte infusion can lead to long-term remission in 50-70% of cases. In response to appreciation of the importance of the graft-versus-leukemia effect, less toxic forms of allogeneic transplantation (nonmyeloablative) have been developed that require much less initial cytoreductive therapy and rely exclusively on the immune effect for long-term disease control. This approach has been encouraging and is likely to further expand the role of allogeneic transplant for CML.

Course & Prognosis

In the past, median survival was 3-4 years. With interferon-based therapies, this was increased to 5-6 years. It is anticipated that imatinib will lead to marked improvements in survival rates, but this remains to be proved.

MYELODYSPLASTIC SYNDROMES

Essentials of Diagnosis

- Cytopenias with a hypercellular bone marrow.
- Morphologic abnormalities in two or more hematopoietic cell lines.

General Considerations

The myelodysplastic syndromes are a group of acquired clonal disorders of the hematopoietic stem cell. They are characterized by the constellation of cytopenias, a hypercellular marrow, and a number of morphologic and cytogenetic abnormalities. The disorders are usually idiopathic but may be seen after cytotoxic chemotherapy—especially mechlorethamine and procarbazine for Hodgkin's disease and melphalan for multiple myeloma or ovarian carcinoma.

Despite the presence of adequate numbers of hematopoietic progenitor cells, "ineffective hematopoiesis" occurs, resulting in various cytopenias. Ultimately, the disorder may evolve into acute myelogenous leukemia, and the term "preleukemia" has been used to describe these disorders. Although no specific chromosomal abnormality is seen in myelodysplasia, there are frequently abnormalities involving the long arm of chromosome 5 (which contains a number of genes encoding both growth factors and receptors involved in myelopoiesis) as well as deletions of chromosomes 5 and 7.

Myelodysplasia encompasses several heterogeneous syndromes. Those without excess bone marrow blasts are termed "refractory anemia," with or without ringed sideroblasts. Those with excess blasts are diagnosed as "refractory anemia with excess blasts" (RAEB 5-19% blasts). Those with a proliferative syndrome including peripheral blood monocytosis greater than 1000/uL are termed chronic myelomonocytic leukemia (CMML).

Clinical Findings

A. Symptoms and Signs

Patients are usually over age 60. Many are diagnosed while asymptomatic because of the finding of abnormal blood counts. Patients usually present with fatigue, infection, or bleeding related to bone marrow failure. The course may be indolent, and the disease may present as a wasting illness with fever, weight loss, and general debility. On examination, splenomegaly may be present in combination with pallor, bleeding, and various signs of infection.

B. Laboratory Findings

Anemia may be marked and may require transfusion support. The MCV is normal or increased, and macro-ovalocytes may be seen on the peripheral blood smear. The reticulocyte count is usually reduced. The white blood cell count is usually normal or reduced, and neutropenia is common. The neutrophils may exhibit morphologic abnormalities, including deficient numbers of granules or a bilobed nucleus (Pelger-Huet). The myeloid series may be left-shifted, and small numbers of promyelocytes or blasts may be seen. The platelet count is normal or reduced, and hypogranular platelets may be present.

The bone marrow is characteristically hypercellular. Erythroid hyperplasia is common, and signs of abnormal erythropoiesis include megaloblastic features, nuclear budding, or multinucleated erythroid precursors. The Prussian blue stain may demonstrate ringed sideroblasts. The myeloid series is often left-shifted, with variable increases in blasts. Deficient or abnormal granules may be seen. A characteristic abnormality is the presence of dwarf megakaryocytes with a unilobed nucleus. A variety of cytogenetic abnormalities in the bone marrow are characteristic of myelodysplasia. Some patients with an indolent form of the disease have an isolated partial deletion of chromosome 5 (5q- syndrome). The presence of other abnormalities such as monosomy 7 is associated with more aggressive disease.

Differential Diagnosis

In subtle cases, cytogenetic evaluation of the bone marrow may help distinguish this clonal disorder from other causes of cytopenias. As the number of blasts increases in the bone marrow, myelodysplasia is arbitrarily separated from acute myelogenous leukemia by the presence of less than 20% blasts.

Treatment

Patients affected primarily by anemia are supported with red blood cell transfusions. Those with severe neutropenia may benefit from the use of myeloid growth factors such as G-CSF or GM-CSF. Erythropoietin (epoetin alfa), 30,000 units subcutaneously weekly, reduces the red cell transfusion requirement in some patients. The response rate is 20% or less, but a 4-week trial of epoetin alfa is reasonable since it will be of benefit and cost-effective for the subgroup of responders. The combination of myeloid growth factors and high doses of epoetin alfa produces a higher response rate, but the cost is prohibitive. Azacitidine (5-azacytidine) improves both symptoms and blood counts and prolongs the time to conversion to acute leukemia. It may become the treatment of choice for many patients. In patients with low-risk myelodysplasia—especially those with the 5q- syndrome—the investigational immunomodulatory agent CC-5013 (Revimid) may hold promise.

Patients under age 60 with matched sibling donors can be treated with allogeneic bone marrow transplantation. Cure rates are 30-50%. The use of less toxic allogeneic transplant regimens is being explored and may increase the role of this therapy in patients with less aggressive forms of the disease (without excess blasts).

Course & Prognosis

Myelodysplasia is an ultimately fatal disease. Patients most commonly succumb to infections or bleeding. The risk of transformation to acute myelogenous leukemia depends on the percentage of blasts in the bone marrow. Patients with refractory anemia may survive many years, and the risk of leukemia is low (< 10%). Those with excess blasts or CMML have short survivals (usually < 2 years) and have a higher (20-50%) risk of developing acute leukemia. The finding of full deletions of chromosomes 5 and 7 is associated with a poor prognosis.

ACUTE LEUKEMIA

Essentials of Diagnosis

- Short duration of symptoms, including fatigue, fever, and bleeding.
- Cytopenias or pancytopenia.
- More than 20% blasts in the bone marrow.
- Blasts in peripheral blood in 90%.

General Considerations

Acute leukemia is a malignancy of the hematopoietic progenitor cell. The malignant cell loses its ability to mature and differentiate. These cells proliferate in an uncontrolled fashion and replace normal bone marrow elements. Most cases arise with no clear cause. However, radiation and some toxins (benzene) are leukemogenic. In addition, a number of chemotherapeutic agents (especially procarbazine, melphalan, other alkylating agents, and etoposide) may cause leukemia. The leukemias seen after toxin or chemotherapy exposure often develop from a myelodysplastic prodrome and are associated with abnormalities in chromosomes 5 and 7.

Much as been learned about the molecular biology of the leukemias. One subtype, acute promyelocytic leukemia, is characterized by chromosomal translocation t(15;17), which produces fusion gene *PML-RARα*. This change in the retinoic acid receptor produces a block in differentiation that can be overcome with pharmacologic doses of retinoic acid (see below).

Most of the clinical findings in acute leukemia are due to replacement of normal bone marrow elements by the malignant cell. Less common manifestations result from organ infiltration (skin, gastrointestinal tract, meninges). Acute leukemia is potentially curable with combination chemotherapy.

Acute lymphoblastic leukemia (ALL) comprises 80% of the acute leukemias of childhood. The peak incidence is between 3 and 7 years of age. It is also seen in adults, causing approximately 20% of adult acute leukemias. Acute myelogenous leukemia (AML) is chiefly an adult disease with a median age at presentation of 60 years and an increasing incidence with advanced age.

Clinical Findings

A. Symptoms and Signs

Most patients have been ill only for days or weeks. Bleeding (usually due to thrombocytopenia) occurs in the skin and mucosal surfaces, with gingival bleeding, epistaxis, or menorrhagia. Less commonly, widespread bleeding is seen in patients with disseminated intravascular coagulation (in acute promyelocytic leukemia and monocytic leukemia). Infection is due to neutropenia, with the risk of infection rising as the neutrophil count falls below 500/uL; with neutrophil counts less than 100/uL, infection within days is the rule. The most common pathogens are gram-negative bacteria (*E coli*, *klebsiella*, *pseudomonas*) or fungi (*candida*, *aspergillus*). Common presentations include cellulitis, pneumonia, and perirectal infections; death within a few hours may occur if treatment with appropriate antibiotics is delayed.

Patients may also seek medical attention because of gum hypertrophy and bone and joint pain. The most dramatic presentation is hyperleukocytosis, in which a markedly elevated circulating blast count (usually > 200,000/uL) leads to impaired circulation, presenting as headache, confusion, and dyspnea. Such patients require

emergent leukapheresis and chemotherapy.

On examination, patients appear pale and have purpura and petechiae; signs of infection may not be present. Stomatitis and gum hypertrophy may be seen in patients with monocytic leukemia, as may rectal fissures. There is variable enlargement of the liver, spleen, and lymph nodes. Bone tenderness may be present, particularly in the sternum, tibia, and femur.

B. Laboratory Findings

The hallmark of acute leukemia is the combination of pancytopenia with circulating blasts. However, blasts may be absent from the peripheral smear in as many as 10% of cases ("aleukemic leukemia"). The bone marrow is hypercellular and dominated by blasts. More than 20% blasts are required to make a diagnosis of acute leukemia.

A number of other laboratory abnormalities are noted. Hyperuricemia may be seen. If disseminated intravascular coagulation is present, the fibrinogen level will be reduced, the prothrombin time prolonged, and fibrin degradation products or fibrin D-dimers present. Patients with acute lymphoblastic leukemia (especially T cell) may have a mediastinal mass visible on chest radiograph. Meningeal leukemia will have blasts present in the spinal fluid, seen in approximately 5% of cases at diagnosis; it is more common in monocytic types of acute myelogenous leukemia.

Acute leukemia should be classified as either acute lymphoblastic or acute myelogenous leukemia. The Auer rod, an eosinophilic needle-like inclusion in the cytoplasm, is pathognomonic of acute myelogenous leukemia. To confirm the myeloid nature of the cells, histochemical stains demonstrating myeloid enzymes such as peroxidase may be useful. Monocytic lineage can be established by the finding of butyrate esterase. Acute lymphoblastic leukemia is considered when there is no morphologic or histochemical evidence of myeloid or monocytic lineage. The diagnosis is confirmed by demonstrating surface markers characteristic of primitive lymphoid cells; terminal deoxynucleotidyl transferase (TdT) is present in 95% of cases of acute lymphoblastic leukemia. A variety of monoclonal antibodies have been used to define other phenotypes of acute lymphoblastic leukemia. Primitive B lymphocyte antigens include CD19 and sometimes CD10. T cell acute lymphoblastic leukemia is diagnosed by the finding of CD2, CD5, and CD7.

Acute myelogenous leukemia is usually categorized on the basis of morphology and histochemistry as follows: acute undifferentiated leukemia (M0), acute myeloblastic leukemia (M1), acute myeloblastic leukemia with differentiation (M2), acute promyelocytic leukemia (M3), acute myelomonocytic leukemia (M4), acute monoblastic leukemia (M5), erythroleukemia (M6), and megakaryoblastic leukemia (M7). The World Health Organization (WHO) has sponsored a new classification of the leukemias and other hematologic malignancies that incorporates cytogenetic, molecular, and immunophenotype information.

Acute lymphoblastic leukemia is most usefully classified by immunologic phenotype as follows: common, early B lineage, and T cell.

Cytogenetic studies are the most powerful prognostic factors in the acute leukemias. Favorable cytogenetics in acute myeloid leukemia include t(8;21), t(15;17), and inv(16)(p13;q22). These patients have a higher chance of achieving both short- and long-term disease control. In acute lymphoblastic leukemia, the hyperdiploid states are associated with a better prognosis. Unfavorable cytogenetics in AML are monosomy 5 and 7 and complex abnormalities; unfavorable cytogenetics in ALL are the Philadelphia chromosomes t(9;22) and t(4;11).

Differential Diagnosis

Acute myelogenous leukemia must be distinguished from other myeloproliferative disorders, chronic myelogenous leukemia, and myelodysplastic syndromes. Acute leukemia also resembles a left-shifted bone marrow recovering from a previous toxic insult. If the question is in doubt, a bone marrow study should be repeated in several days to see if maturation has taken place. Acute lymphoblastic leukemia must be separated from other lymphoproliferative disease such as chronic lymphocytic leukemia, lymphomas, and hairy cell leukemia. It may also be confused with the atypical lymphocytosis of mononucleosis and pertussis.

Treatment

Most young patients with acute leukemia are treated with the objective of effecting a cure. The first step in treatment is to obtain complete remission, defined as normal peripheral blood with resolution of cytopenias, normal bone marrow with no excess blasts, and normal clinical status. The type of initial chemotherapy depends on the subtype of leukemia. Most patients with acute myeloid leukemia are treated with a combination of an anthracycline (daunorubicin or idarubicin) plus cytarabine. This therapy will produce complete remissions in 70-80% of patients under age 60 and in 40-60% of older patients. The treatment of patients with acute promyelocytic leukemia has been dramatically improved by the use of all-*trans*-retinoic acid. This agent is an analog of vitamin A that leads to terminal differentiation of acute promyelocytic leukemia cells through an interaction with the abnormal retinoic acid receptor created by a specific chromosomal translocation which is the hallmark of the subtype of leukemia. Patients with acute promyelocytic leukemia should be treated with anthracyclines plus all-*trans*-retinoic acid, and more than 90% will achieve complete remission. Adults with acute lymphoblastic leukemia are treated with combination chemotherapy, including daunorubicin, vincristine, prednisone, and asparaginase. This treatment produces complete remissions in 80-90% of patients.

Once a patient has entered remission, postremission therapy is given with curative intent. Options include standard chemotherapy and autologous and allogeneic transplantation. The optimal treatment strategy depends on the patient's age and clinical status and the risk factor profile of the leukemia. Acute promyelocytic leukemia is generally treated with chemotherapy plus retinoic acid, and 60-70% of patients remain in long-term remission. Arsenic trioxide as an additional agent during remission is under investigation in the hope of increasing cure rates. For average-risk patients with acute myeloid leukemia, cure rates for postremission therapy are 25-30% for chemotherapy, 50% for autologous transplantation, and 50-60% for allogeneic transplantation. Some types of acute myeloid leukemia have a more favorable prognosis, with cure rates of 40-60% with chemotherapy and 70% with autologous transplantation. Patients who do not enter remission or who have high-risk cytogenetics (such as monosomy 7) do far more poorly. Allogeneic transplantation is the treatment of choice, but cure rates are only 20%.

Once leukemia has recurred after initial chemotherapy, the prognosis is much more guarded. For patients in second remission, transplantation (autologous or allogeneic) offers a 30-50% chance of cure. For those patients with acute promyelocytic leukemia who relapse, arsenic trioxide is a novel therapy which can produce second remissions. The role of arsenic trioxide in primary treatment may hold promise.

Acute lymphoblastic leukemia is treated initially with combination chemotherapy, including daunorubicin, vincristine, prednisone, and asparaginase. Remission induction therapy for acute lymphoblastic leukemia is less myelosuppressive than treatment for acute myelogenous leukemia and does not necessarily produce marrow aplasia. After achieving complete remission, patients receive central nervous system prophylaxis so that meningeal sequestration of leukemic cells does not develop. As with acute myelogenous leukemia, patients may be treated with either chemotherapy or high-dose chemotherapy plus bone marrow transplantation. Treatment decisions are made based on patient age and risk factors of the disease. High-risk patients with adverse cytogenetics or poor responses to chemotherapy are best treated with allogeneic transplantation. Autologous transplantation is a possibility in high-risk patients who lack a suitable donor.

Prognosis

Approximately 70-80% of adults with acute myelogenous leukemia under age 60 achieve complete remission. High-dose postremission chemotherapy leads to cure in 30-40% of these patients, and high-dose cytarabine has been shown to be superior to therapy with lower doses. Allogeneic bone marrow transplantation (for younger adults with HLA-matched siblings) is curative in approximately 60% of cases. Autologous bone marrow transplantation is a promising new form of therapy that may cure 50-70% of patients in first remission; it may be superior to nonablative chemotherapy. Older adults with acute myelogenous leukemia achieve complete remission in up to 50% of instances.

CHRONIC LYMPHOCYTIC LEUKEMIA

Essentials of Diagnosis

- Most patients asymptomatic at presentation.
- Splenomegaly typical.
- Lymphocytosis > 5000/uL.
- Mature appearance of lymphocytes.
- Co-expression of CD19, CD5.

General Considerations

Chronic lymphocytic leukemia (CLL) is a clonal malignancy of B lymphocytes. The disease is usually indolent, with slowly progressive accumulation of long-lived small lymphocytes. These cells are immunoincompetent and respond poorly to antigenic stimulation.

Chronic lymphocytic leukemia is manifested clinically by immunosuppression, bone marrow failure, and organ infiltration with lymphocytes. Immunodeficiency is also related to inadequate antibody production by the abnormal B cells. With advanced disease, chronic lymphocytic leukemia may cause damage by direct tissue infiltration.

Clinical Findings

A. Symptoms and Signs

Chronic lymphocytic leukemia is a disease of older patients, with 90% of cases occurring after age 50 and a median age at presentation of 65. Many patients will be incidentally discovered to have lymphocytosis. Others present with fatigue or lymphadenopathy. On examination, 80% of patients will have lymphadenopathy and half will have enlargement of the liver or spleen.

A prognostically useful staging system (Rai system) has been developed as follows: stage 0, lymphocytosis only; stage I, lymphocytosis plus lymphadenopathy; stage II, organomegaly; stage III, anemia; and stage IV, thrombocytopenia.

Chronic lymphocytic leukemia usually pursues an indolent course; a variant, prolymphocytic leukemia, is more aggressive. The morphology of the latter cases is different, characterized by larger and more immature cells. In 5-10% of cases, chronic lymphocytic leukemia may be complicated by autoimmune hemolytic anemia or autoimmune thrombocytopenia. In approximately 5% of cases, while the systemic disease remains stable, an isolated lymph node transforms into an aggressive large cell lymphoma (**Richter's syndrome**).

B. Laboratory Findings

The hallmark of chronic lymphocytic leukemia is isolated lymphocytosis. The white blood count is usually greater than 20,000/uL and may be markedly elevated to several hundred thousand. Usually 75-98% of the circulating cells are lymphocytes. Lymphocytes appear small and mature, with condensed nuclear chromatin, and are morphologically indistinguishable from normal small lymphocytes. The hematocrit and platelet count are usually normal at presentation. The bone marrow is variably infiltrated with small lymphocytes. The malignant cells weakly express surface immunoglobulin, and the monoclonal nature of the cells can be demonstrated by the finding of a single light chain type on the surface. The immunophenotype of CLL is unique in that it co-expresses the B lymphocyte lineage marker CD19 with the T lymphocyte marker CD5. Patients whose CLL cells have mutated forms of the immunoglobulin gene appear to have a more indolent form of disease; these cells typically express low levels of the surface antigen CD38. Conversely, patients whose cells have unmutated IgV genes and high levels of CD38 expression do less well.

Hypogammaglobulinemia is present in half and becomes more common with advanced disease. In some, a small amount of IgM paraprotein is present in the serum. Pathologic changes in lymph nodes are the same as in diffuse small cell lymphocytic lymphoma.

Differential Diagnosis

Few syndromes can be confused with chronic lymphocytic leukemia. Viral infections producing lymphocytosis should be obvious from the presence of fever and other clinical findings; however, fever may occur in CLL from concomitant bacterial infection. Pertussis may cause a particularly high total lymphocyte count. Other lymphoproliferative diseases such as Waldenstrom's macroglobulinemia, hairy cell leukemia, or lymphoma in the leukemic phase are distinguished on the basis of the morphology and immunophenotype of circulating lymphocytes and bone marrow.

Treatment

Most cases of early indolent chronic lymphocytic leukemia require no specific therapy. Indications for treatment include progressive fatigue, symptomatic lymphadenopathy, or anemia or thrombocytopenia. These patients have either symptomatic and progressive stage II disease or stage III/IV disease. Fludarabine has now replaced chlorambucil as front-line therapy. It has been shown to produce a higher response rate and responses that are more complete and long-lasting. Fludarabine requires intravenous infusion 5 days a week once a month for 4-6 months and causes immunosuppression that is often long-lasting. Combination therapy with fludarabine plus either rituximab or cyclophosphamide (or both) produces better rates of response and complete response. Whether combination therapy will improve remission duration or survival is as yet uncertain. Chlorambucil, 0.6-1 mg/kg orally every 3 weeks for approximately 6 months, was the standard treatment prior to the development of fludarabine. This treatment is convenient, well tolerated, and usually effective and remains a reasonable first choice for elderly patients. The monoclonal antibody alemtuzumab has been approved for treatment of refractory CLL.

Associated autoimmune hemolytic anemia or immune thrombocytopenia may require treatment with prednisone or splenectomy. Fludarabine should be avoided in patients with autoimmune hemolytic anemia since it may exacerbate this condition.

Allogeneic transplantation offers potentially curative treatment for patients with CLL, but it should be used only in patients whose disease cannot be controlled by standard therapies. Nonmyeloablative allogeneic transplant has produced encouraging results and may expand the role of transplant in CLL.

Prognosis

Median survival is approximately 6 years, and 25% of patients live more than 10 years. Patients with stage 0 or stage I disease have a median survival of 10 years, and these patients may be reassured that they can live a normal life for many years. Patients with stage III or stage IV disease have a median survival of less than 2 years, and allogeneic transplant offers a possibility of improving the outcome. Biologic markers such as gene mutation status, CD38 expression, and cytogenetic abnormalities will better predict outcomes of subsets of patients with CLL.

HAIRY CELL LEUKEMIA

Essentials of Diagnosis

- Pancytopenia.
- Splenomegaly, often massive.
- Hairy cells present on blood smear and especially in bone marrow biopsy.

General Considerations

Hairy cell leukemia, an uncommon form of leukemia, is an indolent cancer of B lymphocytes.

Clinical Findings

A. Symptoms and Signs

The disease characteristically presents in middle-aged men. The median age at presentation is 55 years, and there is a striking 5:1 male predominance. Most patients present with gradual onset of fatigue, others complain of symptoms related to markedly enlarged spleen, and some come to attention because of infection.

Splenomegaly is almost invariably present and may be massive. The liver is enlarged in half of cases; lymphadenopathy is uncommon.

Hairy cell leukemia is usually an indolent disorder whose course is dominated by pancytopenia and recurrent infections, including mycobacterial infections.

B. Laboratory Findings

The hallmark of hairy cell leukemia is pancytopenia. Anemia is nearly universal, and 75% have thrombocytopenia and neutropenia. Nearly all patients have striking monocytopenia, which is encountered in almost no other condition. The "hairy cells" are usually present in small numbers on the peripheral blood smear and have a characteristic appearance with numerous cytoplasmic projections. The bone marrow is usually inaspirable (dry tap), and the diagnosis is made by characteristic morphology on bone marrow biopsy. The hairy cells have a characteristic histochemical staining pattern, with tartrate-resistant acid phosphatase (TRAP). On immunophenotyping, the cells co-express the antigens CD11c and CD22. Pathologic examination of the spleen shows marked infiltration of the red pulp with hairy cells. This is in contrast to the usual predilection of lymphomas to involve the white pulp of the spleen.

Differential Diagnosis

Hairy cell leukemia should be distinguished from other lymphoproliferative diseases such as Waldenstrom's macroglobulinemia and non-Hodgkin's lymphomas. It also may be confused with other causes of pancytopenia, including hypersplenism due to any cause and paroxysmal nocturnal hemoglobinuria.

Treatment

The treatment of choice is cladribine (2-chlorodeoxyadenosine; CdA), 0.14 mg/kg daily for 7 days. This is a relatively nontoxic drug that produces benefit in 95% of cases and complete remission in more than 80%. Responses are long-lasting, with few patients relapsing in the first few years. Treatment with pentostatin produces similar results, but that drug is more cumbersome to administer.

Course & Prognosis

The development of new therapies has changed the prognosis of this disease. Formerly, median survival was 6 years, and only one-third of patients survived longer than 10 years. It now appears that most patients with hairy cell leukemia will live longer than 10 years. With current trends in treatment, the prognosis appears open-ended at this time.

■ LYMPHOMAS

NON-HODGKIN'S LYMPHOMAS

The non-Hodgkin's lymphomas are a heterogeneous group of cancers of lymphocytes. The disorders vary in clinical presentation and course from indolent to rapidly progressive.

Molecular biology has provided clues to the pathogenesis of these disorders. The best-studied example is Burkitt's lymphoma, in which a characteristic cytogenetic abnormality of translocation between the long arms of chromosomes 8 and 14 has been identified. The proto-oncogene *c-myc* is translocated from its normal position on chromosome 8 to the heavy chain locus on chromosome 14. Cells committed to B cell differentiation are likely to have enhanced expression of this heavy chain locus, and it is likely that overexpression of *c-myc* (in its new anomalous position) is related to malignant transformation. In the follicular lymphomas, translocations of a possible oncogene *bcl-2* from chromosome 8 to the heavy chain locus on chromosome 14 causes over-expression of *bcl-2*, which appears to protect the lymphoma cell against apoptosis, the normal pathway to cell death.

Classification of the lymphomas is a controversial area still undergoing evolution. The most recent grouping (see [Table 13-16](#)) separates diseases based on both clinical and pathologic features.

Clinical Findings

A. Symptoms and Signs

Patients with indolent lymphomas usually present with painless lymphadenopathy, which may be isolated or widespread. Involved lymph nodes may be present in the retroperitoneum, mesentery, and pelvis. The indolent lymphomas are often disseminated at the time of diagnosis, and bone marrow involvement is frequent. Patients with intermediate and high-grade lymphomas also have constitutional symptoms such as fever, drenching night sweats, or weight loss.

On examination, lymphadenopathy may be isolated, or extranodal sites of disease (skin, gastrointestinal tract) may be found. Patients with Burkitt's lymphoma are noted to have abdominal pain or abdominal fullness because of the predilection of the disease for the abdomen.

Once a pathologic diagnosis is established, the patient is staged. Chest x-ray and CT scan of the abdomen and pelvis, bone marrow biopsy, and—in selected cases with high-risk morphology—a lumbar puncture are performed.

B. Laboratory Findings

The peripheral blood is usually normal, but a number of lymphomas may present in a leukemic phase.

Bone marrow involvement is manifested as paratrabecular lymphoid aggregates. In some high-grade lymphomas, the meninges are involved and malignant cells are found with cerebrospinal fluid cytology. The chest radiograph may show a mediastinal mass in lymphoblastic lymphoma. The serum LDH has been shown to be a useful prognostic marker and is now incorporated in risk stratification of treatment.

The diagnosis of lymphoma is made by tissue biopsy. Needle aspiration may yield suspicious results, but a lymph node biopsy (or biopsy of involved extranodal tissue) is required for diagnosis and staging.

Treatment

The treatment of indolent lymphoma depends on the stage of disease and the clinical status of the patient. A small number of patients have limited disease with only one abnormal lymph node and are treated with localized irradiation. Most patients with indolent lymphoma have disseminated disease at the time of diagnosis. If the disease is not bulky and the patient not symptomatic, no initial therapy may be required. Some patients will have spontaneous remissions and may defer treatment for 1-3 years. There are an increasing number of reasonable treatment options for low-grade lymphomas, but no clear consensus has emerged on the best strategy. In the past, standard chemotherapy for patients requiring treatment has been alkylators such as chlorambucil, 0.6-1 mg/kg every 3 weeks, or combination therapy with cyclophosphamide, vincristine, and prednisone (CVP). Fludarabine may produce equivalent results. A monoclonal antibody (rituximab) directed against the B cell surface antigen CD20 is effective both as salvage therapy for relapsed low-grade B cell lymphomas and as initial therapy. Radioimmunoconjugates that fuse anti-B cell antibodies with radiation may produce improved results with modest increases in toxicity compared with antibody alone, and one such agent (yttrium-90 ibritumomab tiuxetan) is in use. Some patients with clinically aggressive low-grade lymphomas may be appropriate candidates for allogeneic transplantation. As in other hematologic malignancies, the use of less toxic nonmyeloablative regimens for allogeneic transplant may expand the role of transplant in this disease. The role of autologous transplantation remains uncertain, but some patients with recurrent disease appear to have prolonged remissions.

Patients with intermediate-grade lymphomas such as diffuse large cell lymphoma are treated with curative intent. Those with localized disease receive either short-course chemotherapy (such as three courses of cyclophosphamide, doxorubicin [hydroxydaunomycin; Adriamycin], vincristine [Oncovin], and prednisone [CHOP]) plus localized radiation or six courses of chemotherapy without radiation. Most patients who have more advanced disease are treated with six to eight cycles of chemotherapy such as CHOP. The addition of rituximab to CHOP chemotherapy has improved outcomes and is now standard practice in patients with B cell

lymphomas. Individuals with high-risk lymphoma are best treated with autologous stem cell transplantation early in the course. Patients with intermediate-grade lymphoma who relapse after initial chemotherapy may still be cured by autologous stem cell transplantation if their disease remains responsive to chemotherapy.

Persons with special forms of lymphoma require individualized therapy. Burkitt's lymphoma is treated with intensive regimens specifically tailored for this histologic type. Those with lymphoblastic lymphoma receive regimens similar to those used for T cell acute lymphoblastic leukemia. Mantle cell lymphoma is not effectively treated with standard chemotherapy regimens. The role of high-dose therapy with allogeneic or autologous transplantation is under study. Patients with mucosal associated lymphoid tumors (MALT lymphomas) of the stomach may be appropriately treated with combination antibiotics directed against *Helicobacter pylori* but require frequent endoscopic monitoring.

Prognosis

The median survival of patients with indolent lymphomas is 6-8 years. These diseases ultimately become refractory to chemotherapy. This often occurs at the time of histologic progression of the disease to a more aggressive form of lymphoma.

The International Prognostic Index is now widely used to categorize patients with intermediate-grade lymphoma into risk groups. Factors that confer adverse prognosis are age over 60 years, elevated serum LDH, stage III or stage IV disease, and poor performance status. Patients with no risk factors or one risk factor have high complete response rates (80%) to standard chemotherapy, and most responses (80%) are durable. Patients with two risk factors have a 70% complete response rate, 70% being long-lasting. Patients with higher-risk disease have lower response rates and poor survival with standard regimens, and alternative treatments are needed. Early treatment with high-dose therapy and autologous stem cell transplantation improves the outcome.

For patients who relapse after initial chemotherapy, the prognosis depends on whether the lymphoma is still partially sensitive to chemotherapy. If it is, autologous transplantation offers a 50% chance of long-term salvage.

The treatment of older patients with lymphoma has been difficult because of poorer tolerance of aggressive chemotherapy. The use of myeloid growth factors and prophylactic antibiotics to reduce neutropenic complications may improve outcomes.

New techniques of molecular profiling using gene array technology are being studied to better define subsets of lymphomas with different biologic features and prognoses.

HODGKIN'S DISEASE

Essentials of Diagnosis

- Painless lymphadenopathy.
- Constitutional symptoms may or may not be present.
- Pathologic diagnosis by lymph node biopsy.

General Considerations

Hodgkin's disease is a group of cancers characterized by Reed-Sternberg cells in an appropriate reactive cellular background. The nature of the malignant cell is a subject of controversy.

Clinical Findings

There is a bimodal age distribution, with one peak in the 20s and a second over age 50. Most patients present because of a painless mass, commonly in the neck. Others may seek medical attention because of constitutional symptoms such as fever, weight loss, or drenching night sweats, or because of generalized pruritus. An unusual symptom of Hodgkin's disease is pain in an involved lymph node following alcohol ingestion.

An important feature of Hodgkin's disease is its tendency to arise within single lymph node areas and spread in an orderly fashion to contiguous areas of lymph nodes. Only late in the course of the disease will vascular invasion lead to widespread hematogenous dissemination.

Hodgkin's disease is divided into several subtypes: lymphocyte predominance, nodular sclerosis, mixed cellularity, and lymphocyte depletion. Hodgkin's disease should be distinguished pathologically from other malignant lymphomas and may occasionally be confused with reactive lymph nodes seen in infectious mononucleosis, cat-scratch disease, or drug reactions (eg, phenytoin).

Patients undergo a staging evaluation to determine the extent of disease. The staging nomenclature (Ann Arbor) is as follows: stage I, one lymph node region involved; stage II, involvement of two lymph node areas on one side of the diaphragm; stage III, lymph node regions involved on both sides of the diaphragm; and stage IV, disseminated disease with bone marrow or liver involvement. In addition, patients are designated stage A if they lack constitutional symptoms and stage B if 10% weight loss over 6 months, fever, or night sweats are present. If symptoms indicate careful evaluation for higher numerical stage, clinical stage IB (for example) is highly likely to emerge as stage II or stage IIIB.

Treatment

The treatment of Hodgkin's disease has evolved, with radiation therapy used as initial treatment only for patients with low-risk stage IA and IIA disease. Staging is usually clinical, and laparotomy is no longer routinely performed. The addition of limited chemotherapy for some patients treated with radiation appears promising.

Most patients with Hodgkin's disease (including all with stage IIIB and IV disease) are best treated with combination chemotherapy using doxorubicin (Adriamycin), bleomycin, vincristine, and dacarbazine (ABVD). New shorter and more intensive regimens have produced promising results and may supplant ABVD in the treatment of advanced disease.

Prognosis

All patients with both localized and disseminated disease should be treated with curative intent. The prognosis of patients with stage IA or IIA disease treated by radiotherapy is excellent, with 10-year survival rates in excess of 80%. Patients with disseminated disease (IIIB, IV) have 5-year survival rates of 50-60%. Poorer results are seen in patients who are older, those who have bulky disease, and those with lymphocyte depletion or mixed cellularity on histologic examination. Others whose disease recurs after initial radiotherapy treatment may still be curable with chemotherapy. The treatment of choice for patients who relapse after initial chemotherapy is high-dose chemotherapy with autologous stem cell transplantation. This offers a 35-50% chance of cure when disease is still chemotherapy-sensitive.

Horning SJ et al: Stanford V and radiotherapy for locally extensive and advanced Hodgkin's disease: mature results of a prospective clinical trial. J Clin Oncol 2002;20:630. [PMID: 11821442]

MULTIPLE MYELOMA

Essentials of Diagnosis

- Bone pain, often in the lower back.
- Monoclonal paraprotein by serum and urine protein electrophoresis or immunoelectrophoresis.
- Replacement of bone marrow by malignant plasma cells.

General Considerations

Multiple myeloma is a malignancy of plasma cells characterized by replacement of the bone marrow, bone destruction, and paraprotein formation. There is evidence that a new herpesvirus may be implicated in pathogenesis. Myeloma causes clinical symptoms and signs through a variety of mechanisms.

Replacement of the bone marrow (and perhaps humoral suppression of myelopoiesis) leads initially to anemia and later to general bone marrow failure. Malignant plasma cells can form tumors (plasmacytomas) that may cause spinal cord compression. Bone involvement causes bone pain, osteoporosis, lytic lesions, pathologic fractures, and hypercalcemia. The pathogenesis of osteoclast activation in myeloma appears to involve osteoprotegerin ligand, and the decoy receptor osteoprotegerin may be able to interfere with this pathway.

The paraproteins secreted by the malignant plasma cells may cause problems in their own right. Very high paraprotein levels (either IgG or IgA) may cause hyperviscosity, though this is more often caused by IgM in Waldenstrom's macroglobulinemia. The light chain component of the immunoglobulin often leads to renal failure (often aggravated by hypercalcemia). Light chain components may be deposited in tissues as amyloid, worsening renal failure with albuminuria and causing a vast array of systemic symptoms.

Myeloma patients are prone to recurrent infections for a number of reasons, including neutropenia and the immunosuppressive effects of chemotherapy. More often, there is a failure of antibody production in response to antigen challenge, and myeloma patients are especially prone to infections with encapsulated organisms such as *Streptococcus pneumoniae* and *Haemophilus influenzae*.

Clinical Findings

A. Symptoms and Signs

Myeloma is a disease of older adults (median age at presentation, 65 years). The most common presenting complaints are those related to anemia, bone pain, and infection. Bone pain is most common in the back or ribs or may present as a pathologic fracture, especially of the femoral neck. Patients may also come to medical attention because of renal failure, spinal cord compression, or the hyperviscosity syndrome (mucosal bleeding, vertigo, nausea, visual disturbances, alterations in mental status). Equally as often, patients are diagnosed because of laboratory findings of hypercalcemia, proteinuria, elevated sedimentation rate, or abnormalities on serum protein electrophoresis obtained for symptoms or in routine screening studies. A few patients come to medical attention because of amyloidosis.

Examination may reveal pallor, bone tenderness, and soft tissue masses. Patients may have neurologic signs related to neuropathy and spinal cord compression. Patients with amyloidosis may have an enlarged tongue, neuropathy, congestive heart failure, or hepatomegaly. Splenomegaly is absent unless amyloidosis is present. Fever occurs only with infection.

B. Laboratory Findings

Anemia is nearly universal. Red blood cell morphology is normal, but rouleau formation is common and may be marked. The neutrophil and platelet counts are usually normal at presentation. Only rarely will plasma cells be visible on peripheral smear (plasma cell leukemia).

The hallmark of myeloma is the finding of a paraprotein on serum protein electrophoresis (SPEP). The majority of patients will have a monoclonal spike visible in the beta or gamma globulin region. Immunoelectrophoresis (IEP) will reveal this to be a monoclonal protein. Approximately 15% of patients will have no demonstrable paraprotein in the serum. In these, IEP of the urine will reveal either complete immunoglobulin or light chains. Overall, approximately 60% of myeloma patients will have an IgG paraprotein, 25% an IgA, and 15% light chains only. In sporadic cases, no paraprotein is present ("nonsecretory myeloma"); these patients have particularly aggressive disease.

The bone marrow will be infiltrated by variable numbers of plasma cells ranging from 5% to 100%. Occasionally the plasma cells will appear normal but more commonly are not. Many benign processes can result in highly atypical plasma cells; the most useful feature is the appearance of sheets of these cells. Bone radiographs are important in establishing the diagnosis of myeloma. Lytic lesions are most commonly seen in the axial skeleton: skull, spine, proximal long bones, and ribs. At other times, only generalized osteoporosis is seen. The radionuclide bone scan is not useful in detecting bone lesions in myeloma, as there is usually no osteoblastic component.

The level of β_2 -microglobulin has strong prognostic significance in myeloma, with levels > 3 mg/L associated with poor survival. Bone marrow cytogenetic characteristics have greater prognostic significance, with deletions of chromosome 13q associated with a dismal outcome. Other laboratory features include hypercalcemia, renal failure, and an elevated erythrocyte sedimentation rate; alkaline phosphatase is not elevated despite extensive bony involvement. Some patients have proximal renal tubular acidosis, with phosphaturia, glycosuria, uricosuria, and aminoaciduria. The urinalysis may reveal proteinuria, but the dipstick test (which detects primarily albumin) is unreliable for light chains. Often there is a narrow anion gap when the paraprotein is cationic (70% of cases).

Differential Diagnosis

When a patient is discovered to have a monoclonal paraprotein, the distinction between myeloma and monoclonal gammopathy of unknown significance (MGUS) must be made. MGUS is present in 1% of all adults and 3% of adults over age 70. Thus, if one considers all patients with paraproteins, MGUS is far more common than myeloma. Most commonly, patients with MGUS will have a monoclonal IgG spike less than 2.5 g/dL, and the height of the spike remains stable. In approximately 25% of cases, MGUS progresses to overt malignant disease, but this may take many years.

Myeloma is distinguished from MGUS by findings of replacement of the bone marrow, bone destruction, and progression. Although the height of the paraprotein spike should not be used by itself to distinguish benign from malignant disease, nearly all patients with IgG spikes greater than 3.5 g/dL prove to have myeloma; an IgA spike of > 2 g/dL is similarly suggestive. If there is doubt about whether paraproteinemia is benign or malignant, the patient should be observed without therapy, since there is no advantage to early treatment of asymptomatic multiple myeloma.

Myeloma must be distinguished from reactive polyclonal hypergammaglobulinemia. Myeloma may also be similar to other malignant lymphoproliferative diseases such as Waldenstrom's macroglobulinemia, lymphomas, and primary amyloidosis (with which it is commonly associated).

Treatment

Patients with minimal disease or in whom the diagnosis of malignancy is in doubt should be observed without treatment. Most commonly, patients require treatment at diagnosis because of bone pain or other symptoms related to the disease. The best chemotherapy regimen has not been determined. The combination of vincristine, doxorubicin (Adriamycin), and dexamethasone (VAD) has replaced oral melphalan as primary treatment in younger patients because of the lack of bone marrow and stem cell damage. The combination of thalidomide plus dexamethasone may be as effective as VAD chemotherapy for initial disease control.

The optimal initial therapy for patients under age 70 with myeloma is autologous stem cell transplantation. Early aggressive treatment prolongs both remission duration and overall survival. Autologous transplantation is also useful in management of patients with relapsed disease if the disease is still chemotherapy-sensitive. The height of the paraprotein spike on SPEP is a useful marker for monitoring response to therapy. Thalidomide has emerged in the treatment of myeloma, and responses have been seen even in patients whose disease no longer responds to chemotherapy. Derivatives of thalidomide with improved in vitro potency may prove to be effective, and the experimental agents CC-5013 (Revimid), an immunomodulatory derivative of thalidomide, and PS-341 (Velcade), a protease inhibitor, have also produced promising results in patients with refractory disease.

Allogeneic transplantation is potentially curative in myeloma, but its role has been limited because of the unusually high mortality rate (40-50%) in myeloma patients. Newer and less toxic forms of allogeneic transplantation using nonmyeloablative regimens have produced encouraging results, especially when performed early in the

course of disease, such as the minimal disease state following autologous stem cell transplantation.

Localized radiotherapy may be useful for palliation of bone pain or for eradicating tumor at the site of pathologic fracture. Hypercalcemia should be treated aggressively and immobilization and dehydration avoided. The bisphosphonates (pamidronate 90 mg or zoledronate 4 mg intravenously monthly) reduce pathologic fractures in patients with significant bony disease and are an important adjunct in this subset of patients.

Prognosis

The median survival of patients with myeloma has been 3 years, but the outlook appears to be changing with new treatment approaches. The prognosis is markedly affected by a number of prognostic features, with shorter survivals in those with high paraprotein spikes, renal failure, hypercalcemia, or extensive bony disease. Patients are said to have a low tumor burden if the IgG spike is less than 5 g/dL, there is no more than one lytic bone lesion, and there is no evidence of hypercalcemia or renal failure. Such patients have a median survival of 5-6 years. Conversely, patients with a high tumor burden have an IgG spike greater than 7 g/dL, hematocrit less than 25%, calcium greater than 12 mg/dL, or more than three lytic bone lesions. Median survival for this group was formerly 1-2 years, but early intervention with autologous stem cell transplantation prolongs median survival to 5-6 years in this group. Broader use of immunotherapy with allogeneic transplantation may improve the outlook further, and it is likely that the investigational agents CC-5013 (Revimid) and PS-341 (Velcade) will lead to additional therapeutic gains.

WALDENSTROM'S MACROGLOBULINEMIA

Essentials of Diagnosis

- Symptoms nonspecific; splenomegaly common on examination.
- Monoclonal IgM paraprotein.
- Infiltration of bone marrow by plasmacytic lymphocytes.
- Absence of lytic bone disease.

General Considerations

Waldenstrom's macroglobulinemia is a malignant disease of B cells that appear to be a hybrid of lymphocytes and plasma cells. These cells characteristically secrete an IgM paraprotein, and many clinical manifestations of the disease are related to this macroglobulin.

Clinical Findings

A. Symptoms and Signs

This disease characteristically develops insidiously in patients in their 60s or 70s. Patients usually present with fatigue related to anemia. Hyperviscosity of serum may be manifested in a number of ways. Mucosal and gastrointestinal bleeding are related to engorged blood vessels and platelet dysfunction. Other complaints include nausea, vertigo, and visual disturbances. Alterations in consciousness vary from mild lethargy to stupor and coma. The IgM paraprotein may also cause symptoms of cold agglutinin disease or peripheral neuropathy.

On examination, there may be hepatosplenomegaly or lymphadenopathy. The retinal veins are engorged. Purpura may be present. There should be no bone tenderness.

B. Laboratory Findings

Anemia is nearly universal, and rouleau formation is common. The anemia is related in part to expansion of the plasma volume by 50-100% due to the presence of the paraprotein. Other blood counts are usually normal. The abnormal plasmacytic lymphocytes usually appear in small numbers on the peripheral blood smear. The bone marrow is characteristically infiltrated by the plasmacytic lymphocytes.

The hallmark of macroglobulinemia is the presence of a monoclonal IgM spike seen on serum protein electrophoresis (SPEP) in the beta or gamma globulin region. The serum viscosity is usually increased above the normal of 1.4-1.8 times that of water. Symptoms of hyperviscosity usually develop when the serum viscosity is over four times that of water, and marked symptoms usually arise when the viscosity is over six times that of water. Because paraproteins vary in their physicochemical properties, there is no strict correlation between the concentration of paraprotein and serum viscosity.

The IgM paraprotein may cause a positive Coombs test or have cold agglutinin or cryoglobulin properties. If one suspects macroglobulinemia but the SPEP shows only hypogammaglobulinemia, one should repeat the test while taking special measures to maintain the blood at 37°C, since the paraprotein may precipitate out at room temperature if it is cryoprecipitable.

Bone radiographs are normal, and there is no evidence of renal failure.

Differential Diagnosis

Waldenstrom's macroglobulinemia is differentiated from monoclonal gammopathy of unknown significance by the finding of bone marrow infiltration. It is distinguished from chronic lymphocytic leukemia and multiple myeloma by bone marrow morphology and the finding of the characteristic IgM spike, and also on clinical grounds.

Treatment

Patients who present with marked hyperviscosity syndrome (stupor or coma) should be treated on an emergency basis with plasmapheresis. On a chronic basis, some patients can be managed with periodic plasmapheresis alone. Others are treated with intermittent chemotherapy with chlorambucil or cyclophosphamide. New agents such as cladribine, fludarabine, and rituximab have produced encouraging results, and these drugs are being increasingly used as initial treatment.

As with multiple myeloma, autologous stem cell transplantation is playing a more important role in management and is considered in younger patients with more aggressive disease.

Prognosis

Waldenstrom's macroglobulinemia is an indolent disease with a median survival rate of 3-5 years. However, patients may survive 10 years or longer.

■ DISORDERS OF HEMOSTASIS

Disorders of hemostasis may be due to defects in either platelet number or function or to problems in formation of a fibrin clot (coagulation). Bleeding due to platelet disorders is typically mucosal or dermatologic. Common problems include epistaxis, gum bleeding, menorrhagia, gastrointestinal bleeding, purpura, and petechiae. Petechiae are seen almost exclusively in conditions of thrombocytopenia and not platelet dysfunction. Bleeding due to coagulopathy may occur as deep muscle hematomas as well as skin bleeding. Spontaneous hemarthroses are seen only in severe hemophilia.

IDIOPATHIC (AUTOIMMUNE) THROMBOCYTOPENIC PURPURA

Essentials of Diagnosis

- Isolated thrombocytopenia.
- Other hematopoietic cell lines normal.
- No systemic illness.
- Spleen not palpable.
- Normal bone marrow with normal or increased megakaryocytes.

General Considerations

Idiopathic thrombocytopenic purpura is an autoimmune disorder in which an IgG autoantibody is formed that binds to platelets. It is not clear which antigen on the platelet surface is involved. Although the antiplatelet antibody may bind complement, platelets are not destroyed by direct lysis. Rather, destruction takes place in the spleen, where splenic macrophages with Fc receptors bind to antibody-coated platelets. Since the spleen is the major site both of antibody production and platelet sequestration, splenectomy is highly effective therapy.

Clinical Findings

A. Symptoms and Signs

Idiopathic thrombocytopenic purpura occurs commonly in childhood, frequently precipitated by viral infection and usually self-limited. In contrast, the adult form is usually a chronic disease and only infrequently follows a viral infection. It is a disease of young persons, with peak incidence between ages 20 and 50, and there is a 2:1 female predominance.

Patients are systemically well and usually not febrile. The presenting complaint is mucosal or skin bleeding. Common types of bleeding are epistaxis, oral bleeding, menorrhagia, purpura, and petechiae.

On examination, the patient appears well, and there are no abnormal findings other than those related to bleeding. An enlarged spleen should lead one to doubt the diagnosis. Common signs of bleeding are purpura, petechiae, and hemorrhagic bullae in the mouth.

B. Laboratory Findings

The hallmark of the disease is thrombocytopenia, which may be less than 10,000/uL. Other counts are usually normal except for occasional mild anemia, which can be explained by bleeding or associated hemolysis. Peripheral blood cell morphology is normal except that platelets are slightly enlarged (megathrombocytes). These larger platelets are young platelets produced in response to enhanced platelet destruction. Approximately 10% of patients will have coexistent autoimmune hemolytic anemia (**Evans syndrome**), and in these cases one will see anemia, reticulocytosis, and spherocytes on peripheral smear. Red blood cell fragmentation should not be seen.

The bone marrow will appear normal, with a normal or increased number of megakaryocytes. Coagulation studies will be entirely normal.

Differential Diagnosis

Thrombocytopenia may be produced either by abnormal bone marrow function or by peripheral destruction ([Table 13-17](#)). Although most bone marrow disorders produce abnormalities in addition to isolated thrombocytopenia, diagnoses such as myelodysplasia can only be excluded by examining the bone marrow. Most causes of thrombocytopenia resulting from peripheral destruction can be ruled out by initial evaluation. Disorders such as disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome, hypersplenism, and sepsis are easily excluded by the absence of systemic illness. Thus, patients with isolated thrombocytopenia with no other abnormal findings almost certainly have immune thrombocytopenia. Patients should be questioned regarding drug use, especially sulfonamides, quinine, thiazides, cimetidine, gold, and heparin. Heparin is now the most common cause of drug-induced thrombocytopenia in hospitalized patients. Systemic lupus erythematosus and chronic lymphocytic leukemia are common causes of secondary thrombocytopenic purpura, hematologically identical to idiopathic thrombocytopenic purpura.

Treatment

Few adults with idiopathic thrombocytopenic purpura will have spontaneous remissions, and most will require treatment. Initial treatment is with prednisone, 1-2 mg/kg/d. Prednisone works primarily by decreasing the affinity of splenic macrophages for antibody-coated platelets. High-dose prednisone therapy also reduces the binding of antibody to the platelet surface, and long-term therapy may decrease antibody production. Bleeding will often diminish within 1 day after beginning prednisone—even before the platelet count begins to rise. This effect has been attributed to enhanced vascular stability. The platelet count will usually begin to rise within a week, and responses are almost always seen within 3 weeks. About 80% of patients will respond, and the platelet count will usually return to normal. High-dose therapy should be continued until the platelet count is normal, and the dose should then be gradually tapered. In most, thrombocytopenia will recur if prednisone is completely withdrawn, and one aims to find a dose that will maintain an adequate platelet count. It is not necessary for the platelet count to be entirely normal; the risk of bleeding is small with platelet counts above 50,000/uL.

Splenectomy is the most definitive treatment for idiopathic thrombocytopenic purpura, and most adult patients will ultimately undergo splenectomy. High-dose prednisone therapy should not be continued indefinitely in an attempt to avoid surgery. Splenectomy is indicated if patients do not respond to prednisone initially or require unacceptably high doses to maintain an adequate platelet count. Other patients may be intolerant of prednisone or may simply prefer the surgical alternative. Splenectomy can be performed safely even with platelet counts less than 10,000/uL. Eighty percent of patients benefit from splenectomy with either complete or partial remission.

High-dose intravenous immunoglobulin, 1 g/kg for 1 or 2 days, is highly effective in rapidly raising the platelet count. The response rate is 90%, and the platelet count rises within 1-5 days. However, this treatment is expensive, and the beneficial effect lasts only 1-2 weeks. Immunoglobulin treatment should be reserved for bleeding emergencies or situations such as preparing a severely thrombocytopenic patient for surgery.

For patients who fail to respond to prednisone and splenectomy, danazol, 600 mg/d, has been used, with responses obtained in about half of cases. Immunosuppressive agents employed in refractory cases include vincristine, azathioprine, cyclosporine, and cyclophosphamide. Rituximab can produce good responses in some patients with refractory disease. Rare patients with severe and refractory disease are now being treated with high-dose immunosuppression and autologous stem cell transplantation.

Platelet transfusions are rarely used in the treatment of idiopathic thrombocytopenic purpura, since exogenous platelets will survive no better than the patient's own and will survive less than a few hours. Platelet transfusion should be reserved for cases of life-threatening bleeding in which even fleeting hemostasis may be of benefit.

Prognosis

The prognosis for remission is good. In most cases, the disease is initially controlled with prednisone, and splenectomy offers definitive therapy. The major concern during the initial phases is cerebral hemorrhage, which becomes a risk when the platelet count is less than 5000/uL. These patients usually exhibit warning signs of mucosal bleeding. However, even at these very low platelet counts, fatal bleeding is rare.

THROMBOTIC THROMBOCYTOPENIC PURPURA

Essentials of Diagnosis

- Thrombocytopenia
- Microangiopathic hemolytic anemia.
- Neurologic and renal abnormalities, fever.
- Normal coagulation tests.
- Elevated serum LDH.

General Considerations

Thrombotic thrombocytopenic purpura (TTP) is an uncommon syndrome with microangiopathic hemolytic anemia, thrombocytopenia, and a markedly elevated serum LDH. Noninfectious fever, neurologic disorders, and renal abnormalities are less commonly seen. The pathogenesis of TTP appears to be a deficiency of a von Willebrand factor-cleaving protease, in some cases due to an antibody directed against the protease.

Thrombotic thrombocytopenic purpura is seen primarily in young adults between ages 20 and 50, and there is a slight female predominance. The syndrome is occasionally precipitated by estrogen use, pregnancy, drugs, or infections and may occur in association with HIV disease.

Clinical Findings

A. Symptoms and Signs

Patients come to medical attention because of anemia, bleeding, or neurologic abnormalities. The neurologic symptoms and signs are unusual in that they may wax and wane over minutes. Neurologic symptoms include headache, confusion, aphasia, and alterations in consciousness from lethargy to coma. With more advanced disease, one may see hemiparesis and seizures.

On examination, the patient appears acutely ill and is usually febrile. One may detect pallor, purpura, petechiae, and signs of neurologic dysfunction. Patients may have abdominal pain and tenderness due to pancreatitis.

B. Laboratory Findings

Anemia is universal and may be marked. There is usually marked reticulocytosis and occasional circulating nucleated red blood cells. The hallmark is a microangiopathic blood picture with fragmented red blood cells (schistocytes, helmet cells, triangle forms) on the smear. One cannot make the diagnosis without significant red blood cell fragmentation. Thrombocytopenia is invariably present and may be severe.

Hemolysis may be manifested by increasing indirect bilirubin and occasionally hemoglobinemia and hemoglobinuria; methemalbuminemia may impart a brown color to the plasma. The LDH is markedly elevated in proportion to the severity of hemolysis; the Coombs test is negative.

Coagulation tests (prothrombin time, partial thromboplastin time, fibrinogen) are normal unless ischemic tissue damage causes secondary DIC. Elevated fibrin degradation products may be seen, as in other acutely ill patients. Renal insufficiency may be present, with an abnormal urinalysis.

Pathologically, one may see thrombi in capillaries and small arteries, with no evidence of inflammation.

Differential Diagnosis

The normal values of coagulation tests differentiate thrombotic thrombocytopenic purpura from disseminated intravascular coagulation (DIC). Other conditions causing microangiopathic hemolysis ([Table 13-18](#)) should be excluded. Evans's syndrome is the combination of autoimmune thrombocytopenia and autoimmune hemolytic anemia, but the peripheral smear will show spherocytes and not red blood cell fragments. Skin biopsy is usually not necessary for diagnosis but may be helpful when vasculitis is a consideration. Thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome are not distinct disease entities—rather, there is a spectrum of disease, with thrombotic thrombocytopenic purpura characterized by more neurologic findings and more severe thrombocytopenia and hemolytic-uremic syndrome with more renal failure.

Treatment

Thrombotic thrombocytopenic purpura should be treated emergently with large-volume plasmapheresis. Sixty to 80 mL/kg of plasma should be removed and replaced with fresh-frozen plasma. Treatment should be continued daily until the patient is in complete remission. The optimal duration of plasmapheresis after remission is unknown. Prednisone and antiplatelet agents (aspirin [325 mg three times daily] and dipyridamole [75 mg three times daily]) have been used in addition to plasmapheresis, but their role is unclear.

The management of patients who do not respond to plasmapheresis or who have rapid recurrences is controversial. The combination of splenectomy, corticosteroids, and dextran has been used with success. Splenectomy performed in remission may prevent subsequent relapses. Immunosuppression with drugs such as cyclophosphamide has also been effective.

Prognosis

With the advent of plasmapheresis, the formerly dismal prognosis of thrombotic thrombocytopenic purpura has been dramatically changed. Eighty to 90 percent of patients now recover completely. Neurologic abnormalities are almost always completely reversed. Most complete responses are durable, but in 20% of cases the disease will be chronic and relapsing.

HEMOLYTIC-UREMIC SYNDROME

Essentials of Diagnosis

- Microangiopathic hemolytic anemia.
- Thrombocytopenia and renal failure.
- Elevated serum LDH.
- Normal coagulation tests.
- Absence of neurologic abnormalities.

General Considerations

Hemolytic-uremic syndrome is an uncommon disorder consisting of microangiopathic hemolytic anemia, thrombocytopenia, and renal failure due to microangiopathy (with decreased glomerular filtration, proteinuria, and hematuria). The cause is unclear. The disease is similar to thrombotic thrombocytopenic purpura except that different vascular beds are involved. The pathogenesis of the two disorders is probably similar, and a platelet-agglutinating factor found in plasma may be involved. In children, hemolytic-uremic syndrome frequently occurs after a diarrheal illness secondary to infections with shigella, salmonella, *E coli* strain O157:H7, or viral agents.

The mortality rate of this form is low (< 5%). In adults, this syndrome is often precipitated by estrogen use or by the postpartum state. Hemolytic-uremic syndrome may be seen as a delayed complication of high-dose corticosteroid therapy and autologous bone marrow or stem cell transplantation, or of the use of cyclosporine or tacrolimus as immunosuppression in allogeneic transplantation. A familial (hereditary) type has been identified in which members of a family have recurrent episodes over several years.

Clinical Findings

A. Symptoms and Signs

Patients present with anemia, bleeding, or renal failure. The renal failure may or may not be oliguric. In contrast to thrombotic thrombocytopenic purpura, there are no neurologic manifestations other than those due to the uremic state.

B. Laboratory Findings

As in thrombotic thrombocytopenic purpura, there is microangiopathic hemolytic anemia and thrombocytopenia, but the thrombocytopenia is often less severe. The peripheral blood smear should show striking red blood cell fragmentation, and the diagnosis is untenable without this finding. The LDH is usually elevated out of proportion to the degree of hemolysis, and the Coombs test is negative. Coagulation tests are normal with the exception of elevated fibrin degradation products.

Kidney biopsy will show endothelial hyaline thrombi in the afferent arterioles and glomeruli. Ischemic necrosis in the renal cortex may occur with obstruction from intravascular coagulation.

Differential Diagnosis

Disseminated intravascular coagulation is excluded by normal coagulation results. Other causes of microangiopathic hemolytic anemia (Table 13-18) should be entertained. Occasionally, vasculitis or acute glomerulonephritis is considered, and in these cases renal biopsy may be necessary to establish the diagnosis if the platelet count will allow it.

Hemolytic-uremic syndrome is arbitrarily distinguished from thrombotic thrombocytopenic purpura by the consistent presence of renal failure and the lack of neurologic findings.

Treatment

In children, hemolytic-uremic syndrome is almost always self-limited and requires only conservative management of acute renal failure. In adults, however, without treatment, there is a high rate of permanent renal insufficiency and death. The treatment of choice (as in thrombotic thrombocytopenic purpura) is large-volume plasmapheresis with fresh-frozen replacement (exchange of up to 80 mL/kg), repeated daily until remission is achieved.

Prognosis

The prognosis of hemolytic-uremic syndrome in adults remains unclear. Without effective therapy, up to 40% of patients have died, and 80% have had chronic renal insufficiency. Early institution of aggressive therapy with plasmapheresis promises to be beneficial. Survival and correction of hematologic abnormalities are the rule, but restoration of renal function requires that treatment be initiated early.

CONGENITAL QUALITATIVE PLATELET DISORDERS

Bleeding disorders characterized by prolonged bleeding times despite a normal platelet count are called qualitative platelet disorders. Patients have a family history or lifelong personal history of the defect. The disorders may be classified as (1) von Willebrand's disease, a congenital disorder of a plasma protein necessary for platelet adhesion, and (2) congenital disorders intrinsic to the platelet (Table 13-19). When an intrinsic qualitative platelet disorder is suspected, platelet aggregation studies should be evaluated to make a specific diagnosis.

1. Von Willebrand's Disease

Essentials of Diagnosis

- Family history with autosomal dominant pattern of inheritance.
- Prolonged bleeding time, either at baseline or after challenge with aspirin.
- Reduced levels of factor VIII antigen or ristocetin cofactor.
- Reduced levels of factor VIII coagulant activity in some patients.

General Considerations

Von Willebrand's disease is the most common congenital disorder of hemostasis. It is transmitted in an autosomal dominant pattern. It is a group of disorders characterized by deficient or defective von Willebrand factor (vWF), a protein that mediates platelet adhesion. Adhesion is a process separate from platelet aggregation. Platelets adhere to the subendothelium via vWF, which is bound to a specific receptor on the platelet composed of glycoprotein Ib (and missing in Bernard-Soulier syndrome). Platelets aggregate via fibrinogen, which binds to a different receptor composed of glycoproteins IIb and IIIa (deficient in Glanzmann's thrombasthenia). The platelet aggregation system is entirely normal in von Willebrand's disease.

Von Willebrand factor is synthesized in megakaryocytes and endothelial cells and circulates in plasma as multimers of varying size. Only the large multimeric forms are functional in mediating platelet adhesion. Von Willebrand factor has a separate function of binding the factor VIII coagulant protein and protecting it from degradation. The factor VIII coagulant protein (factor VIII:C), a protein encoded by a gene on the X chromosome, is the protein deficient in classic hemophilia. Any of the multimeric forms of vWF can bind and protect factor VIII:C. Von Willebrand's disease, although primarily a disorder of platelet function, may secondarily cause a coagulation disturbance because of deficient levels of factor VIII:C. However, this coagulopathy is rarely severe.

There are several subtypes of von Willebrand's disease. The most common type (type I, 80% of all cases) is caused by a quantitative decrease in vWF. Type IIa is caused by a qualitative abnormality in protein that prevents multimer formation. Only small multimers are present, and both intermediate and large forms that mediate platelet adhesion are missing. Type IIb von Willebrand's disease is caused by a qualitative abnormality in the protein that causes rapid clearance of the large multimeric forms. Type III von Willebrand's disease is a rare autosomal recessive disorder in which vWF is nearly absent. Pseudo-von Willebrand disease is a rare disorder manifested as an abnormal platelet membrane with excessive avidity for the large multimeric forms of vWF, causing their clearance from plasma.

Clinical Findings

A. Symptoms and Signs

Von Willebrand's disease is a common disorder affecting both men and women. Most cases are mild. Most bleeding is mucosal (epistaxis, gingival bleeding, menorrhagia), but gastrointestinal bleeding may occur. In most cases, incisional bleeding occurs after surgery or dental extractions. Von Willebrand's disease is rarely as severe as hemophilia, and spontaneous hemarthroses do not occur. The bleeding tendency is exacerbated by aspirin. Characteristically, bleeding decreases during pregnancy or estrogen use.

B. Laboratory Findings

Platelet number and morphology are normal, and the bleeding time is usually (not always) prolonged. The bleeding time should be ascertained whenever this diagnosis is considered; it correlates most closely with clinical bleeding. When the bleeding time is normal, it is prolonged markedly by aspirin. Normal persons will prolong their bleeding time to a minor extent with aspirin but rarely out of the normal range. In the most common form of von Willebrand's disease (type I), vWF levels in plasma are reduced. This may be measured by factor VIII antigen, which measures the immunologic presence of vWF, or by ristocetin cofactor activity, which measures functional properties of vWF in mediating platelet adhesion.

When factor VIII antigen is reduced, one may also see a decrease in factor VIII coagulant (factor VIII:C) levels. When factor VIII:C levels are less than 25%, the partial thromboplastin time (PTT) will be prolonged. Platelet aggregation studies with standard agonists (ADP, collagen, thrombin) are normal, but platelet aggregation in

response to ristocetin may be subnormal.

In difficult cases, it may be helpful to assay directly the multimeric composition of vWF.

Differential Diagnosis

When patients present with a prolonged bleeding time, one must distinguish von Willebrand's disease from other qualitative platelet disorders ([Table 13-19](#)). Acquired qualitative disorders are suggested by recent onset of the bleeding tendency. Congenital intrinsic platelet disorders may present with a positive family history and lifelong history of bleeding episodes. Von Willebrand's disease is diagnosed by the finding of abnormal measurements of vWF and by normal results of platelet aggregation.

When patients present with a prolonged PTT, measurements of factor VIII:C will distinguish von Willebrand's disease from all disorders except hemophilia ([Table 13-20](#)). Hemophilia is diagnosed when factor VIII:C is reduced but all measurements of vWF (factor VIII antigen, ristocetin cofactor activity) are normal.

Patients with a suspicious bleeding history but with normal bleeding time and PTT pose a diagnostic problem. On occasion, the postaspirin bleeding time can be used to unmask a bleeding disorder. At other times, one must perform further plasma assays of vWF to make the diagnosis. Von Willebrand's disease waxes and wanes in severity and may be difficult to diagnose, especially in a woman taking estrogens, which raise vWF levels.

It is often useful to distinguish between subtypes of von Willebrand's disease ([Table 13-21](#)), because type I usually responds to desmopressin and type IIb may be aggravated by its use.

Treatment

The bleeding disorder is characteristically mild, and no treatment is routinely given other than avoidance of aspirin. However, patients often need to be prepared for surgical or dental procedures. The bleeding time is probably the best indicator of the likelihood of bleeding, and prophylactic therapy may be reasonably withheld if the procedure is minor and the bleeding time is normal.

Desmopressin acetate is useful for mild type I von Willebrand's disease and should be considered first. The dose is 0.3 ug/kg, after which vWF levels usually rise two- to threefold in 30-90 minutes. Desmopressin acetate appears to cause release of stored vWF from endothelial cells. The treatment can be given only every 24 hours as stores of vWF become depleted. The drug is not effective in type IIa von Willebrand's disease, in which no endothelial stores are present, and may be harmful in type IIb, leading to thrombocytopenia and increased bleeding.

Factor VIII concentrates are available that replace cryoprecipitate as the treatment of choice for von Willebrand's disease if factor replacement is required. Some (not all) of these products now contain functional vWF and do not transmit HIV or hepatitis. One appropriate product is Humate-P (Armour). The dose is 20-50 units/kg depending on disease severity.

The antifibrinolytic agent tranexamic acid is useful as adjunctive therapy during dental procedures. After either cryoprecipitate or desmopressin acetate, the patient is given 25 mg/kg three times daily for 5-7 days to reduce the likelihood of bleeding.

Prognosis

The prognosis is excellent. In most cases, the bleeding disorder is mild, and in the more serious cases replacement therapy is effective.

2. Disorders Intrinsic to the Platelets

Glanzmann's Thrombasthenia

This is a rare autosomal recessive intrinsic platelet disorder causing bleeding. Platelets are unable to aggregate because of lack of receptors (containing glycoproteins IIb and IIIa) for fibrinogen, which form the bridges between platelets during aggregation. Clinically, it is manifested chiefly as mucosal (epistaxis, gingival bleeding, menorrhagia) and postoperative bleeding. The defect is of variable severity but may be severe.

Platelet numbers and morphology are normal, but the bleeding time is markedly prolonged. Platelets fail to aggregate in response to typical agonists (ADP, collagen, thrombin) but aggregate normally in response to ristocetin, which causes platelet clumping by a separate mechanism.

Patients are treated with platelet transfusions when necessary. Platelet transfusion therapy is limited by the tendency of these patients to develop multiple alloantibodies.

Bernard-Soulier Syndrome

This is a rare autosomal recessive intrinsic platelet disorder causing bleeding. Platelets cannot adhere to subendothelium because they lack receptors (composed of glycoprotein Ib) for von Willebrand factor, which mediates platelet adhesion. This is often a severe bleeding disorder with mucosal and postoperative bleeding.

Thrombocytopenia may be present, and platelets on smear are abnormally large. The bleeding time is markedly prolonged. Platelet aggregation is normal in response to standard agonists (collagen, ADP, thrombin), but platelets fail to aggregate in response to ristocetin. Measurements of von Willebrand factor in the plasma are normal. Patients are treated with platelet transfusion when necessary.

Storage Pool Disease

This is a group of mild bleeding disorders characterized by defective secretion of platelet granule contents (especially ADP) that stimulate platelet aggregation. Most patients are mildly affected and have increased bruising and postoperative bleeding.

Platelets are normal in number and morphology, but the bleeding time is slightly prolonged. In some cases, the baseline bleeding time is normal, but it becomes markedly prolonged after aspirin. There are variable abnormalities in platelet aggregation studies.

Most patients do not require treatment but should avoid aspirin. Platelet transfusions transiently correct the bleeding tendency. Some patients respond to desmopressin acetate, 0.3 ug/kg every 24 hours.

Peretz H et al: Glanzmann's thrombasthenia associated with deletion-insertion and alternative splicing in the glycoprotein IIb gene. Blood 1995;85:414. [\[PMID: 7529063\]](#)

ACQUIRED QUALITATIVE PLATELET DISORDERS

A number of acquired disorders lead to abnormal platelet function ([Table 13-19](#)).

Uremia

Uremia causes abnormal platelet function by unknown mechanisms. The severity of the bleeding tendency is roughly proportionate to the degree of renal insufficiency. Bleeding is most commonly mucosal and gastrointestinal and may occasionally be severe. Dialysis is effective in reducing the bleeding tendency but may not completely eliminate it. Patients respond to desmopressin acetate, 0.3 ug/kg every 24 hours.

Myeloproliferative Disorders

All the myeloproliferative disorders can produce abnormalities in platelet function. A number of biochemical abnormalities are present in these platelets, but the cause

of the bleeding tendency is unclear. The severity of the bleeding tendency correlates roughly with the height of the platelet count, although conditions causing reactive thrombocytosis of normal platelets are not associated with abnormal function. Bleeding decreases when the platelet count is controlled with myelosuppressive therapy. In cases of life-threatening bleeding with high platelet counts, plateletpheresis may be necessary.

Other Disorders

Aspirin causes a mild bleeding tendency by irreversibly acetylating cyclooxygenase, an enzyme that participates in platelet aggregation. The effect lasts for the life of the platelet and may be manifest for 7-10 days, although the major effect lasts 3-5 days. The effect is not dose-dependent, and 65 mg of aspirin is sufficient.

Aspirin by itself does not cause significant bleeding, but it may unmask bleeding disorders such as mild von Willebrand's disease or mild thrombocytopenia. Certain antibiotics (ticarcillin, some cephalosporins) cause a mild bleeding tendency, presumably by coating the surface of platelets. Nonsteroidal anti-inflammatory drugs cause an aspirin-like effect that disappears when the drug leaves the system.

Patients with autoantibodies against platelets may have prolonged bleeding times even in the absence of thrombocytopenia. Platelet-associated IgG levels should be high, and the bleeding tendency responds quickly to modest doses of prednisone, eg, 20 mg/d. Acquired storage pool disease refers to the circulation of "exhausted platelets" that have been stimulated to release their granule contents and hence are no longer functional. Such granule release occurs in response to cardiopulmonary bypass and severe vasculitis.

Noris M et al: Uremic bleeding: closing the circle after 30 years of controversies? Blood 1999;94:2569. [PMID: 10515859]

HEMOPHILIA A

Essentials of Diagnosis

- X-linked recessive pattern of inheritance with only males affected.
- Low factor VIII coagulant (VIII:C) activity.
- Normal factor VIII antigen.
- Spontaneous hemarthroses.

General Considerations

Hemophilia A (classic hemophilia, factor VIII deficiency hemophilia) is a hereditary disorder in which bleeding is due to deficiency of the coagulation factor VIII (VIII:C). In most cases, the factor VIII coagulant protein is quantitatively reduced, but in a small number of cases the coagulant protein is present by immunoassay but defective.

Hemophilia is an X-linked recessive disease, and as a rule only males are affected. In rare instances, female carriers are clinically affected if their normal X chromosomes are disproportionately inactivated. Females may also become affected if they are the offspring of a hemophiliac father and carrier mother.

Hemophilia is classified as severe if factor VIII:C levels are less than 1%, moderate if levels are 1-5%, and mild if levels are greater than 5%. Families tend to breed true in the severity of hemophilia produced.

Clinical Findings

A. Symptoms and Signs

Hemophilia A is the most common severe bleeding disorder and after von Willebrand's disease is the most common congenital bleeding disorder overall. Approximately one in 10,000 males is affected. The bleeding tendency is related to factor VIII:C levels. Bleeding may occur anywhere. The most common sites of bleeding are into joints (knees, ankles, elbows), into muscles, and from the gastrointestinal tract. Spontaneous hemarthroses are so characteristic of hemophilia that they are virtually diagnostic of the disorder. Patients with mild hemophilia bleed only after major trauma or surgery, those with moderately severe hemophilia bleed with mild trauma or surgery, and those with severe disease bleed spontaneously.

Many hemophiliacs are now seropositive for HIV infection transmitted via factor VIII concentrate, and many have already developed AIDS. HIV-associated immune thrombocytopenia may aggravate the bleeding tendency.

B. Laboratory Findings

The partial thromboplastin time (PTT) is prolonged, and other measures of coagulation, including prothrombin time, bleeding time, and fibrinogen level, are normal. Levels of factor VIII:C are reduced, but measurements of von Willebrand factor are normal ([Table 13-21](#)).

If one mixes plasma from a hemophiliac patient with normal plasma, the PTT will become normal. Failure of the PTT to normalize in such a mixing test is diagnostic of the presence of a factor VIII inhibitor.

A low platelet count should raise a suspicion of HIV-associated immune thrombocytopenia.

Differential Diagnosis

The finding of a reduced factor VIII:C level will distinguish this disorder from other causes of prolonged PTT ([Table 13-20](#)). Clinically, factor VIII hemophilia is indistinguishable from factor IX hemophilia, and only specific factor assays can distinguish these disorders. In cases of mild hemophilia, the disorder needs to be distinguished from von Willebrand's disease by VIII:A assay, which shows normal levels of factor VIII antigen in the former.

An important issue for the families of hemophiliac patients is identifying which females are carriers. They can usually be identified by the presence of low or normal levels of factor VIII:C with normal levels of factor VIII antigen.

Treatment

Standard treatment is based on infusion of factor VIII concentrates, now heat-treated to reduce the likelihood of transmission of HIV. Recombinant factor VIII appears safe and effective, though expensive, and should impose no risk of transmitting HIV or other viruses. The level of factor VIII one aims to achieve in plasma depends on the severity of the bleeding problem. In response to minor bleeding, it may be necessary only to raise factor VIII:C levels to 25% with one infusion. For moderate bleeding (such as deep muscle hematomas), it is adequate to raise the level initially to 50% and maintain the level at greater than 25% with repeated infusion for 2-3 days. When major surgery is to be performed, one raises the factor VIII:C level to 100% and then maintains the factor level at greater than 50% continuously for 10-14 days. Head injuries (with or without neurologic signs) should be emergently treated as though major bleeding were present.

The dose of factor VIII concentrate is calculated assuming that one unit of factor VIII is the amount present in 1 mL of plasma. Plasma volume is 40 mL/kg, and the volume of distribution of factor VIII:C is 1.5 times the plasma volume. Thus, to raise the level 100%, the dose should be $40 \times 1.5 = 60$ units/kg, or approximately 4000 units for a 70-kg individual. To raise the levels to 25% would require 1000 units. The half-life of factor VIII:C is approximately 12 hours. Thus, during major surgery, to achieve an initial level of 100% and maintain it continuously at greater than 50%, a dose of 60 units/kg (approximately 4000 units) initially followed by 30 units/kg (approximately 2000 units) every 12 hours should be adequate. During surgery, one should initially verify that these doses give the anticipated factor VIII levels. If factor VIII levels fail to rise as expected, one should suspect an inhibitor.

For mild hemophiliacs, desmopressin acetate, 0.3 ug/kg every 24 hours, may be useful in preparing for minor surgical procedures. Desmopressin acetate causes release of factor VIII:C and will raise the factor VIII:C levels two- to threefold for several hours. In the management of persistent bleeding following use of either desmopressin acetate or factor VIII concentrate, patients may be treated with aminocaproic acid (EACA; Amicar), 4 g orally every 4 hours for several days.

Aspirin should be avoided in these patients.

Prognosis

The prognosis of patients with hemophilia has been transformed by the availability of factor VIII replacement. The major limiting factor is disability from recurrent joint bleeding. Hepatitis B and C and HIV infection from recurrent transfusion are diminishing in incidence. Approximately 15% of patients develop inhibitors to factor VIII, and these patients cannot be adequately supported with factor VIII.

Mannucci PM et al: The hemophilias—from royal genes to gene therapy. N Engl J Med 2001;344:1773. [\[PMID: 11396445\]](#)

ACQUIRED FACTOR VIII ANTIBODIES

Antibodies to factor VIII may develop either postpartum or with no underlying illness. Factor VIII antibodies also occur in 15% of patients with factor VIII hemophilia who have received infusions of plasma concentrates.

Factor VIII antibodies usually produce a severe bleeding disorder. The PTT is prolonged, and the fibrinogen level, prothrombin time, and platelet count are not affected. A plasma mixing test will usually reveal the presence of an inhibitor by the failure of normal plasma to correct the prolonged PTT. However, the mixing test may require incubation for 2-4 hours to reveal the inhibitor. Factor VIII coagulant levels are low.

Factor VIII antibodies should be suspected in any acquired severe bleeding disorder associated with a prolonged PTT. Factor VIII antibodies are distinguished from lupus anticoagulants both by the presence of clinical bleeding and more importantly by the reduced factor VIII:C level. The diagnosis is confirmed by mixing tests and in vivo by the failure of factor VIII concentrates to raise the factor VIII:C levels by the expected amount.

The treatment of choice is cyclophosphamide, usually combined with prednisone. In the interim, aggressive factor VIII replacement may be necessary. Products that bypass factor VIII, such as activated factor VII, may be effective but are expensive.

Colowick AB et al: Immunotolerance induction in hemophilia patients with inhibitors: costly can be cheaper. Blood 2000;96:1698. [\[PMID: 10961866\]](#)

HEMOPHILIA B

Essentials of Diagnosis

- X-linked recessive inheritance, with only males affected.
- Low levels of factor IX coagulant activity.
- Spontaneous hemarthroses.

General Considerations

Hemophilia B (Christmas disease, factor IX hemophilia) is a hereditary bleeding disorder due to deficiency of coagulation factor IX. Most commonly, factor IX is quantitatively reduced, but in one-third of cases an abnormally functioning molecule is immunologically present. Factor IX deficiency is one-seventh as common as factor VIII deficiency hemophilia but is otherwise clinically and genetically identical.

The PTT is prolonged, and factor IX levels are reduced when measured by specific factor assays. Other laboratory features are the same as for factor VIII hemophilia.

Treatment

Factor IX hemophilia is managed with factor IX concentrates. Factor VIII concentrates are ineffective in this type of hemophilia. The same dosing considerations apply as in factor VIII hemophilia, with the exception that the volume of distribution of factor IX is twice the plasma volume, so that 80 units/kg are necessary to achieve a 100% level. In addition, the half-life of factor IX is 18 hours. Thus, to maintain a patient through major surgery, the dosage should be 80 units/kg (approximately 6000 units) initially followed by 40 units/kg (3000 units) every 18 hours. Factor IX levels should be measured to ensure that expected levels are achieved and that an inhibitor is not present.

Unlike factor VIII concentrates, factor IX concentrates contain a number of other proteins, including activated coagulating factors that appear to contribute to a risk of thrombosis with recurrent usage of factor IX concentrates. Because of the risk of thrombosis, more care is needed in deciding to use these concentrates. Desmopressin acetate is not useful in this disorder, and patients should be cautioned to avoid aspirin.

Prognosis

The prognosis for these patients is the same as for those with factor VIII hemophilia.

Roth DA et al: Human recombinant factor IX: safety and efficacy studies in hemophilia B patients previously treated with plasma-derived factor IX concentrates. Blood 2001;98: 3600. [\[PMID: 11739163\]](#)

OTHER CONGENITAL COAGULATION DISORDERS

Factor XI Deficiency

This disorder is seen primarily among Ashkenazi Jews and is autosomal recessive. The PTT may be markedly prolonged, and specific assays of factor XI will show reduced levels. This is usually a mild bleeding disorder manifested primarily by postoperative bleeding. Factor replacement is given with fresh-frozen plasma when necessary.

Afibrinogenemia

In this rare disorder, fibrinogen is absent and both prothrombin time and partial thromboplastin time are markedly prolonged. These patients may have a severe bleeding disorder similar to hemophilia. Fibrinogen is replaced with cryoprecipitate.

Other Coagulation Disorders

Bleeding disorders due to isolated deficiency of factors II, V, X, or VII are extremely rare. Deficiencies of factor XII and the contact pathway factors cause a markedly prolonged PTT but are not associated with any increased bleeding.

Factor XIII deficiency results in delayed bleeding after trauma or surgery. All coagulation tests are normal. The disorder is diagnosed by showing instability of the fibrin clot in 8-molar urea. Factor XIII is replaced with cryoprecipitate or plasma. A rare cause of bleeding is deficiency of the normal inhibitors of fibrinolytic activity: α_2 -antiplasmin and plasminogen activator inhibitor.

COAGULOPATHY OF LIVER DISEASE

The liver is the site of synthesis of all the coagulation factors except factor VIII. As hepatic insufficiency develops, the vitamin K-dependent factors (factors II, VII, IX, X) and factor V are the first to be affected. Because of its rapid turnover (half-life 6 hours), factor VII levels are the first to decline. Conversely, fibrinogen levels are remarkably well conserved, and decreased fibrinogen synthesis does not occur unless liver disease is very severe.

Liver disease has a number of other effects on the hemostatic system. Increased fibrinolysis occurs because the liver synthesizes α_2 -antiplasmin (the main inhibitor of fibrinolysis), which is responsible for the clearance of plasminogen activator. Biliary tract disease may lead to malabsorption of vitamin K, and congestive splenomegaly may produce mild thrombocytopenia. A variety of chronic liver diseases cause abnormal posttranslational modification of fibrinogen with resultant dysfibrinogenemia. The majority of patients with cirrhosis have very low levels of thrombopoietin, and this may contribute to the thrombocytopenia.

Long-term treatment of hepatic coagulopathy with factor replacement is usually ineffective. Fresh-frozen plasma is the treatment of choice, and volume overload will limit one's ability to maintain hemostatic factor levels. For example, to maintain factor levels greater than 25%, one must initially raise the level to 50% with 50% of the plasma volume (20 mL/kg) and then replace 10 mL/kg every 6 hours to maintain adequate factor VII levels. In average-sized persons, this will require transfusion of 1400 mL of plasma initially followed by 700 mL every 6 hours. Factor IX concentrates are contraindicated in liver disease because of their tendency to cause disseminated intravascular coagulation. If thrombocytopenia is present, platelet transfusion may be of some help, but platelet recovery is usually disappointing because of hypersplenism.

The prognosis is that of the underlying liver disease.

VITAMIN K DEFICIENCY

Essentials of Diagnosis

- Underlying dietary deficiency or antibiotic use.
- Prothrombin time more prolonged than PTT.
- Rapid correction with vitamin K replacement.

General Considerations

Vitamin K plays a role in coagulation by acting as a cofactor for the posttranslational γ -carboxylation of zymogens II, VII, IX, and X. The modified zymogens (with γ -carboxyglutamic acid residues) are able to bind to platelets in a calcium-dependent reaction and consequently better participate in the complex reactions that activate factors X and II. Without γ -carboxylation, these reactions on the platelet surface occur slowly and hemostasis is impaired.

Vitamin K is supplied in the diet primarily in leafy vegetables and endogenously from synthesis by intestinal bacteria. Factors that contribute to vitamin K deficiency include poor diet, malabsorption, and broad-spectrum antibiotics suppressing colonic flora. A characteristic setting for vitamin K deficiency is a postoperative patient who is not eating and who is receiving antibiotics. Body stores of vitamin K are small, and deficiency may develop in as little as 1 week.

Clinical Findings

A. Symptoms and Signs

There are no specific clinical features, and bleeding may occur at any site.

B. Laboratory Findings

The prothrombin time is prolonged to a greater extent than the PTT, and with mild vitamin K deficiency only the PT is defective ([Tables 13-22](#) and [13-23](#)). Fibrinogen level, thrombin time, and platelet count are not affected.

Differential Diagnosis

Vitamin K deficiency can be distinguished from hepatic coagulopathy only by assessing the response to vitamin K therapy. Surreptitious warfarin use will produce laboratory features indistinguishable from those of vitamin K deficiency.

Vitamin K deficiency differs from disseminated intravascular coagulation by normal platelet count and fibrinogen levels in the former.

Treatment

Vitamin K deficiency responds rapidly to subcutaneous vitamin K, and a single dose of 15 mg will completely correct laboratory abnormalities in 12-24 hours.

Prognosis

The prognosis is excellent, as vitamin K deficiency can be completely corrected with replacement.

DISSEMINATED INTRAVASCULAR COAGULATION (DIC)

Essentials of Diagnosis

- Underlying serious illness.
- Microangiopathic hemolytic anemia may be present.
- Hypofibrinogenemia, thrombocytopenia, fibrin degradation products, and prolonged prothrombin time.

General Considerations

Coagulation is usually confined to a localized area by the combination of blood flow and circulating inhibitors of coagulation, especially antithrombin III. If the stimulus to coagulation is too great, these control mechanisms can be overwhelmed, leading to the syndrome of disseminated intravascular coagulation. In pathophysiologic terms, disseminated intravascular coagulation can be thought of as the consequence of the presence of circulating thrombin (normally confined to a localized area). The effects of thrombin are to cleave fibrinogen to fibrin monomer, stimulate platelet aggregation, activate factors V and VIII, and release plasminogen activator, which generates plasmin. Plasmin in turn cleaves fibrin, generating fibrin degradation products, and further inactivates factors V and VIII. Thus, the excess thrombin activity produces hypofibrinogenemia, thrombocytopenia, depletion of coagulation factors, and fibrinolysis.

Disseminated intravascular coagulation can be caused by a number of serious illnesses, including sepsis (especially with gram-negative bacteria but possible with any widespread bacterial or fungal infection), severe tissue injury (especially burns and head injury), obstetric complications (amniotic fluid embolus, septic abortion, retained fetus), cancer (acute promyelocytic leukemia, mucinous adenocarcinomas), and major hemolytic transfusion reactions.

Clinical Findings

A. Symptoms and Signs

Disseminated intravascular coagulation leads to both bleeding and thrombosis. Bleeding is far more common than thrombosis, but the latter may dominate if coagulation is activated to a far greater extent than fibrinolysis. Bleeding may occur at any site, but spontaneous bleeding and oozing at venipuncture sites or wounds are important clues to the diagnosis. Thrombosis is most commonly manifested by digital ischemia and gangrene, but catastrophic events such as renal cortical necrosis and hemorrhagic adrenal infarction may occur. Disseminated intravascular coagulation may also secondarily produce microangiopathic hemolytic anemia.

Subacute disseminated intravascular coagulation is seen primarily in cancer patients and is manifested primarily as recurrent superficial and deep venous thromboses (**Trousseau's syndrome**).

B. Laboratory Findings

Disseminated intravascular coagulation produces a complex coagulopathy with the characteristic constellation of hypofibrinogenemia, elevated fibrin degradation products, thrombocytopenia, and a prolonged prothrombin time. Of the fibrin degradation products, the D-dimer is the most sensitive, since its cross-linking implies origin from fibrin in a clot. All fibrin degradation products are cleared by the liver and thus may be elevated in hepatic dysfunction. Hypofibrinogenemia is another important diagnostic laboratory feature, because only a few other disorders (congenital hypofibrinogenemia, severe liver disease) will lower the fibrinogen level. In some cases of disseminated intravascular coagulation, when the patient's baseline fibrinogen level is markedly elevated, the initial fibrinogen level may be normal. However, since the half-life of fibrinogen is approximately 4 days, a declining fibrinogen level will confirm the diagnosis of disseminated intravascular coagulation.

Other laboratory abnormalities are variably present. The partial thromboplastin time may or may not be prolonged. In approximately one-fourth of cases, a microangiopathic hemolytic anemia is present, and fragmented red blood cells are seen on the peripheral smear. Antithrombin III levels may be markedly depleted. When fibrinolysis is activated, levels of plasminogen and α_2 -antiplasmin may be low.

Subacute disseminated intravascular coagulation produces a very different laboratory picture. Thrombocytopenia and elevated D-dimer are usually the only abnormalities. Fibrinogen levels are normal, and the PTT may be normal.

Differential Diagnosis

Liver disease may prolong both the PT and PTT, but fibrinogen levels are usually normal, and the platelet count is usually normal or only slightly reduced. However, severe liver disease may be difficult to distinguish from disseminated intravascular coagulation. Vitamin K deficiency will not affect the fibrinogen level or platelet count and will be completely corrected by vitamin K replacement.

Sepsis may produce thrombocytopenia and digital ischemia, and coagulopathy may be present because of vitamin K deficiency. However, in these cases, the fibrinogen level should be normal.

Thrombotic thrombocytopenic purpura may produce fever and microangiopathic hemolytic anemia. However, fibrinogen levels and other coagulation studies should be normal.

Treatment

The primary focus should be the diagnosis and treatment of the underlying disorder that has given rise to disseminated intravascular coagulation. In many cases, disseminated intravascular coagulation will produce laboratory abnormalities with only mild clinical manifestations, and in these cases no specific therapy is required.

When the underlying cause of disseminated intravascular coagulation is rapidly reversible (such as in obstetric cases), replacement therapy alone may be indicated. The role of heparin in the treatment of disseminated intravascular coagulation is controversial. In some cases, when any increase in bleeding is unacceptable (neurosurgical procedures), heparin therapy is contraindicated. However, when disseminated intravascular coagulation is producing serious clinical consequences and the underlying cause is not rapidly reversible, heparin may be necessary. Such therapy is routinely used in the treatment of acute promyelocytic leukemia.

In replacement therapy, platelet transfusion should be used to maintain a platelet count greater than 30,000/uL, and 50,000/uL if possible. Fibrinogen is replaced with cryoprecipitate, and one should aim for a plasma fibrinogen level of 150 mg/dL. One unit of cryoprecipitate usually raises the fibrinogen level by 6-8 mg/dL, so that 15 units of cryoprecipitate will raise the level from 50 to 150 mg/dL. Coagulation factor deficiency may require replacement with fresh-frozen plasma.

Heparin must be used in combination with replacement therapy, since heparin alone will lead to an unacceptable increase in bleeding. A dose of 500-750 units per hour is necessary. Heparin cannot be effective if antithrombin III levels are markedly depleted. Antithrombin III levels should be measured, and fresh-frozen plasma used to raise levels to greater than 50%. In using heparin, it is not necessary to prolong the PTT. Successful therapy is indicated by a rising fibrinogen level. Fibrin degradation products will decline over 1-2 days. Improvement in the platelet count may lag as much as 1 week behind control of the coagulopathy.

In some cases, when disseminated intravascular coagulation is complicated by excessive fibrinolysis, even the combination of heparin and replacement therapy may not be adequate to control bleeding. In these cases, aminocaproic acid, 1 g intravenously per hour, or tranexamic acid, 10 mg/kg intravenously every 8 hours, should be added to decrease the rate of fibrinolysis, raise the fibrinogen level, and control bleeding. Aminocaproic acid can *never* be used without heparin in disseminated intravascular coagulation because of the risk of thrombosis.

Prognosis

The prognosis is that of the underlying disease.

Levi M et al: Novel approaches to the management of disseminated intravascular coagulation. Crit Care Med 2000; 28:S20. [\[PMID: 11007192\]](#)

Schmaier AH: Disseminated intravascular coagulation. N Engl J Med 1999;341:1937. [\[PMID: 10610481\]](#)

■ HYPERCOAGULABLE STATES

In many cases, thrombosis is related to local factors causing stasis of blood flow or damage to a blood vessel. Common examples are deep venous thrombosis in the legs following prolonged sitting in one position and thrombosis in the femoral and iliac veins following hip surgery. However, in other cases a systemic disorder causes a general increase in the risk of thrombosis ([Table 13-24](#)).

Cancer is associated with an increased risk of both venous and arterial thrombosis. In some cases, low-grade disseminated intravascular coagulation appears to be responsible. In unusual cases, a unique cancer procoagulant stimulates the clotting system. Myeloproliferative disorders such as polycythemia vera, essential thrombocytosis, and paroxysmal nocturnal hemoglobinuria are associated with a high incidence of thrombosis, caused by qualitative platelet abnormalities. Venous thrombosis may occur in unusual locations such as the mesenteric, hepatic, or splenic venous beds. Arterial thrombosis occurs as well and may be manifested as large vessel occlusion (stroke, myocardial infarction) or as microvascular events with burning in the hands and feet.

Heparin is an uncommon but important cause of hypercoagulability. Heparin has been associated with thrombocytopenia in about 10% of treatment courses. Often the thrombocytopenia is modest and resolves spontaneously. However, in some cases severe thrombocytopenia occurs. It is most often in this setting that arterial thrombosis occurs as a complication. The arteries involved are often large ones, such as the iliac artery or even the aorta. Heparin is discontinued in this setting, as death may occur otherwise.

A number of congenital biochemical defects have also been associated with hypercoagulability ([Table 13-24](#)). A family history is usually present. The thromboses are almost always venous and may occur in the large veins of the abdomen. Thromboses often occur during early adulthood rather than in childhood and are often precipitated by factors such as trauma or pregnancy. The most common of these disorders is an abnormal factor V (factor V Leiden), which is resistant to degradation by activated protein C. Dysfibrinogenemia is diagnosed by a prolonged reptilase time.

The syndrome of **warfarin-induced skin necrosis** may occur in patients with undiagnosed protein C deficiency. Protein C is vitamin K-dependent and has a shorter half-life than the coagulation proteins. Warfarin, by creating a vitamin K-dependent state, will transiently deplete protein C before it leads to anticoagulation. During the period of hypercoagulability due to unopposed protein C depletion, thrombosis of skin vessels may lead to infarction and necrosis. The syndrome can be prevented by the use of heparin for 5-7 days until warfarin induces anticoagulation.

Treatment

If a patient is recognized to be at increased risk of thrombosis, effective prophylactic therapy is usually available. Preoperatively, minidose heparin (5000 units every 8-12 hours) may be useful in reducing the risk of thrombosis in the perioperative period. The hypercoagulable state associated with cancer may benefit from treatment with heparin, 10,000 units subcutaneously every 12 hours. Low-molecular-weight heparin is a more convenient agent which is equally effective and requires less laboratory monitoring (see [Chapter 9](#)). Warfarin is usually ineffective in preventing thrombosis in this situation, most likely because low-grade disseminated intravascular coagulation is the cause. In patients with myeloproliferative disease who have had symptoms of thrombosis, antiplatelet therapy may be helpful. However, such therapy should not be used indiscriminately, because these patients are also at increased risk of bleeding. For patients with **erythromelalgia** (painful redness and burning of the hands), aspirin, 325 mg daily, is effective.

In congenital biochemical defects such as deficiency of antithrombin III or the vitamin K-dependent proteins C and S, warfarin is effective and is given indefinitely. Family members are screened for the presence of the defect.

LUPUS ANTICOAGULANT

The lupus anticoagulant is an IgM or IgG immunoglobulin that produces a prolonged PTT by binding to the phospholipid used in the in vitro PTT assay. As such, it is a laboratory artifact and does not cause a clinical bleeding disorder. The "lupus anticoagulant" is seen in 5-10% of patients with systemic lupus erythematosus. More commonly, it is seen without an underlying disorder or in patients taking phenothiazines.

There is no bleeding defect unless a second disorder such as thrombocytopenia, hypoprothrombinemia, or a prolonged bleeding time is present. In fact, the lupus anticoagulant has been associated with an increased risk of thrombosis and of recurrent spontaneous abortions.

The PTT is prolonged and fails to correct when the patient's plasma is mixed in a 1:1 dilution with normal plasma. The PT is either normal or slightly prolonged. The fibrinogen level and thrombin time are normal. The Russell viper venom (RVV) time is a more sensitive assay and is specifically designed to demonstrate the presence of a lupus anticoagulant. An antiphospholipid, the lupus anticoagulant will cause a false-positive VDRL test for syphilis. A related autoantibody, anticardiolipin, can be detected by separate assays.

Lupus anticoagulant should be suspected in cases of a markedly prolonged PTT without clinical bleeding (other causes are factor XII or contact factor deficiency). The plasma mixing test will demonstrate the presence of an inhibitor by the failure of normal plasma to correct the PTT. When acquired factor VIII inhibitors are being considered, a factor VIII:C level may be measured; this will be normal in patients with lupus anticoagulant.

No specific treatment is necessary. Prednisone will usually rapidly eliminate the lupus anticoagulant, and it has been suggested that prednisone therapy reduces spontaneous abortions in this syndrome. It is not clear whether prednisone has any effect on the thrombotic tendency associated with lupus anticoagulant. Patients with thromboses should be treated with anticoagulation in standard doses. Because of the artificially prolonged PTT, heparin therapy is difficult to monitor properly, and low-molecular-weight heparin may be preferred. The dose of warfarin administered may also be inadequate if the baseline PT is prolonged.

■ BLOOD TRANSFUSIONS

RED BLOOD CELL TRANSFUSIONS

Red blood cell transfusions are given to raise the hematocrit levels in patients with anemia or to replace losses after acute bleeding episodes.

Sources of Red Cells for Transfusion

Several types of components containing red blood cells are available.

A. Fresh Whole Blood

The advantage of whole blood for transfusion is the simultaneous presence of red blood cells, plasma, and fresh platelets. Fresh whole blood is never absolutely necessary, since all the above components are available separately. The major indications for use of whole blood are cardiac surgery or massive hemorrhage when more than 10 units of blood are required in a 24-hour period.

B. Packed Red Blood Cells

Packed red cells are the component most commonly used to raise the hematocrit. Each unit has a volume of about 300 mL, of which approximately 200 mL consists of red blood cells. One unit of packed red cells will usually raise the hematocrit by approximately 4%. The expected rise in hematocrit can be calculated using an estimated red blood cell volume of 200 mL/unit and a total blood volume of about 70 mL/kg. For example, a 70-kg man will have a total blood volume of 4900 mL, and each unit of packed red blood cells will raise the hematocrit by $200 \div 4900$ equals 4%.

C. Leukopoor Blood

Patients with severe leukoagglutinin reactions to packed red blood cells may require depletion of white blood cells and platelets from transfused units. White blood cells can be removed either by centrifugation or by washing. Preparation of leukopoor blood is expensive and leads to some loss of red cells.

D. Frozen Blood

Red blood cells can be frozen and stored for up to 3 years, but the technique is cumbersome and expensive, and frozen blood should be used sparingly. The major application is for the purpose of maintaining a supply of rare blood types. Patients with such types may donate units for autologous transfusion should the need arise. Frozen red cells are also occasionally needed for patients with severe leukoagglutinin reactions or anaphylactic reactions to plasma proteins, since frozen blood has essentially all white blood cells and plasma components removed.

E. Autologous Packed Red Blood Cells

Patients scheduled for elective surgery may donate blood for autologous transfusion. These units may be stored for up to 35 days.

Compatibility Testing

Before transfusion, the recipient's and the donor's blood are cross-matched to avoid hemolytic transfusion reactions. Although many antigen systems are present on red blood cells, only the ABO and Rh systems are specifically tested prior to all transfusions. The A and B antigens are the most important, because everyone who lacks one or both red cell antigens has isoantibodies against the missing antigen or antigens in his or her plasma. These antibodies activate complement and can cause rapid intravascular lysis of the incompatible red cells. In emergencies, type O blood can be given to any recipient, but only packed cells should be given to avoid transfusion of donor plasma containing anti-A or anti-B antibodies.

The other important antigen routinely tested for is the D antigen of the Rh system. Approximately 15% of the population lack this antigen. In patients lacking the antigen, anti-D antibodies are not naturally present, but the antigen is highly immunogenic. A recipient whose red cells lack D and who receives D-positive blood may develop anti-D antibodies that can cause severe lysis of subsequent transfusions of D-positive red cells.

Blood typing includes assay of recipient serum for unusual antibodies by mixing the serum with panels of red cells representing commonly occurring weak antigens. The screening is particularly important if the recipient has had previous transfusions.

Hemolytic Transfusion Reactions

The most severe reactions are those involving mismatches in the ABO system. Most of these cases are due to clerical errors and mislabeled specimens. Hemolysis is rapid and intravascular, releasing free hemoglobin into the plasma. The severity of these reactions depends on the dose of red blood cells given. The most severe reactions are those seen in surgical patients under anesthesia.

Hemolytic transfusion reactions caused by minor antigen systems are typically less severe. The hemolysis usually takes place at a slower rate and is extravascular. Sometimes these transfusion reactions may be delayed for 5-10 days after transfusion. In such cases, the recipient has received blood containing an immunogenic action, and in the time since transfusion, a new alloantibody has been formed. The most common antigens involved in such reactions are Duffy, Kidd, Kell, and C and E loci of the Rh system.

A. Symptoms and Signs

Major hemolytic transfusion reactions cause fever and chills, with backache and headache. In severe cases, there may be apprehension, dyspnea, hypotension, and vascular collapse. *The transfusion must be stopped immediately.* In severe cases, disseminated intravascular coagulation, acute renal failure from tubular necrosis, or both can occur.

Patients under general anesthesia will not manifest such signs, and the first indication may be generalized bleeding and oliguria.

B. Laboratory Findings

Identification of the recipient and of the blood should be checked. The donor transfusion bag with its pilot tube must be returned to the blood bank, and a fresh sample of the recipient's blood must accompany the donor bag for retyping of donor and recipient blood samples and for repeat of the cross-match.

The hematocrit will fail to rise by the expected amount. Serum chemistries and coagulation studies may reveal evidence of renal failure and disseminated intravascular coagulation. Hemoglobinemia will turn the plasma pink and eventually result in hemoglobinuria. In cases of delayed hemolytic reactions, the hematocrit will fall and the indirect bilirubin will rise. In these cases, the new offending alloantibody is easily detected in the patient's serum.

C. Treatment

If a hemolytic transfusion reaction is suspected, the transfusion should be stopped at once. A sample of anticoagulated blood from the recipient should be centrifuged to detect free hemoglobin in the plasma. If hemoglobinemia is present, the patient should be vigorously hydrated to prevent acute tubular necrosis. Forced diuresis with mannitol may help prevent renal damage.

Leukoagglutinin Reactions

Most transfusion reactions are not hemolytic but represent reactions to antigens present on white blood cells in patients who have been sensitized to the antigens through previous transfusions or pregnancy. Most commonly, patients will develop fever and chills within 12 hours after transfusion. In severe cases, cough and dyspnea may occur and the chest x-ray may show transient pulmonary infiltrates. Because no hemolysis is involved, the hematocrit rises by the expected amount despite the reaction.

Leukoagglutinin reactions may respond to acetaminophen and diphenhydramine; corticosteroids are also of value. Removal of leukocytes by filtration before blood storage will reduce the incidence of these reactions.

Anaphylactic Reactions

Rarely, patients will develop urticaria or bronchospasm during a transfusion. These reactions are almost always due to plasma proteins rather than white blood cells. Patients who are IgA-deficient may develop these reactions because of antibodies to IgA. Patients with such reactions may require transfusion of washed or even frozen red blood cells to avoid future severe reactions.

Contaminated Blood

Rarely, blood is contaminated with gram-negative bacteria. Transfusion can lead to septicemia and shock from endotoxin. If this is suspected, the offending unit should be cultured and the patient treated with antibiotics as indicated.

Diseases Transmitted Through Transfusion

Despite the use of only volunteer blood donors and the routine screening of blood, transfusion-associated viral diseases remain a problem. All blood products (red blood cells, platelets, plasma, cryoprecipitate) can transmit viral diseases. All blood donors are screened with questionnaires designed to detect donors at high risk of transmitting diseases. All blood is now screened for hepatitis B surface antigen, antibody to hepatitis B core antigen, syphilis, p24 antigen and antibody to HIV, antibody to HCV, antibody to HTLV, and West Nile virus.

With improved screening, the risk of posttransfusion hepatitis has steadily decreased. The risk of hepatitis B is 1:200,000 per unit and of HIV 1:250,000 per unit. The risk of seroconversion to HTLV is 1:70,000, but clinical sequelae when this occurs are rare. The major infectious risk of blood products is hepatitis C, with a seroconversion rate of 1:3300 per unit transfused. Most of these cases are clinically silent, but there is a high incidence of chronic hepatitis.

Platelet Transfusion

Platelet transfusions are indicated in cases of thrombocytopenia due to decreased platelet production. They are not useful in immune thrombocytopenia, since transfused platelets will last no longer than the patient's endogenous platelets. The risk of spontaneous bleeding rises when the platelet count falls to less than 10,000/uL, and the risk of life-threatening bleeding increases when the platelet count is less than 5000/uL. Because of this, prophylactic platelet transfusions are often given at these very low levels. Platelet transfusions are also given prior to invasive procedures or surgery, and the goal should be to raise the platelet count to over 50,000/uL.

Platelets are most commonly derived from donated blood units. One unit of platelets (derived from 1 unit of blood) usually contains $5-7 \times 10^{10}$ platelets suspended in 35 mL of plasma. Ideally, 1 platelet unit will raise the recipient's platelet count by 10,000/uL, and transfused platelets will last for 2 or 3 days. However, responses are often suboptimal, with poor platelet increments and short survival times. This may be due to sepsis, splenomegaly, or alloimmunization. Most alloantibodies causing platelet destruction are directed at HLA antigens. Patients requiring long periods of platelet transfusion support should be monitored to document adequate responses to transfusions so that the most appropriate product can be used. Patients may benefit from HLA-matched platelets derived from either volunteer donors or family members, with platelets obtained by plateletpheresis. Techniques of cross-matching platelets have been developed and appear to identify suitable platelet donors (nonreactive with the patient's serum) without the need for HLA typing. Such single-donor platelets usually contain the equivalent of six units of random platelets, or $30-50 \times 10^{10}$ platelets suspended in 200 mL of plasma. Ideally, these platelet concentrates will raise the recipient's platelet count by 60,000/uL. Leukocyte depletion of platelets has been shown to delay the onset of alloimmunization.

Granulocyte Transfusions

Granulocyte transfusions are seldom indicated and have largely been replaced by the use of myeloid growth factors (G-CSF and GM-CSF) that speed neutrophil recovery. However, they may be beneficial in patients with profound neutropenia (< 100/uL) who have gram-negative sepsis or progressive soft tissue infection despite optimal antibiotic therapy. In these cases, it is clear that progressive infection is due to failure of host defenses. In such situations, daily granulocyte transfusions should be given and continued until the neutrophil count rises to above 500/uL. Such granulocytes must be derived from ABO-matched donors. Although HLA matching is not necessary, it is preferred, since patients with alloantibodies to donor white blood cells will have severe reactions and no benefit.

The donor cells usually contain some immunocompetent lymphocytes capable of producing graft-versus-host disease in HLA-incompatible hosts whose immunocompetence may be impaired. Irradiation of the units of cells with 1500 cGy will destroy the lymphocytes without harm to the granulocytes or platelets.

TRANSFUSION OF PLASMA COMPONENTS

Fresh-frozen plasma is available in units of approximately 200 mL. Fresh plasma contains normal levels of all coagulation factors (about 1 unit/mL). Fresh frozen plasma is used to correct coagulation factor deficiencies and to treat thrombotic thrombocytopenic purpura. The risk of transmitting viral disease is comparable to that associated with transfusion of red blood cells.

Cryoprecipitate is made from fresh plasma. One unit has a volume of approximately 20 mL and contains approximately 250 mg of fibrinogen and between 80 and 100 units of factor VIII and von Willebrand factor. Cryoprecipitate is used to supplement fibrinogen in cases of congenital deficiency of fibrinogen or disseminated intravascular coagulation. One unit of cryoprecipitate will raise the fibrinogen level by about 8 mg/dL.

■ SYMPTOMS & SIGNS OF GASTROINTESTINAL DISEASE

DYSPEPSIA

A working team defines dyspepsia as pain or discomfort centered in the upper abdomen. The discomfort may be characterized by or associated with upper abdominal fullness, early satiety, burning, bloating, belching, nausea, retching, or vomiting. Heartburn (retrosternal burning) should be distinguished from dyspepsia. Patients with dyspepsia often have heartburn as an additional symptom. When heartburn is the dominant complaint, gastroesophageal reflux is nearly always present. Dyspepsia occurs in one-fourth of the adult population and accounts for 3% of general medical office visits.

Etiology

A. Food or Drug Intolerance

Acute, self-limited "indigestion" may be caused by overeating, eating too quickly, eating high-fat foods, eating during stressful situations, or drinking too much alcohol or coffee. Many medications cause dyspepsia, including aspirin, NSAIDs, antibiotics (metronidazole, macrolides), corticosteroids, digoxin, theophylline, iron, and narcotics.

B. Luminal Gastrointestinal Tract Dysfunction

Peptic ulcer disease is present in 15-25% of patients with dyspepsia. Gastroesophageal reflux disease is present in up to 20% of patients with dyspepsia, even without significant heartburn. Gastric cancer is identified in 1% but is rare in persons under age 45. Other causes include gastroparesis (especially in diabetes mellitus), lactose intolerance or malabsorptive conditions, and parasitic infection (giardia, strongyloides).

C. *Helicobacter pylori* Infection

Chronic gastric infection with *H pylori* as a cause of dyspepsia remains controversial. The prevalence of *H pylori*-associated chronic gastritis in patients with dyspepsia without peptic ulcer disease is 20-50%, the same as in the general population. *H pylori* eradication treatment seldom helps.

D. Pancreatic Disease

Pancreatic carcinoma, chronic pancreatitis.

E. Biliary Tract Disease

The abrupt onset of epigastric or right upper quadrant pain due to cholelithiasis or choledocholithiasis should be readily distinguished from dyspepsia.

F. Other Conditions

Diabetes, thyroid disease, renal insufficiency, myocardial ischemia, intra-abdominal malignancy, gastric volvulus or paraesophageal hernia, and pregnancy are sometimes accompanied by dyspepsia.

G. Functional or "Nonulcer" Dyspepsia

This is the most common cause of chronic dyspepsia. Up to two-thirds of patients have no obvious organic cause for their symptoms after evaluation. Symptoms may arise from a complex interaction of increased visceral afferent sensitivity, gastric delayed emptying or impaired accommodation to food, or psychosocial stressors. While benign, these symptoms may be chronic and difficult to treat.

Clinical Findings

A. Symptoms and Signs

Given the nonspecific nature of dyspeptic symptoms, the history has limited diagnostic utility. It should clarify the chronicity, location, and quality of the discomfort. Concomitant weight loss, persistent vomiting, constant or severe pain, dysphagia, hematemesis, or melena warrant endoscopy or abdominal imaging. Potentially offending medications and excessive alcohol use should be identified and discontinued if possible. The patient's reason for seeking care should be determined. Many patients report a fear of a serious underlying condition. Recent changes in employment, marital discord, physical and sexual abuse, anxiety, and depression may all contribute to the development and reporting of symptoms.

The symptom profile alone does not differentiate between nonulcer dyspepsia and peptic ulcer disease. Nevertheless, patients with peptic ulcer disease are more likely to be older (> 45 years), to smoke, and to have pain relieved by food or antacids. Patients with nonulcer dyspepsia are younger, report a variety of abdominal and extragastrointestinal complaints, show signs of anxiety or depression, or have a history of use of psychotropic medications.

The physical examination is rarely helpful. Signs of serious organic disease such as weight loss, organomegaly, abdominal mass, or fecal occult blood are further evaluated. In patients over age 45, initial laboratory work should include a blood count, electrolytes, liver enzymes, calcium, and thyroid function tests.

B. Special Examinations

Upper endoscopy is the study of choice to diagnose gastroduodenal ulcers, erosive esophagitis, and upper gastrointestinal malignancy. Upper gastrointestinal barium radiography is inferior to endoscopy for the evaluation of dyspepsia.

The optimal cost-effective approach to dyspepsia is controversial. Upper endoscopy is indicated in all patients over age 45 years with new-onset dyspepsia and in all patients with weight loss, dysphagia, recurrent vomiting, evidence of bleeding, or anemia. It is also helpful for patients who are concerned about serious underlying disease.

Recognition of the role of *H pylori* in peptic ulcer disease has altered the approach to younger patients with uncomplicated dyspepsia, in whom gastric cancer is rare. Consensus guidelines recommend an initial noninvasive test for *H pylori* (IgG serology, fecal antigen test, or urea breath test) in most young, uncomplicated patients with dyspepsia. If negative in a patient not taking NSAIDs, peptic ulcer disease is virtually excluded. The majority of these *H pylori*-negative patients have functional dyspepsia or atypical gastroesophageal reflux disease and can be treated with an antisecretory agent (H₂ antagonist or proton pump inhibitor) for 2-4 weeks. If symptoms fail to respond or rapidly recur after stopping treatment, endoscopy is recommended. In patients testing positive for *H pylori*, antibiotic therapy proves definitive for over 90% of peptic ulcers and may improve symptoms in a small subset (4-9%) of infected patients with functional dyspepsia. Endoscopic evaluation is warranted when symptoms fail to respond.

Abdominal imaging (ultrasonography or computerized tomography) is performed only when pancreatic or biliary tract disease is suspected. Gastric emptying studies are valuable only in patients with recurrent vomiting. Ambulatory esophageal pH testing may be of value when atypical gastroesophageal reflux is suspected.

Treatment of Functional Dyspepsia

In patients with functional dyspepsia, the following should be considered.

A. General Measures

A stable physician-patient interaction is the most important aspect of therapy. Patients require reassurance that the condition is not serious but may be chronic. Alcohol and caffeine intake should be reduced or discontinued. A food diary, in which patients record their food intake, symptoms, and daily events, may reveal dietary or psychosocial precipitants of pain.

B. Pharmacologic Agents

One-third of patients derive relief from placebo. Antisecretory therapy for 2-4 weeks with either H₂-receptor antagonists (ranitidine or nizatidine, 150 mg twice daily, famotidine, 20 mg twice daily, or cimetidine, 400-800 mg twice daily) or proton pump inhibitors (omeprazole, esomeprazole, or rabeprazole 20 mg, lansoprazole 30 mg, or pantoprazole 40 mg) may benefit 10-20% of patients, particularly those with dyspepsia and heartburn ("reflux-like dyspepsia") or epigastric pain. Superiority of proton pump inhibitors to H₂ antagonists has not been established. Low doses of antidepressants (eg, desipramine or nortriptyline, 10-50 mg at bedtime) are believed to benefit some patients, possibly by moderating visceral afferent sensitivity. However, side effects are common and response is patient-specific. Doses should be increased slowly. Prokinetic agents (metoclopramide or cisapride, 10 mg three times daily) improve symptoms in up to 60%. Symptomatic improvement does not correlate with the presence or absence of gastric emptying delay. However, owing to their side effects, neither agent is recommended for treatment of functional dyspepsia. Long-term metoclopramide use is associated with a high incidence of neuropsychiatric side effects. Cisapride has been withdrawn from the market by the manufacturer in the United States as a result of its association with life-threatening ventricular arrhythmias.

C. Anti-*H pylori* Treatment

A meta-analysis has suggested that a small number of patients (5-15%) may derive benefit from *H pylori* eradication therapy.

D. Alternative Therapies

Psychotherapy and hypnotherapy may be of benefit in selected motivated patients. Herbal therapies (peppermint, caraway) may offer benefit with little risk of adverse effects.

NAUSEA & VOMITING

Nausea is a vague, intensely disagreeable sensation of sickness or "queasiness" that may or may not be followed by vomiting and is distinguished from anorexia. Vomiting often follows, as does retching (spasmodic respiratory and abdominal movements). Vomiting should be distinguished from regurgitation, the effortless reflux of liquid or food stomach contents, and from rumination, the chewing and swallowing of food that is regurgitated volitionally after meals.

The medullary vomiting center may be stimulated by four different sources of afferent input: (1) Afferent vagal fibers (rich in serotonin 5-HT₃ receptors) and splanchnic fibers from the gastrointestinal viscera; these may be stimulated by biliary or gastrointestinal distention, mucosal or peritoneal irritation, or infections. (2) Fibers of the vestibular system, which have high concentrations of histamine H₁ and muscarinic cholinergic receptors. (3) Higher central nervous system centers; here, certain sights, smells, or emotional experiences may induce vomiting. For example, patients receiving chemotherapy may develop vomiting in anticipation of its administration. (4) The chemoreceptor trigger zone, located outside the blood-brain barrier in the area postrema of the medulla, which is rich in opioid, serotonin 5-HT₃, and dopamine D₂ receptors. This region may be stimulated by drugs and chemotherapeutic agents, toxins, hypoxia, uremia, acidosis, and radiation therapy. Although the causes of vomiting are many, a simplified list is provided in [Table 14-1](#)

Complications of vomiting include dehydration, hypokalemia, metabolic alkalosis, aspiration, rupture of the esophagus (Boerhaave's syndrome), and bleeding secondary to a mucosal tear at the gastroesophageal junction (Mallory-Weiss syndrome).

Clinical Findings

A. Symptoms and Signs

Acute symptoms without abdominal pain are typically caused by food poisoning, infectious gastroenteritis, cholecystitis, pancreatitis, or drugs. Inquiry should be made into recent changes in medications, diet, other intestinal symptoms, or similar illnesses in family members. The acute onset of severe pain and vomiting suggests peritoneal irritation, acute gastric or intestinal obstruction, or pancreaticobiliary disease. Examination may reveal fever, focal tenderness or rigidity, guarding, or rebound tenderness. Persistent vomiting suggests pregnancy, gastric outlet obstruction, gastroparesis, intestinal dysmotility, psychogenic disorders, and central nervous system or systemic disorders. Vomiting that occurs in the morning before breakfast is common with pregnancy, uremia, alcohol intake, and increased intracranial pressure. Vomiting immediately after meals strongly suggests bulimia or psychogenic causes. Vomiting of undigested food 1 to several hours after meals is characteristic of gastroparesis or a gastric outlet obstruction; physical examination may reveal a succussion splash. Patients with acute or chronic symptoms should be asked about neurologic symptoms that suggest a central nervous system cause such as headache, stiff neck, vertigo, and focal paresthesias or weakness.

B. Special Examinations

In vomiting of acute onset, flat and upright abdominal radiographs are obtained in patients with severe pain or suspicion of mechanical obstruction to look for free intraperitoneal air or dilated loops of small bowel. If mechanical small intestinal or gastric obstruction is thought likely, a nasogastric tube is placed for relief of symptoms. The cause of gastric outlet obstruction is best demonstrated by upper endoscopy, and the cause of small intestinal obstruction is best demonstrated with barium radiography or abdominal CT imaging. Gastroparesis is confirmed by nuclear scintigraphic studies, which show delayed gastric emptying, and either upper endoscopy or barium upper GI series showing no evidence of mechanical gastric outlet obstruction. Abnormal liver function tests or elevated amylase suggests pancreaticobiliary disease, which may be investigated with an abdominal sonogram or CT scan. Central nervous system causes are best evaluated with either CT or MR head imaging.

Treatment

A. General Measures

Most causes of acute vomiting are mild, self-limited, and require no specific treatment. Patients should ingest clear liquids (broths, tea, soups, carbonated beverages) and small quantities of dry foods (soda crackers). For more severe acute vomiting, hospitalization may be required. Owing to inability to eat and loss of gastric fluids, patients may become dehydrated and develop hypokalemia with metabolic alkalosis. Intravenous 0.45% saline solution with 20 meq/L of potassium chloride is given in most cases to maintain hydration. A nasogastric suction tube for gastric decompression improves patient comfort and permits monitoring of fluid loss.

B. Antiemetic Medications

Medications may be given either to prevent or to control vomiting (see above). Combinations of drugs from different classes may provide better control of symptoms with less toxicity in some patients. All of these medications should be avoided in pregnancy. (For dosages, see [Table 14-2](#).)

1. Serotonin 5-HT₃ receptor antagonists—Ondansetron, granisetron, and dolasetron, when initiated prior to treatment, are effective in the prevention of chemotherapy-induced emesis. Single-dose administration schedules are as effective as multiple-dose regimens. The serotonin antagonists are also effective for the treatment of postoperative nausea and vomiting and vomiting due to radiation therapy.

2. Dopamine antagonists—The phenothiazines, butyrophenones, and substituted benzamides have antiemetic properties which are due to dopaminergic blockade as well as to their sedative effects. High doses of these agents are associated with antidopaminergic side effects, including extrapyramidal reactions and depression. These agents are used in a variety of situations. Because cases of QT prolongation leading to ventricular tachycardia (torsade de pointes) have been reported in several patients receiving droperidol, that agent is no longer recommended for treatment of nausea and vomiting.

3. Antihistamines and anticholinergics—These drugs (eg, meclizine, dimenhydrinate, transdermal scopolamine) may be valuable in the prevention of vomiting arising from stimulation of the labyrinth, ie, motion sickness, vertigo, and migraines. They may induce drowsiness.

4. Sedatives—Benzodiazepines are used in psychogenic and anticipatory vomiting.

5. Corticosteroids—The combination of corticosteroids and serotonin receptor antagonists provides the best antiemetic protection with a low incidence of adverse effects for the prevention and treatment of chemotherapy-associated nausea and vomiting.

6. Cannabinoids—Marijuana has been used widely as an appetite stimulant and antiemetic. Pure ?9-tetrahydrocannabinol (THC) is the major active ingredient in marijuana and is available by prescription as dronabinol. In doses of 5-15 mg/m², oral dronabinol is effective in treating nausea associated with chemotherapy, but it is associated with central nervous system side effects in most patients.

HICCUPS (SINGULTUS)

Though usually a benign and self-limited annoyance, hiccups may be persistent and a sign of serious underlying illness. In patients being maintained on mechanical ventilation, hiccups can trigger a full respiratory cycle and result in respiratory alkalosis.

Causes of benign, self-limited hiccups include gastric distention (carbonated beverages, air swallowing, overeating), sudden temperature changes (hot then cold liquids, hot then cold shower), alcohol ingestion, and states of heightened emotion (excitement, stress, laughing). There are over 100 causes of recurrent or persistent hiccups, grouped into the following categories:

Central nervous system: Neoplasms, infections, cerebrovascular accident, trauma.

Metabolic: Uremia, hypocapnia (hyperventilation).

Irritation of the vagus or phrenic nerve: (1) Head, neck: Foreign body in ear, goiter, neoplasms. (2) Thorax: Pneumonia, empyema, neoplasms, myocardial infarction, pericarditis, aneurysm, esophageal obstruction, reflux esophagitis. (3) Abdomen: Subphrenic abscess, hepatomegaly, hepatitis, cholecystitis, gastric distention, gastric neoplasm, pancreatitis, or pancreatic malignancy.

Surgical: General anesthesia, postoperative.

Psychogenic and idiopathic

Clinical Findings

Evaluation of the patient with persistent hiccups should include a detailed neurologic examination, serum creatinine, liver chemistry tests, and a chest radiograph. When the cause remains unclear, CT of the head, chest, and abdomen, echocardiography, bronchoscopy, and upper endoscopy may help. On occasion, hiccups may be unilateral; chest fluoroscopy will make the diagnosis.

Treatment

A number of simple remedies may be helpful in patients with acute benign hiccups. (1) Irritation of the nasopharynx by tongue traction, lifting the uvula with a spoon, catheter stimulation of the nasopharynx, or eating 1 tsp of dry granulated sugar. (2) Interruption of the respiratory cycle by breath holding, Valsalva's maneuver, sneezing, gasping (fright stimulus), or rebreathing into a bag. (3) Stimulation of the vagus, carotid massage. (4) Irritation of the diaphragm by holding knees to chest or by continuous positive airway pressure during mechanical ventilation. (5) Relief of gastric distention by belching or insertion of a nasogastric tube.

A number of drugs have been promoted as being useful in the treatment of hiccups. Chlorpromazine, 25-50 mg orally or intramuscularly, is most commonly used. Other agents reported to be effective include anticonvulsants (phenytoin, carbamazepine), benzodiazepines (lorazepam, diazepam), metoclopramide, baclofen, and occasionally general anesthesia.

CONSTIPATION

The first step in evaluating the patient is to determine what is meant by "constipation." In the general population, the "normal" frequency of bowel movements is broad, ranging from three to twelve per week. The complaint may reflect a mistaken perception of what constitutes a normal bowel pattern. Constipation is present when a patient has two or fewer bowel movements per week or excessive difficulty and straining at defecation. The many causes of constipation may be classified as discussed below and summarized in [Table 14-3](#).

Common Identifiable Causes of Constipation

A. Poor Dietary and Behavioral Habits

The majority of constipated patients have mild symptoms that cannot be attributed to any structural abnormalities, intestinal motility disorders, or systemic disease. Dietary review will reveal that most of these patients do not consume adequate fiber and fluids. Ingestion of 10-12 g of fiber per day either by dietary changes or the addition of commercial fiber supplementation is often all that is needed. At least one or two glasses of fluid should be taken with meals. The elderly are predisposed because of poor eating habits, a variety of medications, decreased colonic motility, and, in some cases, inability to sit on a toilet (bed-bound patients).

B. Structural Abnormalities

Colonic lesions that obstruct fecal passage must be excluded in patients with constipation. Particular concern is raised in patients with lifelong constipation (Hirschsprung's disease) and patients over age 50 with new-onset constipation, progressive thinning of stool, or associated weight loss or hematochezia (suggesting colon carcinoma).

C. Systemic Diseases

Medical diseases can cause constipation due to neurologic gut dysfunction, myopathies, endocrine disorders, and electrolyte abnormalities such as hypercalcemia or hypokalemia.

D. Medications

Anticholinergic and opioid agents are common causes of constipation.

Causes of Severe or Refractory Constipation

Patients whose constipation cannot be attributed to the above causes and who do not respond to conservative dietary management present difficult management problems. Conceptually, these patients can be divided into three classes.

A. Slow Colonic Transit

Normal colonic transit time is approximately 35 hours; more than 72 hours is significantly abnormal. Colonic inertia is more common in women, some of whom have a history of psychosocial problems or sexual abuse. It may be part of a more generalized gastrointestinal dysmotility syndrome or may be attributable to years of cathartic use.

B. Pelvic Floor Dysfunction (Outlet Disorders)

Patients with disorders of the rectum or pelvic floor—women more often than men—may have difficulty in moving stool out of the rectum. They may complain of excessive straining with a sense of incomplete evacuation, the need for digital pressure on the vagina or perineum, or even the need for digital disimpaction. Defecatory difficulties can be due to a variety of anatomic problems that impede or obstruct flow, some of which may benefit from surgery.

C. Irritable Bowel Syndrome

Patients with primary complaints of abdominal pain, bloating, or a sense of incomplete evacuation may have irritable bowel syndrome. (See below.)

Evaluation

A. Initial Management

All patients should undergo a history and physical examination, including stool testing for occult blood. Laboratory studies should include a complete blood count, serum electrolytes including calcium, and serum TSH. In otherwise healthy patients with mild symptoms who are under age 50, a trial of fiber is reasonable. In patients

over age 50, those who have failed conservative treatment, or those with anemia or occult blood in the stools, colonoscopy or flexible sigmoidoscopy and barium enema are obtained. Patients without structural, medical, or neurologic disease can be treated initially with fiber supplementation (and osmotic laxatives, if needed).

B. Second Level of Investigation

Patients with refractory constipation not responding to conservative measures may require further investigation by means of colonic transit and pelvic floor function studies in order to distinguish slow colonic transit from outlet disorders.

Standard Treatment of Chronic Constipation

A. Dietary Measures

Proper dietary fluid and fiber intake should be emphasized. Fiber may be given by means of dietary alterations or fiber supplements ([Table 14-4](#)). Increased dietary fiber may cause temporary distention or flatulence, which often diminishes over several days. Response to fiber therapy is not immediate, and increases in dosage should be made gradually over 7-10 days. Whereas fiber may benefit the majority of patients, it normally does not benefit patients with severe colonic inertia or outlet disorders.

B. Stool Surfactant Agents

Docusate sodium, 50-200 mg/d, or mineral oil, 14- 45 mL/d, may be given orally or rectally to promote softening of stools. Aspiration of mineral oil can cause lipoid pneumonia.

C. Osmotic Laxatives

These agents, used to soften stools, may be given alone or in combination with fiber supplements ([Table 14-4](#)). They are commonly employed in older nonambulatory patients to prevent constipation and fecal impaction. They are safe and are titrated to a dose that results in soft to semiliquid stools. The less expensive saline laxatives should be tried first before using more expensive osmotic agents, such as nonabsorbable carbohydrates or polyethylene glycol solution.

1. Saline laxatives—Magnesium-containing saline laxatives (milk of magnesia, magnesium sulfate) are the most commonly used agents for the prevention and treatment of chronic constipation. These agents should not be used in patients with renal insufficiency. Sodium phosphate or magnesium citrate may be used for aggressive treatment of acute constipation or as a purgative prior to surgical, endoscopic, or radiographic procedures.

2. Nonabsorbable carbohydrates—Either sorbitol (70%) or lactulose, 15-30 mL once or twice daily, is efficacious for the prevention or treatment of chronic constipation. These malabsorbed sugars are often limited by their propensity to induce bloating, cramps, and flatulence.

3. Polyethylene glycol solution—Polyethylene glycol is a component of solutions traditionally used for colonic lavage prior to colonoscopy (CoLyte, GoLYTELY, NuLyte). Polyethylene glycol 3350 powder (Miralax) is now available for the treatment of acute or chronic constipation. Seventeen grams of powder may be mixed in water or juice and taken once or twice daily.

D. Stimulant Agents

These agents stimulate fluid secretion and colonic contraction, resulting in a bowel movement within 6-12 hours after oral ingestion or 15-60 minutes after rectal administration. Common preparations include bisacodyl, senna, cascara, and castor oil ([Table 14-4](#)). Phenolphthalein has been removed from the market in the United States because of concerns related to carcinogenicity. Colchicine (0.6 mg) or misoprostol (200 ug) two or three times daily may be helpful in some patients with refractory constipation.

Treatment of Fecal Impaction

Severe impaction of stool in the rectal vault may result in obstruction to further fecal flow, leading to partial or complete large bowel obstruction. Predisposing factors include severe psychiatric disease, prolonged bed rest and debility, neurogenic disorders of the colon, and spinal cord disorders. Clinical presentation includes decreased appetite, nausea and vomiting, and abdominal pain and distention. There may be paradoxical "diarrhea" as liquid stool leaks around the impacted feces. Firm feces are palpable on digital examination of the rectal vault. Initial treatment is directed at relieving the impaction with enemas (saline, mineral oil, or diatrizoate) or digital disruption of the impacted fecal material. Long-term care is directed at maintaining soft stools and regular bowel movements (as above).

GASTROINTESTINAL GAS

Belching

Belching (eructation) is the involuntary or voluntary release of gas from the stomach or esophagus. It occurs most frequently after meals, when gastric distention results in transient lower esophageal sphincter relaxation. Belching is a normal reflex and does not itself denote gastrointestinal dysfunction. Virtually all stomach gas comes from swallowed air. With each swallow, 2-5 mL of air is ingested, and excessive amounts may result in distention, flatulence, and abdominal pain. This may occur with rapid eating, gum chewing, smoking, and the ingestion of carbonated beverages. Chronic excessive belching is almost always caused by aerophagia, common in anxious individuals and institutionalized patients. Evaluation should be restricted to patients with other complaints such as dysphagia, heartburn, early satiety, or vomiting.

Once patients understand the relationship between aerophagia and belching, most can deal with the problem by behavioral modification. Physical defects that hamper normal swallowing (ill-fitting dentures, nasal obstruction) should be corrected. Antacids and simethicone are of no value.

Flatus

The rate and volume of expulsion of flatus is highly variable. Flatus is derived from two sources: swallowed air and bacterial fermentation of undigested carbohydrate. The majority of swallowed air not belched passes through the gut and leaves as flatus. Swallowed air may contribute up to 500 mL of flatus per day (primarily nitrogen). Bacterial fermentation of undigested carbohydrates leads to the additional production of gas, particularly H₂, CO₂, and methane. The majority of this fermentation takes place in the colon. Under normal circumstances, a small substrate of fermentable substances reaches the colon. These substances include fructose, lactose, sorbitol, trehalose (mushrooms), raffinose, and stachyose (legumes, cruciferous vegetables). Complex starches and fiber may also cause gas. Gas production may be increased with ingestion of these carbohydrates or with malabsorption.

Determining abnormal from normal amounts of flatus is difficult. An initial trial of a lactose-free diet is recommended. Common gas-producing foods should be reviewed and the patient given an elimination trial. These include beans of all kinds, peas, lentils, broccoli, brussels sprouts, cauliflower, cabbage, parsnips, leeks, onions, beer, and coffee. Foul odor may be caused by garlic, onion, eggplant, mushrooms, and certain herbs and spices. For patients with persistent complaints, fructose, complex starches, and fiber may be eliminated, but such restrictive diets are unacceptable to most patients. Of refined flours, only rice flour is gas-free.

The nonprescription agent Beano (a-D-galactosidase enzyme) reduces gas caused by foods containing raffinose and stachyose, ie, cruciferous vegetables, legumes, nuts, and some cereals. Activated charcoal may afford relief. Simethicone is of no proved benefit.

Complaints of chronic abdominal distention or bloating are common but do not correlate with increased intra-abdominal gas volumes. Many such patients have an underlying functional gastrointestinal disorder such as irritable bowel syndrome or nonulcer dyspepsia.

DIARRHEA

Diarrhea can range in severity from an acute self-limited episode to a severe, life-threatening illness. To properly evaluate the complaint, the physician must determine the patient's normal bowel pattern and the nature of the current symptoms.

Approximately 10 L of fluid enter the duodenum daily, of which all but 1.5 L are absorbed by the small intestine. The colon absorbs most of the remaining fluid, with only 100 mL lost in the stool. Diarrhea is defined as a stool weight of more than 250 g/24 h, but quantification of stool weight is necessary only in some patients with chronic diarrhea. In most cases, the physician's working definition of diarrhea is increased stool frequency (more than two or three bowel movements per day) or liquidity of feces.

The causes of diarrhea are myriad. In clinical practice, it is helpful to distinguish acute from chronic diarrhea, as the evaluation and treatment are entirely different ([Tables 14-5](#) and [14-7](#)).

1. Acute Diarrhea

Etiology & Clinical Findings

Diarrhea acute in onset and persisting for less than 3 weeks is most commonly caused by infectious agents, bacterial toxins (either preformed or produced in the gut), or drugs. Similar recent illnesses in family members suggests an infectious origin. Ingestion of improperly stored or prepared food implicates food poisoning. Exposure to unpurified water (camping, swimming) or contaminated produce may result in infection with giardia, cryptosporidium, or cyclospora. Recent travel abroad suggests "traveler's diarrhea" (see [Chapter 30](#)). Antibiotic administration within the preceding several weeks increases the likelihood of *Clostridium difficile* colitis. Finally, risk factors for HIV infection or sexually transmitted diseases should be determined. (AIDS-associated diarrhea is discussed in [Chapter 31](#).) Persons practicing unprotected anal intercourse are at risk for a variety of infections that cause proctitis and rectal discharge, including gonorrhea, syphilis, lymphogranuloma venereum, and herpes simplex.

The nature of the diarrhea helps distinguish among different infectious causes ([Table 14-5](#)).

A. Noninflammatory Diarrhea

Watery, nonbloody diarrhea associated with periumbilical cramps, bloating, nausea, or vomiting suggests a small bowel source caused by either a toxin-producing bacterium (enterotoxigenic *E coli* [ETEC], *Staphylococcus aureus*, *Bacillus cereus*, *Clostridium perfringens*) or other agents (viruses, giardia) that disrupt normal absorption and secretory process in the small intestine. Prominent vomiting suggests viral enteritis or *S aureus* food poisoning. Though typically mild, the diarrhea (which originates in the small intestine) can be voluminous and result in dehydration with hypokalemia and metabolic acidosis (eg, cholera). Because tissue invasion does not occur, fecal leukocytes are not present.

B. Inflammatory Diarrhea

The presence of fever and bloody diarrhea (dysentery) indicates colonic tissue damage caused by invasion (shigellosis, salmonellosis, campylobacter or yersinia infection, amebiasis) or a toxin (*C difficile*, *E coli* O157:H7). Because these organisms involve predominantly the colon, the diarrhea is small in volume (< 1 L/d) and associated with left lower quadrant cramps, urgency, and tenesmus. Fecal leukocytes usually are present in infections with invasive organisms. *E coli* O157:H7 is a toxigenic noninvasive organism that may be acquired from contaminated meat or unpasteurized apple juice and has resulted in several outbreaks of an acute, often severe hemorrhagic colitis. In immunocompromised and HIV-infected patients, cytomegalovirus can cause intestinal ulceration with watery or bloody diarrhea.

Infectious dysentery must be distinguished from acute ulcerative colitis, which may also present acutely with fever, abdominal pain, and bloody diarrhea. Diarrhea that persists for more than 14 days is not attributable to bacterial pathogens (except for *C difficile*) and should be evaluated as chronic diarrhea.

Evaluation ([Figure 14-1](#))

In over 90% of patients with acute diarrhea, the illness is mild and self-limited, responding within 5 days to simple rehydration therapy or antidiarrheal agents; diagnostic investigation is unnecessary. The isolation rate of bacterial pathogens from stool cultures in patients with acute diarrhea is under 3%. Thus, the goal of initial evaluation is to distinguish patients with mild disease from those with more serious illness. If diarrhea worsens or persists for more than 7-10 days, stool should be sent for fecal leukocyte determination, ovum and parasite evaluation, and bacterial culture.

Prompt medical evaluation is indicated in the following situations: (1) Signs of inflammatory diarrhea manifested by any of the following: fever (> 38.5 °C), bloody diarrhea, or abdominal pain. (2) The passage of six or more unformed stools in 24 hours. (3) Profuse watery diarrhea and dehydration. (4) Frail older patients. (5) Immunocompromised patients (AIDS, posttransplantation).

Physical examination pays note to mental status and the presence of abdominal tenderness or peritonitis. Peritoneal findings may be present in infection with *C difficile* or enterohemorrhagic *E coli*. Hospitalization is required in patients with severe dehydration, toxicity, or marked abdominal pain, and stool specimens should be sent for examination for fecal leukocytes and bacterial cultures ([Table 14-6](#)). The rate of positive bacterial cultures in such patients is 60-75%. A stool wet mount examination for amebiasis is performed in sexually active homosexuals, those with a history of recent travel to amebiasis-endemic areas, and those whose bacterial cultures are negative. With a history of antibiotic exposure, a stool sample should be tested for *C difficile* toxin. If *E coli* O157:H7 is suspected, serotyping is indicated. Special culture media are required for yersinia, aeromonas, and plesiomonas. In patients with diarrhea that persists for more than 10 days, three stool examinations for ova and parasites should also be performed. The stool giardia antigen assay is more sensitive than stool microscopy for detection of this organism. Rectal swabs may be sent for culture of chlamydia, *Neisseria gonorrhoeae*, and herpes simplex virus in sexually active patients with suspected proctitis.

Prompt sigmoidoscopy is warranted for symptoms of severe proctitis (tenesmus, discharge, rectal pain) or for suspected *C difficile* colitis patients who appear ill. It may also be helpful in distinguishing infectious diarrhea from ulcerative colitis or ischemic colitis.

Treatment

A. Diet

Most mild diarrhea will not lead to dehydration provided the patient takes adequate oral fluids containing carbohydrates and electrolytes. Patients find it more comfortable to rest the bowel by avoiding high-fiber foods, fats, milk products, caffeine, and alcohol. Frequent feedings of fruit drinks, tea, "flat" carbonated beverages, and soft, easily digested foods (eg, soups, crackers) are encouraged.

B. Rehydration

In more severe diarrhea, dehydration can occur quickly, especially in children, the frail, and the elderly. Oral rehydration with fluids containing glucose, Na⁺, K⁺, Cl⁻, and bicarbonate or citrate is preferred when feasible. A convenient mixture is 1/2 tsp salt (3.5 g), 1 tsp baking soda (2.5 g NaHCO₃), 8 tsp sugar (40 g), and 8 oz orange juice (1.5 g KCl), diluted to 1 L with water. Alternatively, oral electrolyte solutions (eg, Pedialyte, Gatorade) are readily available. Fluids should be given at rates of 50-200 mL/kg/24 h depending on the hydration status. Intravenous fluids (lactated Ringer's injection) are preferred in patients with severe dehydration.

C. Antidiarrheal Agents

Antidiarrheal agents may be used safely in patients with mild to moderate diarrheal illnesses to improve patient comfort. Opioid agents help decrease the stool number and liquidity and control fecal urgency. However, they should not be used in patients with bloody diarrhea, high fever, or systemic toxicity and should be discontinued in patients whose diarrhea is worsening despite therapy. With these provisos, such drugs provide excellent symptomatic relief. Loperamide is preferred, in a dosage of 4 mg initially, followed by 2 mg after each loose stool (maximum: 16 mg/24 h).

Bismuth subsalicylate (Pepto-Bismol), two tablets or 30 mL four times daily, reduces symptoms in patients with traveler's diarrhea by virtue of its anti-inflammatory and antibacterial properties. It also reduces vomiting associated with viral enteritis. Anticholinergic agents (eg, diphenoxylate with atropine) are contraindicated in acute diarrhea because of the rare precipitation of toxic megacolon.

D. Antibiotic Therapy

1. Empirical treatment—Empirical antibiotic treatment of all patients with acute diarrhea is not indicated. Even patients with inflammatory diarrhea caused by invasive pathogens usually have symptoms that will resolve within several days without antimicrobials. Empirical treatment is recommended with moderate to severe fever, tenesmus, or bloody stools or the presence of fecal leukocytes while the stool bacterial culture is incubating. The drugs of choice are the fluoroquinolones (eg, ciprofloxacin 500 mg, ofloxacin 400 mg, or norfloxacin 400 mg, twice daily) for 5-7 days. Alternatives include trimethoprim-sulfamethoxazole, 160/800 mg twice daily, or doxycycline, 100 mg twice daily. Macrolides and penicillins are no longer recommended because of widespread microbial resistance to these agents. Metronidazole (250 mg three times daily for 7 days) may also be given when giardia infection is suspected clinically, because over half of stool specimens may be negative in infected patients.

2. Specific antimicrobial treatment—Antibiotics are not recommended in patients with nontyphoid salmonella, campylobacter, aeromonas, yersinia, or *E coli* O157:H7 infection except in severe disease; they do not hasten recovery or reduce the period of fecal bacterial excretion. The infectious diarrheas for which treatment is recommended are shigellosis, cholera, extraintestinal salmonellosis, traveler's diarrhea, *C difficile* infection, giardiasis, amebiasis, and the sexually transmitted infections (gonorrhea, syphilis, chlamydiosis, and herpes simplex infection). Therapy for these infections, traveler's diarrhea, and AIDS-related diarrhea is presented in

other chapters of this book.

2. Chronic Diarrhea

Etiology

The causes of chronic diarrhea may be grouped into seven major pathophysiologic categories (Table 14-7).

A. Osmotic Diarrheas

As stool leaves the colon, fecal osmolality is equal to the serum osmolality, ie, approximately 290 mosm/kg. Under normal circumstances, the major osmoles are Na^+ , K^+ , Cl^- , and HCO_3^- . The stool osmolality may be estimated by multiplying the stool $(\text{Na}^+ + \text{K}^+) \times 2$. The **osmotic gap** is the difference between the *measured* osmolality of the stool (or serum) and the *estimated* stool osmolality and is normally less than 50 mosm/kg. An increased osmotic gap (> 125 mosm/kg) implies that the diarrhea is caused by ingestion or malabsorption of an osmotically active substance. The most common causes are disaccharidase deficiency (lactase deficiency), laxative abuse, and malabsorption syndromes (see below). Osmotic diarrheas resolve during fasting. Those caused by malabsorbed carbohydrates are characterized by abdominal distention, bloating, and flatulence due to increased colonic gas production.

Disaccharidase deficiencies are common and should be considered in all patients with chronic diarrhea. Lactase deficiency occurs in three-fourths of nonwhite adults and up to 25% of Caucasians. It may also be acquired after an episode of viral gastroenteritis, medical illness, or gastrointestinal surgery. Sorbitol is commonly used as a sweetener in gums, candies, and some medications that may cause diarrhea in some patients. The diagnosis of sorbitol or lactose malabsorption may be established by an elimination trial for 2-3 weeks.

Ingestion of magnesium- or phosphate-containing compounds (laxatives, antacids) should be considered in enigmatic chronic diarrhea. Surreptitious use should be considered, especially in patients with a long history of undiagnosed medical ailments or employment in the medical field. The fat substitute olestra is also believed to cause diarrhea and cramps in occasional patients.

B. Secretory Conditions

Increased intestinal secretion or decreased absorption results in a high-volume watery diarrhea with a normal osmotic gap. There is little change in stool output during the fasting state, and dehydration and electrolyte imbalance may develop. Causes include endocrine tumors (stimulating intestinal or pancreatic secretion), bile salt malabsorption (stimulating colonic secretion), and laxative abuse.

C. Inflammatory Conditions

Diarrhea is present in most patients with inflammatory bowel disease (ulcerative colitis, Crohn's disease, microscopic colitis). A variety of other symptoms may be present, including abdominal pain, fever, weight loss, and hematochezia. (See Inflammatory Bowel Disease, below.)

D. Malabsorptive Conditions

The major causes of malabsorption are small mucosal intestinal diseases, intestinal resections, lymphatic obstruction, small intestinal bacterial overgrowth, and pancreatic insufficiency. Its characteristics are weight loss, osmotic diarrhea, and nutritional deficiencies. Significant diarrhea in the absence of weight loss is not likely to be due to malabsorption. The physical and laboratory abnormalities related to deficiencies of vitamins or minerals are discussed in Chapter 29.

E. Motility Disorders

Abnormal intestinal motility secondary to systemic disorders or surgery may result in diarrhea due to rapid transit or to stasis of intestinal contents with bacterial overgrowth, resulting in malabsorption. Probably the most common cause of chronic diarrhea is irritable bowel syndrome (see Irritable Bowel Syndrome, below).

F. Chronic Infections

Chronic parasitic infections may cause diarrhea through a number of mechanisms. Agents most commonly associated with diarrhea include the protozoans giardia, *Entamoeba histolytica*, and cyclospora as well as the intestinal nematodes.

Immunocompromised patients are susceptible to infectious agents that can cause acute or chronic diarrhea (see Chapter 31), including Microsporidia, cryptosporidium, cytomegalovirus, *Isospora belli*, cyclospora, and *Mycobacterium avium* complex.

G. Factitious Diarrhea

Fifteen percent of patients have factitious diarrhea caused by surreptitious laxative abuse or dilution of stool.

Evaluation

The history and physical examination commonly suggest the underlying pathophysiology that guides the subsequent diagnostic workup (Chapter 31).

A. Stool Analysis

1. Twenty-four-hour stool collection for weight and quantitative fecal fat—A stool weight of more than 300 g/24 h confirms diarrhea. A weight greater than 1000-1500 g suggests a secretory process. A fecal fat determination in excess of 10 g/24 h indicates a malabsorptive disorder. (See Celiac Sprue and specific tests for malabsorption, below.)

2. Stool osmolality—Stool osmolality less than serum osmolality implies that water or urine has been added to the specimen (factitious diarrhea). A stool pH less than 5.6 is consistent with carbohydrate malabsorption.

3. Stool laxative screen—In cases of suspected laxative abuse, stool magnesium, phosphate, and sulfate levels may be measured. Phenolphthalein and bisacodyl can be analyzed in stool water, using chromatographic techniques. Anthraquinones and bisacodyl are sought for in the urine.

4. Fecal leukocytes—The presence of fecal leukocytes implies inflammatory diarrhea.

5. Stool for ova and parasites—The presence of giardia and *E histolytica* may be detected in wet mounts. A fecal ELISA for giardia-specific antigen is a more sensitive and specific method of detection. Cryptosporidium and cyclospora are found with modified acid-fast staining.

B. Blood Tests

1. Routine laboratory tests—CBC, serum electrolytes, liver function tests, calcium, phosphorus, albumin, TSH, beta-carotene, and prothrombin time may be of value. Anemia occurs in malabsorption syndromes (folate, iron deficiency [rare], or vitamin B₁₂) as well as inflammatory conditions. Hypoalbuminemia is present in malabsorption, protein-losing enteropathies, and inflammatory diseases. Hyponatremia and non-anion-gap metabolic acidosis occur in secretory diarrheas.

2. Other laboratory tests—In patients with suspected malabsorption, serologic testing for celiac sprue includes IgG and IgA antigliadin or tissue transglutaminase antibodies. Secretory diarrheas due to neuroendocrine tumors are rare. When this is suspected, serum VIP (VIPoma), calcitonin (medullary thyroid carcinoma), gastrin (Zollinger-Ellison syndrome), and glucagon determinations may be diagnostic. Urine should be sent for 5-HIAA (carcinoid), VMA, metanephrine, and histamine determinations.

3. Endoscopic examination and mucosal biopsy—Either sigmoidoscopy or colonoscopy with mucosal biopsy is helpful in the detection of inflammatory bowel disease (including microscopic colitis) and melanosis coli (indicative of chronic anthraquinone laxative use). Upper endoscopy with small bowel biopsy is performed when a small intestinal malabsorptive disorder is suspected (celiac sprue, Whipple's disease) and in patients with AIDS to document cryptosporidium, Microsporidia, and *M avium-intracellulare* infection. If bacterial overgrowth is suspected, the diagnosis is confirmed with noninvasive breath tests (¹⁴C D-xylose, glucose, or lactulose)

or by obtaining an aspirate of small intestinal contents for quantitative aerobic and anaerobic bacterial culture.

4. Other imaging studies—Calcification on a plain abdominal radiograph confirms a diagnosis of chronic pancreatitis, though abdominal CT and endoscopic ultrasonography are more sensitive for the diagnosis of chronic pancreatitis as well as pancreatic cancer. Small intestinal barium radiography is helpful in the diagnosis of Crohn's disease, small bowel lymphoma, carcinoid, and jejunal diverticula. Neuroendocrine tumors may be localized using somatostatin receptor scintigraphy.

Treatment

A number of antidiarrheal agents may be used in certain patients with chronic diarrheal conditions and are listed below. Opioids are safe in most patients with chronic, stable symptoms.

Loperamide: 4 mg initially, then 2 mg after each loose stool (maximum: 16 mg/d).

Diphenoxylate with atropine: one tablet three or four times daily as needed.

Codeine and deodorized tincture of opium: Because of potential habituation, these drugs are avoided except in cases of chronic, intractable diarrhea. Codeine may be given in a dosage of 15-60 mg every 4 hours; tincture of opium, 10-25 drops every 6 hours as needed.

Clonidine: α_2 -Adrenergic agonists inhibit intestinal electrolyte secretion. Clonidine, 0.1-0.6 mg twice daily, or a clonidine patch, 0.1-0.2 mg/d, may help in some patients with secretory diarrheas, diabetic diarrhea, or cryptosporidiosis.

Octreotide: This somatostatin analog stimulates intestinal fluid and electrolyte absorption and inhibits intestinal fluid secretion and the release of gastrointestinal peptides. It is given for secretory diarrheas due to neuroendocrine tumors (VIPomas, carcinoid) and in some cases of AIDS-related diarrhea. Effective doses range from 50 to 250 ug subcutaneously three times daily.

Cholestyramine: This bile salt-binding resin may be useful in patients with bile salt-induced diarrhea secondary to intestinal resection or ileal disease. A dosage of 4 g once to three times daily is recommended.

GASTROINTESTINAL BLEEDING

1. Acute Upper Gastrointestinal Bleeding

Essentials of Diagnosis

- Hematemesis (bright red blood or "coffee grounds").
- Melena in most cases; hematochezia in massive upper gastrointestinal bleeds.
- Volume status to determine severity of blood loss; hematocrit is a poor early indicator of blood loss.
- Endoscopy diagnostic and may be therapeutic.

General Considerations

There are over 350,000 hospitalizations a year in the United States for acute upper gastrointestinal bleeding, with a mortality rate of 10%. Approximately half of patients are over 60 years of age, and in this age group the mortality rate is even higher. Patients seldom die of exsanguination but rather from complications of an underlying disease.

The most common presentation of upper gastrointestinal bleeding is hematemesis or melena. Hematemesis may be either bright red blood or brown "coffee grounds" material. Melena develops after as little as 50-100 mL of blood loss in the upper gastrointestinal tract, whereas hematochezia requires a loss of more than 1000 mL. Although hematochezia generally suggests a lower bleeding source (eg, colonic), upper gastrointestinal bleeding may present with hematochezia in 10% of cases.

Upper gastrointestinal bleeding is self-limited in 80% of patients; urgent medical therapy and endoscopic evaluation are obligatory in the rest. Patients with bleeding more than 48 hours prior to presentation have a low risk of recurrent bleeding.

Etiology

Acute upper gastrointestinal bleeding may originate from a number of sources. These are listed in order of the frequency and discussed in detail below.

A. Peptic Ulcer Disease

Peptic ulcers account for half of major upper gastrointestinal bleeding with an overall acute mortality rate of 6-10%. However, in North America the incidence of bleeding from ulcers is declining, perhaps due to eradication of *Helicobacter pylori*, use of safer nonsteroidal anti-inflammatory drugs, and prophylaxis with proton pump inhibitors in high-risk patients.

B. Portal Hypertension

Portal hypertension causes bleeding from varices (most commonly esophageal; rarely, gastric or duodenal) or portal hypertensive gastropathy. Less than one-third of patients with portal hypertension and varices will develop acute bleeding. However, these lesions account for 10-20% of significant gastrointestinal hemorrhages, with a hospital mortality rate of 15-40%. If untreated, half will rebleed during hospitalization. A mortality rate of 60-80% is expected at 1-4 years. Bleeding from the gastric mucosa in portal hypertensive gastropathy is responsible for 20% of cases of upper gastrointestinal bleeding in patients with cirrhosis.

C. Mallory-Weiss Tears

Lacerations of the gastroesophageal junction cause 5-10% of cases of upper gastrointestinal bleeding. Many patients report a history of heavy alcohol use or retching. Less than 10% have continued or recurrent bleeding.

D. Vascular Anomalies

Vascular anomalies are found throughout the gastrointestinal tract and may be the source of chronic or acute gastrointestinal bleeding. They account for 7% of cases of acute upper tract bleeding. **Vascular ectasias** (angiodysplasias) have a bright red stellate appearance. They may be part of systemic conditions (hereditary hemorrhagic telangiectasia, CREST syndrome) or may occur sporadically. There is an increased incidence in patients with chronic renal failure.

E. Gastric Neoplasms

Gastric neoplasms result in 1% of upper gastrointestinal hemorrhages.

F. Erosive Gastritis

Because this process is superficial, it is a relatively unusual cause of severe gastrointestinal bleeding (< 5% of cases) and more commonly results in chronic blood loss. Gastric mucosal erosions are due to NSAIDs, alcohol, or severe medical or surgical illness (stress gastritis).

G. Erosive Esophagitis

Severe erosive esophagitis due to chronic gastroesophageal reflux may rarely cause significant upper gastrointestinal bleeding.

H. Others

An aortoenteric fistula complicates 2% of abdominal aortic grafts or can occur as the initial presentation of a previously untreated aneurysm. Usually located between the graft or aneurysm and the third portion of the duodenum, these fistulas characteristically present with a herald nonexsanguinating initial hemorrhage, with melena and hematemesis, or with chronic intermittent bleeding. The diagnosis may be suspected by upper endoscopy or abdominal CT. Surgery is mandatory to prevent

exsanguinating hemorrhage; patients are at very high risk, especially those with graft-enteric fistulas in whom graft infection is always present. Other rare causes of upper gastrointestinal bleeding include hemobilia (from hepatic tumor, angioma, penetrating trauma), pancreatic malignancy, pseudoaneurysm (hemosuccus pancreaticus), and Dieulafoy's lesion (aberrant gastric submucosal artery).

Initial Evaluation & Management

A. Stabilization

The initial step is assessment of the hemodynamic status. A systolic blood pressure less than 100 mm Hg (irrespective of heart rate) identifies a high-risk patient with severe acute bleeding. A heart rate over 100/min with a systolic blood pressure over 100 mm Hg signifies moderate acute blood loss. A normal systolic blood pressure and heart rate suggests relatively minor hemorrhage. Postural hypotension and tachycardia are useful when present but may be due to causes other than blood loss. Because the hematocrit may take 24-72 hours to equilibrate with the extravascular fluid, it is not a reliable indicator of the severity of acute bleeding.

In patients with significant bleeding, two 18-gauge or larger intravenous lines should be started prior to further diagnostic tests. Blood is sent for complete blood count, prothrombin time with INR, serum creatinine, liver enzymes and serologies, and cross-matching for 2-4 units or more of packed red blood cells. In patients without hemodynamic compromise or overt active bleeding, aggressive fluid repletion can be delayed until the extent of the bleeding is further clarified. Patients with evidence of hemodynamic compromise are given 0.9% saline or lactated Ringer's injection and cross-matched blood. It is rarely necessary to administer type-specific or O-negative blood. Central venous pressure monitoring is desirable in some cases, but line placement should not interfere with rapid volume resuscitation.

A nasogastric tube should be placed in all patients with suspected upper tract bleeding. The aspiration of red blood or "coffee grounds" confirms an upper gastrointestinal source of bleeding, though 10% of patients with confirmed upper tract sources of bleeding have nonbloody aspirates—especially when bleeding originates in the duodenum. An aspirate of bright red blood indicates active bleeding and is associated with the highest risk of further bleeding, and complications, while a clear aspirate identifies patients at lower initial risk. Efforts to stop or slow bleeding by gastric lavage with large volumes of fluid are of no benefit and expose the patient to an increased risk of aspiration. Periodic reaspiration of the nasogastric tube serves as an indicator of ongoing bleeding or rebleeding.

B. Blood Replacement

The amount of fluid and blood products required is based upon assessment of vital signs, evidence of active bleeding from nasogastric aspirate, and laboratory tests. Sufficient packed red blood cells should be given to maintain a hematocrit of 25-30%. In the absence of continued bleeding, the hematocrit should rise 3% for each unit of transfused packed red cells. Transfusion of blood should not be withheld from patients with brisk active bleeding regardless of the hematocrit. It is desirable to transfuse blood in anticipation of the nadir hematocrit. In actively bleeding patients, platelets are transfused if the platelet count is under 50,000/uL and considered if there is impaired platelet function due to aspirin use (regardless of the platelet count). Uremic patients (who also have dysfunctional platelets) with active bleeding are given three doses of desmopressin (DDAVP), 0.3 ug/kg intravenously, at 12-hour intervals. Fresh frozen plasma is administered for actively bleeding patients with a coagulopathy and an INR > 1.5. The INR is intended to guide warfarin therapy and is not a reliable marker of bleeding risk in the setting of liver disease. In the face of massive bleeding, 1 unit of fresh frozen plasma should be given for each 5 units of packed red blood cells transfused.

C. Initial Triage

A preliminary assessment of risk based upon several clinical factors aids in the resuscitation as well as the rational triage of the patient.

1. Very low risk—Reliable patients without serious comorbid medical illnesses or advanced liver disease who have normal hemodynamics, no evidence of overt bleeding (hematemesis or melena) within 48 hours, a negative nasogastric lavage, and normal laboratory tests do not require hospital admission and can undergo further evaluation as outpatients as indicated.

2. Low to moderate risk—Patients in this category are admitted after appropriate stabilization for further evaluation and treatment. In some centers, these patients undergo urgent upper endoscopy in order to help decide appropriate triage. Based upon the findings at endoscopy, patients deemed at endoscopy to be at low risk of rebleeding may be discharged and followed as outpatients. In other centers, patients without evidence of active bleeding are admitted to the hospital and undergo elective endoscopy usually within 24 hours.

3. High risk—Patients with active bleeding manifested by hematemesis or bright red blood on nasogastric aspirate, an estimated loss of more than 5 units of blood, persistent hemodynamic derangement despite fluid resuscitation, serious comorbid medical illness, or evidence of advanced liver disease require ICU admission.

Subsequent Evaluation & Treatment

Specific treatment of the various causes of upper gastrointestinal bleeding is discussed elsewhere in this chapter. The following general comments apply to most patients with bleeding:

A. History and Physical Examination

The physician's impression of the bleeding source is correct in only 40% of cases. Signs of chronic liver disease implicate bleeding due to portal hypertension, but a different lesion is identified in 25-50% of patients with cirrhosis. A history of dyspepsia, NSAID use, or peptic ulcer disease suggests peptic ulcer. Acute bleeding preceded by heavy alcohol ingestion or retching suggests a Mallory-Weiss tear, though most of these patients have neither.

B. Upper Endoscopy

Virtually all patients with upper tract bleeding should undergo upper endoscopy, performed after the patient is hemodynamically stable, usually within 12 hours after admission. High-risk patients or those with continued active bleeding require more urgent endoscopic evaluation. The benefits of endoscopy in this setting are threefold.

1. To identify the source of bleeding—The appropriate acute and long-term medical therapy is determined by the cause of bleeding. Patients with portal hypertension will be treated differently from those with ulcer disease. If surgery is required for uncontrolled bleeding, the source of bleeding as determined at endoscopy will determine the approach.

2. To determine the risk of rebleeding—Patients with a nonbleeding Mallory-Weiss tear, esophagitis, gastritis, and ulcers that have a clean, white base have a very low risk of rebleeding. It may be safe and cost-effective to discharge such patients from the emergency room without admission. Patients with ulcers that are actively bleeding or have a visible vessel or who have variceal bleeding require initial management in an ICU setting.

3. To render endoscopic therapy—Hemostasis can be achieved in actively bleeding lesions with endoscopic modalities such as cautery or injection. About 90% of actively bleeding varices can be effectively treated acutely with injection of a sclerosant or application of a rubber band to the bleeding varix. Similarly, 90% of actively bleeding ulcers, angiomas, or Mallory-Weiss tears can be controlled with either injection of epinephrine or direct cauterization of the vessel by a heater probe or multipolar electrocautery probe. Certain nonbleeding lesions such as esophageal varices, ulcers with visible blood vessels, and angiomas are also treated with these therapies. Specific endoscopic therapy of varices, peptic ulcers, and Mallory-Weiss tears is dealt with elsewhere in this chapter.

C. Acute Pharmacologic Therapies

1. Acid inhibitory therapy—H₂ receptor antagonists do not stop acute bleeding or reduce the incidence of rebleeding. Intravenous proton pump inhibitors (omeprazole or pantoprazole, 80 mg bolus, followed by 8 mg/h continuous infusion for 72 hours) reduce the risk of rebleeding in patients with peptic ulcers with high-risk features (active bleeding, visible vessel, or adherent clot) after endoscopic treatment. High doses of oral proton pump inhibitors (omeprazole 40 mg or lansoprazole 60 mg, twice daily for 5 days) may also be effective. Pending the results of endoscopic examination, it may be reasonable to initiate therapy with a high-dose proton pump inhibitor (intravenously or orally) in patients with suspected peptic ulcer bleeding.

2. Octreotide—Continuous intravenous infusion of octreotide (100-ug bolus, followed by 50-100 ug/h) reduces splanchnic blood flow and portal blood pressures and is effective in the initial control of bleeding related to portal hypertension. It is administered promptly to all patients with active upper gastrointestinal bleeding and evidence of liver disease or portal hypertension until the source of bleeding can be determined by endoscopy.

3. Vasopressin—Intravenous vasopressin is not used in the treatment of upper gastrointestinal bleeding. Octreotide has superior efficacy and is virtually devoid of short-term side effects.

D. Other Treatment

1. Intra-arterial embolization or vasopressin—Angiographic treatment is used rarely in patients with persistent bleeding from ulcers, angiomas, or Mallory-Weiss tears who have failed endoscopic therapy and are poor operative risks.

2. Transvenous intrahepatic portosystemic shunts (TIPS)—Placement of a wire stent from the hepatic vein through the liver to the portal vein provides effective decompression of the portal venous system and control of acute variceal bleeding. It is indicated in patients in whom endoscopic modalities have failed to control acute variceal bleeding.

2. Acute Lower Gastrointestinal Bleeding

Essentials of Diagnosis

- Hematochezia usually present.
- Ten percent of cases of hematochezia due to upper gastrointestinal source.
- Evaluation with colonoscopy in stable patients.
- Massive active bleeding calls for evaluation with sigmoidoscopy, upper endoscopy, angiography, or nuclear bleeding scan.

General Considerations

Lower gastrointestinal bleeding is defined as that arising below the ligament of Treitz, ie, the small intestine or colon; however, over 95% of cases arise from the colon. The severity of lower gastrointestinal bleeding ranges from mild anorectal bleeding to massive, large-volume hematochezia. Bright red blood that drips into the bowl after a bowel movement or is mixed with solid brown stool signifies mild bleeding, usually from an anorectosigmoid source, and can be evaluated in the outpatient setting. Serious lower gastrointestinal bleeding is more common in older men. In patients hospitalized with gastrointestinal bleeding, lower tract bleeding is one-fourth as common as upper gastrointestinal hemorrhage and tends to have a more benign course. Patients hospitalized with lower gastrointestinal tract bleeding are less likely to present with shock or orthostasis (< 20%) or to require transfusions (< 40%). Spontaneous cessation of bleeding occurs in over 85% of cases, and hospital mortality is less than 3%.

Etiology

The cause of these lesions is dependent upon both the age of the patient and the severity of the bleeding. In patients under 50 years of age, the most common causes are infectious colitis, anorectal disease, and inflammatory bowel disease. In older patients, significant hematochezia is most often seen with diverticulosis, vascular ectasias, malignancy, or ischemia. In 20% of acute bleeding episodes, no source of bleeding can be identified.

A. Diverticulosis

Hemorrhage occurs in 3-5% of all patients with diverticulosis and is the most common cause of major lower tract bleeding, accounting for 50% of cases. A significant percentage of cases are associated with the use of nonsteroidal anti-inflammatory agents. Although diverticula are more prevalent on the left side of the colon, bleeding more commonly originates on the right side. Diverticular bleeding usually presents as acute, painless, large-volume maroon or bright red hematochezia in patients over age 50. More than 95% of cases require less than 4 units of blood transfusion. Bleeding subsides spontaneously in 80% but may recur in up to 25% of patients.

B. Vascular Ectasias

Vascular ectasias (or angiodysplasias) occur throughout the upper and lower intestinal tracts and cause painless bleeding ranging from melena or hematochezia to occult blood loss. They are responsible for 5-10% of cases of lower gastrointestinal bleeding, where they are most often seen in the cecum and ascending colon. They are flat, red lesions (2-10 mm) with ectatic peripheral vessels radiating from a central vessel, and are most common in patients over 70 and in those with chronic renal failure. Bleeding in younger patients more commonly arises from the small intestine.

Most colonic ectasias are degenerative lesions that are felt to arise from chronic colonic mucosal contraction obstructing venous mucosal drainage. Over time, the mucosal capillaries dilate and become incompetent. The cause of gastric and small intestinal ectasias is unknown. Some are congenital, part of an inherited syndrome such as hereditary hemorrhagic telangiectasia, or related to autoimmune disorders, typically scleroderma. Ectasias can be identified in up to 25% of subjects over age 60, so their mere presence does not prove that the lesion is the source of bleeding, as active bleeding is seldom seen.

C. Neoplasms

Benign polyps and carcinoma are associated with chronic occult blood loss or intermittent anorectal hematochezia. However, colonic neoplasms may cause up to 10% of acute lower gastrointestinal hemorrhage. After endoscopic removal of colonic polyps, important bleeding may occur up to 2 weeks later in 0.3% of patients. Delayed bleeding can be managed conservatively (ie, without repeat colonoscopy) in 70% of cases.

D. Inflammatory Bowel Disease

Patients with inflammatory bowel disease (especially ulcerative colitis) often have diarrhea with variable amounts of hematochezia. Bleeding varies from occult blood loss to recurrent hematochezia usually mixed with stool. Symptoms of abdominal pain, tenesmus, and urgency are often present.

E. Anorectal Disease

Anorectal disease commonly results in small amounts of bright red blood noted on the toilet paper, streaking of the stool, or dripping into the toilet bowl. The bleeding is slight and seldom results in significant blood loss. Painless bleeding is commonly caused by internal hemorrhoids. Bleeding associated with pain during bowel movements suggests an anal fissure.

F. Ischemic Colitis

This entity is seen commonly in older patients, most of whom have atherosclerotic disease. Most cases occur spontaneously due to transient episodes of nonocclusive ischemia. Ischemic colitis may also occur in 5% of patients after surgery for ileoaortic or abdominal aortic aneurysm. Young patients may develop colonic ischemia due to vasculitis, coagulation disorders, estrogen therapy, and long distance running. Ischemic colitis results in hematochezia or bloody diarrhea associated with mild cramps. In most, the bleeding is mild and self-limited.

G. Others

Radiation-induced proctitis causes anorectal bleeding that may develop months to years after pelvic radiation. Endoscopy reveals multiple rectal telangiectasias. Acute infectious colitis (see Acute Diarrhea, above) commonly causes bloody diarrhea. Rare causes of lower tract bleeding include vasculitic ischemia, solitary rectal ulcer, NSAID-induced ulcers in the small bowel or right colon, small bowel diverticula, and colonic varices.

Evaluation & Management

The color of the stool helps distinguish upper from lower gastrointestinal bleeding, especially when observed by the physician. Brown stools mixed or streaked with blood predict a source in the rectosigmoid or anus. Large volumes of bright red blood suggest a colonic source; maroon stools imply a lesion in the right colon or small intestine; and black stools (melena) predict a source proximal to the ligament of Treitz. Although 10% of patients admitted with self-reported hematochezia have an upper gastrointestinal source of bleeding (eg, peptic ulcer), bright red blood per rectum occurs uncommonly with upper tract bleeding and almost always in the setting of massive hemorrhage with shock. Painless large-volume bleeding usually suggests diverticular bleeding or vascular ectasias. Bloody diarrhea associated with cramping abdominal pain, urgency, or tenesmus is characteristic of inflammatory bowel disease, infectious colitis, or ischemic colitis.

Important considerations in management include the following.

A. Exclusion of an Upper Tract Source

A nasogastric tube aspirating red blood or dark brown ("coffee grounds") guaiac-positive material strongly implicates an upper gastrointestinal source of bleeding. If blood is not seen and bile is aspirated, an upper source is found in only 1% of patients.

B. Anoscopy and Sigmoidoscopy

In otherwise healthy patients under age 45 with small-volume bleeding, anoscopy and sigmoidoscopy are performed to look for evidence of anorectal disease, inflammatory bowel disease, or infectious colitis. If a lesion is found, no further evaluation is needed immediately unless the bleeding persists or is recurrent. In patients over age 45 with small-volume hematochezia, the entire colon must be evaluated with either colonoscopy or sigmoidoscopy and barium enema, to exclude tumor.

C. Colonoscopy

In order to determine the probable site of bleeding, colonoscopy should be performed within 6-24 hours of admission after adequate resuscitation and colonic lavage in all patients with lower gastrointestinal bleeding that appears to have ceased. For patients with severe or active lower gastrointestinal bleeding, many physicians choose first to obtain a nuclear bleeding scan or angiogram in an attempt to localize the site of active bleeding. Increasingly it is recommended that urgent colonoscopy be performed in patients with severe or ongoing hemorrhage within 1 hour after administration of a rapid, high-volume colonic lavage solution, given until the effluent is clear of blood and clots (GoLYTELY, CoLYTE, NuLYTE, 4-8 L given orally or by nasogastric tube over 3-5 hours). In most cases in which bleeding has stopped, a diagnosis of diverticular hemorrhage is made presumptively after identification of diverticula at colonoscopy with no other source of blood loss. At urgent colonoscopy, the probable site of bleeding can be identified in 70-85% of patients, and a high-risk lesion can be identified and treated in up to 20%.

D. Small Intestine Push Enteroscopy or Capsule Imaging

Less than 5% of acute episodes of lower gastrointestinal bleeding arise from the small intestine, eluding diagnostic evaluation with upper endoscopy and colonoscopy. Because of the difficulty of examining the small intestine and its relative rarity as a source of acute bleeding, evaluation of the small bowel is not usually pursued in patients during the initial episode of acute lower gastrointestinal bleeding. However, the small intestine is investigated in patients with unexplained recurrent hemorrhage of obscure origin. "Push enteroscopy" consists of passage of a long, small-diameter endoscope that may reach from the proximal to the distal jejunum. Vascular ectasias identified within reach of the enteroscope can be cauterized. Likewise, a wireless video capsule device allows video imaging of the entire small bowel. The small capsule (about 2 cm in diameter) is ingested and reaches the small intestine in a matter of hours. Video images are transmitted to a portable recorder. This technique allows identification of vascular ectasias and other bleeding lesions but does not permit precise localization or therapy.

E. Nuclear Bleeding Scans and Angiography

Significant continued bleeding occurs in only 15% of patients but may limit the diagnostic effectiveness of endoscopy. In such patients, either angiographic embolization or surgery may become necessary to control the bleeding. Localization of the site guides the surgical approach. Technetium-labeled red blood cell scanning can detect significant active bleeding and localize it to the small intestine, right colon, or left colon. Because bleeding may be slow or intermittent, less than half of studies are diagnostic, and the accuracy of a positive study is only 78%. Nuclear bleeding studies are more apt to be positive in patients passing bright red or maroon stools at the time of the scan. Selective mesenteric angiography requires more brisk bleeding (0.5-1 mL/min) for a positive result than technetium scans and leads to major complications in up to 3% of patients. Accordingly, angiograms are performed only in patients with hemodynamically significant, ongoing bleeding or positive technetium scans. Localization of an actively bleeding vessel is possible in up to 50%.

Treatment

A. Discontinue Aspirin and NSAIDs

Up to 80% of patients with lower gastrointestinal tract bleeding have recently ingested aspirin or NSAIDs, which may potentiate bleeding through inhibition of platelet function. These agents should be discontinued. Platelet transfusion (3-6 units) should be administered for persistent bleeding.

B. Therapeutic Colonoscopy

Until recently, colonoscopy served a largely diagnostic role in the patient with lower gastrointestinal bleeding. High-risk lesions (eg, diverticulum with active bleeding or a visible vessel, or a vascular ectasia) may now be treated endoscopically with saline or epinephrine injection, cautery (bipolar or heater probe), or application of metallic clips. In severe diverticular hemorrhage with high-risk lesions identified at colonoscopy, rebleeding occurs in half of untreated patients compared with virtually no rebleeding in patients treated endoscopically. Radiation proctitis is effectively treated with applications of cautery therapy to the rectal telangiectasias, preferably with an argon plasma coagulator.

C. Intra-arterial Vasopressin or Embolization

Selective mesenteric arterial infusion of vasoconstrictors (eg, vasopressin) may arrest bleeding in up to 80% of patients with active bleeding from a diverticulum or vascular ectasia, but bleeding recurs in up to 50%. Intra-arterial embolization, which provides definitive control of bleeding in up to 90%, now is preferred by many angiographers. Embolization may be associated with abdominal pain, fever, and ischemic infarction in up to 15%, though use of microcoils appears to be safer than other embolic agents. Embolization may be preferred to surgery in patients with continued bleeding who are poor operative candidates.

D. Surgical Treatment

Surgery is indicated in patients with ongoing bleeding that requires more than 4-6 units of blood within 24 hours or more than 10 total units. Most such hemorrhages are caused by a bleeding diverticulum or vascular ectasia. With increasing experience with urgent colonoscopy and angiographic embolization, the need for surgical treatment appears to be decreasing. Preoperative localization of the bleeding site by nuclear scan or angiography allows limited resection of the bleeding segment of small intestine or colon. When accurate localization is not possible or when emergency surgery is required for massive hemorrhage, total abdominal colectomy with ileorectal anastomosis is required—with significantly higher morbidity and mortality than limited resections.

Surgery may also be indicated in patients with two or more hospitalizations for diverticular hemorrhage depending upon the severity of bleeding and the patient's other comorbid conditions.

3. Occult Gastrointestinal Bleeding

Occult gastrointestinal bleeding is the presence of a positive fecal occult blood test (FOBT) or of iron deficiency anemia in an adult in the absence of visible fecal blood loss. FOBT may be performed in patients with gastrointestinal symptoms or as a screening test for colorectal neoplasia (see Colorectal Cancer Screening, below). From 1-2.5% of patients in screening programs have a positive FOBT.

In the United States, 2% of men and 5% of women have iron deficiency anemia (serum ferritin < 30-45 ug/L). In premenopausal women, iron deficiency anemia is most commonly attributable to menstrual and pregnancy-associated iron loss; however, a gastrointestinal source of chronic blood loss is present in 10%. Among men and postmenopausal women, a potential gastrointestinal cause of blood loss can be identified in the colon in 15-30% and in the upper gastrointestinal tract in 35-55%; a malignancy is present in 10%. Iron deficiency on rare occasions is caused by malabsorption (especially celiac disease) or malnutrition.

Causes of Occult Gastrointestinal Blood Loss

The most common lesions include: (1) neoplasms, (2) vascular abnormalities (vascular ectasias, portal hypertensive gastropathy), (3) acid-peptic lesions, (4) infections (nematodes, especially hookworm; tuberculosis), (5) medications (especially NSAIDs or aspirin), and (6) other causes such as inflammatory bowel disorder or malabsorption disorders. After complete gastrointestinal evaluation with colonoscopy and upper endoscopy, the origin of positive FOBT or iron deficiency anemia remains unexplained in 30-50% of patients.

Evaluation

All adults over age 40-45 with positive FOBTs or iron deficiency anemia should undergo colonoscopy or upper endoscopy. Endoscopic evaluation is also recommended in premenopausal women and younger men with gastrointestinal symptoms (abdominal pain, dyspepsia or heartburn, change in bowel habits, weight loss), a positive family history of gastrointestinal cancer, or anemia that is disproportionate to the estimated menstrual blood loss. The presence and nature of gastrointestinal symptoms help guide the choice of initial study.

A. Colonoscopy

Unless patients have symptoms referable to the upper gastrointestinal tract, the colon should be evaluated first. Colonoscopy detects over 95% of colorectal polyps and cancer and permits polypectomy, tumor biopsy, or endoscopic cautery of vascular ectasias. The finding on colonoscopy of a significant lesion clearly consistent with chronic bleeding (mass lesion, large ulceration, bleeding ectasias) obviates the need for upper endoscopy. Barium enema examinations are less accurate than colonoscopy, missing up to half of significant adenomas. Furthermore, up to 30-40% of patients with a positive FOBT will have a polyp or mass lesion detected on barium enema, which then necessitates colonoscopic evaluation. For these reasons, barium enema can no longer be recommended except in patients in whom colonoscopy is contraindicated or where expertise in colonoscopy is not available.

B. Upper Endoscopy

Upper endoscopy should be performed first in patients with symptoms referable to the upper gastrointestinal tract (heartburn, dyspepsia, dysphagia, vomiting, weight loss). Upper endoscopy should also be performed in patients with iron deficiency anemia after colonoscopy. In asymptomatic patients with a positive FOBT without iron deficiency anemia whose colonoscopic examination is negative, significant abnormalities are found in almost half of patients on upper endoscopy. Although the cost-effectiveness of evaluation of the upper gastrointestinal tract in this setting is uncertain, upper endoscopy is recommended by many experts. Owing to its lower diagnostic accuracy, upper gastrointestinal radiography should be performed only in patients in whom upper endoscopy is contraindicated or where a gastroenterologist is unavailable.

C. Small Intestinal Evaluation

Patients with occult bleeding who have a negative endoscopic evaluation of the colon and upper gastrointestinal tract may be given a trial of iron supplementation and closely observed. Most require no further evaluation. If there is persistent chronic gastrointestinal blood loss or anemia that responds poorly to iron supplementation, further evaluation for a small intestinal source is indicated. Small bowel enteroscopy permits visualization of the upper one-third to one-half of the small intestine for vascular ectasias. If enteroscopy is unrevealing, a small bowel series or enteroclysis is performed to look for mass lesions; however, barium studies cannot identify small intestinal vascular ectasias. The video capsule device described above captures up to 8 hours of video images of the small intestine which are transmitted to a portable recorder for subsequent viewing. Capsule endoscopy appears to be most useful in the detection of small bowel vascular ectasias; its role relative to push enteroscopy is under investigation.

Rarely, angiography or intraoperative endoscopy of the entire small intestine is indicated in patients with transfusion-dependent chronic or recurrent bleeding that cannot be localized by other means.

■ DISEASES OF THE PERITONEUM

APPROACH TO THE PATIENT WITH ASCITES

Etiology of Ascites

The term "ascites" denotes the pathologic accumulation of fluid in the peritoneal cavity. Healthy men have little or no intraperitoneal fluid, but women normally may have up to 20 mL depending on the phase of the menstrual cycle. The causes of ascites may be classified into two broad pathophysiologic categories: that which is associated with a normal peritoneum and that which occurs due to a diseased peritoneum ([Chapter 15](#)). The most common causes of non-portal hypertensive ascites include infections (tuberculous peritonitis), intra-abdominal malignancy, inflammatory disorders of the peritoneum, and ductal disruptions (chylous, pancreatic, biliary).

Clinical Features

A. Symptoms and Signs

The history usually is one of increasing abdominal girth, with the presence of abdominal pain depending on the cause. Because most ascites is secondary to chronic liver disease with portal hypertension, patients should be asked about risk factors for liver disease, especially ethanol consumption, transfusions, tattoos, intravenous drug use, a history of viral hepatitis or jaundice, and birth in an area endemic for hepatitis. A history of cancer or marked weight loss arouses suspicion of malignant ascites. Fevers may suggest infected peritoneal fluid, including bacterial peritonitis (spontaneous or secondary). Patients with chronic liver disease and ascites are at greatest risk of developing spontaneous bacterial peritonitis. In immigrants, immunocompromised hosts, or severely malnourished alcoholics, tuberculous peritonitis should be considered.

Physical examination should emphasize signs of portal hypertension and chronic liver disease. Elevated jugular venous pressure may suggest right-sided congestive heart failure or constrictive pericarditis. A large tender liver is characteristic of acute alcoholic hepatitis or Budd-Chiari syndrome. The presence of large abdominal wall veins with cephalad flow also suggests portal hypertension; inferiorly directed flow implies hepatic vein obstruction. Signs of chronic liver disease include palmar erythema, cutaneous spider angiomas, gynecomastia, and Dupuytren's contracture. Asterix secondary to hepatic encephalopathy may be present. Anasarca results from cardiac failure or nephrotic syndrome with hypoalbuminemia. Finally, firm lymph nodes in the left supraclavicular region or umbilicus may suggest intra-abdominal malignancy.

The physical examination is relatively insensitive for detecting ascitic fluid. In general, patients must have at least 1500 mL of fluid to be detected reliably by this method. Even the experienced clinician may find it difficult to distinguish between obesity and small-volume ascites. Abdominal ultrasound establishes the presence of fluid.

B. Laboratory Testing

1. Abdominal paracentesis—Abdominal paracentesis is performed as part of the diagnostic evaluation in all patients with new onset of ascites to help determine the cause. It should also be performed to diagnose bacterial peritonitis in all patients admitted to the hospital with cirrhosis and ascites (in whom the prevalence of bacterial peritonitis is 10-30%) and when patients with known ascites develop clinical deterioration (fever, abdominal pain, rapid worsening of renal function, or worsened hepatic encephalopathy).

a. Inspection—Cloudy fluid suggests infection. Milky fluid is seen with chylous ascites due to high triglyceride levels. Bloody fluid is most commonly attributable to a traumatic paracentesis, but up to 20% of cases of malignant ascites are bloody.

b. Routine studies—

(1) Cell count—A white blood cell count is the most important test. Normal ascitic fluid contains < 500 leukocytes/uL and < 250 PMNs/uL. Any inflammatory condition can cause an elevated ascitic white count. A polymorphonuclear neutrophil count of > 250/uL (neutrocytic ascites), with a percentage of > 75% of all white cells is highly suggestive of bacterial peritonitis, either spontaneous primary peritonitis or secondary peritonitis (ie, caused by an intra-abdominal source of infection, such as a perforated viscus or appendicitis). An elevated white count with a predominance of lymphocytes arouses suspicion of tuberculosis or peritoneal carcinomatosis.

(2) Albumin and total protein—The serum-ascites albumin gradient (SAAG) is the best single test for the classification of ascites into portal hypertensive and non-portal hypertensive causes ([Table 14-8](#)). Calculated by subtracting the ascitic fluid albumin from the serum albumin, the gradient correlates directly with the portal pressure. An SAAG = 1.1 g/dL suggests underlying portal hypertension, while gradients < 1.1 g/dL implicate non-portal hypertensive causes.

The accuracy of the SAAG exceeds 95% in classifying ascites. It should be recognized, however, that approximately 4% of patients have "mixed ascites," ie, underlying cirrhosis with portal hypertension complicated by a second cause for ascites formation (such as malignancy or tuberculosis). Thus, a high SAAG is indicative of portal hypertension but does not exclude concomitant malignancy.

The ascitic fluid total protein provides some additional clues to the cause. An elevated SAAG and a high protein level (> 2.5 g/dL) are seen in most cases of hepatic congestion secondary to cardiac disease or Budd-Chiari syndrome. However, an increased ascitic fluid protein is also found in up to 20% of cases of uncomplicated cirrhosis. Two-thirds of patients with malignant ascites have a total protein level > 2.5 g/dL.

(3) Culture and Gram stain—The best technique consists of the inoculation of aerobic and anaerobic blood culture bottles with 5-10 mL of ascitic fluid at the patient's bedside, which increases the sensitivity for detecting bacterial peritonitis to over 85% in patients with neutrocytic ascites (> 250 PMNs/uL), compared with approximately 50% sensitivity by conventional agar plate or broth cultures.

c. Optional studies—Other laboratory tests are of utility in some specific clinical situations. Glucose and LDH may be helpful in distinguishing spontaneous from secondary bacterial peritonitis (see below). Glucose levels are reduced in patients with tuberculous peritonitis. An elevated amylase may suggest pancreatic ascites or a perforation of the gastrointestinal tract with leakage of pancreatic secretions into the ascitic fluid. Perforation of the biliary tree is suspected with an ascitic bilirubin concentration that is greater than the serum bilirubin. An elevated ascitic creatinine suggests leakage of urine from the bladder or ureters. Ascitic fluid cytologic examination is ordered if peritoneal carcinomatosis is suspected.

C. Imaging

Abdominal ultrasound is useful in confirming the presence of ascites and in the guidance of paracentesis. Both ultrasound and CT imaging are useful in distinguishing between causes of portal and non-portal hypertensive ascites. Doppler ultrasound and CT can detect thrombosis of the hepatic veins (Budd-Chiari syndrome) or portal veins. In patients with non-portal hypertensive ascites, these studies are useful in detecting lymphadenopathy and masses of the mesentery and of solid organs such as the liver, ovaries, and pancreas. Furthermore, they permit directed percutaneous needle biopsies of these lesions. Ultrasound and CT are poor procedures for the detection of peritoneal carcinomatosis.

D. Laparoscopy

Laparoscopy is an important test in the evaluation of some patients with non-portal hypertensive ascites (low SAAG) or mixed ascites. It permits direct visualization and biopsy of the peritoneum, liver, and some intra-abdominal lymph nodes. Cases of suspected peritoneal tuberculosis or suspected malignancy with nondiagnostic CT imaging and ascitic fluid cytology are best evaluated by this method.

SPONTANEOUS BACTERIAL PERITONITIS

Essentials of Diagnosis

- A history of chronic liver disease and ascites.
- Fever and abdominal pain.
- Peritoneal finding on examination uncommonly encountered.
- Neutrocytic ascites (> 250 WBCs/uL) with neutrophilic predominance.

General Considerations

"Spontaneous" bacterial infection of ascitic fluid occurs in the absence of an apparent intra-abdominal source of infection. It is seen with few exceptions in patients with ascites caused by chronic liver disease. Translocation of enteric bacteria across the gut wall or mesenteric lymphatics leads to seeding of the ascitic fluid, as may bacteremia from other sites. Approximately 20-30% of cirrhotic patients with ascites develop spontaneous peritonitis; however, the incidence is greater than 40% in patients with ascitic fluid total protein < 1 g/dL, probably due to decreased ascitic fluid opsonic activity.

Virtually all cases of spontaneous bacterial peritonitis are caused by a monomicrobial infection. The most common pathogens are enteric gram-negative bacteria (*Escherichia coli*, *Klebsiella pneumoniae*, *Enterococcus* species) or gram-positive bacteria (*Streptococcus pneumoniae*, viridans streptococci). Anaerobic bacteria are not associated with spontaneous bacterial peritonitis.

Clinical Findings

A. Symptoms and Signs

Eighty to 90 percent of patients with spontaneous bacterial peritonitis are symptomatic; in many cases the presentation is subtle. Spontaneous bacterial peritonitis may be present in 20% of patients hospitalized with chronic liver disease in the absence of any suggestive symptoms or signs.

The most common symptoms are fever and abdominal pain, present in two-thirds of patients. Spontaneous bacterial peritonitis may also present with a change in mental status due to exacerbation or precipitation of hepatic encephalopathy, or sudden worsening of renal function. Physical examination typically demonstrates signs of chronic liver disease with ascites. Abdominal tenderness is present in less than half of patients, and its presence suggests other processes.

B. Laboratory Findings

The most important diagnostic test is abdominal paracentesis. Ascitic fluid should be sent for cell count, and blood culture bottles should be inoculated at the bedside; Gram stain is insensitive. An ascitic fluid total protein of more than 1 g/dL is evidence against spontaneous bacterial peritonitis.

In the proper clinical setting, an ascitic fluid PMN count of > 250 cells/uL (neutrocytic ascites) is presumptive evidence of bacterial peritonitis. The percentage of PMNs is greater than 50-70% of the ascitic fluid white blood cells and commonly approximates 100%. Patients with neutrocytic ascites are presumed to be infected and should be started—regardless of symptoms—on antibiotics. Although 10-30% of patients with neutrocytic ascites have negative ascitic bacterial cultures ("culture-negative neutrocytic ascites"), it is presumed nonetheless that these patients have bacterial peritonitis and should be treated empirically. Occasionally, a positive blood culture identifies the organism when ascitic fluid is sterile.

Differential Diagnosis

Spontaneous bacterial peritonitis must be distinguished from secondary bacterial peritonitis, in which ascitic fluid has become secondarily infected by an intra-abdominal infection. Even in the presence of perforation, clinical symptoms and signs of peritonitis may be lacking in up to 30% of patients owing to the separation of the visceral and parietal peritoneum by the ascitic fluid. Causes of secondary bacterial peritonitis include appendicitis, diverticulitis, perforated peptic ulcer, and perforated gallbladder. Secondary bacterial infection accounts for 3% of cases of infected ascitic fluid.

Ascitic fluid total protein, LDH, and glucose are useful in distinguishing spontaneous bacterial peritonitis from secondary infection. Up to two-thirds of patients with secondary bacterial peritonitis have at least two of the following: decreased glucose level (< 50 mg/dL), an elevated LDH level (greater than serum), and total protein > 1 g/dL. Ascitic neutrophil counts > 10,000/uL also are suspicious; however, most patients with secondary peritonitis have neutrophil counts within the range of spontaneous peritonitis. The presence of multiple organisms on ascitic fluid Gram stain or culture is diagnostic of secondary peritonitis.

If secondary bacterial peritonitis is suspected, plain films, abdominal CT imaging, and water-soluble contrast studies of the upper and lower gastrointestinal tracts should be obtained to look for evidence of an intra-abdominal source of infection. If these studies are negative and secondary peritonitis still is suspected, repeat paracentesis should be performed after 48 hours of antibiotic therapy to confirm that the polymorphonuclear neutrophil count is decreasing. Secondary bacterial peritonitis should be suspected in patients in whom the polymorphonuclear neutrophil count is not below the pretreatment value at 48 hours.

Neutrocytic ascites may also be seen in some patients with peritoneal carcinomatosis, pancreatic ascites, or tuberculous ascites. In these circumstances, however, polymorphonuclear neutrophils account for less than 50% of the ascitic white blood cells.

Prevention

Up to 70% of patients who survive an episode of spontaneous bacterial peritonitis will have another episode within 1 year. Prophylactic therapy—with norfloxacin, 400 mg/d, ciprofloxacin, 750 mg weekly, or trimethoprim-sulfamethoxazole, one double-strength tablet daily—has been shown to reduce the rate of recurrent infections to less than 20% and is recommended. Prophylaxis should be considered also in patients who have not had prior bacterial peritonitis but are at increased risk of infection due to low-protein ascites (total ascitic protein < 1 g/dL). Although improvement in survival in cirrhotic patients with ascites treated with prophylactic antibiotics has not been shown, decision analytic modeling suggests that in patients with prior bacterial peritonitis or low ascitic fluid protein, the use of prophylactic antibiotics is a cost-effective strategy.

Treatment

Empirical therapy for spontaneous bacterial peritonitis should be initiated with a third-generation cephalosporin such as cefotaxime (dosage: 2 g intravenously every

8-12 hours depending on renal function), which covers 98% of causative agents of this disorder. If enterococcus infection is suspected, ampicillin may be added. Because of a high risk of nephrotoxicity in patients with chronic liver disease, aminoglycosides should not be used. Although the optimal duration of therapy is unknown, a course of 5 days is sufficient in most patients, or until the ascites fluid polymorphonuclear neutrophil count decreases to < 250 cells/uL. Renal failure develops in up to 40% of patients and is a major cause of death. In patients given intravenous albumin, 1.5 g/kg on day 1 and 1 g/kg on day 3, the incidence of renal failure and mortality is reduced both during hospitalization and at follow-up. Patients with suspected secondary bacterial peritonitis should be given broad-spectrum coverage for enteric aerobic and anaerobic flora with a third-generation cephalosporin and metronidazole pending identification and definitive (usually surgical) treatment of the cause. In fact, the most effective treatment for spontaneous bacterial peritonitis is liver transplant.

Prognosis

The mortality rate of spontaneous bacterial peritonitis exceeds 30%. However, if the disease is recognized and treated early, the rate is less than 10%. As the majority of patients have underlying severe liver disease, many may die of liver failure, hepatorenal syndrome, or bleeding complications from portal hypertension.

TUBERCULOUS PERITONITIS

Tuberculosis occurs in extrapulmonary sites in 10% of non-HIV-infected people and up to 70% of those infected with HIV. Although tuberculous involvement of the peritoneum accounts for less than 2% of all causes of ascites in the United States, it remains a significant problem in the developing world. In Western countries, its incidence is higher among those with HIV disease, immigrants from underdeveloped countries, the urban poor, and nursing home residents.

The presenting symptoms include low-grade fever, abdominal pain, anorexia, and weight loss. Most patients have abdominal swelling with clinically apparent ascites; over 95% have ascites evident on ultrasound examination. In patients without ascites, there may be a doughy consistency to the abdomen. In Western societies, half of patients have underlying cirrhosis and ascites from portal hypertension. In such patients, a diagnosis of tuberculous peritonitis may go unsuspected because symptoms are attributed to the underlying liver disease. A high index of suspicion is required for prompt diagnosis and treatment.

The diagnosis thus can be difficult to establish, particularly in patients with underlying cirrhosis with ascites. Chest radiographs are abnormal in over 70%, but active tuberculous pulmonary disease is evident in less than one-fourth of patients. Skin tests are positive in half. Smears of ascitic fluid for acid-fast bacilli are usually negative, and cultures are positive in only 20%. Other findings are an ascitic fluid total protein > 3.5 g/dL, LDH > 90 units/L, or mononuclear cell-predominant leukocytosis > 500/uL—each has a sensitivity of 70-80% but limited specificity. Although these values have excellent predictive value in patients with isolated tuberculous peritonitis, their accuracy declines in patients with underlying cirrhotic ascites, nephrogenous ascites, malignant ascites (in whom concomitant infection is rare), and pancreatic ascites. Ascitic fluid adenosine deaminase activity, initially believed to be a valuable study, has been shown to have limited predictive value in the presence of cirrhotic ascites.

In patients with suspected tuberculous peritonitis, laparoscopy establishes the diagnosis. In over 90% of patients, characteristic peritoneal nodules are visible, and granulomas are seen on peritoneal biopsy. Ascitic fluid cultures increase in sensitivity to about 85% with high-volume paracenteses. Peritoneal cultures require at least 4-6 weeks and are positive in less than two-thirds of patients.

Treatment of tuberculosis is discussed in [Chapter 9](#). Improvement is noted if laparotomy is performed for diagnostic reasons.

Inadomi J et al: The laparoscopic evaluation of ascites. *Gastrointest Endosc Clin N Am* 2001;11:79. [PMID: 11175976]

MALIGNANT ASCITES

Two-thirds of cases of malignant ascites are caused by peritoneal carcinomatosis. The most common tumors causing carcinomatosis are primary adenocarcinomas of the ovary, uterus, pancreas, stomach, colon, lung, or breast. The remaining one-third are due to lymphatic obstruction or portal hypertension due to hepatocellular carcinoma or diffuse hepatic metastases. Patients present with nonspecific abdominal discomfort and weight loss associated with increased abdominal girth. Nausea or vomiting may be caused by partial or complete intestinal obstruction. Abdominal CT may be useful to demonstrate the primary malignancy or hepatic metastases but seldom confirms the diagnosis of peritoneal carcinomatosis. In patients with carcinomatosis, paracentesis demonstrates a low serum ascites-albumin gradient (< 1.1 mg/dL), an increased total protein (> 2.5 g/dL), and an elevated white cell count (often both neutrophils and mononuclear cells) but with a lymphocyte predominance. Cytology is positive in over 95%, but laparoscopy may be required in patients with negative cytology to confirm the diagnosis and to exclude tuberculous peritonitis, with which it may be confused. Malignant ascites attributable to portal hypertension usually is associated with an increased serum ascites-albumin gradient (> 1.1 g/dL), a variable total protein, and negative ascitic cytology. Ascites caused by peritoneal carcinomatosis does not respond to diuretics.

Patients may be treated with periodic large-volume paracentesis for symptomatic relief. Intraperitoneal chemotherapy is sometimes used to shrink the tumor, but the overall prognosis is extremely poor, with only 10% survival at 6 months. Ovarian cancers represent an exception to this rule. With newer treatments consisting of surgical debulking and intraperitoneal chemotherapy, long-term survival from ovarian cancer is possible.

FAMILIAL MEDITERRANEAN FEVER

This is a rare autosomal recessive disorder of unknown pathogenesis that almost exclusively affects people of Mediterranean ancestry, especially Sephardic Jews, Armenians, Turks, and Arabs. Patients lack a protease in serosal fluids that normally inactivates interleukin-8 and the chemotactic complement factor 5A. Most patients present with symptoms before the age of 20. It is characterized by episodic bouts of acute peritonitis that may be associated with serositis involving the joints and pleura. Peritoneal attacks are marked by the sudden onset of fever, severe abdominal pain, and abdominal tenderness with guarding or rebound tenderness. If left untreated, attacks resolve within 24-48 hours. Because symptoms resemble those of surgical peritonitis, patients may undergo unnecessary exploratory laparotomy. Colchicine, 0.6 mg two or three times daily, has been shown to decrease the frequency and severity of attacks. Secondary amyloidosis (AA protein) with renal or hepatic involvement may occur in 25% of cases and is the main cause of death. Colchicine prevents or arrests further progression of amyloidosis development. In the absence of amyloidosis, the prognosis is excellent. The gene responsible for familial Mediterranean fever (*MEFV*) has been identified and cloned, and the diagnosis can be established by genetic testing.

Drenth J et al: Hereditary periodic fever. *N Engl J Med* 2001; 345:1748. [PMID: 11742050]

MESOTHELIOMA

Primary malignant mesothelioma is a rare tumor. Over 70% of cases have a history of asbestos exposure. Patients present with abdominal pain or bowel obstruction, increased abdominal girth, and small to moderate ascites. The chest x-ray reveals pulmonary asbestosis in over 50%. The ascitic fluid is hemorrhagic, with a low serum-ascites albumin gradient. Cytology is often negative. Abdominal CT may reveal sheet-like masses involving the mesentery and omentum. Diagnosis is made at laparotomy or laparoscopy. The prognosis is extremely poor, but long-term survivors have been described with a combination of radiation therapy and systemic or intraperitoneal chemotherapy.

Sebbag G et al: Results of treatment of 33 patients with peri-toneal mesothelioma. *Br J Surg* 2000;87:1587. [PMID: 11091251]

MISCELLANEOUS PERITONEAL DISEASES

Chylous ascites is the accumulation of lipid-rich lymph in the peritoneal cavity. The ascitic fluid is characterized by a milky appearance with a triglyceride level > 1000 mg/dL. The usual cause in adults is lymphatic obstruction or leakage caused by malignancy, especially lymphoma. Nonmalignant causes include postoperative trauma, cirrhosis, tuberculosis, pancreatitis, and filariasis.

Pancreatic ascites is the intraperitoneal accumulation of massive amounts of pancreatic secretions due either to disruption of the pancreatic duct or to a pancreatic pseudocyst. It is most commonly seen in patients with chronic pancreatitis and complicates up to 3% of cases of acute pancreatitis. Because the pancreatic enzymes are not activated, pain often is absent. The ascitic fluid is characterized by a high protein level (> 2.5 g/dL) but a low SAAG. Ascitic fluid amylase levels are in excess of 1000 units/L. In nonsurgical cases, initial treatment consists of bowel rest, total parenteral nutrition, and octreotide to decrease pancreatic secretion. Persistent leakage

requires treatment with either endoscopic placement of stents into the pancreatic duct or surgical drainage.

Bile ascites is caused most commonly by complications of biliary tract surgery, percutaneous liver biopsy, or abdominal trauma. Unless the bile is infected, bile ascites usually does not cause abdominal pain, fever, or leukocytosis. Paracentesis reveals yellow fluid with a ratio of ascites bilirubin to serum bilirubin greater than 1.0. Treatment is dependent upon the location and rate of bile leakage. Postcholecystectomy cystic duct leaks may be treated with endoscopic sphincterotomy or biliary stent placement to facilitate bile flow across the sphincter of Oddi. Other leaks may be treated with percutaneous drainage by interventional radiologists or with surgical closure.

■ DISEASES OF THE ESOPHAGUS

EVALUATION OF ESOPHAGEAL DISORDERS

Symptoms

Heartburn, dysphagia, and odynophagia virtually always indicate a primary esophageal disorder.

A. Heartburn

Heartburn (pyrosis) is the feeling of substernal burning, often radiating to the neck. Caused by the reflux of acidic (or, rarely, alkaline) material into the esophagus, it is highly specific for gastroesophageal reflux disease.

B. Dysphagia

Difficulties in swallowing may arise from problems in transferring the food bolus from the oropharynx to the upper esophagus (oropharyngeal dysphagia) or from impaired transport of the bolus through the body of the esophagus (esophageal dysphagia). The history usually leads to the correct diagnosis.

1. Oropharyngeal dysphagia—The oropharyngeal phase of swallowing is a complex process requiring elevation of the tongue, closure of the nasopharynx, relaxation of the upper esophageal sphincter, closure of the airway, and pharyngeal peristalsis. A variety of mechanical and neuromuscular conditions can disrupt this process ([Table 14-9](#)). Problems with the oral phase of swallowing cause drooling or spillage of food from the mouth, inability to chew or initiate swallowing, or dry mouth. Pharyngeal dysphagia is characterized by an immediate sense of the bolus catching in the neck, the need to swallow repeatedly to clear food from the pharynx, or coughing or choking during meals. There may be associated dysphonia, dysarthria, or other neurologic symptoms.

2. Esophageal dysphagia—Esophageal dysphagia may be caused by **mechanical lesions** obstructing the esophagus or by **motility disorders** ([Table 14-10](#)). Patients with mechanical obstruction experience dysphagia, primarily for solids. This is recurrent, predictable, and, if the lesion progresses, will worsen as the lumen narrows. Patients with **motility disorders** have dysphagia for both solids and liquids. It is episodic, unpredictable, and nonprogressive.

C. Odynophagia

Odynophagia is sharp substernal pain on swallowing that may limit oral intake. It usually reflects severe erosive disease. It is most commonly associated with infectious esophagitis due to candida, herpesviruses, or cytomegalovirus, especially in immunocompromised patients. It may also be caused by corrosive injury due to caustic ingestions and by pill-induced ulcers.

Diagnostic Studies

A. Upper Endoscopy

Endoscopy is the study of choice for evaluating persistent heartburn, odynophagia, and structural abnormalities detected on barium esophagography. In addition to direct visualization, it allows biopsy of mucosal abnormalities and dilation of strictures.

B. Videoesophagography

Oropharyngeal dysphagia is best evaluated with rapid-sequence videoesophagography.

C. Barium Esophagography

Patients with esophageal dysphagia often are evaluated first with a radiographic barium study to differentiate between mechanical lesions and motility disorders, providing important information about the latter in particular. In patients in whom there is a high suspicion of a mechanical lesion, many clinicians will proceed first to endoscopic evaluation without a barium study. In patients with esophageal dysphagia and a suspected motility disorder, barium esophagoscopy should be obtained first.

D. Esophageal Manometry

Esophageal motility may be assessed using manometric techniques. They are indicated (1) to determine the location of the lower esophageal sphincter to allow precise placement of a pH probe, (2) to assess peristaltic function in the esophageal body in patients being considered for antireflux surgery, and (3) to establish the diagnosis of achalasia or diffuse esophageal spasm in patients with dysphagia in whom these diagnoses have been first suggested by endoscopy or barium study.

E. Esophageal pH Recording

Esophageal pH may be monitored continuously by means of a small pH probe placed 5 cm above the lower esophageal sphincter. The probe is attached to a portable pH device capable of recording pH for up to 24 hours. The recording provides information about the amount of esophageal acid reflux and on the temporal correlations between symptoms and reflux.

GASTROESOPHAGEAL REFLUX DISEASE

Essentials of Diagnosis

- Heartburn; may be exacerbated by meals, bending, or recumbency.
- Typical uncomplicated cases do not require diagnostic studies.
- Endoscopy demonstrates abnormalities in < 50% of patients.
- Barium esophagography seldom helpful.

General Considerations

Gastroesophageal reflux disease affects 20% of adults, who report at least weekly episodes of heartburn, and up to 10% complain of daily symptoms. Though most patients have mild disease, up to 50% develop esophageal mucosal damage (reflux esophagitis) and a few develop more serious complications. Several factors may contribute to gastroesophageal reflux disease.

A. Incompetent Lower Esophageal Sphincter

The antireflux barrier at the gastroesophageal junction is dependent upon intrinsic lower esophageal sphincter pressure, the intra-abdominal location of the sphincter, and the extrinsic compression of the sphincter by the crural diaphragm. In most patients, baseline lower esophageal sphincter pressures are normal (10-30 mm Hg). In patients without hiatal hernias, about 70% of reflux episodes occur during relaxations of the lower esophageal sphincter that occur spontaneously ("transient relaxations") or as prolonged relaxation after swallowing. The remaining events occur during periods of low sphincter pressure ("hypotensive" sphincter). A small number of patients with more severe involvement (especially those with strictures) have chronically incompetent sphincters (< 10 mm Hg), resulting in free reflux or stress reflux during lifting, bending, or abdominal straining.

B. Hiatal Hernia

Hiatal hernias are common and usually cause no symptoms. In patients with gastroesophageal reflux, however, they are associated with higher amounts of acid reflux and delayed esophageal acid clearance leading to more severe esophagitis, especially Barrett's esophagus. Increased reflux episodes occur during normal swallowing-induced relaxation, periods of sphincter hypotension, and straining due to reflux of acid from the hiatal hernia sac into the esophagus.

C. Irritant Effects of Refluxate

Esophageal mucosal damage is related to the potency of the refluxate and the amount of time it is in contact with the mucosa. Acidic gastric fluid (pH < 4.0) is extremely caustic to the esophageal mucosa and is the major injurious agent in the majority of cases. In some patients, reflux of bile or alkaline pancreatic secretions may be contributory.

D. Abnormal Esophageal Clearance

Acid refluxate normally is cleared and neutralized by esophageal peristalsis and salivary bicarbonate. During sleep, swallowing-induced peristalsis is infrequent, prolonging acid exposure to the esophagus. One-third of patients with severe gastroesophageal reflux disease also have diminished peristaltic clearance. Certain medical conditions such as scleroderma are associated with diminished peristalsis. Sjogren's syndrome, anticholinergic medications, and oral radiation therapy may exacerbate gastroesophageal reflux disease due to impaired salivation.

E. Delayed Gastric Emptying

Impaired gastric emptying due to gastroparesis or partial gastric outlet obstruction potentiates gastroesophageal reflux disease.

Clinical Findings

A. Symptoms and Signs

The typical symptom is heartburn. This most often occurs 30-60 minutes after meals and upon reclining. Patients often report relief from taking antacids or baking soda. When this symptom is dominant, the diagnosis is established with a high degree of reliability. Many patients, however, have less specific dyspeptic symptoms with or without heartburn. Overall, a clinical diagnosis of gastroesophageal reflux has a sensitivity of 80% but a specificity of only 70%. Severity is not correlated with the degree of tissue damage. In fact, some patients with severe esophagitis are only mildly symptomatic. Patients may complain of regurgitation—the spontaneous reflux of sour or bitter gastric contents into the mouth. Less common symptoms include dysphagia, which may be due to abnormal peristalsis or the development of complications such as stricture or Barrett's metaplasia.

"Atypical" manifestations of gastroesophageal disease are being recognized with increasing frequency. These include asthma, chronic cough, chronic laryngitis, sore throat, and noncardiac chest pain. Gastroesophageal reflux may be either a causative or an exacerbating factor in up to 50% of these patients, especially those with refractory symptoms. Because many of these patients do not have heartburn or regurgitation, the diagnosis often is overlooked.

Physical examination and laboratory data are normal in uncomplicated disease.

B. Special Examinations

Uncomplicated patients with typical symptoms of heartburn and regurgitation may be treated empirically for 4 weeks for gastroesophageal reflux disease without the need for diagnostic studies. Further investigation is required in patients with complicated disease and those unresponsive to empirical therapy.

1. Upper endoscopy—Upper endoscopy with biopsy is the standard procedure for documenting the type and extent of tissue damage in gastroesophageal reflux. Fifty percent of patients with proved acid reflux will have visible mucosal abnormalities such as erythema and friability of the squamocolumnar junction and erosions, known as reflux esophagitis. However, endoscopy is normal in up to half of symptomatic patients and does not exclude mild disease. Esophageal abnormalities are graded on a scale of I (mild) to IV (severe erosions, stricture, or Barrett's esophagus). Initial medical therapy for gastroesophageal reflux disease is guided by the presence of symptoms, not the endoscopic findings. Hence, endoscopy is not warranted for most patients with typical symptoms suggesting uncomplicated reflux disease. Endoscopy should be performed in patients whose symptoms have not responded after initial empirical therapy and patients with symptoms suggesting complicated disease (dysphagia, odynophagia, occult or overt bleeding, or iron deficiency anemia). Endoscopy also may be warranted in patients with long-standing symptoms (over 5 years) or patients requiring continuous maintenance therapy, to look for Barrett's esophagus.

2. Barium esophagography—This study plays a limited role. In patients with severe dysphagia, it is sometimes obtained prior to endoscopy to identify a stricture.

3. Ambulatory esophageal pH monitoring—Ambulatory pH monitoring is the best study for documenting acid reflux, but it is unnecessary in most patients. It most commonly is used to measure acid reflux in the distal esophagus (5 cm above the lower esophageal sphincter) by means of a transnasal catheter attached to a recording device or a wireless probe which is affixed to the esophagus and transmits data to a pager-sized receiver. Dual-channel transnasal probes are sometimes used to measure reflux in the proximal esophagus or hypopharynx in patients with atypical reflux symptoms, especially laryngitis, cough, and asthma. Esophageal pH monitoring is indicated in the following situations: (1) to document abnormal esophageal acid exposure in a patient being considered for antireflux surgery who has a normal endoscopy (ie, no evidence of reflux esophagitis), (2) to evaluate patients with a normal endoscopy who have reflux symptoms unresponsive to therapy with a proton pump inhibitor, (3) to detect either abnormal amounts of reflux or an association between reflux episodes and atypical symptoms such as noncardiac chest pain, asthma, chronic cough, laryngitis, and sore throat. It is recommended that most patients with atypical symptoms first be given an empirical trial of antireflux therapy with a double-dose proton pump inhibitor for 2-3 months. If symptoms fail to improve, a pH study is then performed. Recently, devices have become available to measure nonacidic esophageal reflux (impedance monitoring to measure gas and liquid reflux; bilirubin probes to assess bile reflux). The clinical role of these techniques has not yet been established.

Differential Diagnosis

Symptoms of gastroesophageal reflux disease may be similar to those of other diseases such as esophageal motility disorders, peptic ulcer, cholelithiasis, nonulcer dyspepsia, and angina pectoris. Reflux erosive esophagitis may be confused with pill-induced damage, radiation esophagitis, or infections (CMV, herpes, candida).

Complications

A. Barrett's Esophagus

This is a condition in which the squamous epithelium of the esophagus is replaced by metaplastic columnar epithelium containing goblet and columnar cells (specialized intestinal metaplasia). Present in up to 10% of patients with chronic reflux, it arises from chronic reflux-induced injury to the esophageal squamous epithelium. Barrett's esophagus is suspected at endoscopy from the presence of orange, gastric type epithelium that extends upward from the stomach into the distal tubular esophagus in a tongue-like or circumferential fashion. Biopsies obtained at endoscopy confirm the diagnosis. Three types of columnar epithelium may be identified: gastric cardiac, gastric fundic, and specialized intestinal metaplasia. Only the latter is believed to carry an increased risk of neoplasia.

Barrett's esophagus does not provoke specific symptoms but gastroesophageal reflux does. Most patients have a long history of reflux symptoms, such as heartburn and regurgitation. Dysphagia due to impaired motility is common. Paradoxically, one-third of patients report minimal or no symptoms of gastroesophageal reflux disease, suggesting decreased acid sensitivity of Barrett's epithelium. Indeed, over 90% of individuals with Barrett's esophagus in the general population do not seek medical attention. Barrett's esophagus may be complicated by stricture formation or acid-peptic ulceration, which can bleed.

Barrett's esophagus should be treated with long-term proton pump inhibitors. Surgical fundoplication may be desirable in some situations. Medical or surgical therapy may prevent progression, but there is no convincing evidence that regression occurs in most patients. Endoscopic ablation of Barrett's epithelium with cautery probes or photodynamic therapy (using photosensitizers and laser energy) has anecdotally resulted in partial or complete regression of columnar epithelium.

The most serious complication of Barrett's esophagus is esophageal adenocarcinoma, which has an estimated annual incidence of 0.8%, representing a 40-fold risk compared with patients without Barrett's esophagus. Virtually all adenocarcinomas of the esophagus and many such tumors of the gastric cardia arise from Barrett's metaplasia. Thus, patients with Barrett's esophagus who are operative candidates undergo endoscopic surveillance with mucosal biopsies every 2-3 years. Patients with low-grade dysplasia are treated with aggressive medical management and endoscopic surveillance every 6-12 months. The management of high-grade dysplasia is controversial. Since 30-40% may progress to (or already contain) invasive adenocarcinoma, esophagectomy is usually recommended. Otherwise, photodynamic ablation or endoscopic mucosal resection may be considered. Because of the risks of surgery in patients who are elderly or have comorbidities, close endoscopic surveillance every 3-6 months with biopsy may also be considered, reserving surgery or alternative therapies for treatment of proven intramucosal or invasive adenocarcinoma.

Barrett's epithelium of any length carries an increased risk of neoplasia. Although a clinical distinction is sometimes made between "short-segment" (< 3 cm length) and long-segment Barrett's esophagus, both warrant periodic endoscopic surveillance. Specialized intestinal metaplasia is present at the gastroesophageal junction in up to 20% of patients undergoing endoscopy in the absence of visible Barrett's esophagus, but the significance of this entity is unclear.

B. Peptic Stricture

Stricture formation occurs in about 10% of patients with esophagitis. It is manifested by the gradual development of solid food dysphagia progressive over months to

years. Often there is a reduction in heartburn because the stricture acts as a barrier to reflux. Most strictures are located at the gastroesophageal junction. Strictures located above this level usually occur with Barrett's metaplasia. Endoscopy with biopsy is mandatory in all cases to differentiate peptic stricture from other benign or malignant causes of esophageal stricture (Schatzki's ring, esophageal carcinoma). Active erosive esophagitis is often present. Up to 90% of symptomatic patients are effectively treated with dilation with flexible weighted bougies (passed under fluoroscopic guidance), graduated polyvinyl catheters passed over a wire placed at the time of endoscopy or fluoroscopically, or balloons passed fluoroscopically or through an endoscope. Dilation is continued over one to several sessions. A luminal diameter of 13-17 mm is usually sufficient to relieve dysphagia. Chronic therapy with a proton pump inhibitor (omeprazole or lansoprazole) is required to decrease the likelihood of stricture recurrence. Some patients require intermittent stricture dilation to maintain luminal patency, but operative management for strictures that do not respond to dilation is seldom required. Refractory strictures may benefit from endoscopic injection of triamcinolone into the stricture.

Treatment

A. Medical Treatment

The goal of treatment is to provide symptomatic relief, to heal esophagitis (if present), and to prevent complications. In the majority of patients with uncomplicated disease, empirical treatment is initiated based upon a compatible history without the need for further confirmatory studies. Patients not responding and those with suspected complications undergo further evaluation with upper endoscopy or esophageal pH recording.

Patients with known erosive esophagitis, complications (such as a peptic stricture or Barrett's esophagus), or suspected atypical manifestations (such as asthma or laryngitis) are treated initially with a proton pump inhibitor (see below). In most other patients, treatment may proceed in the following stepwise fashion.

1. Mild, intermittent symptoms—Gastroesophageal reflux is a lifelong disease that requires lifestyle modifications as well as medical intervention. The best advice is to avoid lying down within 3 hours after meals, the period of greatest reflux. Elevating the head of the bed on 6-inch blocks or a foam wedge to reduce reflux and enhance esophageal clearance is recommended, especially for patients with nocturnal and atypical symptoms. Patients should be advised to avoid acidic foods (tomato products, citrus fruits, spicy foods, coffee) and agents that relax the lower esophageal sphincter or delay gastric emptying (fatty foods, peppermint, chocolate, alcohol, and smoking). Weight loss, avoidance of bending after meals, and reduction of meal size may also be helpful.

Antacids are the mainstay for rapid relief of occasional heartburn; however, their duration of action is less than 2 hours. Many are available over the counter. Those containing magnesium should not be used in renal failure, and patients with this condition should be cautioned appropriately. Gaviscon is an alginate-antacid combination that decreases reflux in the upright position.

All H₂ receptor antagonists are available in over-the-counter formulations: cimetidine 200 mg, ranitidine and nizatidine 75 mg, famotidine 10 mg—all of which are half of the typical prescription strength. When taken for active heartburn, these agents have a delay in onset of at least 30 minutes; antacids provide more immediate relief. However, once these agents take effect, they provide heartburn relief for up to 8 hours. When taken before meals known to provoke heartburn, these agents reduce the symptom. A combination agent containing famotidine 10 mg and antacid (calcium carbonate and magnesium hydroxide) is now available.

2. Moderate symptoms—Uncomplicated patients with typical reflux symptoms that occur several times per week or daily should be treated empirically with an H₂ receptor antagonist or a proton pump inhibitor. Standard twice-daily prescription doses of H₂ receptor antagonists are ranitidine or nizatidine 150 mg, famotidine 20 mg, or cimetidine 400-800 mg. These agents reduce 24-hour acidity by over 60%. Ranitidine and cimetidine are available in less expensive generic formulations. Treatment twice daily affords improvement in up to two-thirds of patients. Given their superior efficacy and once-daily dosing, proton pump inhibitors increasingly are prescribed as first-line therapy for mild to moderate symptoms in preference to beginning with an H₂ receptor antagonist (see below for dosing). However, generic H₂ receptor antagonists are significantly less expensive than proton pump inhibitors and provide effective symptomatic relief in most patients with mild to moderate reflux symptoms.

For patients whose symptoms persist despite 6 weeks of standard doses of H₂ receptor antagonist therapy, continued therapy or an increase in dosage of H₂ receptor antagonists is seldom effective in providing symptom relief. These patients should be treated with a proton pump inhibitor (once daily omeprazole or rabeprazole 20 mg, lansoprazole 30 mg, esomeprazole 20 mg, or pantoprazole 40 mg). The decision to prescribe proton pump inhibitors is based upon the presence of persistent symptoms, not endoscopic findings.

In those who achieve good symptomatic relief with either an H₂ receptor antagonist or a proton pump inhibitor, therapy should be discontinued after 8-12 weeks. Patients whose symptoms relapse may be treated with either continuous or intermittent courses of therapy depending upon symptom frequency and patient preference. Many patients are controlled adequately with intermittent courses of therapy rather than continuous maintenance treatment.

Promotility drugs (metoclopramide, cisapride) reduce reflux by increasing lower esophageal sphincter pressure and enhancing esophageal peristalsis and gastric emptying; however, side effects preclude the use of these agents for reflux disease. Metoclopramide is a dopamine antagonist that may cause neuropsychiatric side effects in up to one-third of patients, limiting it to short-term use only. Cisapride causes QT prolongation, leading to serious cardiac arrhythmias, and has been withdrawn from the market in the United States.

3. Severe symptoms and erosive disease—For patients with severe symptoms and for patients who undergo endoscopy and have documented erosive esophagitis, the optimal initial therapy is a proton pump inhibitor (omeprazole or rabeprazole 20 mg, lansoprazole 30 mg, pantoprazole 20 mg, or esomeprazole 40 mg) once daily. Proton pump inhibitors given once daily provide symptom relief and healing of esophagitis in over 80% and given twice daily provide relief in over 95% of patients—compared with under 50% with standard doses of H₂ receptor antagonists—and are therefore the drugs of choice for severe or erosive disease. Because there appears to be little difference between these agents in efficacy or side-effect profiles, the choice of agent is determined by cost. Esomeprazole, the S-isomer of omeprazole, provides slightly greater inhibition of 24-hour gastric acidity than the other agents, resulting in a small (5%) improvement in esophagitis healing rates compared with other proton pump inhibitors. Approximately 10- 20% of patients fail to achieve symptom relief with a once-daily dose within 2-4 weeks and require a higher dosage (twice-daily) proton pump inhibitor. Therefore, some recommend initiating therapy with a twice-daily dose of proton pump inhibitor, reducing therapy after 2-4 weeks to a once-daily dose. The initial course of therapy is usually 8-12 weeks. As tissue healing correlates well with symptom resolution, repeat endoscopy is warranted in patients only if they fail to respond to once-daily or twice-daily proton pump inhibitor therapy.

After discontinuation of proton pump inhibitor therapy, relapse of symptoms occurs in 80% of patients within 1 year—the majority of relapses occurring within the first 3 months. Therefore, chronic therapy to maintain symptom remission is required in most but not all patients. Patients with severe erosive esophagitis, Barrett's esophagus, or peptic stricture should be maintained on chronic therapy with a proton pump inhibitor at a dose sufficient to provide complete symptom relief. In other patients, a trial off proton pump inhibitors should be considered. Patients with prolonged symptomatic remissions (over 3 months) may be treated effectively with intermittent 4- to 8-week courses of acute proton pump inhibitor therapy. Patients with prompt recurrence of symptoms (within 3 months) require chronic maintenance therapy with either a proton pump inhibitor or an H₂ receptor antagonist. The therapy should be stepped down to the lowest dose that is effective in controlling reflux symptoms.

The maintenance doses of proton pump inhibitors may escalate over time, with over 20% of patients eventually requiring double or triple doses of proton pump inhibitors to control symptoms.

4. Extraesophageal reflux manifestations—Establishing a causal relationship between gastroesophageal reflux and extraesophageal symptoms (eg, asthma, hoarseness, cough) can be difficult. Although ambulatory esophageal pH testing can document the presence of increased acid esophageal reflux, it does not prove a causative connection. A trial of a twice-daily proton pump inhibitor for 2-3 months helps determine whether these symptoms improve after acid suppression.

5. Unresponsive disease—Approximately 10-20% of patients with gastroesophageal reflux symptoms do not respond to once-daily doses of proton pump inhibitors, and 5% do not respond to twice-daily doses. These patients undergo endoscopy prior to escalation of therapy. Patients without endoscopically visible esophagitis should undergo esophageal pH monitoring to determine the amount of esophageal acid reflux and to assess whether the refractory symptoms are truly acid-related. The presence of active erosive esophagitis usually is indicative of inadequate acid suppression and can almost always be treated successfully with higher proton pump inhibitor doses (eg, omeprazole 40 mg twice daily). Breakthrough acid production appears to occur at night in patients with severe disease. A twice-daily proton pump inhibitor (before breakfast and dinner) and a bedtime dose of an H₂ receptor antagonist may be more effective (and less expensive) in controlling nocturnal acid than a proton pump inhibitor given three times daily. Truly refractory esophagitis may be caused by gastrinoma with gastric acid hypersecretion (Zollinger-Ellison syndrome), pill-induced esophagitis, resistance to proton pump inhibitors, and medical noncompliance.

B. Surgical Treatment

Surgical fundoplication affords good to excellent relief of symptoms and healing of esophagitis in over 85% of properly selected patients and may now be performed laparoscopically with low complication rates in most instances. Cost-effectiveness studies suggest that aggregate medical costs exceed surgical costs after 10 years. The longevity of the beneficial effects of fundoplication are debated. Different surgical centers report 10-year success rates ranging from 60% to 90%. However, over half of patients require continued acid-suppression medication after fundoplication. Furthermore, over 30% of patients develop new symptoms of dysphagia, bloating, increased flatulence, or dyspepsia. Surgical treatment is not recommended for patients who are well controlled with medical therapies but should be considered (1) for otherwise healthy patients with extraesophageal manifestations of reflux, as these symptoms often require high doses of proton pump inhibitors and may be more

effectively controlled with antireflux surgery; (2) for those with severe reflux disease who are unwilling to accept lifelong medical therapy due to its expense, inconvenience, or theoretical risks; and (3) for patients with erosive disease who are intolerant of or resistant to proton pump inhibitors.

C. Endoscopic Therapy

There are three endoscopic modalities under investigation for the treatment of mild to moderate gastroesophageal reflux disease. The first uses an endoscopic "sewing machine" to place sutures below the gastroesophageal junction in the region of the gastric cardia, creating a mucosal plication that may mimic a surgical fundoplication. The second employs an intraesophageal balloon catheter from which needle electrodes are inserted through the mucosa and into the muscularis at multiple levels of the distal esophagus and cardia, permitting application of radiofrequency wave current. It is believed that this current may disrupt neural reflex pathways from the stomach to the esophagus, resulting in a decrease in transient relaxations of the lower esophageal sphincter. The third involves injection of endoscopic injection of Plexiglas microspheres to bolster the lower esophageal sphincter. Several serious complications have occurred, including esophageal perforation and death. Use of this therapy is not recommended.

INFECTIOUS ESOPHAGITIS

Essentials of Diagnosis

- Immunosuppressed patient.
- Odynophagia, dysphagia, and chest pain.
- Endoscopy with biopsy establishes diagnosis.

General Considerations

Infectious esophagitis occurs most commonly in immunosuppressed patients. Patients with AIDS, solid organ transplants, leukemia, lymphoma, and those receiving immunosuppressive drugs are at particular risk for opportunistic infections. *Candida albicans*, herpes simplex, and cytomegalovirus are the most common pathogens. Candida infection may occur also in patients who have uncontrolled diabetes and those being treated with systemic corticosteroids, radiation therapy, or systemic antibiotic therapy. Herpes simplex can affect normal hosts, in which case the infection is generally self-limited.

Clinical Findings

A. Symptoms and Signs

The most common symptoms are odynophagia and dysphagia. Substernal chest pain occurs in some patients. Patients with candidal esophagitis are sometimes asymptomatic. Oral thrush is present in only 75% of patients with candidal esophagitis and 25-50% of patients with viral esophagitis and is therefore an unreliable indicator of the cause of esophageal infection. Patients with esophageal CMV infection may have infection at other sites such as the colon and retina. Oral ulcers (herpes labialis) are often associated with herpes simplex esophagitis.

B. Special Examinations

Treatment may be empirical. For diagnostic certainty, endoscopy with biopsy and brushings (for microbiologic and histopathologic analysis) is preferred because of its high diagnostic accuracy. The endoscopic signs of candidal esophagitis are diffuse, linear, yellow-white plaques adherent to the mucosa. Cytomegalovirus esophagitis is characterized by one to several large, shallow, superficial ulcerations. Herpes esophagitis results in multiple small, deep ulcerations.

Treatment

A. Candidal Esophagitis

Treatment depends on the immune status of the patient and the severity of the illness. Topical therapy is used initially in patients with a normal immune system. Options include topical agents (nystatin, 500,000 units "swish and swallow" five times daily; clotrimazole troches, 10 mg dissolved in mouth five times daily) for 7-14 days. Initial therapy for immunocompromised patients (including AIDS) generally is with fluconazole, 100-200 mg/d orally. Ketoconazole should no longer be used because of its lower efficacy, unpredictable absorption, and greater risk of adverse effects. Patients not responding to oral therapy are treated with low-dose amphotericin B, 0.3-0.5 mg/kg/d. The duration of therapy is not standardized.

B. Cytomegalovirus Esophagitis

Initial therapy is with ganciclovir, 5 mg/kg intravenously every 12 hours for 3-6 weeks. Neutropenia is a frequent dose-limiting side effect. If resolution of symptoms occurs, the drug may be discontinued. If the condition has improved but not resolved, full-dose therapy may be continued for an additional 2-3 weeks. In some cases (especially in patients with AIDS), continuous ganciclovir, 5 mg/kg intravenously daily, is required for suppressive therapy. The role of oral ganciclovir in the maintenance treatment of CMV gastrointestinal disease is not established. Patients who either do not respond to or cannot tolerate ganciclovir are treated acutely with foscarnet, 90 mg/kg intravenously every 12 hours for 3-6 weeks. The principal toxicity is renal failure. In patients with HIV infection, immune restoration with highly active antiretroviral therapy (HAART) is the most effective means of controlling CMV disease.

C. Herpetic Esophagitis

Immune-competent patients may be treated symptomatically and generally do not require specific antiviral therapy. Immunosuppressed patients may be treated with oral acyclovir, 200 mg orally five times daily, or 250 mg/m² intravenously every 8-12 hours, usually for 7-10 days. Famciclovir, 250 mg three times daily, and valacyclovir, 1 g twice daily, are effective but significantly more expensive than generic acyclovir. Nonresponders require therapy with foscarnet, 40 mg/kg intravenously every 8 hours for 21 days.

Prognosis

Most patients with infectious esophagitis can be effectively treated with complete symptom resolution. Depending on the patient's underlying immunodeficiency, relapse of symptoms off therapy can raise difficulties. Chronic suppressive therapy is sometimes required.

PILL-INDUCED ESOPHAGITIS

A number of different medications may injure the esophagus, presumably through direct, prolonged mucosal contact. The most commonly implicated are the NSAIDs, potassium chloride pills, quinidine, zalcitabine, zidovudine, alendronate and risedronate, iron, vitamin C, and antibiotics (doxycycline, tetracycline, clindamycin, trimethoprim-sulfamethoxazole). Because injury is most likely to occur if pills are swallowed without water or while supine, hospitalized or bed-bound patients are at greater risk. Symptoms include severe retrosternal chest pain, odynophagia, and dysphagia, often beginning several hours after taking a pill. These may occur suddenly and persist for days. Some patients (especially the elderly) have relatively little pain, presenting with dysphagia. Endoscopy may reveal one to several discrete ulcers that may be shallow or deep. Chronic injury may result in severe esophagitis with stricture, hemorrhage, or perforation. Healing occurs rapidly when the offending agent is eliminated. To prevent pill-induced damage, patients should take pills with 4 oz of water and remain upright for 30 minutes after ingestion. Known offending agents should not be given to patients with esophageal dysmotility, dysphagia, or strictures.

CAUSTIC ESOPHAGEAL INJURY

Caustic esophageal injury occurs from accidental (usually children) or deliberate (suicidal) ingestion of liquid or crystalline alkali (drain cleaners, etc) or acid. Ingestion is followed almost immediately by severe burning and varying degrees of chest pain, gagging, dysphagia, and drooling. Aspiration results in stridor and wheezing. Initial examination should be directed to circulatory status and to prompt assessment of airway patency, including laryngoscopy. Subsequently, chest and abdominal radiographs are obtained looking for pneumonitis or free perforation. Initial treatment is supportive, with intravenous fluids and analgesics. Nasogastric lavage and oral antidotes may be dangerous and should generally not be administered. Most patients may be managed medically. Endoscopy is usually performed within the first 24 hours to assess the extent of injury. Many patients are discovered to have no mucosal injury to the esophagus or stomach, allowing prompt discharge and psychiatric referral. Patients with evidence of mild damage (edema, erythema, exudates, or superficial ulcers) recover quickly, have low risk of developing stricture, and may be advanced from liquids to a regular diet over 24-48 hours. Nasoenteric feedings should be initiated after 24-48 hours and subsequent oral feedings when the patient is tolerating oral secretions. Patients with signs of severe injury—deep or circumferential ulcers or necrosis (black discoloration) have a high risk (up to 65%) of acute complications, including perforation with mediastinitis or peritonitis, bleeding, stricture, or esophageal-tracheal fistulas. These patients must be kept fasting and monitored closely for signs of deterioration that warrant emergency surgery with possible esophagectomy and colonic or jejunal interposition. A nasoenteric feeding tube is placed after 24 hours. Oral feedings of liquids may be initiated after 2-3 days if the patient is able to tolerate secretions. Neither steroids nor antibiotics are recommended. Esophageal strictures develop in up to 70% of patients with serious esophageal injury weeks to months after the initial injury, requiring recurrent dilations. Endoscopic injection of intralesional corticosteroids (triamcinolone 40 mg) increases the interval between dilations. The risk of esophageal squamous carcinoma is 2-3%, warranting endoscopic surveillance 15-20 years after the caustic ingestion.

BENIGN ESOPHAGEAL LESIONS

1. Mallory-Weiss Syndrome (Mucosal Laceration of the Gastroesophageal Junction)

Essentials of Diagnosis

- Hematemesis; usually self-limited.
- Prior history of vomiting, retching in 50%.
- Endoscopy establishes diagnosis.

General Considerations

Mallory-Weiss syndrome is characterized by a nonpenetrating mucosal tear at the gastroesophageal junction which is hypothesized to arise from events that suddenly raise transabdominal pressure, such as lifting, retching, or vomiting. Alcoholism is a strong predisposing factor. Mallory-Weiss tears are responsible for approximately 5% of cases of upper gastrointestinal bleeding.

Clinical Findings

A. Symptoms and Signs

Patients usually present with hematemesis with or without melena. A history of retching, vomiting, or straining is obtained in about 50% of cases.

B. Special Examinations

As with other causes of upper gastrointestinal hemorrhage, upper endoscopy should be performed after the patient has been appropriately resuscitated. The diagnosis is established by identification of a 0.5-4-cm linear mucosal tear usually located either at the gastroesophageal junction or, more commonly, just below the junction in the gastric mucosa.

Differential Diagnosis

At endoscopy, other potential causes of upper gastrointestinal hemorrhage are found in over 35% of patients with Mallory-Weiss tears, including peptic ulcer disease, erosive gastritis, arteriovenous malformations, and esophageal varices. Patients with underlying portal hypertension are at higher risk of continued or recurrent bleeding.

Treatment

Patients are initially treated as needed with fluid resuscitation and blood transfusions. Most patients stop bleeding spontaneously and require no therapy. Endoscopic hemostatic therapy is employed in patients who have continuing active bleeding. Injection with epinephrine (1:10,000) or cautery with a bipolar or heater probe coagulation device is effective in 90-95% of cases. Angiographic arterial embolization or operative intervention is required in patients who fail endoscopic therapy.

Kortas D et al: Mallory-Weiss tear: predisposing factors and predictors of a complicated course. Am J Gastroenterol 2001;96:2863. [PMID: 11693318]

2. Esophageal Webs & Rings

Esophageal webs are thin, diaphragm-like membranes of squamous mucosa that typically occur in the mid or upper esophagus and may be multiple. They may be congenital but also occur with graft-versus-host disease, pemphigoid, epidermolysis bullosa, pemphigus vulgaris, and, rarely, in association with iron deficiency anemia (Plummer-Vinson syndrome). Esophageal "Schatzki" rings are smooth, circumferential, thin (< 4 mm in thickness) mucosal structures located in the distal esophagus at the squamocolumnar junction. Their pathogenesis is controversial. They are associated in nearly all cases with a hiatal hernia, and reflux symptoms are common, suggesting that acid gastroesophageal reflux may be contributory in many cases. Most webs and rings are over 20 mm in diameter and are asymptomatic. Solid food dysphagia most often occurs with rings less than 13 mm in diameter. Characteristically, dysphagia is intermittent and not progressive. Large poorly chewed food boluses such as beefsteak are most likely to cause symptoms. Obstructing boluses may pass by drinking extra liquids or after regurgitation. In some cases, an impacted bolus must be extracted endoscopically. Esophageal webs and rings are best visualized using a barium esophagogram with full esophageal distention. Endoscopy is less sensitive than barium esophagography.

The majority of symptomatic patients with a single ring or web can be effectively treated with the passage of a large (> 16-mm-diameter) bougie dilator to disrupt the lesion. A single dilation may suffice, but repeat dilations are required in many patients. Patients who have heartburn or who require repeated dilation should receive acid suppressive therapy with a chronic proton pump inhibitor.

Eosinophilic esophagitis is an entity that previously was recognized in children but is increasingly identified in young or middle-aged adults with dysphagia and food impactions. Barium swallowing studies may demonstrate a small-caliber esophagus, long and tapered strictures, or multiple concentric rings. Endoscopic appearances include multiple fine concentric rings, vertical furrowing, and whitish papules. Mucosal biopsy demonstrates multiple mucosal eosinophils. Optimal

treatment is uncertain, but dietary restrictions and topical corticosteroids are reported to be beneficial in uncontrolled trials. Graduated dilation of strictures should be conducted cautiously because there is an increased risk of perforation and postprocedural chest pain.

3. Esophageal Diverticula

Zenker's Diverticulum

Zenker's diverticulum is a protrusion of pharyngeal mucosa that develops at the pharyngoesophageal junction between the inferior pharyngeal constrictor and the cricopharyngeus. The cause is believed to be loss of elasticity of the upper esophageal sphincter, resulting in restricted opening during swallowing. Symptoms of dysphagia and regurgitation tend to develop insidiously over years in older patients. Initial symptoms include vague oropharyngeal dysphagia with coughing or throat discomfort. As the diverticulum enlarges and retains food, patients may note halitosis, spontaneous regurgitation of undigested food, nocturnal choking, gurgling in the throat, or a protrusion in the neck. Complications include aspiration pneumonia, bronchiectasis, and lung abscess. The diagnosis is best established by a barium esophagogram.

Symptomatic patients require upper esophageal myotomy and, in most cases, surgical diverticulectomy. Significant improvement occurs in over 90% of patients treated surgically. Small asymptomatic diverticula may be observed.

American Gastroenterology Association medical position statement on management of oropharyngeal dysphagia. *Gastroenterology* 1999;116:452. [PMID: 9922327]

Esophageal Diverticula

Diverticula may occur in the mid or distal esophagus. These may arise secondary to motility disorders (diffuse esophageal spasm, achalasia) or may develop above esophageal strictures. Diverticula are seldom symptomatic, and treatment is directed at the underlying disorder. On rare occasions they may be entered at endoscopy, with the associated risk of perforation.

Ferraro P et al: Esophageal diverticula. *Chest Surg Clin North Am* 1994;4:741. [PMID: 7859008]

4. Benign Esophageal Neoplasms

Benign tumors of the esophagus are quite rare. They are submucosal, the most common being leiomyoma. Most are asymptomatic and picked up incidentally on endoscopy or barium esophagography. Larger lesions can cause dysphagia. The major clinical importance of these lesions is to distinguish them from malignant neoplasms. At endoscopy, a smooth, sessile nodule is observed with normal overlying mucosa. Because the lesion is submucosal, endoscopic biopsies are generally nonrevealing. Endoscopic ultrasonography is extremely helpful to confirm the submucosal origin of the tumor.

5. Esophageal Varices

Essentials of Diagnosis

- Develop secondary to portal hypertension.
- Found in 50% of patients with cirrhosis.
- One-third of patients with varices develop upper gastrointestinal bleeding.
- Diagnosis established by upper endoscopy.

General Considerations

Esophageal varices are dilated submucosal veins that develop in patients with underlying portal hypertension and may result in serious upper gastrointestinal bleeding. The causes of portal hypertension are discussed elsewhere ([Chapter 15](#)). Under normal circumstances, there is a 2-6 mm Hg pressure gradient between the portal vein and the inferior vena cava. When the gradient exceeds 12 mm Hg, significant portal hypertension exists. Esophageal varices are the most common cause of important gastrointestinal bleeding due to portal hypertension, though gastric varices and, rarely, intestinal varices may also bleed. Bleeding from esophageal varices most commonly occurs in the distal 5 cm of the esophagus.

The most common cause of portal hypertension is cirrhosis. While approximately 50% of patients with cirrhosis have esophageal varices, only one-third of patients with varices develop serious bleeding from the varices. Bleeding esophageal varices have a higher morbidity and mortality rate than any other source of upper gastrointestinal bleeding. The mortality rate within 2 weeks after an acute bleeding episode is 30%. Of people who survive beyond 2 weeks, recurrent hemorrhage occurs in 70% within 1 year (half within 6 weeks) and the mortality rate is 60% at 2 years.

A number of factors have been identified that may portend an increased risk of bleeding from esophageal varices. The most important are (1) the size of the varices, (2) the presence at endoscopy of red wale markings on the varix (longitudinal markings that resemble whip marks or red spots), (3) the severity of liver disease (as assessed by Child scoring), and (4) active alcohol abuse—alcoholic cirrhotics who continue to drink have an extremely high risk of bleeding. The risk of bleeding correlates poorly with the absolute portosystemic pressure gradient, though bleeding almost never occurs with a gradient under 12 mm Hg.

Clinical Findings

A. Symptoms and Signs

Patients with bleeding esophageal varices present with symptoms and signs of acute gastrointestinal hemorrhage. (See Acute Upper Gastrointestinal Bleeding, above.) In some cases, there may be preceding retching or dyspepsia attributable to alcoholic gastritis or withdrawal. Varices per se do not cause symptoms of dyspepsia, dysphagia, or retching. Variceal bleeding usually is severe, resulting in hypovolemia manifested by postural vital signs or shock. Twenty percent of patients with chronic liver disease who develop bleeding—despite findings such as spider angiomas, asterixis, and ascites—do so from some other source.

B. Laboratory Findings

These are identical to those listed above in the section on acute upper gastrointestinal tract bleeding.

Initial Management

A. Acute Resuscitation

The initial management of patients with acute upper gastrointestinal bleeding is also discussed in the section on acute upper gastrointestinal bleeding (see above). Variceal hemorrhage is life-threatening; rapid assessment and resuscitation with fluids or blood products are essential. Overtransfusion should be avoided as it leads to increased central and portal venous pressures, increasing the risk of rebleeding. Many patients with bleeding esophageal varices have coagulopathy due to underlying cirrhosis; fresh frozen plasma (20-mL/kg loading dose, then 10 mg/kg every 6 hours) or platelets should be administered to patients with INRs > 1.8-2.0 or with platelet counts < 50,000/uL in the presence of active bleeding. Patients with advanced liver disease are at high risk for poor outcome regardless of the bleeding source and should be transferred to an ICU. In half of cases, variceal hemorrhage stops spontaneously; without therapy, over half of these will rebleed within 1 week.

B. Emergent Endoscopy

Emergent endoscopy is performed after the patient's hemodynamic status has been appropriately stabilized (usually within 2-12 hours). In patients with active bleeding, endotracheal intubation is commonly performed to protect against aspiration during endoscopy. A vigorous gastric lavage through a large-bore tube is performed prior to endoscopy to facilitate visualization. An endoscopic examination is then performed to exclude other or associated causes of upper gastrointestinal bleeding such as Mallory-Weiss tears, peptic ulcer disease, and portal hypertensive gastropathy. In many patients, variceal bleeding has stopped spontaneously by the time of endoscopy, and the diagnosis of variceal bleeding is made presumptively. Acute endoscopic treatment of the varices is performed with either banding or sclerotherapy.

These techniques arrest active bleeding in 90% of patients and reduce by half (from 70%) the chance of early recurrent bleeding, but their impact upon in-hospital mortality is less clear.

If banding is chosen, repeat sessions are scheduled at intervals of 1-2 weeks until the varices are obliterated or reduced to a small size. Banding achieves lower rates of rebleeding, complications, and death than sclerotherapy and should be considered the endoscopic treatment of choice.

Sclerotherapy is performed by injecting the variceal trunks with a sclerosing agent (eg, ethanolamine, tetradecyl sulfate). A repeat session is conducted at 3-7 days, followed by sessions at 1- to 3-week intervals until the varices are obliterated. Complications occur in 20-30% and include chest pain, fever, bacteremia, esophageal ulceration, stricture, and perforation. However, sclerotherapy is still preferred by some endoscopists in the actively bleeding patient (in whom visualization for banding may be difficult).

C. Pharmacologic Therapy

1. Antibiotic prophylaxis—Cirrhotic patients admitted with upper gastrointestinal bleeding have a greater than 50% chance of developing a severe bacterial infection during hospitalization—such as bacterial peritonitis, pneumonia, or urinary tract infection—with or without sepsis. Most organisms causing infections are of gut origin. Prophylactic therapy by either oral or intravenous administration of antibiotics may reduce the risk of serious infection to 10-20% as well as hospital mortality. Prophylactic treatment with norfloxacin, 400 mg (or another quinolone) orally or per nasogastric tube twice daily for at least 7 days, is recommended routinely.

2. Somatostatin or octreotide—Somatostatin and octreotide infusions reduce portal pressures in ways that are poorly understood. Somatostatin (250 ug/h)—not available in the United States—or octreotide (50-ug intravenous bolus followed by 50 ug/h) reduces splanchnic and hepatic blood flow and portal pressures in cirrhotic patients. Both agents appear to provide acute control of variceal bleeding in up to 80% of patients; however, data about the absolute efficacy of both are conflicting, but they may be comparable in efficacy to endoscopic therapy. Combined treatment with octreotide or somatostatin infusion and endoscopic therapy (band ligation or sclerotherapy) is superior to either modality alone in controlling acute bleeding and early rebleeding, and it may improve survival. In patients with advanced liver disease and upper gastrointestinal hemorrhage, it is reasonable to initiate therapy with octreotide or somatostatin on admission and continue for 5 days. If bleeding is determined by endoscopy not to be secondary to portal hypertension, the infusion can be discontinued.

3. Vitamin K—In cirrhotic patients with an abnormal prothrombin time, vitamin K (10 mg) should be administered subcutaneously.

4. Lactulose—Encephalopathy may complicate an episode of gastrointestinal bleeding in patients with severe liver disease. In patients with encephalopathy, lactulose should be administered in a dosage of 30- 45 mL/h orally until evacuation occurs, then reduced to 15-45 mL/h every 8-12 hours as needed to promote two or three bowel movements daily. (See [Chapter 15](#).)

D. Balloon Tube Tamponade

Mechanical tamponade with specially designed nasogastric tubes containing large gastric and esophageal balloons (Minnesota or Sengstaken-Blakemore tubes) provides initial control of active variceal hemorrhage in 60-90% of patients; rebleeding occurs in 50%. The gastric balloon is inflated first, followed by the esophageal balloon if bleeding continues. After balloon inflation, tension is applied to the tube to directly tamponade the varices. Complications of prolonged balloon inflation include esophageal and oral ulcerations, perforation, aspiration, and airway obstruction (due to a misplaced balloon). Endotracheal intubation is recommended before placement. Given its high rate of complications, mechanical tamponade is used as a temporizing measure only in patients with bleeding that cannot be controlled with pharmacologic or endoscopic techniques until more definitive decompressive therapy (eg, TIPS; see below) can be provided.

E. Portal Decompressive Procedures

In patients with variceal bleeding that cannot be controlled with pharmacologic or endoscopic therapy, emergency portal decompression is necessary.

1. Transvenous intrahepatic portosystemic shunts (TIPS)—Over a wire that is passed through the catheter inserted in the jugular vein, an expandable wire mesh stent (8-12 mm in diameter) is passed through the liver parenchyma, creating a portosystemic shunt from the portal vein to the hepatic vein. TIPS can control acute hemorrhage in over 90% of patients actively bleeding from gastric or esophageal varices. However, posttreatment encephalopathy occurs in 35%, and in patients with decompensated liver disease it may precipitate hepatic failure. Therefore, TIPS is indicated in the 5-10% of patients with acute variceal bleeding who cannot be controlled with pharmacologic and endoscopic therapy—but it is not indicated as initial therapy.

2. Emergency portosystemic shunt surgery—Emergency portosystemic shunt surgery is associated with a 40-60% mortality rate. At centers where TIPS is available, that procedure has become the preferred means of providing emergency portal decompression.

Prevention of Rebleeding

Once the initial bleeding episode has been controlled, the risk of rebleeding is 60-80% without further therapy. The highest incidence of rebleeding is in the first 6 weeks. Several options are available to decrease the likelihood of rebleeding, though their relative merits are controversial. Use of these approaches varies in different medical centers.

A. Endoscopic Techniques

Long-term treatment with sclerotherapy or band ligation reduces the incidence of rebleeding to 20-40%; the mortality rate may also be reduced. Band ligation of the varix appears to be equal or superior to sclerotherapy in preventing rebleeding and is associated with a significantly lower complication rate. In most patients, four to six treatment sessions are needed to eradicate the varices. Where expertise is available, endoscopic therapy is generally the preferred approach to long-term therapy of esophageal varices.

B. Beta-Blockers and Nitrates

Nonselective beta-adrenergic blockers (propranolol, nadolol) are effective in reducing the incidence of rebleeding from esophageal varices and portal hypertensive gastropathy compared with placebo and comparable to that of sclerotherapy. Combination therapy with beta-blockers and sclerotherapy does not appear to be superior to sclerotherapy alone, though it is not known if banding plus beta-blockers confers an advantage. Thus, the choice between beta-blockers and endoscopic therapy to prevent recurrent variceal bleeding is not established and depends upon local experience. Compliant patients with well-compensated liver disease may be optimal candidates for therapy with beta-blockers alone. Most others may be offered endoscopic variceal banding where available. Patients without contraindications to beta-blockers may be started on propranolol, 20 mg twice daily, or nadolol, 40 mg once daily, gradually increasing the dosage until the heart rate falls by 25% or reaches 55 beats/min. The average dosage of propranolol or nadolol is 80 mg daily.

Up to 25% of patients with cirrhosis are intolerant of beta-blockers. Long-acting nitrates such as isosorbide mononitrate also reduce portal pressures but have not demonstrated efficacy in reducing the risk of variceal bleeding when used alone. Combination therapy with isosorbide mononitrate and beta-blockers is more effective and better tolerated than beta-blockers alone in reducing portal pressures and rebleeding. Isosorbide mononitrate is initiated at a dosage of 10 mg daily and gradually increased to 20-40 mg twice daily as tolerated. Side effects include hypotension or headache. Combination therapy with nadolol and isosorbide has been found to be more effective than band ligation alone for the prevention of recurrent variceal bleeding. Whether combined endoscopic and pharmacologic therapies (beta-blockers with or without nitrates) are superior to endoscopic or pharmacologic therapy alone has not yet been determined.

C. Transvenous Intrahepatic Portosystemic Shunt (TIPS)

TIPS has resulted in a significant reduction in recurrent bleeding compared with endoscopic sclerotherapy or band ligation—either alone or in combination with beta-blocker therapy. At 1 year, rebleeding rates in patients treated with TIPS versus various endoscopic therapies average 20% and 40%, respectively. However, TIPS was also associated with a higher incidence of encephalopathy (35% versus 15%) and did not result in a decrease in mortality. Another limitation of TIPS is that stenosis and thrombosis of the stents occur in the majority of patients over time with a consequent risk of rebleeding. Therefore, periodic monitoring with Doppler ultrasonography or hepatic venography is required. Stent patency usually can be maintained by balloon angioplasty or additional stent placement. Given these problems, TIPS should be reserved for patients who have recurrent (two or more) episodes of variceal bleeding that have failed endoscopic or pharmacologic therapies. TIPS is also useful in patients with recurrent bleeding from gastric varices or portal hypertensive gastropathy (for which endoscopic therapies cannot be used). TIPS is likewise considered in patients who are noncompliant with other therapies or who live in remote locations (without access to emergency care).

D. Surgical Portosystemic Shunts

Shunt surgery has a significantly lower rate of rebleeding compared with endoscopic therapy but also a higher incidence of encephalopathy. Selective (distal splenorenal) shunts have a lower incidence of encephalopathy than portacaval shunts but are more difficult to perform. In most centers, shunt surgery has been reserved for patients who have failed sclerotherapy or for noncompliant patients. With the advent of TIPS, the role of surgical shunts is unclear.

E. Liver Transplantation

Candidacy for orthotopic liver transplantation should be assessed in all patients with chronic liver disease and bleeding due to portal hypertension. Transplant candidates should be treated with band ligation or TIPS to control bleeding pretransplant.

Prevention of First Episodes of Variceal Bleeding

Because of the high mortality rate associated with variceal hemorrhage, prevention of the initial bleeding episode is desirable. All patients with cirrhosis should undergo diagnostic endoscopy to determine whether varices are present. Nonselective beta-adrenergic blockers (nadolol, propranolol) in multiple trials decrease the long-term risk of bleeding to less than 15% (compared with about 25% in placebo-treated patients). Because variceal bleeding occurs in only one-third of cirrhotics, it may be reasonable to use beta-blockers in compliant higher-risk patients, ie, patients with large varices or red color markings. Up to one-third of patients do not tolerate beta-blocker therapy. Combination therapy with propranolol and isosorbide mononitrate may be superior to propranolol alone in primary prevention of variceal bleeding. Prophylactic sclerotherapy in those who have never had a variceal hemorrhage results in a higher mortality rate than placebo or treatment with beta-blockers and should not be done. In contrast, a reduction in the incidence of first episodes of variceal bleeding has been noted in patients treated with variceal ligation (banding). At this time, however, prophylactic variceal ligation is not widely employed in patients with varices without prior bleeding.

MALIGNANT ESOPHAGEAL LESIONS (CANCER OF THE ESOPHAGUS)

Essentials of Diagnosis

- Progressive solid food dysphagia.
- Weight loss common.
- Endoscopy with biopsy establishes diagnosis.

General Considerations

Esophageal cancer usually develops in persons between 50 and 70 years of age. The overall ratio of men to women is 3:1. There are two histologic types: squamous cell carcinoma and adenocarcinoma. In the United States, squamous cell cancer is much more common in blacks than in whites. Chronic alcohol and tobacco use are strongly associated with an increased risk of squamous cell carcinoma. The risk of squamous cell cancer is also increased in patients with tylosis (a rare disease transmitted by autosomal dominant inheritance and manifested by hyperkeratosis of the palms and soles), achalasia, caustic-induced esophageal stricture, and other head and neck cancers. Squamous cell cancer has a high incidence in certain regions of China and Southeast Asia. Half of cases occur in the distal third of the esophagus. Adenocarcinoma is more common in whites. It is increasing dramatically in incidence and now is as common as squamous carcinoma. The majority of adenocarcinomas develop as a complication of Barrett's metaplasia due to chronic gastroesophageal reflux. Thus, most adenocarcinomas arise in the distal third of the esophagus.

Clinical Findings

A. Symptoms and Signs

Most patients with esophageal cancer present with advanced, incurable disease. Over 90% have solid food dysphagia, which progresses over weeks to months. Odynophagia is sometimes present. Significant weight loss is common. Local tumor extension into the tracheobronchial tree may result in a tracheoesophageal fistula, characterized by coughing on swallowing or pneumonia. Chest or back pain suggests mediastinal extension. Recurrent laryngeal involvement may produce hoarseness. Physical examination is often unrevealing. The presence of supraclavicular or cervical lymphadenopathy or of hepatomegaly implies metastatic disease.

B. Laboratory Findings

Laboratory findings are nonspecific. Anemia related to chronic disease or occult blood loss is common. Elevated aminotransferase or alkaline phosphatase concentrations suggest hepatic or bony metastases. Hypoalbuminemia may result from malnutrition.

C. Imaging

Chest x-rays may show adenopathy, a widened mediastinum, pulmonary or bony metastases, or signs of tracheoesophageal fistula such as pneumonia. A barium esophagogram is obtained as the first study to evaluate dysphagia. The appearance of a polypoid, infiltrative, or ulcerative lesion is suggestive of carcinoma and requires endoscopic evaluation. However, even lesions felt to be benign by radiography warrant endoscopic evaluation.

D. Upper Endoscopy

Endoscopy with biopsy establishes the diagnosis of esophageal carcinoma with a high degree of reliability. In some cases, significant submucosal spread of the tumor may yield nondiagnostic mucosal biopsies. Repeated biopsy may be necessary.

Differential Diagnosis

Esophageal carcinoma must be distinguished from other causes of progressive dysphagia, including peptic stricture, achalasia, and adenocarcinoma of the gastric cardia with esophageal involvement. Benign-appearing peptic strictures should be biopsied at presentation to exclude occult malignancy.

Staging of Disease

After confirmation of the diagnosis of esophageal carcinoma, the stage of the disease should be determined since doing so influences the choice of therapy. Patients should undergo evaluation with CT of the chest and liver to look for evidence of pulmonary or hepatic metastases, lymphadenopathy, and local tumor extension. If there is no evidence of distant metastases or extensive local spread on CT, endoscopic ultrasonography should be performed, which is superior to CT in demonstrating the level of local mediastinal extension and local lymph node involvement. Bronchoscopy is sometimes required in proximal esophageal cancer to exclude tracheobronchial extension. Apart from distant metastasis, the two most important predictors of poor survival are lymph node involvement and adjacent mediastinal spread.

Stages are determined by the TNM classification as set forth in the accompanying box.

STAGING CRITERIA FOR ESOPHAGEAL CANCER

Primary Tumor (T)
T1: Invasion of lamina propria or submucosa
T2: Invasion of muscularis propria
T3: Invasion of adventitia
T4: Invasion of adjacent structures
Regional Lymph Nodes (N)
N0: No regional lymph node involvement
N1: Regional lymph node involvement
Distant Metastasis (M)
M0: No metastasis
M1: Distant metastasis

M1a: Cervical or celiac lymph nodes
M1b: Other distant metastasis

Based upon these parameters, the tumor is classified as:

Stage I: T1, N0, M0
Stage IIA: T2 or T3, and N0, M0
Stage IIB: T1 or T2, and N1, M0
Stage IIIA: T3, N1, M0
Stage IIIB: T4, Any N, M0
Stage IVA: Any T, Any N, M1a
Stage IVB: Any T, Any N, M1b

Treatment

The approach to esophageal cancer depends upon the tumor stage, patient preference and functional status, and the expertise of the attending surgeons, oncologists, gastroenterologists, and radiotherapists. There is no consensus about the optimal treatment approach. It is helpful, however, to classify patients into two general categories.

A. Palliative Therapy

Patients with extensive local tumor spread (T4) or distant metastases (M1) are incurable, ie, patients with stage IIIB and stage IV tumors. Surgery is not warranted in these patients. The goal is to provide relief from dysphagia and pain, and the optimal palliative approach depends upon the patient's expected survival, patient preference, and local institutional experience. None of the modalities prolong survival, and many patients may prefer concerted efforts at pain relief and care directed at symptom management (see [Chapter 5](#)).

1. Radiation or chemoradiation therapy—Combined radiation therapy and chemotherapy may achieve palliation in two-thirds of patients but is associated with significant side effects. It should be considered for patients with a good functional status without other significant medical problems. Radiation therapy alone may afford significant short-term relief of pain and dysphagia and may be suitable for patients with poor functional status or underlying medical problems. During therapy, esophagitis may lead to worsening of dysphagia and odynophagia.

2. Local antitumor therapy—Patients with advanced esophageal cancer may have a poor functional and nutritional status and an average survival of less than 12 weeks from diagnosis. Radiation or chemoradiation is poorly tolerated. Rapid palliation of dysphagia may be achieved by peroral placement of permanent expandable wire stents, application of endoscopic laser therapy, or photodynamic therapy. Although dysphagia and quality of life are improved significantly, patients can seldom eat normally. Complications of stents occur in 20-40% and include perforation, migration, and tumor ingrowth. These are most suitable for patients with a short life expectancy, patients with tracheoesophageal fistula, patients who have failed radiation therapy, or patients in locations where optimal surgical or radiation modalities are not available. Laser therapy (Nd:YAG laser) maintains luminal patency in up to 90% of patients but involves multiple treatment sessions and can be difficult to administer. Photodynamic therapy has been shown to be superior to laser therapy. A photosensitizing agent (porfimer sodium) in combination with a low-power 630 nm laser results in significant tumor necrosis. Side effects include sun sensitivity of the skin for 4-6 weeks and the development of esophageal stricture. Both laser therapy and photodynamic therapy require expensive equipment that is not available at many institutions.

B. "Curable" Disease

There are three broad categories of therapy that may be considered depending upon institutional experience.

1. Surgery alone—Patients with stage I and stage IIA cancer have high cure rates with surgery alone. There is controversy over the optimal surgical approach. The procedure with the lowest morbidity is transhiatal esophagectomy with anastomosis of the stomach to the cervical esophagus. Critics of this approach note that because it does not involve sampling or removal of mediastinal lymph nodes, it is not suitable as a "curative" approach for node-positive disease. Alternatively, many surgeons recommend transthoracic excision of the esophagus with nodal resection. They believe that it has a higher morbidity and no better survival than the transhiatal approach. Regardless of the approach elected, overall 3-year survival after surgery is less than 15% in most series. Patients with small early-stage tumors who are too ill to undergo esophagectomy may be treated with endoscopic mucosal resection of the tumor at qualified centers.

2. Chemotherapy plus radiation therapy—Combined therapy with chemotherapy and radiation therapy is superior to radiation therapy alone and has achieved overall survival rates that equal or exceed those of historical surgical cohorts, though there have been no trials specifically comparing these approaches. However, severe side effects occur commonly with combined therapy. The most promising chemotherapeutic agents have been cisplatin and fluorouracil. Chemoradiation therapy alone should be considered in patients with localized disease (stage II or IIIA) who are poor surgical candidates due to serious medical illness or poor functional status (ECOG score > 2).

3. Surgery with neoadjuvant chemotherapy and radiation therapy—If lymph node metastases have occurred (stage IIB and stage IIIA), the rate of cure with surgery alone is reduced to less than 10%. Trials of adjuvant (postoperative) or neoadjuvant (preoperative) radiation therapy or chemotherapy have not demonstrated benefits over surgery alone. However, neoadjuvant treatment with combination radiation therapy and chemotherapy (cisplatin and fluorouracil) results in complete pathologic remission (no evidence of tumor at the time of surgery) in up to 25% of patients. However, prospective trials comparing neoadjuvant chemoradiation plus surgery to surgery alone have yielded inconsistent results with respect to long-term survival. At present, multimodal treatment (neoadjuvant chemoradiation plus surgery) may be considered, preferably in the context of a clinical trial.

Prognosis

The overall 5-year survival rate of esophageal carcinoma is less than 15%. Despite improvements in surgical mortality and increased surgical resectability rates, the prognosis of this disease has not changed for years, in part because most patients present with advanced disease. This suggests that surgical approaches alone are inadequate for most patients. For those patients whose disease progresses despite chemotherapy, meticulous efforts at palliative care are essential (see [Chapter 5](#)).

ESOPHAGEAL MOTILITY DISORDERS

1. Achalasia

Essentials of Diagnosis

- Gradual, progressive dysphagia for solids and liquids.
- Regurgitation of undigested food.
- Barium esophagogram with "bird's beak" distal esophagus.
- Esophageal manometry confirms diagnosis.

General Considerations

Achalasia is an idiopathic motility disorder characterized by loss of peristalsis in the distal two-thirds (smooth muscle) of the esophagus and impaired relaxation of the lower esophageal sphincter. There appears to be denervation of the esophagus resulting primarily from loss of nitric oxide-producing inhibitory neurons in the myenteric

plexus. The cause of the neuronal degeneration is unknown.

Clinical Findings

A. Symptoms and Signs

There is a steady increase in the incidence of achalasia with age; however, it can be seen in individuals as young as 25 years. Patients complain of the gradual onset of dysphagia for solid foods and, in the majority, of liquids also. Symptoms at presentation may have persisted for months to years. Substernal discomfort or fullness may be noted after eating. Many patients eat more slowly and adopt specific maneuvers such as lifting the neck or throwing the shoulders back in order to enhance esophageal emptying. Regurgitation of undigested food is common and may occur during meals or up to several hours later. Nocturnal regurgitation can provoke coughing or aspiration. Up to half of patients report substernal chest pain that is unrelated to meals or exercise and may last up to hours. Weight loss is common. Physical examination is unhelpful.

B. Imaging

Chest x-rays may show an air-fluid level in the enlarged, fluid-filled esophagus. Barium esophagography discloses characteristic findings, including esophageal dilation, loss of esophageal peristalsis, poor esophageal emptying, and a smooth, symmetric "bird's beak" tapering of the distal esophagus. Without treatment, the esophagus may become markedly dilated ("sigmoid esophagus").

C. Special Examinations

After esophagography, endoscopy is always performed to evaluate the distal esophagus and gastroesophageal junction in order to exclude a distal stricture or a submucosal infiltrating carcinoma. The diagnosis is confirmed by esophageal manometry. The typical manometric features are as follows: (1) Complete absence of peristalsis; swallowing results in simultaneous waves which are usually of low amplitude. (2) Incomplete lower esophageal sphincter relaxation with swallowing. Whereas the normal sphincter relaxes by over 90%, relaxation with most swallows in patients with achalasia is less than 50%. In many patients, the baseline lower esophageal sphincter pressure is quite elevated. (3) Intraesophageal pressures are greater than gastric pressures due to a fluid- and food-filled esophagus.

Differential Diagnosis

Chagas' disease is associated with esophageal dysfunction that is indistinguishable from idiopathic achalasia and should be considered in patients from endemic regions (Central and South America); it is becoming more common in the southern United States. Primary or metastatic tumors can invade the gastroesophageal junction, resulting in a picture resembling that of achalasia, called "pseudoachalasia." Endoscopic ultrasonography and chest CT may be required to examine the distal esophagus in suspicious cases. Tumors such as small cell lung cancer can cause a paraneoplastic syndrome resembling achalasia due to secretion of antineuronal nuclear antibodies (ANNA-1 or Anti-Hu) that affect the myenteric plexus. Achalasia must be distinguished from other motility disorders such as diffuse esophageal spasm and scleroderma esophagus with a peptic stricture.

Treatment

A. Botulinum Toxin Injection

Endoscopically guided injection of botulinum toxin directly into the lower esophageal sphincter results in a marked reduction in lower esophageal sphincter pressure with initial improvement in symptoms in 85% of patients. However, symptom relapse occurs in over 50% of patients within 6-9 months and in all patients within 2 years. Three-fourths of initial responders who relapse have improvement with repeated injections. Because it is inferior to pneumatic dilation therapy and surgery in producing sustained symptomatic relief, this therapy is most appropriate for patients with comorbidities who are poor candidates for more invasive procedures.

B. Pneumatic Dilation

Over three-fourths of patients derive good to excellent relief of dysphagia after one or two sessions of pneumatic dilation of the lower esophageal sphincter. However, only half of patients achieve long-term relief, and multiple dilations may be required. Perforations occur in less than 3% of dilations and may require operative repair.

C. Surgical Myotomy

A modified Heller cardiomyotomy of the lower esophageal sphincter and cardia results in good to excellent symptomatic improvement in over 85% of patients. Because gastroesophageal reflux may develop in up to 20% of patients after myotomy, most surgeons also perform an antireflux procedure (fundoplication). Myotomy is now performed with a laparoscopic approach and is preferred to the open surgical approach. Indeed, the low morbidity of laparoscopic surgery has led some experts to recommend it for initial treatment. In experienced hands, the initial efficacies of pneumatic dilation and laparoscopic myotomy are nearly equivalent. Cost-effectiveness analysis indicates that pneumatic dilation may be a more cost-effective strategy than either botulinum toxin injection or laparoscopic myotomy. The success of laparoscopic surgery is not compromised by prior therapy with either botulinum injection or pneumatic dilation.

2. Other Primary Esophageal Motility Disorders

Abnormalities in esophageal motility may cause dysphagia or chest pain. Dysphagia for liquids as well as solids tends to be intermittent and nonprogressive. Periods of normal swallowing may alternate with periods of dysphagia, which usually is mild though bothersome—rarely severe enough to result in significant alterations in lifestyle or weight loss. Dysphagia may be provoked by stress, large boluses of food, or hot or cold liquids. Some patients may experience anterior chest pain that may be confused with angina pectoris but usually is nonexertional. The pain generally is unrelated to eating. (See Chest Pain of Undetermined Origin, below.)

The evaluation of suspected esophageal motility disorders includes barium esophagography, upper endoscopy, and, in some cases, esophageal manometry. Barium esophagography is useful to exclude mechanical obstruction and to evaluate esophageal motility. The presence of simultaneous contractions (spasm), disordered peristalsis, or failed peristalsis supports a diagnosis of esophageal dysmotility. Upper endoscopy also is performed to exclude a mechanical obstruction (as a cause of dysphagia) and to look for evidence of erosive reflux esophagitis (a common cause of chest pain).

The further evaluation of noncardiac chest pain is discussed in a subsequent section. For patients with disabling symptoms of dysphagia, stationary esophageal manometry should be performed. Manometry should not be routinely used for mild to moderate symptoms because the findings seldom influence further medical management. Based upon the findings of esophageal manometry, patients may be diagnosed with the following conditions: (1) Diffuse esophageal spasm: normal primary peristalsis with more than 20% simultaneous contractions. (2) Nutcracker esophagus: normal peristalsis but increased duration and high amplitude of distal contractions (> 180 mm Hg). (3) Hypertensive lower esophageal sphincter: elevated lower esophageal sphincter pressure (> 45 mm Hg) with normal peristalsis. (4) Nonspecific esophageal motility disorder: intermittent normal peristalsis with any of a number of abnormalities that do not allow classification into one of the above (> 20% nontransmitted peristaltic waves, prolonged duration of contractions, abnormal-appearing wave forms, low amplitude of peristaltic waves).

For patients with mild symptoms, therapy is directed at symptom reduction and reassurance. Patients with dysphagia should be instructed to eat more slowly and take smaller boluses of food. In some cases, a warm liquid at the start of a meal may facilitate swallowing. Treatment of more severe cases with nitrates (isosorbide, 10-20 mg four times daily) or nitroglycerin (0.4 mg sublingually as needed) and calcium channel blockers (nifedipine 10 mg or diltiazem 60-90 mg, 30-45 minutes before meals) may be tried; their efficacy is unproved. Injection of botulinum toxin into the lower esophagus may improve chest pain and dysphagia in over 70% for a limited time. For unclear reasons, dilation with esophageal Maloney bougies provides symptomatic relief in some cases. In debilitated patients, a long surgical myotomy (which may be performed via a thoracoscopic approach) may lead to improvement in 70-80% of cases.

CHEST PAIN OF UNDETERMINED ORIGIN

One-third of patients with chest pain undergo negative cardiac evaluation. Patients with recurrent noncardiac chest pain thus pose a difficult clinical problem. Because coronary artery disease is common and can present atypically, it must be excluded prior to evaluation for other causes.

Causes of noncardiac chest pain may include the following.

A. Chest Wall and Thoracic Spine Disease

These are easily diagnosed by history and physical examination.

B. Gastroesophageal Reflux

Up to 50% of patients have increased amounts of gastroesophageal acid reflux or a correlation between acid reflux episodes and chest pain demonstrated on esophageal pH testing. An empirical 8-week trial of acid-suppressive therapy with a high-dose proton pump inhibitor is recommended (eg, omeprazole or rabeprazole, 40 mg twice daily, lansoprazole, 30-60 mg twice daily, or esomeprazole or pantoprazole, 40 mg twice daily), especially in patients with reflux symptoms. Symptomatic improvement strongly suggests that the pain is due to acid esophageal reflux. The sensitivity and specificity of this treatment are 78% and 86%, respectively, compared with therapy based on results of esophageal pH testing. In patients with persistent symptoms, an ambulatory esophageal pH study while continuing antisecretory therapy is useful to definitively exclude a relationship between acid reflux episodes and chest pain events.

C. Heightened Visceral Sensitivity

Studies suggest that many patients with noncardiac chest pain report pain in response to a variety of minor noxious stimuli such as intraesophageal acid infusion, inflation of balloons within the esophageal lumen, injection of intravenous edrophonium (a cholinergic stimulus), or intracardiac catheter manipulation. Low doses of antidepressants such as trazodone 50 mg or imipramine 50 mg reduce chest pain symptoms and are thought to reduce visceral afferent awareness.

D. Psychologic Disorders

A significant number of patients have underlying depression, anxiety, and panic disorder. Patients reporting dyspnea, sweating, tachycardia, suffocation, or fear of dying should be evaluated for panic disorder.

E. Esophageal Dysmotility

Esophageal motility abnormalities such as diffuse esophageal spasm, or nutcracker esophagus are rare causes of noncardiac chest pain. In patients with chest pain and dysphagia, barium swallow x-ray should be obtained to look for evidence of achalasia or diffuse esophageal spasm. Stationary or ambulatory manometry is not routinely performed because of low specificity and the unlikelihood of finding a clinically significant disorder, but these procedures may be recommended in patients with frequent symptoms.

■ DISEASES OF THE STOMACH & DUODENUM

GASTRITIS & GASTROPATHY

The term "gastropathy" is used increasingly to denote conditions in which there is epithelial or endothelial damage without inflammation. Gastritis may be divided into three categories: (1) erosive and hemorrhagic gastritis, (2) nonerosive, nonspecific (histologic) gastritis, and (3) specific types of gastritis, characterized by distinctive histologic and endoscopic features diagnostic of specific disorders.

1. Erosive & Hemorrhagic Gastritis

Essentials of Diagnosis

- Most commonly seen in alcoholics, critically ill patients, or patients taking NSAIDs.
- Often asymptomatic; may cause epigastric pain, nausea, and vomiting.
- May cause hematemesis; usually not significant bleeding.

General Considerations

The most common causes of erosive gastritis are drugs (especially NSAIDs), alcohol, stress due to severe medical or surgical illness, and portal hypertension ("portal gastropathy"). Uncommon causes include caustic ingestion and radiation. Erosive gastritis and hemorrhagic gastritis typically are diagnosed at endoscopy, often being performed because of dyspepsia or upper gastrointestinal bleeding. Endoscopic findings include subepithelial hemorrhages, petechiae, and erosions. These lesions are superficial, vary in size and number, and may be focal or diffuse. There usually is no significant inflammation on histologic examination, though gastropathy may be present.

Clinical Findings

A. Symptoms and Signs

Erosive gastritis is usually asymptomatic. Symptoms, when they occur, include anorexia, epigastric pain, nausea, and vomiting. There is poor correlation between symptoms and the number or severity of endoscopic abnormalities. The most common clinical manifestation of erosive gastritis is upper gastrointestinal bleeding, which presents as hematemesis, "coffee grounds" emesis, or bloody aspirate in a patient receiving nasogastric suction, or as melena. Because erosive gastritis is superficial, hemodynamically significant bleeding is rare.

B. Laboratory Findings

The laboratory findings are nonspecific. The hematocrit is low if significant bleeding has occurred; iron deficiency may be found.

C. Special Examinations

Upper endoscopy is the most sensitive method of diagnosis. Although bleeding from gastritis is usually insignificant, it cannot be distinguished on clinical grounds from more serious lesions such as peptic ulcers or esophageal varices. Hence, endoscopy is generally performed within 24 hours in patients with upper gastrointestinal bleeding to identify the source. An upper gastrointestinal series is sometimes obtained in lieu of endoscopy in patients with hemodynamically insignificant upper gastrointestinal bleeds to exclude serious lesions but is insensitive for the detection of gastritis.

Differential Diagnosis

Epigastric pain may be due to peptic ulcer, gastroesophageal reflux, gastric cancer, biliary tract disease, food poisoning, viral gastroenteritis, and functional dyspepsia. With severe pain, one should consider a perforated or penetrating ulcer, pancreatic disease, esophageal rupture, ruptured aortic aneurysm, gastric volvulus, and myocardial colic. Causes of upper gastrointestinal bleeding include peptic ulcer disease, esophageal varices, Mallory-Weiss tear, and arteriovenous malformations.

Specific Causes & Treatment

A. Stress Gastritis

1. Prophylaxis—Stress-related mucosal erosions and subepithelial hemorrhages develop within 72 hours in the majority of critically ill patients. Clinically overt bleeding occurs in 6%, but clinically important bleeding in less than 3%. Bleeding is associated with a higher mortality rate but is seldom the cause of death. Major risk factors include mechanical ventilation, coagulopathy, trauma, burns, hypotension, sepsis, central nervous system injury, hepatic or renal failure, and multiorgan failure. The use of enteral nutrition reduces the risk of stress-related bleeding.

Pharmacologic prophylaxis with H₂ receptor antagonists or sucralfate in critically ill patients has been shown to reduce the incidence of clinically overt and significant bleeding by 50%. Prophylaxis should be routinely administered upon admission to critically ill patients with risk factors for significant bleeding. Two of the most important risk factors are coagulopathy and respiratory failure with the need for mechanical ventilation for over 48 hours. When these two risk factors are absent, the risk of significant bleeding is only 0.1%.

Infusions of H₂ receptor antagonists at a dose sufficient to maintain intragastric pH above 4.0 are recommended for prophylaxis in patients with risk factors for stress-related mucosal bleeding. Cimetidine (900- 1200 mg), ranitidine (150 mg), or famotidine (20 mg) by continuous intravenous infusion over 24 hours is adequate to control pH in most patients. After 4 hours of infusion, the pH should be checked by nasogastric aspirate and the dose doubled if the pH is under 4.0. Sucralfate should be used in patients intolerant of the H₂ receptor antagonists.

Sucralfate suspension (1 g orally every 4-6 hours) is effective also for the prevention of stress-related bleeding, and a reduction of nosocomial pneumonia had been observed compared with H₂ receptor antagonists. However, there is a higher incidence of clinically important upper gastrointestinal bleeding with sucralfate (4%) versus H₂ receptor antagonists (2%) with no difference in nosocomial pneumonia in more recent studies. In most ICUs, intravenous H₂ receptor antagonists are preferred because of their ease of administration.

Intravenous proton pump inhibitors may be superior to H₂ receptor antagonists in maintaining intragastric pH > 4.0. They are increasingly used in many ICUs for prophylaxis of stress-related mucosal bleeding despite an absence of proof of superiority to less expensive agents. In the United States, only pantoprazole currently is available in an intravenous formulation. The optimal dosage for prophylaxis against stress-related bleeding is unknown. Oral proton pump inhibitors are not being used in the ICU for prophylaxis owing to their unpredictable absorption and the need for high doses in such patients.

2. Treatment—Once bleeding occurs, patients should receive continuous infusions of an H₂ receptor antagonist or proton pump inhibitor as well as sucralfate suspension. Because bleeding is diffuse, endoscopic hemostasis techniques are not helpful. Nevertheless, endoscopy is often performed in such patients to look for other treatable causes of upper gastrointestinal bleeding.

B. NSAID Gastritis

Although half of patients receiving NSAIDs on a chronic basis have gastritis at endoscopy, symptoms of dyspepsia develop in less than one-fourth. Furthermore, of patients with dyspepsia, up to half do not have significant mucosal abnormalities. Given the frequency of dyspeptic symptoms in patients taking NSAIDs, it is neither feasible nor desirable to investigate all such patients. Symptoms may improve with discontinuation of the agent, reduction to the lowest effective dose, or administration with meals. Patients with persistent symptoms despite conservative measures or patients at high risk for NSAID-induced ulcers (see section on peptic ulcer disease) should undergo diagnostic endoscopy. Those without significant NSAID ulceration may be treated symptomatically with sucralfate (1 g four times daily), with H₂ receptor antagonists given twice daily (cimetidine 400 mg, ranitidine 150 mg, or famotidine 20 mg), or with proton pump inhibitors once daily (omeprazole 20 mg, rabeprazole 20 mg, pantoprazole 40 mg, or lansoprazole 30 mg). Upper gastrointestinal bleeding due to NSAID gastritis is usually not severe.

C. Alcoholic Gastritis

Erosive gastritis and hemorrhagic gastritis account for 20% of episodes of upper gastrointestinal bleeding in chronic alcoholics. Therapy with H₂ receptor antagonists or sucralfate for 2-4 weeks often is prescribed. On occasion, bleeding may be brisk.

D. Portal Hypertensive Gastropathy

Portal hypertension results in gastric mucosal and submucosal congestion of capillaries and venules. Bleeding from congestive gastropathy accounts for 25% of episodes of upper gastrointestinal bleeding in patients with portal hypertension. It may present suddenly with hematemesis or insidiously with iron deficiency anemia. Recurrent acute bleeding is common. Treatment with propranolol or nadolol reduces the incidence of recurrent acute bleeding by lowering portal pressures. Patients who fail propranolol therapy may be successfully treated with portal decompressive procedures (see section on treatment of esophageal varices).

2. Nonerosive, Nonspecific Gastritis

The diagnosis of nonerosive gastritis is based upon histologic assessment of mucosal biopsies. Endoscopic findings are normal in many cases and do not reliably predict the presence of histologic inflammation. The main types of nonerosive gastritis are those due to *H pylori* infection, those associated with pernicious anemia, and lymphocytic gastritis. (See Specific Types of Gastritis, below.)

Helicobacter pylori Gastritis

H pylori is a spiral gram-negative rod that resides beneath the gastric mucous layer adjacent to gastric epithelial cells. Although not invasive, it causes gastric mucosal inflammation with polymorphonuclear neutrophils and lymphocytes. The mechanisms of injury and inflammation may in part be related to the products of two genes, *vacA* and *cagA*.

In the United States, the prevalence of infection rises from less than 10% in Caucasians under age 30 to over 50% in those over age 60. The prevalence is higher in non-Caucasians and immigrants from developing countries and is correlated inversely with socioeconomic status. Transmission is from person to person, and an important mode of spread may be gastro-oral (ie, through exposure to vomitus). The majority of infections are probably acquired in childhood.

Acute infection with *H pylori* may cause a transient clinical illness characterized by nausea and abdominal pain that may last for several days and is associated with acute histologic gastritis with polymorphonuclear neutrophils. After these symptoms resolve, the majority progress to chronic infection with chronic, diffuse mucosal inflammation characterized by polymorphonuclear neutrophils and lymphocytes. Inflammation may be confined to the superficial gastric epithelium or may extend deeper into the gastric glands, resulting in varying degrees of gland atrophy (atrophic gastritis) and metaplasia of the gastric epithelium to intestinal type epithelium. Eradication of *H pylori* may be achieved with antibiotics in over 85% of patients and leads to resolution of the chronic gastritis (see section on peptic ulcer disease).

Although chronic *H pylori* infection with gastritis is present in 30-50% of the population, the majority are asymptomatic and suffer no sequelae. *H pylori* infection is strongly associated with peptic ulcer disease; however, only 15% of people with chronic infection develop a peptic ulcer (see section on peptic ulcer disease). Chronic *H pylori* gastritis is associated with a two- to sixfold increased risk of gastric adenocarcinoma and low-grade B cell gastric lymphoma (mucosa-associated lymphoid tissue lymphoma; MALToma). There is little evidence that chronic *H pylori*-associated gastritis is a cause of dyspeptic symptoms. (See Dyspepsia, at the beginning of this chapter.)

Testing is indicated for patients with either active or a past history of documented peptic ulcer disease or gastric MALToma and probably for patients with a family history of gastric carcinoma, especially if they are of Asian descent. Testing and empirical treatment may also be cost-effective in young patients (< 45 years) with uncomplicated dyspepsia prior to further medical evaluation. The role of testing and treating *H pylori* in patients with nonulcer dyspepsia remains controversial (see Dyspepsia, above). Because *H pylori* is a common organism but infrequently causes disease, screening of the general population is not indicated.

A. Noninvasive Testing for *H pylori*

Either serologic tests or fecal antigen tests are recommended as the most cost-effective initial tests for *H pylori*. Laboratory-based quantitative serologic ELISA tests have sensitivity and specificity of over 90% and cost \$40-\$75. Qualitative office-based kits using whole blood from a finger-stick have a lower (80%) sensitivity and specificity but can be performed within 10 minutes at a cost of \$10. Positive serologic tests do not necessarily imply ongoing active infection. After *H pylori* eradication with antibiotics, antibody levels decline to undetectable levels in 50% of patients by 12-18 months. A fecal antigen immunoassay has excellent sensitivity and specificity (90%) at a cost of \$60. Because a positive test is indicative of active infection, the fecal antigen assay may be the preferred noninvasive screening test for *H pylori*. However, the cost-effectiveness of each diagnostic test is dependent upon the prevalence of infection and the cost of the tests, which vary greatly.

The ¹³C-urea and ¹⁴C-urea breath tests also have excellent sensitivity and specificity (90%), and a positive test is indicative of active infection. However, their greater cost (\$60-\$300) make them less attractive than other noninvasive tests in most clinical settings. In circumstances where testing is clinically indicated (complicated peptic ulcer disease, MALT lymphoma), either a urea breath test (or, where urea testing is not available, a fecal antigen test) should be used to confirm *H pylori* eradication. Proton pump inhibitors significantly reduce the sensitivity of urea breath tests and fecal antigen assays (but not serologic tests) and should be discontinued 7-14 days prior to testing.

B. Endoscopic Testing for *H pylori*

Endoscopy is not indicated to diagnose *H pylori* infection in most circumstances. However, when it is performed for another reason, gastric biopsy specimens can be obtained for detection of *H pylori* and tested for active infection by urease production. This simple, inexpensive (\$10) test has excellent sensitivity and specificity (90%). In patients with active upper gastrointestinal bleeding or patients taking proton pump inhibitors, histologic assessment for *H pylori* is preferred. Histologic assessment of biopsies from the gastric antrum and body is more definitive but more expensive (\$150-\$250) than a rapid urease test. Histologic assessment is also indicated in patients with suspected MALTomas and, possibly, in patients with suspected infection whose rapid urease test is negative. However, serologic testing is the most cost-effective means of confirming *H pylori* infection in patients with a negative rapid urease test.

Pernicious Anemia Gastritis

Pernicious anemia gastritis is an autoimmune disorder involving the fundic glands with resultant achlorhydria and vitamin B₁₂ malabsorption. Fundic histology is characterized by severe gland atrophy and intestinal metaplasia. Parietal cell antibodies directed against the H⁺-K⁺ ATPase pump are present in 90% of patients. Inflammation and autoimmune destruction of the acid-secreting parietal cells leads to secondary loss of fundic zymogen cells, which secrete intrinsic factor. Achlorhydria leads to pronounced hypergastrinemia (> 1000 pg/mL) due to loss of acid inhibition of gastrin G cells. Hypergastrinemia may induce hyperplasia of gastric enterochromaffin-like cells that may lead to the development of small, multicentric carcinoid tumors in 5% of patients. Metastatic spread is uncommon in lesions smaller than 2 cm. The risk of adenocarcinoma is increased threefold, with a prevalence of 1-3%. Endoscopy with biopsy is indicated in patients with pernicious anemia at the time of diagnosis. Patients with dysplasia or small carcinoids require periodic endoscopic surveillance. Pernicious anemia is discussed in detail in [Chapter 13](#).

3. Specific Types of Gastritis

A number of disorders are associated with specific mucosal histologic features.

Infections

Acute bacterial infection of the gastric submucosa and muscularis with a variety of aerobic or anaerobic organisms produces a rare, rapidly progressive, life-threatening condition known as phlegmonous or necrotizing gastritis which requires emergency gastric resection and antibiotic therapy. Viral infection with CMV is commonly seen in patients with AIDS and after bone marrow or solid organ transplantation. Endoscopic findings include thickened gastric folds and ulcerations. Fungal infection with candida may occur in immunocompromised patients. Larvae of *Anisakis marina* ingested in raw fish or sushi may become embedded in the gastric mucosa, producing severe abdominal pain. Pain persists for several days until the larvae die. Endoscopic removal of the larvae provides rapid symptomatic relief.

Granulomatous Gastritis

Chronic granulomatous inflammation may be caused by a variety of systemic diseases, including tuberculosis, syphilis, fungal infections, sarcoidosis, or Crohn's disease. These may be asymptomatic or associated with a variety of gastrointestinal complaints.

Eosinophilic Gastritis

This is a rare disorder in which eosinophils infiltrate the antrum and sometimes the proximal intestine. Infiltration may involve the mucosa, muscularis, or serosa. Peripheral eosinophilia is prominent. Symptoms include anemia from mucosal blood loss, abdominal pain, early satiety, and postprandial vomiting. Treatment with corticosteroids is beneficial in the majority of patients.

Lymphocytic Gastritis

This is an idiopathic condition characterized by fluctuating abdominal pain, nausea, and vomiting. Endoscopic features include mucosal erosions and a varioliform ("pox-like") appearance. Biopsies reveal a diffuse lymphocytic gastritis. There is no established effective therapy.

Menetrier's Disease (Hypertrophic Gastropathy)

This is an idiopathic entity characterized by giant thickened gastric folds involving predominantly the body of the stomach. Patients complain of nausea, epigastric pain, weight loss, and diarrhea. Because of chronic protein loss, patients may develop severe hypoproteinemia and anasarca. The cause is unknown. Treatment is directed at symptoms. Gastric resection is required in severe cases. There are case reports of resolution of symptoms and improvement in histologic appearance after *H pylori* eradication.

Kawasaki M et al: Menetrier's disease associated with *Helicobacter pylori* infection: resolution of enlarged gastric folds and hypoproteinemia after antibacterial treatment. Am J Gastroenterol 1997;92:1909. [\[PMID: 9382064\]](#)

PEPTIC ULCER DISEASE

Essentials of Diagnosis

- History of nonspecific epigastric pain present in 80-90% of patients with variable relationship to meals.
- Ulcer symptoms characterized by rhythmicity and periodicity.
- Ten to 20 percent of patients present with ulcer complications without antecedent symptoms.
- Of NSAID-induced ulcers, 30-50% are asymptomatic.
- Upper endoscopy with antral biopsy for *H pylori* is diagnostic procedure of choice in most patients.
- Gastric ulcer biopsy or documentation of complete healing necessary to exclude gastric malignancy.

General Considerations

Peptic ulcer is a break in the gastric or duodenal mucosa that arises when the normal mucosal defensive factors are impaired or are overwhelmed by aggressive luminal factors such as acid and pepsin. By definition, ulcers extend through the muscularis mucosae and are usually over 5 mm in diameter. In the United States, there are about 500,000 new cases per year of peptic ulcer and 4 million ulcer recurrences; the lifetime prevalence of ulcers in the adult population is approximately 10%. Ulcers occur five times more commonly in the duodenum, where over 95% are in the bulb or pyloric channel. In the stomach, benign ulcers are located most commonly in the antrum (60%) and at the junction of the antrum and body on the lesser curvature (25%).

Ulcers occur slightly more commonly in men than in women (1.3:1). Although ulcers can occur in any age group, duodenal ulcers most commonly occur between the ages of 30 and 55, whereas gastric ulcers are more common between the ages of 55 and 70. Ulcers are more common in smokers and in patients taking NSAIDs on a chronic basis (see below). Alcohol and dietary factors do not appear to cause ulcer disease. The role of stress is uncertain. The incidence of duodenal ulcer disease has been declining dramatically for the past 30 years, but the incidence of gastric ulcers appears to be increasing, perhaps as a result of the widespread use of NSAIDs and low-dose aspirin.

Etiology

Three major causes of peptic ulcer disease are now recognized: NSAIDs, chronic *H pylori* infection, and acid hypersecretory states such as Zollinger-Ellison syndrome. Evidence of *H pylori* infection or NSAID ingestion should be sought in all patients with peptic ulcer. NSAID- and *H pylori*-associated ulcers will be considered in the present section; Zollinger-Ellison syndrome will be discussed subsequently. Up to one-fourth of ulcers are idiopathic.

A. *H pylori*-Associated Ulcers

H pylori appears to be a necessary cofactor for the majority of duodenal and gastric ulcers not associated with NSAIDs. Overall, it is estimated that one in six infected patients will develop ulcer disease. The prevalence of *H pylori* infection in duodenal ulcer patients is about 70-75%. Most *H pylori*-infected duodenal ulcer patients have infection predominantly in the gastric antrum, which is associated with increased gastric acid secretion and decreased duodenal mucosal bicarbonate secretion. It is hypothesized that increased acid exposure can give rise to small islands of gastric metaplasia in the duodenal bulb. Colonization of these islands by *H pylori* may lead to duodenitis or duodenal ulcer. The association with gastric ulcers is lower, but *H pylori* is found in the majority of patients in whom NSAIDs cannot be implicated. *H pylori*-associated gastric ulcers tend to form at the junction of the body and antrum—the site of transition from oxyntic to pyloric epithelium. Most *H pylori*-infected gastric ulcer patients have infection that predominates in the gastric body and is associated with decreased acid secretion. It is hypothesized that chronic inflammation overwhelms the gastric mucosal defense mechanisms.

The natural history of *H pylori*-associated peptic ulcer disease is well defined. In the absence of specific antibiotic treatment to eradicate the organism, 85% of patients will have an endoscopically visible recurrence within 1 year. Half of these will be symptomatic. After successful eradication of *H pylori* with antibiotics, ulcer recurrence rates are reduced dramatically to 5-20% at 1 year. Some of these ulcer recurrences may be due to NSAID use or reinfection with *H pylori*.

B. NSAID-Induced Ulcers

There is a 10-20% prevalence of gastric ulcers and a 2-5% prevalence of duodenal ulcers in chronic NSAID users. The relative risk of gastric ulcers is increased 40-fold, but the risk of duodenal ulcers is only slightly increased. Users of NSAIDs are at least three times more likely than nonusers to suffer serious gastrointestinal complications from these ulcers such as bleeding, perforation, or death. It is noteworthy that gastric ulcers and duodenal ulcers cause about the same number of complications. Approximately 1-2% of chronic NSAID users will have a major complication within 1 year. Aspirin is the most ulcerogenic NSAID. The risk appears to be dose-related, with some risk even at doses as low as 81 mg every other day. The risk of NSAID complications is greater with higher NSAID dosage, during the first 3 months of administration, with advanced age, and with a prior history of ulcer disease, concomitant corticosteroid administration, or serious medical illness. Celecoxib, rofecoxib, and valdecoxib are the first members of a new class of NSAIDs that selectively inhibit cyclooxygenase-2 (COX-2)—the principal enzyme involved in prostaglandin production at sites of inflammation—while sparing cyclooxygenase-1 (COX-1), the principal enzyme involved with prostaglandin production in the gastroduodenal mucosa and gastric cytoprotection. The incidence of endoscopically visible ulcers after 6-12 weeks of COX-2 therapy (4%) is not increased compared with patients treated with placebo and significantly lower than the incidence among those receiving nonselective NSAIDs (15-25%). Likewise, the risk of significant clinical events (obstruction, perforation, or severe bleeding) was 0.6-0.76% in patients taking COX-2 selective agents and 1.4% in patients taking nonselective NSAIDs—a relative risk reduction of 0.4-0.5. Concurrent use of low-dose aspirin appears to partially negate the mucosa-sparing effects of COX-2 selective agents. Among patients taking low-dose aspirin, the risk of a serious clinical event was not significantly different between patients taking COX-2 selective agents and standard NSAIDs. Other NSAIDs—etodolac, nabumetone, and meloxicam—appear to be partially selective for COX-2 at lower doses and may be safer than nonselective NSAIDs. These less expensive NSAIDs have not been compared with celecoxib or rofecoxib.

H pylori infection increases the risk of ulcer disease over threefold in patients taking NSAIDs or low-dose aspirin. The highest risk of developing ulcer complications among *H pylori*-infected patients is within the first 3 months after initiating NSAID treatment. It is hypothesized that NSAID initiation may potentiate or aggravate ulcer disease in susceptible infected individuals.

Clinical Findings

A. Symptoms and Signs

Epigastric pain (dyspepsia), the hallmark of peptic ulcer disease, is present in 80-90% of patients. However, this complaint is not sensitive or specific enough to serve as a reliable diagnostic criterion for peptic ulcer disease. The clinical history cannot accurately distinguish duodenal from gastric ulcers. Less than one-fourth of patients with dyspepsia have ulcer disease at endoscopy. Twenty percent of patients with ulcer complications such as bleeding have no antecedent symptoms ("silent ulcers").

In patients with NSAID-induced ulcers, half are asymptomatic. Nearly 60% of patients with NSAID complications do not have prior symptoms.

Pain is typically well localized to the epigastrium and not severe. It is described as gnawing, dull, aching, or "hunger-like." Approximately half of patients report relief of pain with food or antacids (especially duodenal ulcers) and a recurrence of pain 2-4 hours later. However, many patients deny any relationship to meals or report worsening of pain. Two-thirds of duodenal ulcers and one-third of gastric ulcers cause nocturnal pain that awakens the patient. A change from a patient's typical rhythmic discomfort to constant or radiating pain may reflect ulcer penetration or perforation. Most patients have symptomatic periods lasting up to several weeks with intervals of months to years in which they are pain-free (periodicity).

Nausea and anorexia may occur with gastric ulcers. Significant vomiting and weight loss are unusual with uncomplicated ulcer disease and suggest gastric outlet obstruction or gastric malignancy.

The physical examination is often normal in uncomplicated peptic ulcer disease. Mild, localized epigastric tenderness to deep palpation may be present. Fecal occult blood testing is positive in one-third of patients.

B. Laboratory Findings

Laboratory tests are normal in uncomplicated peptic ulcer disease but are ordered to exclude ulcer complications or confounding disease entities. Anemia may occur with acute blood loss from a bleeding ulcer or less commonly from chronic blood loss. Leukocytosis suggests ulcer penetration or perforation. An elevated serum amylase in a patient with severe epigastric pain suggests ulcer penetration into the pancreas. A fasting serum gastrin level to screen for Zollinger-Ellison syndrome is obtained in some patients (see below). Because acid inhibition may raise serum gastrin levels, H₂ receptor antagonists should be withheld for 24 hours and proton pump inhibitors for 1 week before a gastrin level is measured.

C. Endoscopy

Upper endoscopy is the procedure of choice for the diagnosis of duodenal and gastric ulcers. Endoscopy provides better diagnostic accuracy than barium radiography and the ability to biopsy for the presence of malignancy and *H pylori* infection. Duodenal ulcers are virtually never malignant and do not require biopsy. Three to 5 percent of benign-appearing gastric ulcers prove to be malignant. Hence, cytologic brushings and biopsies of the ulcer margin are almost always performed. Provided that the gastric ulcer appears benign to the endoscopist and adequate biopsy specimens reveal no evidence of cancer, dysplasia, or atypia, the patient may be followed without further endoscopy. If these conditions are not fulfilled, follow-up endoscopy should be performed 12 weeks after the start of therapy to document complete healing; nonhealing ulcers are suspicious for malignancy.

D. Imaging

Barium upper gastrointestinal series is an acceptable alternative to screening of uncomplicated patients with dyspepsia. However, because it has limited accuracy in distinguishing benign from malignant gastric ulcers, all gastric ulcers diagnosed by x-ray should be reevaluated with endoscopy after 8-12 weeks of therapy.

E. Testing for *H pylori*

In patients in whom an ulcer is diagnosed by endoscopy, gastric mucosal biopsies should be obtained both for a rapid urease test and for histologic examination. The specimens for histology are discarded if the urease test is positive. Alternatively, serologic testing may be the most cost-effective means of confirming *H pylori* infection in patients with a negative rapid urease test. (See section on *H pylori* gastritis, above.)

In patients with a history of peptic ulcer or when an ulcer is diagnosed by upper gastrointestinal series, noninvasive assessment for *H pylori* with fecal antigen assay, serologic testing, or urea breath testing should be done. Proton pump inhibitors may cause false-negative urea breath tests and fecal antigen tests and should be withheld for at least 7 days before testing.

Differential Diagnosis

Peptic ulcer disease must be distinguished from other causes of epigastric distress (dyspepsia). Over half of patients with dyspepsia have no obvious organic explanation for their symptoms and are classified as having functional dyspepsia (see sections above on dyspepsia and functional dyspepsia). Atypical gastroesophageal reflux may be manifested by epigastric symptoms. Biliary tract disease is characterized by discrete, intermittent episodes of pain that should not be confused with other causes of dyspepsia. Severe epigastric pain is atypical for peptic ulcer disease unless complicated by a perforation or penetration. Other causes include acute pancreatitis, acute cholecystitis or choledocholithiasis, esophageal rupture, gastric volvulus, and ruptured aortic aneurysm.

Pharmacologic Agents

The pharmacology of several agents that enhance the healing of peptic ulcers is briefly discussed here. They may be divided into three categories: (1) acid-antisecretory agents, (2) mucosal protective agents, and (3) agents that promote healing through eradication of *H pylori*. Recommendations for their use are provided in subsequent sections.

A. Acid-Antisecretory Agents

1. Proton pump inhibitors—Proton pump inhibitors covalently bind the acid-secreting enzyme H⁺-K⁺ ATPase, or "proton pump," permanently inactivating it. Restoration of acid secretion requires synthesis of new pumps, which have a half-life of 18 hours. Thus, although these agents have a serum half-life of less than 60 minutes, their duration of action exceeds 24 hours. The available agents—omeprazole or rabeprazole 20 mg, lansoprazole 30 mg, esomeprazole or pantoprazole 40 mg—inhibit over 90% of 24-hour acid secretion, compared with under 65% for H₂ receptor antagonists in standard dosages. Proton pump inhibitors should be administered 30 minutes before meals (usually breakfast).

Each of the four proton pump inhibitors results in over 90% healing of duodenal ulcers after 4 weeks and 90% of gastric ulcers after 8 weeks when given once daily. Compared with H₂ receptor antagonists, proton pump inhibitors provide faster pain relief and more rapid ulcer healing. However, nearly equivalent overall healing rates may be achieved with longer courses of H₂ receptor antagonists.

The proton pump inhibitors are remarkably safe in short-term therapy. Serum gastrin levels rise significantly (> 500 pg/mL) in 10% of patients receiving chronic therapy, which is associated with the development of gastric enterochromaffin-like cell hyperplasia in humans and gastric carcinoid tumors in rats. Clinical experience with these agents for over 10 years has not detected any significant toxicity in humans. Long-term use may lead to a mild decrease in vitamin B₁₂ and iron absorption of unclear significance. Long-term use is unnecessary in peptic ulcer disease but is frequently required in gastroesophageal reflux disease.

2. H₂ receptor antagonists—Although H₂ receptor antagonists are effective in the treatment of peptic ulcer disease, proton pump inhibitors are now the preferred agents because of their ease of use and superior efficacy. Four H₂ receptor antagonists are available: cimetidine, ranitidine, famotidine, and nizatidine. All four agents effectively inhibit nocturnal acid output, but they are less effective at inhibiting meal-stimulated acid secretion. For uncomplicated peptic ulcers, H₂ receptor antagonists may be administered once daily at bedtime as follows: ranitidine and nizatidine 300 mg, famotidine 40 mg, and cimetidine 800 mg. Ulcer symptom relief usually occurs within 2 weeks. Duodenal and gastric ulcer healing rates of 85-90% are obtained within 6 weeks and 8 weeks, respectively. All four agents are well tolerated, and serious adverse effects are rare. Cimetidine is uncommonly used because it inhibits hepatic cytochrome P450 metabolism (raising the serum concentration of theophylline, warfarin, lidocaine, and phenytoin) and may cause gynecomastia or impotence. Ranitidine binds P450 with one-tenth the avidity of cimetidine; famotidine and nizatidine have negligible effects.

B. Agents Enhancing Mucosal Defenses

Sucralfate, bismuth, misoprostol, and low doses of aluminum-containing antacids all have been shown to promote ulcer healing through the enhancement of mucosal defensive mechanisms. Given the greater efficacy and safety of antisecretory agents and better compliance of patients, sucralfate and these other agents are no longer used as first-line therapy for active ulcers in most clinical settings. Because of the rapid relief of ulcer symptoms they provide, antacids are commonly used as needed to supplement antisecretory agents during the first few days of treatment. Sucralfate, 1 g four times daily, is sometimes added to antisecretory therapy in patients with refractory ulcers. Bismuth has direct antibacterial action against *H pylori* and may be used in combination with antibiotics for eradication (see below). Misoprostol is a prostaglandin analog that stimulates gastroduodenal mucus and bicarbonate secretion. It is effective as a prophylactic agent in reducing the incidence of gastroduodenal ulcers in patients taking nonselective NSAIDs but must be given three or four times daily and causes diarrhea in 10-20% of patients. With the advent of proton pump inhibitors and COX-2 selective NSAIDs, it is now less commonly used for this indication.

C. *H pylori* Eradication Therapy

Eradication of *H pylori* has proved difficult. Combination regimens that employ two antibiotics with a proton pump inhibitor or bismuth are required to achieve adequate rates of eradication and to reduce the number of failures due to antibiotic resistance. Therapies employing only one or two antibiotics cannot be recommended. Resistance develops rapidly to metronidazole and clarithromycin but not to amoxicillin or tetracycline. In the United States, up to 50% of strains are resistant to metronidazole and 7% are resistant to clarithromycin. It is advisable to include amoxicillin in first-line therapy in most patients, reserving metronidazole for penicillin-allergic patients. Recommended regimens are listed in [Table 14-11](#). All currently recommended regimens achieve rates of eradication greater than 85% after 10-14 days of treatment. Proton pump inhibitors have direct antimicrobial action against *H pylori*; furthermore, by raising intragastric pH, they suppress bacterial growth

and optimize antibiotic efficacy. In most centers in the United States, the preferred regimen is with a 10- 14-day course of treatment with a proton pump inhibitor—omeprazole or rabeprazole 20 mg twice daily, lansoprazole 30 mg twice daily, pantoprazole 40 mg twice daily, or esomeprazole 40 mg once daily—plus amoxicillin 1 g twice daily and clarithromycin 500 mg twice daily. In patients whose infection persists after an initial course of antibiotic therapy, the optimal regimen may be quadruple therapy with a proton pump inhibitor, bismuth subsalicylate, tetracycline, and metronidazole for 14 days ([Table 14-11](#)).

Medical Treatment

Patients should be encouraged to eat balanced meals at regular intervals. There is no justification for bland or restrictive diets. Moderate alcohol intake is not harmful. Smoking retards the rate of ulcer healing and increases the frequency of recurrences and should be discouraged.

A. Treatment of *H pylori*-Associated Ulcers

1. Treatment of active ulcer—The goals of treatment of active *H pylori*-associated ulcers are to relieve dyspeptic symptoms, to promote ulcer healing, and to eradicate *H pylori* infection. Uncomplicated *H pylori*-associated ulcers should be treated for the first 10-14 days with one of the proton pump inhibitor-based *H pylori* eradication regimens listed in [Table 14-11](#). An antisecretory agent must be administered for an additional 2-4 weeks (duodenal ulcer) or 4-6 weeks (gastric ulcer) after completion of the antibiotic regimen to ensure complete ulcer healing. A once-daily proton pump inhibitor (omeprazole or rabeprazole 20 mg, lansoprazole 30 mg, pantoprazole or esomeprazole 40 mg) is most convenient, but H₂ receptor antagonists may be chosen as less expensive therapy. Confirmation of *H pylori* eradication in patients with uncomplicated ulcers is not necessary. Confirmation is required in all patients with ulcers complicated by bleeding, perforation, or obstruction.

2. Therapy to prevent recurrence—Successful eradication reduces ulcer recurrences to less than 20% after 1-2 years. Therefore, antisecretory therapy can be discontinued after 4-8 weeks in patients with uncomplicated ulcers and the patient observed for recurrence of symptoms. The most common cause of recurrence after antibiotic therapy is failure to achieve successful eradication, which must be evaluated. Once cure has been achieved, reinfection rates are less than 0.5% per year. Although *H pylori* has reduced the need for chronic maintenance antisecretory therapy to prevent ulcer recurrences, there remains a subset of patients who require chronic therapy with either a proton pump inhibitor once daily or an H₂ receptor antagonist at bedtime. This subset includes patients with *H pylori*-positive ulcers who have failed recurrent attempts at eradication therapy, patients with a history of *H pylori*-positive ulcers who have recurrent ulcers despite successful eradication, and patients with idiopathic ulcers (ie, *H pylori*-negative and not taking NSAIDs). In all patients with recurrent ulcers, NSAID usage (unintentional or surreptitious) and hypersecretory states (including gastrinoma) should be excluded.

B. Treatment of NSAID-Associated Ulcers

1. Treatment of active ulcers—In patients with NSAID-induced ulcers, the offending agent should be discontinued whenever possible. Both gastric and duodenal ulcers respond rapidly to therapy with H₂ receptor antagonists or proton pump inhibitors ([Table 14-11](#)) once NSAIDs are eliminated. In some patients with severe inflammatory diseases, it may not be feasible to discontinue NSAIDs. These patients should be treated with proton pump inhibitors once daily, which result in ulcer healing rates of approximately 80% at 8 weeks in patients continuing to take NSAIDs. All patients with NSAID-associated ulcers should undergo testing for *H pylori* infection. Antibiotic eradication therapy should be given if *H pylori* tests are positive.

2. Prevention of NSAID-induced ulcers—The goal of prophylactic therapy is to prevent ulcer complications, which occur in only 1-2% of NSAID-treated patients per year. Therefore, prophylactic therapy should be reserved for patients at high risk for developing complications. High-risk factors include a history of ulcer disease or complications, concurrent therapy with corticosteroids or anticoagulants, serious underlying medical illness, and age over 60. Such patients have a greater than 5% chance per year of developing a complicated ulcer from taking a nonselective NSAID. Whenever possible, NSAIDs should be avoided in this high-risk population. If NSAIDs must be given, the following options can be considered. (At this time, the optimal cost-effective approach has not been determined.)

a. Test for and treat *H pylori* infection—All patients who are started on nonselective NSAIDs should have noninvasive testing for *H pylori* infection followed by treatment, if positive. Eradication of *H pylori* reduces the incidence of endoscopic ulcers in acute NSAID users from 26-34% to 7-12% within 12 weeks.

b. COX-2 selective agent—For most patients at high risk of NSAID-induced complications, therapy with a COX-2 selective agent is recommended. The relative risk of significant clinical events (obstruction, perforation, or severe bleeding) in patients taking COX-2 selective agents (celecoxib, rofecoxib, and valdecoxib) is 0.5 compared with patients taking nonselective NSAIDs. Patients with multiple risk factors have a relative risk reduction but still have a significant risk of complications. In patients who require concurrent therapy with low-dose aspirin for cardiovascular prophylaxis, the safety of a COX-2 selective agent is partially negated.

c. Proton pump inhibitor—Treatment with a proton pump inhibitor given once daily (omeprazole or rabeprazole 20 mg, lansoprazole 30 mg, or pantoprazole or esomeprazole 40 mg) appears to be effective in the prevention of NSAID-induced gastric and duodenal ulcers and is approved by the FDA for this indication. For patients taking a daily proton pump inhibitor for another indication (such as gastroesophageal reflux disease), a nonselective NSAID may be more cost-effective than a COX-2 selective agent.

d. Misoprostol—The prostaglandin analog misoprostol is effective in the prevention of NSAID-induced gastric and duodenal ulcers when given at a dosage of 100-200 ug four times daily. In short studies of NSAID users with a history of gastric ulcers, the incidence among patients treated with misoprostol is one-third the incidence in those treated with a proton pump inhibitor. However, misoprostol is less commonly used as a prophylactic agent against NSAID-induced complications than either COX-2 selective agents or concurrent therapy with a proton pump inhibitor because of its high side-effect profile and the need for dosing four times daily.

e. Multiple NSAID risk factors—Patients with multiple risk factors are at particularly high risk of NSAID-induced complications. The optimal cost-effective approach to management of these patients is unknown. Options include a COX-2 selective agent alone, a standard NSAID and a prophylactic agent (proton pump inhibitor or misoprostol), or a COX-2 selective agent and a prophylactic agent. All high-risk patients treated with low-dose aspirin should receive a proton pump inhibitor.

D. Refractory Ulcers

Ulcers that are truly refractory to medical therapy are now uncommon. Less than 5% of ulcers are unhealed after 8 weeks of therapy with proton pump inhibitors. Noncompliance is the most common cause of ulcer nonhealing. Cigarettes retard ulcer healing and should be proscribed. NSAID and aspirin use, sometimes surreptitious, are commonly implicated in refractory ulcers and must be stopped. *H pylori* eradication enhances healing and decreases the high recurrence rates of refractory ulcers. Therefore, evidence of *H pylori* infection should be sought and the infection treated, if present, in all refractory ulcer patients. Fasting serum gastrin levels should be obtained to exclude gastrinoma with acid hypersecretion (Zollinger-Ellison syndrome). Nonhealing gastric ulcers raise concerns that an undiagnosed gastric malignancy may be masquerading as a benign gastric ulcer. Repeat ulcer biopsies are mandatory after 2-3 months of therapy in all nonhealed gastric ulcers, and they should be followed with serial endoscopies to verify complete healing. Almost all benign refractory ulcers heal within 8 weeks with a proton pump inhibitor twice daily (omeprazole or rabeprazole 20 mg twice daily, lansoprazole 30 mg twice daily). Patients with persistent nonhealing ulcers are referred for surgical therapy after exclusion of NSAID use and persistent *H pylori* infection.

COMPLICATIONS OF PEPTIC ULCER DISEASE

1. Gastrointestinal Hemorrhage

Essentials of Diagnosis

- "Coffee grounds" emesis, hematemesis, melena, or hematochezia.
- Emergent upper endoscopy is diagnostic and therapeutic.

General Considerations

Approximately 50% of all episodes of upper gastrointestinal bleeding are due to peptic ulcer. Clinically significant bleeding occurs in 10-20% of ulcer patients. About 80% of patients stop bleeding spontaneously and generally have an uneventful recovery; the remainder have more severe bleeding. The overall mortality rate for ulcer bleeding is 6-10%, but it is higher in the elderly, in patients with comorbid medical problems, and in patients with nosocomial bleeding. Mortality is also higher in patients who present with persistent hypertension or shock, bright red blood in the vomitus or nasogastric lavage fluid, or severe coagulopathy.

Clinical Findings

A. Symptoms and Signs

Up to 20% of patients have no antecedent symptoms of pain; this is particularly true of patients receiving NSAIDs. Common presenting signs include melena and hematemesis. Massive upper gastrointestinal bleeding or rapid gastrointestinal transit may result in hematochezia rather than melena; this may be misinterpreted as signifying a lower tract bleeding source. Nasogastric lavage that demonstrates "coffee grounds" or bright red blood confirms an upper tract source. Recovered nasogastric lavage fluid that is negative for blood does not exclude active bleeding from a duodenal ulcer.

B. Laboratory Findings

The hematocrit may fall as a result of bleeding or expansion of the intravascular volume with intravenous fluids. The BUN may rise as a result of absorption of blood nitrogen from the small intestine and prerenal azotemia.

Treatment

The assessment and initial management of upper gastrointestinal tract bleeding are discussed elsewhere in this chapter. Specific issues pertaining to peptic ulcer bleeding are described below.

A. Medical Therapy

1. Antisecretory agents—Intravenous or high-dose oral proton pump inhibitors have been associated with a reduction in rebleeding, transfusions, and the need for further endoscopic therapy in the subset of patients with ulcers whose endoscopic appearance suggests a high risk of rebleeding (as described below). Intravenous omeprazole (80-mg bolus injection, followed by 8-mg/h continuous infusion for 72 hours) has undergone the most clinical testing, but the intravenous formulation is not available in the United States. Intravenous pantoprazole is available in the United States, but the optimal dosage for this indication has not been determined. The potential benefit and minimal cost support the use of intravenous proton pump inhibitors or high-dose oral proton pump inhibitors (eg, omeprazole, 40 mg twice daily) for 3 days in patients with ulcers whose endoscopic appearance suggests a high risk of rebleeding. Many physicians choose to administer a high-dose proton pump inhibitor prior to endoscopy in all patients admitted to the hospital with gastrointestinal bleeding suspected to be due to peptic ulcer, discontinuing therapy after endoscopy in patients with ulcers deemed to be at low risk of rebleeding. Intravenous H₂ receptor antagonists have not been demonstrated to be of any benefit in the treatment of acute ulcer bleeding.

2. Somatostatin and octreotide—Intravenous somatostatin (250 ug/h; not available in the United States) and its long-acting analog, octreotide (100-ug bolus; 25-50 ug/h) reduce splanchnic blood flow and inhibit gastric acid secretion. The efficacy of these agents has not been demonstrated convincingly except by meta-analysis showing reduction in rebleeding. Their role at this time is unclear. They may be useful adjunctive agents in patients in whom endoscopic therapy is unsuccessful in controlling bleeding or when endoscopy is not available.

3. Long-term prevention of rebleeding—One-third of patients develop recurrent ulcer bleeding within 3 years if no specific therapy is given. Unblinded studies have demonstrated that in patients with bleeding ulcers who are *H pylori*-positive, successful eradication effectively prevents recurrent ulcer bleeding in virtually all cases. It is therefore recommended that all patients with bleeding ulcers be tested for *H pylori* infection and treated if positive. Four to 8 weeks after completion of antibiotic therapy, a urea breath or fecal antigen test for *H pylori* should be administered or endoscopy performed with biopsy for histologic confirmation of successful eradication. In patients in whom *H pylori* persists or those whose ulcers are not associated with NSAIDs or *H pylori*, chronic acid suppression with a bedtime dose of an H₂ antagonist (ranitidine 150 mg) or a once-daily proton pump inhibitor should be prescribed to reduce the likelihood of recurrence of bleeding.

B. Endoscopy

Endoscopy is the preferred diagnostic procedure in virtually all cases of upper gastrointestinal bleeding because of its high diagnostic accuracy, its ability to predict the likelihood of recurrent bleeding, and its availability for therapeutic intervention in high-risk lesions. Endoscopy should be performed within 12-24 hours in virtually all cases. In cases of severe active bleeding, endoscopy is performed as soon as patients have been appropriately resuscitated and are hemodynamically stable.

On the basis of clinical and endoscopic criteria, it is possible to predict which patients are at a higher risk of rebleeding and therefore to make more rational use of hospital resources. Nonbleeding ulcers under 2 cm in size with a base that is clean have a less than 5% chance of rebleeding. Most young (under age 60), otherwise healthy patients with clean-based ulcers may be monitored in the emergency room or on the hospital ward for 24 hours before discharge. Low-risk patients can be safely discharged from the hospital or emergency room immediately after endoscopy. Ulcers that have only a flat red or black spot have a less than 10% chance of significant rebleeding, and those with a firmly adherent clot have a 12-33% rebleeding risk. Patients who are hemodynamically stable with these findings should be admitted to a hospital ward for 48-72 hours and may begin immediate oral feedings and antiulcer (or anti-*H pylori*) medication.

By contrast, the risk of rebleeding or continued bleeding in ulcers with a nonbleeding visible vessel is 50%, and with active bleeding it is 80-90%. Endoscopic therapy with injection or thermocoagulation techniques now is the standard of care for such lesions because it reduces the risk of rebleeding, the number of transfusions, and the need for subsequent surgery. Injection is performed into and around the ulcer vessel with epinephrine (1:10,000). Thermocoagulation is achieved with contact cautery probes applied directly to the ulcer vessel. Using any of these techniques, successful hemostasis of actively bleeding lesions is achieved in 90%. For actively bleeding ulcers, a combination of epinephrine injection followed by thermocoagulation yields better control of bleeding than either modality alone. Significant rebleeding occurs in 10-20% of cases, of which over 70% can be managed successfully with repeat endoscopic treatment. After endoscopic therapy, the risk of rebleeding declines significantly over 3 days to less than 3%. Patients with these high-risk lesions should receive a high-dose intravenous or oral proton pump inhibitor regimen for 72 hours. After endoscopic treatment, high-risk patients should be monitored in an ICU setting for at least 24 hours and should remain hospitalized for at least 72 hours.

C. Surgical Treatment

Patients with high-risk endoscopic lesions and those whose condition warrants ICU admission should be evaluated by a surgeon. However, less than 10% of patients treated with hemostatic therapy require surgery for continued or recurrent bleeding. Overall surgical mortality for emergency ulcer bleeding is less than 6%. The prognosis is poorer for patients over age 60, those with serious underlying medical illnesses or chronic renal failure, and those who require more than 10 units of blood transfusion.

2. Ulcer Perforation

Perforations develop in 5% of ulcer patients, usually from ulcers on the anterior wall of the stomach or duodenum. The incidence of perforations may be increasing, perhaps as a consequence of using NSAIDs or crack cocaine. Zollinger-Ellison disease should be considered in patients who present with ulcer perforation. Perforation results in a chemical peritonitis that causes sudden, severe generalized abdominal pain that prompts most patients to seek immediate attention. Elderly or debilitated patients and those receiving chronic steroid therapy may experience minimal initial symptoms, presenting late with bacterial peritonitis, sepsis, and shock. On physical examination, patients appear ill, with a rigid, quiet abdomen and rebound tenderness. Hypotension develops later after bacterial peritonitis has developed. If hypotension is present early with the onset of pain, one should consider other abdominal emergencies such as a ruptured aortic aneurysm, mesenteric infarction, or acute pancreatitis. Leukocytosis is almost always present. A mildly elevated serum amylase (less than twice normal) is sometimes seen. Upright or decubitus films of the abdomen reveal free intraperitoneal air in 75% of cases, and in most cases this establishes the diagnosis without need for further studies. The absence of free air may lead to a misdiagnosis of pancreatitis, cholecystitis, or appendicitis. Upper gastrointestinal radiography with water-soluble contrast may be useful in this setting. Barium studies are contraindicated in patients with possible perforation.

Traditional surgical dogma held that the majority of patients with perforated ulcers should undergo emergency laparotomy. Closure of the perforation was performed with an omental ("Graham") patch and, in stable patients, a proximal gastric vagotomy was performed to decrease the chance of ulcer recurrence. This approach is changing as a result of two factors. The first is minimally invasive surgical technique. Laparoscopic perforation closure can be performed in many centers, significantly reducing operative morbidity. Second is the recognition that *H pylori* infection is associated with most ulcers and ulcer perforations. Postoperative treatment of *H pylori* reduces the risk of ulcer recurrence, obviating the need for intraoperative vagotomy. The overall mortality rate in patients treated surgically is 5%.

Up to 40% of ulcer perforations seal spontaneously by the adherence of omentum or adjacent organs to the lesion and do not have significant intraperitoneal spillage. Thus, some centers advocate initial nonoperative management for patients whose onset of symptoms is less than 12 hours and whose upper gastrointestinal series with water-soluble contrast medium does not demonstrate leakage. At present, such conservative therapy is most appropriate for patients who are poor operative candidates. Patients should be monitored closely while receiving fluids, nasogastric suction, antisecretory agents, and broad-spectrum antibiotics. If their condition deteriorates over the first 12 hours (as evidenced by increasing pain, rising pulse or temperature, or worsening peritonitis), they should be taken to the operating room.

3. Ulcer Penetration

An ulcer located along the posterior wall of the duodenum or stomach may perforate into contiguous structures such as the pancreas, liver, or biliary tree. Patients complain of a change in the intensity and rhythmicity of their ulcer symptoms. The pain becomes more severe and constant, may radiate to the back, and is unresponsive to antacids or food. Physical examination and laboratory tests are nonspecific. Mild amylase elevations may sometimes occur. Endoscopy and barium x-ray studies confirm the ulceration but are not diagnostic of an actual penetration. Patients should be given intravenous H₂ receptor antagonists (as above) or omeprazole, 40 mg/d, and followed closely. Those who fail to improve should be considered for surgical therapy.

4. Gastric Outlet Obstruction

Gastric outlet obstruction occurs in 2% of patients with ulcer disease and is due to edema or cicatricial narrowing of the pylorus or duodenal bulb. Most patients have a prior known history of ulcer disease. Obstruction is less commonly caused by gastric neoplasms or extrinsic duodenal obstruction by intra-abdominal neoplasms. The most common symptoms are early satiety, vomiting, and weight loss. Early symptoms are epigastric fullness or heaviness after meals. Later, vomiting may develop that typically occurs 1 to several hours after eating and consists of partially digested food contents. Chronic obstruction may result in a grossly dilated, atonic stomach, severe weight loss, and malnutrition. Patients may develop dehydration, metabolic alkalosis, and hypokalemia. On physical examination, a succussion splash may be heard in the epigastrium. In most cases, nasogastric aspiration will result in evacuation of a large amount (> 200 mL) of foul-smelling fluid, which establishes the diagnosis. More subtle obstruction is diagnosed by a saline load test or by a nuclear gastric emptying study. Patients are treated initially with intravenous isotonic saline and KCl to correct fluid and electrolyte disorders, intravenous H₂ receptor antagonists (see treatment of stress gastritis, above), and nasogastric decompression of the stomach. Severely malnourished patients should receive total parenteral nutrition. Upper endoscopy is performed after 24-72 hours to define the nature of the obstruction and to exclude gastric neoplasm. At 72 hours, all patients should be evaluated with a saline load test. A positive test consists of more than 400 mL of residual volume 30 minutes after instillation of 750 mL of 0.9% saline into the stomach by nasogastric tube. Patients with a negative load test may be started on clear liquids and their diet advanced as tolerated. The remainder should remain on nasogastric suction for 5-7 days. Traditionally, patients unimproved after that time have been recommended for surgical treatment with vagotomy and either pyloroplasty or antrectomy. However, upper endoscopy with dilation of the gastric obstruction by hydrostatic balloons passed through the instrument has achieved success in two-thirds of patients. It may be reasonable to pursue dilation first in patients with milder symptoms, reserving surgery for those who fail to respond.

ZOLLINGER-ELLISON SYNDROME (GASTRINOMA)

Essentials of Diagnosis

- Peptic ulcer disease; may be severe and atypical.
- Gastric acid hypersecretion.
- Diarrhea common, relieved by nasogastric suction.
- Most cases are sporadic; 25% with MEN 1.

General Considerations

Zollinger-Ellison syndrome is caused by gastrin-secreting gut neuroendocrine tumors (gastrinomas), which result in hypergastrinemia and acid hypersecretion. Less than 1% of peptic ulcer disease is caused by gastrinomas. Primary gastrinomas may arise in the pancreas (25%), duodenal wall (45%), or lymph nodes (5-15%); in about 20% they are in other locations or are of unknown origin. Approximately 80% arise within the "gastrinoma triangle" bounded by the porta hepatis, the neck of the pancreas, and the third portion of the duodenum. Most gastrinomas are solitary or multifocal nodules that are potentially resectable. Over two-thirds of gastrinomas are malignant, and one-third have already metastasized to the liver at initial presentation. Approximately 25% of patients have small multicentric gastrinomas associated with MEN 1 that are more difficult to resect.

Clinical Findings

A. Symptoms and Signs

Over 90% of patients with Zollinger-Ellison syndrome develop peptic ulcers. In most cases, the symptoms are indistinguishable from other causes of peptic ulcer disease and therefore may go undetected for years. Ulcers usually are solitary and located in the duodenal bulb, but they may be multiple or occur more distally in the duodenum. Isolated gastric ulcers do not occur. Gastroesophageal reflux symptoms occur often. Diarrhea occurs in one-third of patients, in some cases in the absence of peptic symptoms. Gastric acid hypersecretion can cause direct intestinal mucosal injury and pancreatic enzyme inactivation, resulting in diarrhea, steatorrhea, and weight loss; nasogastric aspiration of stomach acid stops the diarrhea. Screening for Zollinger-Ellison syndrome with fasting gastrin levels should be obtained in patients with ulcers that are refractory to standard therapies, giant ulcers (> 2 cm), ulcers located distal to the duodenal bulb, multiple duodenal ulcers, frequent ulcer recurrences, ulcers associated with diarrhea, ulcers occurring after ulcer surgery, and patients with ulcer complications. Ulcer patients with hypercalcemia or family histories of ulcers (suggesting MEN 1) should also be screened. Finally, patients with peptic ulcers who are *H pylori*-negative and who are not taking NSAIDs should be screened.

B. Laboratory Findings

The most sensitive and specific method for identifying Zollinger-Ellison syndrome is demonstration of an increased fasting serum gastrin concentration (> 150 pg/mL). Levels should be obtained with patients not taking H₂ receptor antagonists for 24 hours or omeprazole for 6 days. The median gastrin level is 500-700 pg/mL, and 60% have levels less than 1000 pg/mL. Hypochlorhydria with increased gastric pH is a much more common cause of hypergastrinemia than is gastrinoma. Therefore, a measurement of gastric pH (and, where available, gastric secretory studies) is performed in patients with fasting hypergastrinemia. Most patients have a basal acid output of over 15 meq/h. A gastric pH of > 3.0 implies hypochlorhydria and excludes gastrinoma. In a patient with a serum gastrin level of > 1000 pg/mL and acid hypersecretion, the diagnosis of Zollinger-Ellison syndrome is established. With lower gastrin levels (150-1000 pg/mL) and acid secretion, a secretin stimulation test is performed to distinguish Zollinger-Ellison syndrome from other causes of hypergastrinemia. Intravenous secretin (2 units/kg) produces a rise in serum gastrin of over 200 pg/mL within 2-30 minutes in 85% of patients with gastrinoma. An elevated serum calcium suggests hyperparathyroidism and MEN 1 syndrome. In all patients with Zollinger-Ellison syndrome, a serum PTH, prolactin, LH-FSH, and GH level should be obtained to exclude MEN 1.

C. Imaging

Imaging studies are obtained in an attempt to determine whether there is metastatic disease and, if not, to identify the site of the primary tumor. Although conventional radiologic studies such as CT, MRI, and transabdominal ultrasound are commonly obtained, their sensitivity is less than 50-70% for hepatic metastases and 35% for primary tumors. These studies are being supplanted by somatostatin receptor scintigraphy (SRS) and endoscopic ultrasonography (EUS). The former should be the first study obtained because of its high sensitivity (> 90%) for detecting hepatic metastases, though its sensitivity for detecting the primary gastrinoma is much lower. If SRS is positive for tumor localization, further imaging studies are not necessary. In patients with negative SRS, EUS is indicated. This study has a sensitivity of > 90% for tumors of the pancreatic head and can visualize half of tumors in the duodenal wall or adjacent lymph nodes. With a combination of SRS and EUS, more than 90% of primary gastrinomas now can be localized preoperatively.

Differential Diagnosis

Gastrinomas are one of several gut neuroendocrine tumors that have similar histopathologic features and arise either from the gut or pancreas. These include carcinoid, insulinoma, VIPoma, glucagonoma, and somatostatinoma. These tumors usually are differentiated by the gut peptides that they secrete; however, poorly differentiated neuroendocrine tumors may not secrete any hormones. Patients may present with symptoms caused by tumor metastases (jaundice, hepatomegaly) rather than functional symptoms. Once a diagnosis of a neuroendocrine tumor is established from the liver biopsy, the specific type of tumor can subsequently be determined. Both carcinoids and gastrinomas may be detected incidentally during endoscopy after biopsy of a submucosal nodule and must be distinguished by subsequent studies.

Hypergastrinemia due to gastrinoma must be distinguished from other causes of hypergastrinemia. Atrophic gastritis with decreased acid secretion is detected by gastric secretory analysis. Other conditions associated with hypergastrinemia (eg, gastric outlet obstruction, vagotomy, chronic renal failure) are associated with a negative secretin stimulation test.

Treatment

A. Metastatic Disease

The most important predictor of survival is the presence of hepatic metastases. In patients with multiple hepatic metastases, initial therapy should be directed at controlling hypersecretion. Proton pump inhibitors (omeprazole, rabeprazole, pantoprazole, or lansoprazole) are given at a dose of 40-120 mg/d, titrated to achieve a basal acid output of < 10 meq/h. At this level, there is complete symptomatic relief and ulcer healing. In patients with isolated hepatic metastases, surgical resection may decrease the need for antisecretory medications and may prolong survival. Owing to the slow growth of these tumors, 30% of patients with hepatic metastases have a survival of 10 years.

B. Localized Disease

Cure can be achieved only if the gastrinoma can be resected before hepatic metastatic spread has occurred. Lymph node metastases do not adversely affect prognosis. Laparotomy should be considered in all patients in whom preoperative studies fail to demonstrate hepatic or other distant metastases. A combination of preoperative studies and intraoperative palpation and sonography allows successful localization and resection in the majority of cases. The 15-year survival of patients who do not have liver metastases at initial presentation is over 80%.

Li ML et al: Gastrinoma. Curr Treat Options Oncol 2001;2:337. [PMID: 12057114]

BENIGN TUMORS OF THE STOMACH

Gastric epithelial polyps are usually detected incidentally at endoscopy. The majority are hyperplastic polyps, which are small, single or multiple, have no malignant potential, and do not require removal or endoscopic surveillance. Adenomatous polyps account for 10-20% of gastric polyps. They are usually solitary lesions. In rare instances they ulcerate, causing chronic blood loss. Because of their premalignant potential, endoscopic removal is indicated. Annual endoscopic surveillance is recommended to screen for further polyp development. Submucosal gastric polypoid lesions include benign gastric stromal tumors (commonly known as leiomyomas) and pancreatic rests.

MALIGNANT TUMORS OF THE STOMACH

1. Gastric Adenocarcinoma

Essentials of Diagnosis

- Dyspeptic symptoms with weight loss in patients over age 40.
- Iron deficiency anemia; occult blood in stools.
- Abnormality detected on upper gastrointestinal series or endoscopy.

General Considerations

Although gastric adenocarcinoma is the most common cancer (other than skin cancer) worldwide, its incidence in the United States has declined by two-thirds over the last 30 years to 20,000 cases annually. Gastric cancer is uncommon under age 40; the mean age at diagnosis is 63 years. Men are affected twice as often as women. The incidence is higher in Latinos, African-Americans, and Asian-Americans. Certain regions such as Chile, Colombia, Central America, and Japan have rates as high as 80 per 100,000 population. Although most gastric cancers arise in the antrum, the incidence of proximal tumors of the cardia and fundus is increasing dramatically.

Chronic *H pylori* gastritis is a strong risk factor for gastric carcinoma of the distal (but not proximal) stomach, increasing the relative risk four- to sixfold. It is estimated that 35-90% of cases of distal gastric carcinoma may be attributable to *H pylori*. Less than 1% of chronically infected individuals will develop carcinoma. Other risk factors for gastric cancer include chronic atrophic gastritis with intestinal metaplasia (often secondary to chronic *H pylori* infection), pernicious anemia, and a history of partial gastric resection more than 15 years previously.

Gastric cancer may occur in a variety of morphologic types: (1) polypoid or fungating intraluminal masses; (2) ulcerating masses; (3) diffusely spreading (linitis plastica), in which the tumor spreads through the submucosa, resulting in a rigid, atonic stomach with thickened folds (prognosis dismal); and (4) superficially spreading or "early" gastric cancer—confined to the mucosa or submucosa (with or without lymph node metastases) and associated with an excellent prognosis.

Clinical Findings

A. Symptoms and Signs

Gastric carcinoma is generally asymptomatic until the disease is quite advanced. Symptoms are nonspecific and are determined in part by the location of the tumor. Dyspepsia, vague epigastric pain, anorexia, early satiety, and weight loss are the presenting symptoms in most patients. Patients may derive initial symptomatic relief from over-the-counter remedies, further delaying diagnosis. Ulcerating lesions can lead to acute gastrointestinal bleeding with hematemesis or melena. Pyloric obstruction results in postprandial vomiting. Lower esophageal obstruction causes progressive dysphagia. Physical examination is rarely helpful. A gastric mass is palpated in less than one-fifth of patients. Signs of metastatic spread include a left supraclavicular lymph node (Virchow's node), an umbilical nodule (Sister Mary Joseph nodule), a rigid rectal shelf (Blumer's shelf), and ovarian metastases (Krukenberg tumor). Guaiac-positive stools may be detectable.

B. Laboratory Findings

Iron deficiency anemia due to chronic blood loss or anemia of chronic disease is common. Liver function test abnormalities may be present if there is metastatic liver spread. Other tumor markers are of no value.

C. Endoscopy

Upper endoscopy should be obtained in all patients over age 45 with new onset of epigastric symptoms (dyspepsia) and in anyone with dyspepsia that is persistent or fails to respond to a short trial of antisecretory therapy. Endoscopy with cytologic brushings and biopsies of suspicious lesions is highly sensitive for detecting gastric carcinoma. It can be difficult to obtain adequate biopsy specimens in linitis plastica lesions. Because of the high incidence of gastric carcinoma in Japan, screening upper endoscopy is performed to detect early gastric carcinoma. Approximately 40% of tumors detected by screening are early, with a 5-year survival rate of almost 90%. Screening programs are not recommended in the United States.

D. Imaging

A barium upper gastrointestinal series is an acceptable alternative when endoscopy is not readily available but may not detect small or superficial lesions and cannot reliably distinguish benign from malignant ulcerations. Any abnormalities detected with this procedure require endoscopic confirmation.

Once a gastric cancer is diagnosed, preoperative evaluation with abdominal CT and endoscopic ultrasonography is indicated to delineate the local extent of the primary tumor as well as nodal or distant metastases. Abdominal CT is valuable in identifying distant metastases and direct invasion of adjacent structures. Endoscopic ultrasound imaging is superior to CT in determining the depth of tumor penetration and nodal metastases.

E. Staging

Staging is defined according to the TNM system, in which T1 tumors invade to the submucosa, T2 invade the muscularis propria, T3 penetrate the serosa, and T4 invade adjacent structures. Nodes are graded as N0 if there is no involvement, N1 if there are metastases to perigastric nodes, and N2 if regional lymph nodes are involved. M1 signifies the presence of metastatic disease. The stages are defined as shown in the accompanying box.

STAGING CRITERIA FOR GASTRIC ADENOCARCINOMA

Stage I: T1N0, T1N1, T2N0, all M0
Stage II: T1N2, T2N1, T3N0, all M0
Stage III: T2N2, T3N1, T4N0, all M0
Stage IV: T4N2M0, any M1

Differential Diagnosis

Ulcerating gastric adenocarcinomas are distinguished from benign gastric ulcers by biopsies. Approximately 3% of gastric ulcers initially believed to be benign later prove to be malignant. To exclude malignancy, all gastric ulcers identified at endoscopy should be biopsied. Ulcers that are suspicious for malignancy to the endoscopist or that have atypia or dysplasia on histologic examination warrant repeat endoscopy in 2-3 months to verify healing and exclude malignancy. Nonhealing ulcers should be considered for resection. Infiltrative carcinoma with thickened gastric folds must be distinguished from lymphoma and other hypertrophic gastropathies such as Menetrier's disease.

Treatment

A. Curative Surgical Resection

Surgical resection is the only therapy with curative potential. After preoperative staging, about two-thirds of patients will be found to have localized disease (ie, stages I-III) and should undergo surgical exploration. At surgery, approximately one-fourth of these patients will be found to have locally unresectable tumors or peritoneal, hepatic, or distant lymph node metastases for which "curative" surgical resection is not warranted (see below). The remaining patients with confirmed localized disease should undergo radical surgical resection with curative intent. For adenocarcinoma localized to the distal two-thirds of the stomach, a subtotal distal gastrectomy should be performed. For proximal gastric cancer or diffusely infiltrating disease, total gastrectomy is necessary. Although lymph node dissection should be performed for curative resections, there has been ongoing debate about whether an extended (perigastric and regional) lymph node dissection or a limited (perigastric) dissection is needed. A recent study has demonstrated greater short-term morbidity and no long-term survival advantage for extended lymph node dissection. Adjuvant therapy following curative resection has not conferred a survival benefit for postoperative chemotherapy.

B. Palliative Modalities

Many patients will be found either preoperatively or at the time of surgical exploration to have advanced disease that is not amenable to "curative" surgery due to peritoneal or distant metastases or local invasion of other organs. In many of these cases, palliative resection of the tumor nonetheless may be indicated. Such resection removes the risk of bleeding and obstruction, leads to improved quality of life, and improves survival. For patients with unresectable disease, gastrojejunostomy may be indicated to prevent obstruction. Bleeding or obstruction from unresected tumors may be treated with endoscopic laser or stent therapy, radiation therapy, or angiographic embolization. Although chemotherapy has not been shown to prolong life, single-agent or combination therapies with fluorouracil, doxorubicin, and cisplatin or mitomycin may provide palliation in up to 30%.

Prognosis

The long-term survival of gastric carcinoma is less than 15%. However, 5-year survival in patients who undergo successful curative resection is over 45%. Survival is related to tumor stage, location, and histologic features. Stage I and stage II tumors resected for cure have a greater than 50% long-term survival. Patients with stage III tumors have a poor prognosis (< 20% long-term survival) and should be considered for enrollment in clinical trials. Tumors of the diffuse and signet ring type have a worse prognosis than the intestinal type. Tumors of the proximal stomach (fundus and cardia) carry a far worse prognosis than distal lesions. Even with apparently localized disease, proximal tumors have a 5-year survival of less than 15%. For those whose disease progresses despite therapy, meticulous efforts at palliative care are essential (see [Chapter 5](#)).

De Vivo R et al: The role of chemotherapy in the management of gastric cancer. J Clin Gastroenterol 2000;30:364. [\[PMID: 10875463\]](#)

2. Lymphoma

Lymphoma is the second most common gastric malignancy, accounting for 3-6% of gastric cancers. More than 95% of these are non-Hodgkin's B cell lymphomas. Gastric lymphomas may be primary (arising from the gastric mucosa) or may represent a site of secondary involvement in patients with nodal lymphomas. About 60% of primary gastric lymphomas are believed to arise from mucosa-associated lymphoid tissue (MALT). Distinguishing advanced primary gastric lymphoma with adjacent nodal spread from advanced nodal lymphoma with secondary gastric spread can be problematic. Because the prognosis and treatment of primary and secondary gastric lymphomas are entirely different, the distinction is important. B cells of nodal origin may be distinguished from those derived from MALT (CD19- and CD20-positive).

Infection with *H pylori* may be an important risk factor for the development of primary gastric lymphoma. Chronic infection with *H pylori* causes an intense lymphocytic inflammatory response that may lead to the development of lymphoid follicles. Over 85% of low-grade primary gastric lymphomas and 40% of high-grade lymphomas are associated with *H pylori* infection. The risk of developing lymphoma is increased sevenfold in patients with chronic *H pylori* infection. It is hypothesized that chronic antigenic stimulation may result in a monoclonal lymphoproliferation that may culminate in a low-grade MALT lymphoma. At present, the relationship between high-grade primary lymphomas, MALT, and *H pylori* infection is unclear.

The clinical presentation and endoscopic appearance of gastric lymphoma are similar to those of adenocarcinoma. The majority of patients present with abdominal pain, weight loss, or bleeding. Night sweats are absent in primary lymphoma. At endoscopy, lymphoma may appear as an ulcer, mass, or diffusely infiltrating lesion. The diagnosis is established with endoscopic biopsy. All patients should undergo staging with abdominal and chest CT. Endoscopic ultrasonography is the most sensitive test for determining the presence of perigastric lymphadenopathy.

Nodal lymphomas with secondary gastrointestinal involvement usually present at an advanced stage with widely disseminated disease and are seldom curable. Their treatment is addressed in [Chapter 13](#). By contrast, primary low-grade gastric lymphomas usually are localized to the stomach wall (stage IE) or adjacent lymph nodes (stage IIE) and have an excellent prognosis. Patients with primary low-grade gastric MALT-lymphoma should be tested for *H pylori* infection and treated if positive. Where available, endoscopic ultrasonography should be performed to accurately determine tumor stage. Complete lymphoma regression after successful *H pylori* eradication occurs in 75% of cases of stage IE low-grade lymphoma. Remission may take as long as a year. Patients with stage IE or IIE low-grade lymphomas who either are not infected with *H pylori* or fail to respond to eradication therapy can be treated successfully with surgical resection, local radiation therapy, or combination therapy. Stage IE or 2E high-grade lymphomas may be treated with resection and CHOP chemotherapy. Stage III and stage IV primary lymphomas are treated with combination chemotherapy. Because of a low risk of perforation with either radiation therapy or chemotherapy, surgical resection is no longer recommended. The long-term survival of primary gastric lymphoma for stage I is over 85% and for stage II is 35-65%.

Fischbach W et al: Primary gastric B-cell lymphoma: results of a prospective multicenter study. The German-Austrian Gastrointestinal Lymphoma Study Group. Gastroenterology 2000;119:1191. [\[PMID: 11054376\]](#)

3. Carcinoid Tumors

Gastric carcinoids are rare tumors that make up less than 1% of gastric neoplasms. They may occur sporadically or secondary to chronic hypergastrinemia that results in hyperplasia and transformation of enterochromaffin cells in the gastric fundus. Sporadic carcinoids account for 20% of gastric carcinoids. Most are solitary, over 2 cm

in size, and have a strong propensity for metastatic spread. Most sporadic carcinoids already have carcinoid syndrome and hepatic or pulmonary metastatic involvement at initial presentation. Localized sporadic carcinoids should be treated with radical gastrectomy.

The majority of carcinoids caused by hypergastrinemia occur in association with either pernicious anemia (75%) or Zollinger-Ellison syndrome (5%). Carcinoids associated with Zollinger-Ellison syndrome occur almost exclusively in patients with MEN 1, in which loss of 11q13 has been reported. Carcinoids caused by hypergastrinemia tend to be multicentric, less than 1 cm in size, and have a low potential for metastatic spread or development of carcinoid syndrome. Small lesions may be successfully treated with endoscopic resection followed by periodic endoscopic surveillance. Antrectomy reduces serum gastrin levels and may lead to regression of small tumors. Patients with large or multiple carcinoids should undergo surgical tumor resection.

Kulke M et al: Carcinoid tumors. N Engl J Med 1999;340:858. [\[PMID: 10080850\]](#)

4. Stromal Tumors

Gastrointestinal stromal tumors (leiomyomas and leiomyosarcomas) occur throughout the gastrointestinal tract, but approximately two-thirds occur in the stomach. They derive from mesenchymal stem cells and have an epithelioid or spindle cell histologic pattern, resembling smooth muscle. Most have a mutation in the proto-oncogene *c-kit* tyrosine kinase and stain positively for CD117 and CD34. Tumors may grow quite large before causing symptoms, mainly acute or chronic bleeding due to central ulceration within the tumor. At endoscopy, they appear as a submucosal mass that may have central umbilication or ulceration. Endoscopic ultrasound with fine-needle aspiration is the optimal study for assessing these tumors. It is difficult to distinguish benign ("leiomyoma") from malignant ("leiomyosarcoma") stromal tumors on clinical or histologic grounds. Surgery is therefore recommended for tumors over 3-5 cm in size, those that have an irregular border or cystic spaces, and those that have increased mitotic activity (more than two mitoses per high-power field). Mitotic activity may be more accurately assessed by nuclear immunohistochemical staining with Ki-67. Surgical resection is the only effective therapy for localized malignant stromal tumors. Overall 5-year survival is 30%. Metastatic tumors are aggressive and carry a poor prognosis. The tyrosine kinase inhibitor imatinib has recently been found to induce partial remission and clinical improvement in patients with metastatic disease.

■ DISEASES OF THE SMALL INTESTINE

MALABSORPTION

The term "malabsorption" denotes disorders in which there is a disruption of digestion and nutrient absorption. The clinical and laboratory manifestations of malabsorption are summarized in [Table 14-12](#).

Normal Digestion

Normal digestion and absorption may be divided into three phases.

A. Intraluminal Phase

Dietary fats, proteins, and carbohydrates are hydrolyzed and solubilized by pancreatic and biliary secretions. Fats are broken down by pancreatic lipase to monoglycerides and fatty acids that form micelles with bile salts. Micelles are important for the solubilization and absorption of fat-soluble vitamins (A, D, E, K). Proteins are hydrolyzed by pancreatic proteases to di- and tripeptides and amino acids. Impaired intraluminal digestion may be caused by insufficient intraluminal concentrations of pancreatic enzymes or bile salts. These conditions will not be covered in detail here (see [Chapter 15](#)).

Pancreatic insufficiency may be caused by chronic pancreatitis, cystic fibrosis, or pancreatic cancer. Pancreatic enzymes may also be inactivated within the intestinal lumen by acid hypersecretion (Zollinger-Ellison syndrome). Significant pancreatic enzyme insufficiency generally results in significant steatorrhea (due to malabsorption of triglycerides)—often more than 20-40 g/24 h—resulting in weight loss, gaseous distention and flatulence, and large, greasy, foul-smelling stools. The digestion of proteins and carbohydrates is affected to a far lesser degree and is generally not clinically significant. Because micellar function and intestinal absorption are normal, signs of other nutrient or vitamin deficiencies are rare.

Decreased bile salt concentrations may be due to biliary obstruction or cholestatic liver diseases. Because bile salts are resorbed in the terminal ileum, resection or disease of this area (eg, Crohn's disease) can lead to insufficient intraluminal bile salts. Finally, destruction or loss of bile salts may be caused by bacterial overgrowth, massive acid hypersecretion, or medications that bind bile salts (eg, cholestyramine). (Bacterial overgrowth is discussed below.) Insufficient concentrations of intraluminal bile salts lead to mild steatorrhea (due to malabsorption of fatty acids and monoglycerides), though generally less than 20 g/d. Weight loss is minimal. Impaired absorption of fat-soluble vitamins (A, D, E, K) is common, resulting in bleeding tendencies, osteoporosis, and hypocalcemia ([Table 14-12](#)). Other nutrient absorption is intact. Intestinal loss of bile salts into the colon may cause a watery secretory diarrhea.

B. Mucosal Phase

The mucosal phase requires a sufficient surface area of intact small intestinal epithelium. Brush border enzymes are important in the hydrolysis of disaccharides and di- and tripeptides. Malabsorption of specific nutrients may occur as a result of deficiency in an isolated brush border enzyme. With the exception of lactase deficiency, these are rare congenital disorders that are evident in childhood. Malabsorption due to primary mucosal diseases, extensive intestinal resections (short bowel syndrome), or lymphoma is discussed below. These disorders result in malabsorption of all nutrients: fats, proteins, and amino acids. Depending upon the severity of malabsorption, patients may manifest a number of symptoms and signs, as outlined in [Table 14-12](#).

C. Absorptive Phase

Obstruction of the lymphatic system results in impaired absorption of chylomicrons and lipoproteins. This may lead to steatorrhea and significant enteric protein losses or "protein-losing enteropathy," discussed below.

1. Celiac Disease

Essentials of Diagnosis

- Typical symptoms: weight loss, chronic diarrhea, abdominal distention, growth retardation.
- Atypical symptoms: dermatitis herpetiformis, iron deficiency anemia, osteoporosis.
- Abnormal serologic test results.
- Abnormal small bowel biopsy.
- Clinical improvement on gluten-free diet.

General Considerations

Also known as gluten enteropathy or celiac sprue, celiac disease is characterized by diffuse damage to the proximal small intestinal mucosa that results in malabsorption of most nutrients. Although typical symptoms commonly manifest between 6 months and 24 months of age after the introduction of weaning foods, up to half of cases present with atypical symptoms in childhood or adulthood. Population screening with serologic tests suggests that the disease is present in 1:250 whites of Northern European ancestry but is rare in Africans and Asians. A clinical diagnosis of celiac disease is made in only 1:5000 people in the United States, suggesting that most cases are undiagnosed. Celiac disease is strongly associated with selected HLA class II molecules, particularly HLA-DQ2 and -DQ8. While the precise mechanism of damage is unknown, it is clear that removal of gluten from the diet results in resolution of symptoms and intestinal healing in most patients. Glutens are storage proteins that are present in certain grains such as wheat, rye, and barley but not oats, rice, or corn. It is hypothesized that in a genetically susceptible host gluten stimulates an inappropriate T cell-mediated autoimmune response in the intestinal submucosa that results in destruction of mucosal enterocytes. One target of this autoimmune response is tissue transglutaminase (tTG), an enzyme that modifies a component of gluten (gliadin) to a form which more strongly stimulates T cells.

Clinical Findings

A. Symptoms and Signs

The symptoms and signs of celiac disease depend upon the length of small intestine involved and the age at which the patient presents. Infants (< 2 years) are more likely to present with typical symptoms of malabsorption, including diarrhea, weight loss, abdominal distention, weakness, muscle wasting, or growth retardation. The stools are characteristically loose to soft, large, floating, oily or greasy, and foul-smelling. However, they may also be watery and frequent in number (up to 10-12 daily).

Children and adults are less likely to manifest signs of serious malabsorption. They may report chronic diarrhea, dyspepsia, or flatulence due to colonic bacterial digestion of malabsorbed nutrients, but the severity of weight loss is variable. Many adults have minimal or no gastrointestinal symptoms but present with fatigue, short stature, amenorrhea or reduced fertility, osteoporosis, dental enamel hypoplasia, and anemia. Physical examination may be normal in mild cases or may reveal signs of malabsorption such as loss of muscle mass or subcutaneous fat, pallor due to anemia, easy bruising due to vitamin K deficiency, hyperkeratosis due to vitamin A deficiency, bone pain due to osteomalacia, or neurologic signs (peripheral neuropathy, ataxia) due to vitamin B₁₂ or vitamin E deficiency. Abdominal examination may reveal distention with hyperactive bowel sounds.

Dermatitis herpetiformis is regarded as a cutaneous variant of celiac disease. It is a characteristic skin rash consisting of pruritic papulovesicles over the extensor surfaces of the extremities and over the trunk, scalp, and neck. Dermatitis herpetiformis occurs in less than 10% of patients with celiac disease; however, almost all patients who present with dermatitis herpetiformis have evidence of celiac disease on intestinal mucosal biopsy, though it may not be clinically evident.

B. Laboratory Findings

1. Routine laboratory tests—Laboratory abnormalities depend upon the extent of intestinal involvement. A complete blood count, serum iron or ferritin, red cell folate, vitamin B₁₂ level, serum calcium, alkaline phosphatase, albumin, beta-carotene, and prothrombin time should be obtained in all patients with suspected malabsorption. Limited proximal involvement may result only in microcytic anemia due to iron deficiency. More than 10% of adults with iron deficiency not due to gastrointestinal blood loss may have undiagnosed celiac disease. More extensive involvement results in a megaloblastic anemia due to folate or vitamin B₁₂ deficiency. Low serum calcium or elevated alkaline phosphatase may reflect impaired calcium or vitamin D absorption with osteomalacia or osteoporosis. Dual-energy x-ray densitometry scanning is recommended for all patients with sprue to screen for osteoporosis. Elevations of prothrombin time or a decreased serum beta-carotene reflects impaired fat-soluble vitamin absorption. Severe diarrhea may result in a non-anion gap acidosis and hypokalemia.

2. Specific tests for malabsorption—Steatorrhea is usually present but may be absent in mild disease. It may be detected by a qualitative (Sudan stain) or quantitative stool assessment for fecal fat. A positive Sudan stain is strong evidence of steatorrhea and usually obviates the need for quantitative analysis, but it is falsely negative in 25%. A quantitative 72-hour stool collection taken while patients are consuming a 100-g fat diet is a more sensitive means of detecting fat malabsorption. Excretion of more than 10 g/d of fat is abnormal and warrants further evaluation for malabsorption. Other tests of malabsorption such as the D-xylose test to provide evidence of mucosal malabsorption are no longer required with the availability of serologic screening for celiac disease.

3. Serologic tests—A number of serologic tests can be used to screen for celiac disease and to monitor for patient adherence to the gluten-free diet. IgG and IgA antigliadin antibodies are present in over 90% of patients with celiac sprue but are elevated also in other mucosal diseases. The IgG antibody is more sensitive, and the IgA antibody is more specific. Because up to 10% of celiac disease patients have IgA deficiency, both tests should be performed. A combination of the two tests provides sensitivity and specificity of over 95%. IgA endomysial antibody and IgA anti-tTG antibody tests have over 95% sensitivity and specificity for the diagnosis of celiac disease and have become the preferred serologic tests for screening for celiac disease in many centers. Testing for IgG antigliadin is still necessary for the subset of patients with IgA deficiency. Levels of IgA antigliadin, antiendomysial, and anti-tTG antibodies become undetectable after 6-12 months of dietary gluten withdrawal and may be used to monitor dietary compliance, especially in patients whose symptoms fail to resolve after institution of a gluten-free diet.

C. Mucosal Biopsy

Endoscopic mucosal biopsy of the distal duodenum or proximal jejunum is the standard method for confirmation of the diagnosis in patients with a positive serologic test for celiac disease. Rarely, mucosal biopsy may be pursued in patients with negative serologies when symptoms are suggestive of celiac disease. Duodenal mucosal biopsy should also be performed in patients with iron deficiency anemia who are undergoing upper and lower endoscopy to exclude a source of gastrointestinal blood loss, as 5-10% may have celiac sprue. At endoscopy, atrophy or scalloping of the duodenal folds may be observed. Histology reveals loss or blunting of intestinal villi, hypertrophy of the intestinal crypts, and extensive infiltration of the lamina propria with lymphocytes and plasma cells. An adequate normal biopsy excludes the diagnosis. Reversion of these abnormalities on repeat biopsy after a patient is placed on a gluten-free diet establishes the diagnosis. However, if a patient with a compatible biopsy demonstrates prompt clinical improvement on a gluten-free diet and a decrease in antigliadin antibodies, a repeat biopsy is unnecessary.

Differential Diagnosis

Because of its protean manifestations, celiac disease is underdiagnosed in the adult population. Many patients with chronic diarrhea or flatulence are erroneously diagnosed as having irritable bowel syndrome. Symptoms are present for more than 10 years in most patients before the correct diagnosis is established. Celiac sprue must be distinguished from other causes of malabsorption, as outlined above. Severe panmalabsorption of multiple nutrients is almost always caused by mucosal disease. In a patient with steatorrhea, a normal D-xylose test points to pancreatic insufficiency, reduced bile salts, or lymphatic obstruction. If the D-xylose test, however, is also abnormal, it strongly implicates mucosal disorders or bacterial overgrowth. The histologic appearance of celiac sprue may resemble other mucosal diseases such as tropical sprue, bacterial overgrowth, cow's milk intolerance, viral gastroenteritis, eosinophilic gastroenteritis, and mucosal damage caused by acid hypersecretion associated with gastrinoma. Documentation of clinical response to gluten withdrawal therefore is essential to the diagnosis.

Treatment

Removal of all gluten from the diet is essential to therapy—all wheat, rye, and barley must be eliminated. Although oats previously were felt to be toxic to these patients, moderate amounts are without adverse effects. Rice, soybean, potato, and corn flours are safe. Because of the pervasive use of gluten products in manufactured foods and additives, in medications, and by restaurants, it is imperative that patients and their families confer with a knowledgeable dietitian in order to comply satisfactorily with this lifelong diet. Several excellent dietary guides are available. Most patients with celiac disease also have lactose intolerance either temporarily or permanently and should avoid dairy products until the intestinal symptoms have improved on the gluten-free diet. Dietary supplements (folate, iron, calcium, and vitamins A, B₁₂, D, and E) should be provided in the initial stages of therapy but usually are not required long term with a gluten-free diet. Patients with confirmed osteoporosis may require chronic calcium, vitamin D, and bisphosphonate therapy.

Improvement in symptoms should be evident within a few weeks on the gluten-free diet. The most common reason for treatment failure is incomplete removal of gluten.

Prognosis & Complications

If appropriately diagnosed and treated, patients with celiac disease have an excellent prognosis. Celiac disease may be associated with other autoimmune disorders, including Addison's disease, Graves' disease, type 1 diabetes mellitus, myasthenia gravis, scleroderma, Sjogren's syndrome, atrophic gastritis, and pancreatic insufficiency. In some patients, celiac disease may evolve and become refractory to the gluten-free diet. The most common cause is intentional or unintentional dietary noncompliance, which may be suggested by positive serologic tests. Celiac disease that is truly refractory to gluten withdrawal generally carries a poor prognosis. It may be caused by the development of ulcerative jejunitis or enteropathy or by associated T cell lymphoma, which occurs in up to 10% of patients. These conditions should be considered in patients previously responsive to the gluten-free diet who develop new weight loss, abdominal pain, and malabsorption. Many other patients with refractory symptoms have a "cryptic" intestinal lymphoma, ie, a monoclonal expansion of the intraepithelial T lymphocyte that may or may not progress. Patients with refractory sprue who do not have intestinal T cell lymphoma or ulcerative jejunitis may respond to corticosteroids or immunosuppression with azathioprine or cyclosporine.

Shan L et al: Structural basis for gluten intolerance in celiac sprue. *Science* 2002;297:2275. [PMID: 12351792]

2. Whipple's Disease

Essentials of Diagnosis

- Multisystemic disease.
- Fever, lymphadenopathy, arthralgias.
- Malabsorption.
- Duodenal biopsy with PAS-positive macrophages with characteristic bacillus.

General Considerations

Whipple's disease is a rare multisystemic illness caused by infection with the bacillus *Tropheryma whippelii*. It may occur at any age but most commonly affects white men in the fourth to sixth decades. The source of infection is unknown, but no cases of human-to-human spread have been documented.

Clinical Findings

A. Symptoms and Signs

The clinical manifestations are protean. Arthralgias or a migratory, nondeforming arthritis occurs in 80% and is typically the first symptom experienced. Gastrointestinal symptoms occur in approximately 75% of cases. They include abdominal pain, diarrhea, and some degree of malabsorption with distention, flatulence, and steatorrhea. Weight loss, present in almost all patients, is the most common presenting symptom. Loss of protein due to intestinal or lymphatic involvement may result in protein-losing enteropathy with hypoalbuminemia and edema. In the absence of gastrointestinal symptoms, the diagnosis often is delayed for several years. Intermittent low-grade fever occurs in over 50% of cases. Chronic cough is common. There may be generalized lymphadenopathy that resembles sarcoidosis. Myocardial or valvular involvement may lead to congestive failure or valvular regurgitation. Ocular findings include uveitis, vitreitis, keratitis, retinitis, and retinal hemorrhages. Central nervous system involvement in approximately 10% of cases is manifested by a variety of findings such as dementia, lethargy, coma, seizures, myoclonus, or hypothalamic signs. Cranial nerve findings include ophthalmoplegia or nystagmus.

Physical examination may reveal hypotension (a late finding), low-grade fever, and evidence of malabsorption (see [Table 14-12](#)). Lymphadenopathy is present in 50%. Heart murmurs due to valvular involvement may be evident. Peripheral joints may be enlarged or warm, and peripheral edema may be present. Neurologic findings are cited above. Hyperpigmentation on sun-exposed areas is evident in up to 40%.

B. Laboratory Findings

If significant malabsorption is present, patients may have laboratory abnormalities as outlined in [Table 14-12](#). There may be steatorrhea.

C. Histologic Evaluation

The diagnosis of Whipple's disease is established by histologic evaluation of the involved tissues. In most cases, the diagnosis is established by endoscopic biopsy of the duodenum, which demonstrates infiltration of the lamina propria with PAS-positive macrophages that contain gram-positive bacilli (which are not acid-fast) and dilation of the lacteals. The Whipple bacillus has a characteristic electron microscopic appearance. In some patients who present with nongastrointestinal symptoms, the duodenal biopsy may be normal, and biopsy of other involved organs or lymph nodes may be necessary. Because the PAS stain is less sensitive and specific for extraintestinal Whipple's disease, PCR is used to confirm the diagnosis by demonstrating the presence of 16S ribosomal RNA of *T whippelii* in blood, cerebrospinal fluid, vitreous fluid, synovial fluid, or cardiac valves. The sensitivity of PCR is 97% and the specificity 100%.

Differential Diagnosis

Whipple's disease should be considered in patients who present with signs of malabsorption, fever of unknown origin, lymphadenopathy, seronegative arthritis, culture-negative endocarditis, or multisystemic disease. Small bowel biopsy readily distinguishes Whipple's disease from other mucosal malabsorptive disorders, such as celiac sprue. Patients with AIDS and infection of the small intestine with *Mycobacterium avium* complex may have a similar clinical and histologic picture; although both conditions are characterized by PAS-positive macrophages, they may be distinguished by the acid-fast stain, which is positive for MAC and negative for the Whipple bacillus. Other conditions that may be confused with Whipple's disease include sarcoidosis, Reiter's syndrome, familial Mediterranean fever, systemic vasculitides, Behcet's disease, intestinal lymphoma, and subacute infective endocarditis.

Treatment

Antibiotic therapy results in a dramatic clinical improvement within several weeks, even in some patients with neurologic involvement. The optimal regimen is unknown. Complete clinical response usually is evident within 1-3 months; however, relapse may occur in up to one-third of patients after discontinuation of treatment. Therefore, prolonged treatment for at least 1 year is required. Drugs that cross the blood-brain barrier are preferred. Trimethoprim-sulfamethoxazole (one double-strength tablet twice daily for 1 year) is recommended as first-line therapy. In patients allergic to sulfonamides, ceftriaxone or chloramphenicol may be reasonable; there is an anecdotal report of a patient with central nervous system disease refractory to antibiotics treated successfully with interferon gamma. After treatment, repeat biopsies may be obtained for PCR. Negative results predict a low likelihood of clinical relapse.

Prognosis

If untreated, the disease is fatal. Because some neurologic signs may be permanent, the goal of treatment is to prevent this progression. Patients must be followed closely after treatment for signs of symptom recurrence.

Ratnaike RN: Whipple's disease. Postgrad Med J 2000;76:760. [\[PMID: 11085766\]](#)

3. Bacterial Overgrowth

The small intestine normally contains a small number of bacteria. Bacterial overgrowth in the small intestine of whatever cause may result in malabsorption via a number of mechanisms. Bacterial deconjugation of bile salts may lead to inadequate micelle formation, resulting in decreased fat absorption with steatorrhea. Microbial uptake of specific nutrients reduces absorption of vitamin B₁₂ and carbohydrates. Bacterial proliferation also causes direct damage to intestinal epithelial cells and the brush border, further impairing absorption of proteins and carbohydrates. Passage of the malabsorbed bile acids and carbohydrates into the colon leads to an osmotic and secretory diarrhea.

Causes of bacterial overgrowth include the following: (1) gastric achlorhydria (especially if other predisposing conditions present), (2) anatomic abnormalities of the small intestine with stagnation (afferent limb of Billroth II gastrectomy, small intestine diverticula, obstruction, blind loop, radiation enteritis), (3) small intestine motility disorders (scleroderma, diabetic enteropathy, chronic intestinal pseudo-obstruction), (4) gastroduodenal or coloenteric fistula (Crohn's disease, malignancy, surgical resection), and (5) miscellaneous disorders (AIDS, chronic pancreatitis). Bacterial overgrowth is an important cause of malabsorption in the elderly, perhaps because of decreased gastric acidity or impaired intestinal motility.

Clinical Findings

Many patients with bacterial overgrowth are asymptomatic. Patients with severe overgrowth have symptoms and signs of malabsorption, including distention, weight loss, and steatorrhea ([Table 14-12](#)). Watery diarrhea is common. Megaloblastic anemia or neurologic signs due to vitamin B₁₂ deficiency are common findings and may be manifest at presentation. In patients with vitamin B₁₂ deficiency, the Schilling test is diagnostic of bacterial overgrowth if it is abnormal in phase I and II (without and with intrinsic factor) but normalizes after a course of antibiotics. Qualitative or quantitative fecal fat assessment typically is abnormal. D-Xylose absorption is also abnormal due to bacterial uptake of the carbohydrate.

Bacterial overgrowth should be considered in any patient with diarrhea, steatorrhea, weight loss, or macrocytic anemia, especially if the patient has a predisposing cause (such as prior gastrointestinal surgery). A stool collection should be obtained to corroborate the presence of steatorrhea. Small bowel barium radiography may be helpful to document conditions predisposing to intestinal stasis. Where indicated, a small intestinal biopsy may be necessary to exclude other mucosal malabsorptive conditions. A specific diagnosis can be established firmly only by an aspirate and culture of proximal jejunal secretion that demonstrates over 10⁵ organisms/mL. However, this is an invasive and laborious test, not done in some clinical settings. A number of noninvasive breath tests have been developed but lack sufficient sensitivity and specificity to be of great utility. The ¹³C- or ¹⁴C-xylose breath test is the most reliable. In this test, bacterial uptake and degradation of the isotope lead to the release of ¹³CO₂ or ¹⁴CO₂, which can be measured in exhaled breath. Breath hydrogen tests with glucose, lactose, or lactulose as substrate are commonly employed because of their ease of use, but they have limited sensitivity (< 65%) and specificity (< 85%).

Owing to the lack of an optimal test for bacterial overgrowth, many clinicians employ an empirical antibiotic trial as a diagnostic and therapeutic maneuver in patients with predisposing conditions for bacterial overgrowth who develop unexplained diarrhea or steatorrhea.

Treatment

Where possible, the anatomic defect that has potentiated bacterial overgrowth should be corrected. Otherwise, treatment as follows for 1-2 weeks with broad-spectrum antibiotics effective against enteric aerobes and anaerobes usually leads to dramatic improvement: twice daily ciprofloxacin 500 mg, norfloxacin 400 mg, or amoxicillin

clavulanate 875 mg, or a combination of metronidazole 250 mg three times daily plus either trimethoprim-sulfamethoxazole (one double-strength tablet) twice daily or cephalexin 250 mg four times daily.

In patients in whom symptoms recur off antibiotics, cyclic therapy (eg, 1 week out of 4) may be sufficient. Continuous antibiotics should be avoided, if possible, to avoid development of bacterial antibiotic resistance.

In patients with severe intestinal dysmotility, treatment with small doses of octreotide may prove to be of benefit.

4. Short Bowel Syndrome

Short bowel syndrome is the malabsorptive condition that arises secondary to removal of significant segments of the small intestine. The most common causes in adults are Crohn's disease, mesenteric infarction, radiation enteritis, and trauma. The type and degree of malabsorption depend upon the length and site of the resection and the degree of adaptation of the remaining bowel.

Terminal Ileal Resection

Resection of the terminal ileum results in malabsorption of bile salts and vitamin B₁₂, which are normally absorbed in this region. Patients with low serum vitamin B₁₂ levels, an abnormal Schilling test, or resection of over 50 cm of ileum require monthly intramuscular vitamin B₁₂ injections. In patients with less than 100 cm of ileal resection, bile salt malabsorption stimulates fluid secretion from the colon, resulting in watery diarrhea. This may be treated with bile salt binding resins (cholestyramine, 2-4 g three times daily with meals). Resection of over 100 cm of ileum leads to a reduction in the bile salt pool that results in steatorrhea and malabsorption of fat-soluble vitamins. Treatment is with a low-fat diet and vitamins supplemented with medium-chain triglycerides, which do not require micellar solubilization. Unabsorbed fatty acids bind with calcium, reducing its absorption and enhancing the absorption of oxalate. Oxalate kidney stones may develop. Calcium supplements should be administered to bind oxalate and increase serum calcium. Cholesterol gallstones due to decreased bile salts are common also. In patients with resection of the ileocolonic valve, bacterial overgrowth may occur in the small intestine, further complicating malabsorption (as outlined above).

Extensive Small Bowel Resection

Resection of 40-50% of the total length of small intestine usually is well tolerated. A more massive resection may result in "short bowel syndrome," characterized by weight loss and diarrhea due to nutrient, water, and electrolyte malabsorption. After resection, the remaining small intestine has a remarkable ability to adapt, gradually increasing its absorptive capacity up to fourfold over 1 year. The colon also plays an important role in absorption of fluids, electrolytes, and digestion of complex carbohydrates (through bacterial fermentation to short-chain fatty acids) after small bowel resection. If the colon is preserved, 100 cm of proximal jejunum may be sufficient to maintain adequate oral nutrition with a low-fat, high complex-carbohydrate diet, though fluid and electrolyte losses may still be significant. In patients in whom the colon has been removed, at least 200 cm of proximal jejunum is typically required to maintain oral nutrition. Duodenal resection may result in folate, iron, or calcium malabsorption. Levels of other minerals such as zinc and magnesium should be monitored. Parenteral vitamin supplementation may be necessary. Antidiarrheal agents (loperamide, 2-4 mg three times daily) slow transit and reduce diarrheal volume. Octreotide reduces intestinal transit time and fluid and electrolyte secretion. Gastric hypersecretion usually complicates intestinal resection and should be treated with H₂ receptor antagonists.

Patients with less than 100-200 cm of proximal jejunum remaining almost always require parenteral nutrition. Of patients who do, the estimated annual mortality rate is 2-5% per year. Death is most commonly due to TPN-induced liver disease, sepsis, or loss of venous access. Small intestine transplantation is now being performed with reported 5-year graft survival rates of 40%. Currently, it is performed chiefly in patients who develop serious problems due to parenteral nutrition.

Scolapio JS: Treatment of short-bowel syndrome. Curr Opin Clin Nutr Metab Care 2001;4:557. [PMID: 11706294]

5. Lactase Deficiency

Lactase is a brush border enzyme that hydrolyzes the disaccharide lactose into glucose and galactose. The concentration of lactase enzyme levels is high at birth but declines steadily in most people of non-European ancestry during childhood and adolescence and into adulthood. Thus, approximately 50 million people in the United States have partial to complete lactose intolerance. As many as 90% of Asian-Americans, 70% of African-Americans, 95% of Native Americans, 50% of Mexican-Americans, and 60% of Jewish Americans are lactose-intolerant compared with less than 25% of Caucasian adults. Lactase deficiency may also arise secondary to other gastrointestinal disorders that affect the proximal small intestinal mucosa. These include Crohn's disease, sprue, viral gastroenteritis, giardiasis, short bowel syndrome, and malnutrition. Malabsorbed lactose is fermented by intestinal bacteria, producing gas and organic acids. The nonmetabolized lactose and organic acids result in an increased stool osmotic load with an obligatory fluid loss.

Clinical Findings

A. Symptoms and Signs

Patients have great variability in clinical symptoms, depending both on the severity of lactase deficiency and the amount of lactose ingested. Because of the nonspecific nature of these symptoms, there is a tendency for both lactose-intolerant and lactose-tolerant individuals to mistakenly attribute a variety of abdominal symptoms to lactose intolerance. Most patients with lactose intolerance can drink one or two 8 oz glasses of milk daily without symptoms if taken with food at wide intervals, though rare patients have almost complete intolerance. With mild to moderate amounts of lactose malabsorption, patients may experience bloating, abdominal cramps, and flatulence. With higher lactose ingestions, an osmotic diarrhea will result. Isolated lactase deficiency does not result in other signs of malabsorption or weight loss. If these findings are present, other gastrointestinal disorders should be pursued. Diarrheal specimens reveal an increased osmotic gap and a pH of less than 6.0.

B. Laboratory Findings

The most widely available test for the diagnosis of lactase deficiency is the hydrogen breath test. After ingestion of 50 g of lactose, a rise in breath hydrogen of greater than 20 ppm within 90 minutes is a positive test, indicative of bacterial carbohydrate metabolism. In clinical practice, many physicians prescribe an empirical trial of a lactose-free diet for 2 weeks. Resolution of symptoms (bloating, flatulence, diarrhea) is highly suggestive of lactase deficiency (though a placebo response cannot be excluded) and may be confirmed, if necessary, with a breath hydrogen study.

Differential Diagnosis

The symptoms of late-onset lactose intolerance are nonspecific and may mimic a number of gastrointestinal disorders, such as inflammatory bowel disease, mucosal malabsorptive disorders, irritable bowel syndrome, and pancreatic insufficiency. Furthermore, lactase deficiency frequently develops secondary to other gastrointestinal disorders (as listed above). Concomitant lactase deficiency should always be considered in these gastrointestinal disorders.

Treatment

The goal of treatment in patients with isolated lactase deficiency is achieving patient comfort. Patients usually find their "threshold" of intake at which symptoms will occur. Foods that are high in lactose include milk (12 g/cup), ice cream (9 g/cup), and cottage cheese (8 g/cup). Aged cheeses have a lower lactose content (0.5 g/oz). Unpasteurized yogurt contains bacteria that produce lactase and is generally well tolerated.

Many patients will choose simply to restrict or eliminate milk products. By spreading dairy product intake throughout the day in quantities of less than 12 g of lactose (one cup of milk), most patients can take dairy products without symptoms and do not require lactase supplements. Calcium supplementation should be considered in susceptible patients to prevent osteoporosis. Most food markets provide milk that has been pretreated with lactase, rendering it 70-100% lactose-free. Lactase enzyme replacement is commercially available as a nonprescription formulation (Lactaid). Caplets of lactase may be taken with milk products, improving lactose absorption and eliminating symptoms. The number of caplets ingested depends upon the degree of lactose intolerance.

INTESTINAL MOTILITY DISORDERS

1. Acute Paralytic Ileus

Essentials of Diagnosis

- Precipitating factors: surgery, peritonitis, electrolyte abnormalities, severe medical illness.
- Nausea, vomiting, obstipation, distention.
- Minimal abdominal tenderness; decreased bowel sounds.
- Plain abdominal radiography with gas and fluid distention in small and large bowel.

General Considerations

Ileus is a condition in which there is neurogenic failure or loss of peristalsis in the intestine in the absence of any mechanical obstruction. It is commonly seen in hospitalized patients as a result of (1) intra-abdominal processes such as recent gastrointestinal or abdominal surgery or peritoneal irritation (peritonitis, pancreatitis, ruptured viscus, hemorrhage); (2) severe medical illness such as pneumonia, respiratory failure requiring intubation, sepsis or severe infections, uremia, diabetic ketoacidosis, and electrolyte abnormalities (hypokalemia, hypercalcemia, hypomagnesemia, hypophosphatemia); and (3) medications that affect intestinal motility (opioids, anticholinergics, phenothiazines).

Clinical Findings

A. Symptoms and Signs

Patients who are conscious report mild diffuse, continuous abdominal discomfort with nausea and vomiting. Generalized abdominal distention is present with minimal abdominal tenderness but no signs of peritoneal irritation (unless due to the primary disease). Bowel sounds are diminished to absent.

B. Laboratory Findings

The laboratory abnormalities are attributable to the underlying condition. Serum electrolytes, including potassium, magnesium, phosphorus, and calcium, should be obtained to exclude abnormalities as contributing factors.

C. Imaging

Plain film radiography of the abdomen demonstrates distended gas-filled loops of small and large intestine. Air-fluid levels may be seen. Under some circumstances, it may be difficult to distinguish ileus from partial small bowel obstruction. A limited barium small bowel series or a CT scan may be useful in such instances to exclude mechanical obstruction, especially in postoperative patients.

Differential Diagnosis

Ileus must be distinguished from mechanical obstruction of the small bowel or proximal colon. Pain from small bowel mechanical obstruction is usually intermittent, cramping, and associated initially with profuse vomiting. Acute gastroenteritis, acute appendicitis, and acute pancreatitis may all present with ileus.

Treatment

The primary medical or surgical illness that has precipitated adynamic ileus should be treated. Most cases of ileus respond to restriction of oral intake with gradual liberalization of diet as bowel function returns. Severe or prolonged ileus requires nasogastric suction and parenteral administration of fluids and electrolytes.

Kehlet H et al: Review of postoperative ileus. Am J Surg 2001; 182(Suppl 5A):3S. [\[PMID: 11755891\]](#)

Taguchi A et al: Selective postoperative inhibition of gastrointestinal opioid receptors. N Engl J Med 2001;345:935. [\[PMID: 11575284\]](#)

2. Acute Colonic Pseudo-obstruction (Ogilvie's Syndrome)

Essentials of Diagnosis

- Severe abdominal distention.
- Arises in postoperative state or with severe medical illness.
- May be precipitated by electrolyte imbalances, medications.
- Absent to mild abdominal pain; minimal tenderness.
- Massive dilation of cecum or right colon.

General Considerations

Spontaneous massive dilation of the cecum and proximal colon may occur in a number of different settings in hospitalized patients. Progressive cecal dilation may lead to spontaneous perforation with dire consequences. The risk of perforation correlates poorly with absolute cecal size. Colonic pseudo-obstruction is most commonly detected in surgical patients after trauma or burns or in the postoperative period and in medical patients with respiratory failure, metabolic imbalance, malignancy, myocardial infarction, congestive heart failure, pancreatitis, or a recent neurologic event (stroke, subarachnoid hemorrhage, trauma). Liberal use of narcotics or anticholinergic agents may precipitate colonic pseudo-obstruction in susceptible patients. It may also occur as a manifestation of colonic ischemia. The etiology of colonic pseudo-obstruction is unknown, but an imbalance between gut sympathetic activity and sacral parasympathetic innervation of the distal colon is hypothesized.

Clinical Findings

A. Symptoms and Signs

Many patients are on ventilatory support or are unable to report symptoms due to altered mental status. Abdominal distention is frequently noted by the clinician as the first sign, often leading to a plain film radiograph that demonstrates colonic dilation. Some patients are asymptomatic, though most report constant but mild abdominal pain. Nausea and vomiting may be present. Bowel movements usually are absent. Abdominal tenderness with some degree of guarding or rebound tenderness may be detected; however, signs of peritonitis are absent unless perforation has occurred. Bowel sounds may be normal or decreased.

B. Laboratory Findings

Laboratory findings reflect the underlying medical or surgical problems. Serum sodium, potassium, magnesium, phosphorus, and calcium should be obtained. Significant fever or leukocytosis raises concern for colonic perforation.

C. Imaging

Plain film radiographs demonstrate colonic dilation, usually confined to the cecum and proximal colon. The upper limit of normal for cecal size is 9 cm. A cecal diameter greater than 10-12 cm is associated with an increased risk of colonic perforation. Varying amounts of small intestinal dilation and air-fluid levels due to adynamic ileus may be seen.

Differential Diagnosis

The dilated appearance of the colon may raise concern that there is a distal colonic mechanical obstruction due to malignancy, volvulus, or fecal impaction. In many centers a Hypaque (diatrizoate meglumine) enema is performed both to exclude colonic obstruction and in an attempt to decompress the colon and evacuate distal fecal material. Colonic pseudo-obstruction should be distinguished from toxic megacolon, which is acute dilation of the colon due to inflammation (inflammatory bowel disease) or infection (*Clostridium difficile*-associated colitis, cytomegalovirus). Patients with toxic megacolon manifest fever, dehydration, significant abdominal pain, leukocytosis, and diarrhea, which is often bloody.

Treatment

Conservative treatment is the appropriate first step for patients with no or minimal abdominal tenderness, no fever, no leukocytosis, and a cecal diameter less than 12 cm. The underlying illness is treated appropriately. A nasogastric tube and a rectal tube should be placed. Patients should not remain in one position but should be periodically rolled from side to side and to the prone position in an effort to promote expulsion of colonic gas. All drugs that reduce intestinal motility, such as narcotics, anticholinergics, and calcium channel blockers, are discontinued if possible. Enemas may be administered judiciously if large amounts of stool are evident on radiography. Oral laxatives are not helpful and may cause perforation, pain, or electrolyte abnormalities.

Conservative treatment is successful in over 80% of cases. Patients must be watched for signs of worsening distention or abdominal tenderness. Cecal size should be assessed by abdominal radiographs every 12 hours. Intervention should be considered in patients with sustained or progressive cecal dilation to 10-12 cm or more despite 24 hours of conservative treatment and in those showing signs of clinical deterioration. Neostigmine injection should be given unless contraindicated. A single dose (2 mg intravenously) results in rapid (within 30 minutes) colonic decompression in 75-90% of patients. Cardiac monitoring during neostigmine infusion is indicated for possible bradycardia that may require atropine administration. Colonoscopic decompression is indicated in patients who fail to respond to neostigmine. Colonic decompression with aspiration of air or placement of a decompression tube is successful in up to 90% of patients. However, the procedure is technically difficult in an unprepared bowel and has been associated with perforations in the distended colon. Dilation recurs in up to half of patients. In patients in whom colonoscopy is unsuccessful, a tube cecostomy can be created through a small laparotomy or with percutaneous radiologically guided placement.

Prognosis

In most cases, the prognosis is related to the underlying illness. With aggressive therapy, the development of perforation is unusual.

CHRONIC INTESTINAL PSEUDO-OBSTRUCTION & GASTROPARESIS

Gastroparesis and chronic intestinal pseudo-obstruction are chronic conditions characterized by intermittent, waxing and waning symptoms and signs of gastric or intestinal obstruction in the absence of any mechanical lesions to account for the findings. They are caused by a heterogeneous group of endocrine disorders (diabetes mellitus, hypothyroidism, cortisol deficiency), postsurgical conditions (vagotomy, partial gastric resection, fundoplication, gastric bypass, Whipple procedure), neurologic conditions (Parkinson's disease, muscular and myotonic dystrophy, autonomic dysfunction, multiple sclerosis, postpolio syndrome, porphyria), rheumatologic syndromes (progressive systemic sclerosis), infections (postviral, Chagas' disease), amyloidosis, paraneoplastic syndromes, medications, and eating disorders (anorexia); a cause may not always be identified. Gastric involvement leads to chronic or intermittent symptoms of gastroparesis with early satiety, nausea, and postprandial vomiting (1-3 hours after meals).

Patients with predominantly small bowel involvement may have abdominal distention, vomiting, diarrhea, and varying degrees of malnutrition. Abdominal pain is not common and should prompt investigation for structural causes of obstruction. Bacterial overgrowth in the stagnant intestine may result in malabsorption. Colonic involvement may result in constipation or alternating diarrhea and constipation.

Plain film radiography may demonstrate dilation of the esophagus, stomach, small intestine, or colon resembling ileus or mechanical obstruction. Mechanical obstruction of the stomach, small intestine, or colon is much more common than gastroparesis or intestinal pseudo-obstruction and must be excluded with endoscopy or barium radiography (upper gastrointestinal series with small bowel follow-through), especially in patients with prior surgery, recent onset of symptoms, or abdominal pain. In cases of unclear origin, studies based on the clinical picture are obtained to exclude underlying systemic disease. Gastric scintigraphy with a low-fat solid meal is the optimal means for assessing gastric emptying. Gastric retention of 60% after 2 hours or more than 10% after 4 hours is abnormal. Small bowel manometry is useful for distinguishing visceral from myopathic disorders and for excluding cases of mechanical obstruction that are otherwise difficult to diagnose by endoscopy or radiographic studies.

There is no specific therapy for gastroparesis or pseudo-obstruction. Acute exacerbations are treated with nasogastric suction and intravenous fluids. Chronic treatment is directed at maintaining nutrition. Patients should eat small, frequent meals that are low in fiber, milk, gas-forming foods, and fat. Some patients may require liquid enteral supplements. Agents that reduce gastrointestinal motility (opioids, anticholinergics) should be avoided. In diabetics, glucose levels should be maintained below 200 mg/dL, as hyperglycemia may slow gastric emptying even in the absence of diabetic neuropathy. Metoclopramide (5-20 mg orally or 5-10 mg intravenously or subcutaneously four times daily before meals) and erythromycin (125-250 mg orally twice daily or 1-2 mg/kg intravenously every 6 hours) are of benefit in treatment of gastroparesis but not small bowel dysmotility. Bacterial overgrowth should be treated with intermittent antibiotics (see above). Patients with predominant small bowel distention may require a venting gastrostomy to relieve distress. Some patients may require surgical placement of a jejunostomy for long-term enteral nutrition. Gastric pacing with internally implanted neurostimulators is being clinically tested for patients with gastroparesis. Patients unable to maintain adequate enteral nutrition require total parenteral nutrition or small bowel transplantation. Difficult cases should be referred to centers with expertise in this area.

TUMORS OF THE SMALL INTESTINE

Benign and malignant tumors of the small intestine are rare. They often cause no symptoms or signs. However, they may cause acute gastrointestinal bleeding with hematochezia or melena or chronic gastrointestinal blood loss resulting in fatigue and iron deficiency anemia. Small bowel tumors may cause obstruction due to luminal narrowing or intussusception of a polypoid mass. Small bowel tumors usually are identified by barium radiographic studies, either enteroclysis or a small bowel series. Visualization and biopsy of duodenal and proximal jejunal mass lesions are performed with a long upper endoscope known as an enteroscope.

1. Benign Tumors of Small Intestine

Benign polyps may be symptomatic or may be incidental findings detected on endoscopy or radiographic study. Most occur singly, and the presence of multiple polyps is suggestive of hereditary polyposis syndrome (discussed under Diseases of the Colon and Rectum). With the exception of lipomas, surgical or endoscopic excision usually is recommended. Adenomatous polyps are the most common benign mucosal tumor. The majority are asymptomatic, though acute or chronic bleeding may occur. Because malignant transformation does occur, endoscopic or surgical resection is warranted. Villous adenomas occur most commonly in the periampullary region of the duodenum (especially in patients with familial adenomatous polyposis) and carry a high risk for development of invasive cancer. Periodic endoscopic surveillance to detect early ampullary neoplasms is recommended in patients with familial adenomatous polyposis. Evaluation with ERCP and endoscopic ultrasound is required to exclude invasive carcinoma. Ampullary adenomas may be removed by endoscopic or surgical techniques. Lipomas occur commonly in the ileum. Most are asymptomatic and identified incidentally at endoscopy or radiography; however, they rarely may cause obstruction with intussusception. Benign stromal tumors (formerly called leiomyomas) are found at all levels of the intestine. These submucosal mesenchymal lesions may be intraluminal, intramural, or extraluminal. Although most are asymptomatic, they may ulcerate and cause acute or chronic bleeding or obstruction. It is difficult to distinguish benign from malignant stromal tumors (leiomyosarcomas) except by excision.

2. Malignant Tumors of Small Intestine

Malignant tumors of the small intestine are extremely rare, accounting for less than 2% of all gastrointestinal malignancies. They may present with anemia, bleeding, obstruction, or evidence of metastatic disease.

Adenocarcinoma

These are aggressive tumors that occur most commonly in the duodenum or proximal jejunum. The ampulla of Vater is the most common site of small bowel carcinoma, and the incidence of ampullary carcinoma is increased more than 200-fold in patients with familial adenomatous polyposis. Ampullary carcinoma may present with jaundice due to bile duct obstruction or bleeding. Surgical resection of early lesions is curative in up to 40% of patients. Periodic endoscopic surveillance to detect early ampullary neoplasms therefore is recommended in patients with this disorder. Nonampullary adenocarcinoma of the small intestine accounts for 30-40% of small bowel cancers. Most present with symptoms of obstruction, acute or chronic bleeding, or weight loss. Eighty percent have already metastasized at the time of diagnosis. Resection is recommended for control of symptoms. Patients with Crohn's disease have an increased risk of small intestine adenocarcinoma, most commonly in the ileum, which may be difficult to distinguish from disease-related fibrous strictures.

Lymphoma

Gastrointestinal lymphomas may arise in the gastrointestinal tract or involve it secondarily with disseminated disease. In Western countries, primary gastrointestinal lymphomas account for 5% of lymphomas and 20% of small bowel malignancies. They occur most commonly in the distal small intestine. The majority are non-Hodgkin's intermediate or high-grade B cell lymphomas. However, T cell lymphomas may arise in patients with celiac sprue. In the Middle East, lymphomas may arise also in the setting of immunoproliferative small intestinal disease. In this condition, there is diffuse lymphoplasmacytic infiltration with IgA-secreting B lymphocytes of the mucosa and submucosa that results in weight loss, diarrhea, and malabsorption which may lead to lymphomatous transformation. A characteristic feature of the disease is the presence of alpha heavy chains in the serum in 70% produced by clones of IgA plasma cells. The early, premalignant phase may respond to antibiotic therapy for *H pylori* alone.

([Table 14-11](#)) Presenting symptoms or signs of primary lymphoma include abdominal pain, weight loss, nausea and vomiting, distention, anemia, and occult blood in the stool. Fevers are unusual. Protein-losing enteropathy may result in hypoalbuminemia, but other signs of malabsorption are unusual. Barium radiography helps to localize the site of the lesion. The diagnosis requires endoscopic, percutaneous, or laparoscopic biopsy. In order to determine tumor stage, patients must undergo chest and abdominal CT, bone marrow biopsy, and, in some cases, lymphangiography.

Treatment depends on the stage of disease. Resection of primary intestinal lymphoma, if feasible, is usually recommended. Even in cases of stage III or stage IV disease, surgical debulking may improve survival. In patients with limited disease (stage IE) that is resected, the role of adjuvant chemotherapy is unclear. Most patients with more extensive disease are treated with systemic chemotherapy with or without radiation therapy (see [Chapters 4](#) and [40](#)).

Carcinoid Tumors

Carcinoids are the most common neuroendocrine tumors arising from the gastrointestinal tract. They derive from a variety of neuroendocrine cells, but the term "carcinoid" usually refers to tumors that secrete serotonin or its precursors. Although many behave in an indolent fashion, the overall 5-year survival rate for patients with carcinoids is 50%, suggesting that most are malignant. The risk of metastatic spread is closely related to tumor size and tumor location. Many small carcinoids are detected incidentally at endoscopy or autopsy. It is not possible by histologic examination to distinguish benign from malignant disease. The best indicator of prognosis is evidence of invasive growth and the presence of regional or distant metastasis.

Over 95% of gastrointestinal carcinoids occur in one of three sites: the rectum, the appendix, or the small intestine. Carcinoids account for up to one-third of small intestinal tumors. Rectal carcinoids are usually detected incidentally as submucosal nodules during proctoscopic examination. Similarly, appendiceal carcinoids are identified in 0.3% of appendectomies. Almost 80% of these tumors are less than 1 cm in size, and 90% are less than 2 cm. Rectal carcinoids less than 1 cm and appendiceal carcinoids less than 2 cm virtually never metastasize and are treated effectively with local excision or simple appendectomy. Tumors larger than 2 cm are associated with the development of metastasis in over 20% of appendiceal carcinoids and 10% of rectal carcinoids. Hence, in younger patients who are good operative risks, a more extensive cancer resection operation is warranted.

Small intestinal carcinoids most commonly arise in the ileum. Up to one-third are multicentric. Although 60% are less than 2 cm in size, even these small carcinoids may metastasize. Almost all tumors over 2 cm are associated with metastasis. Most smaller lesions are asymptomatic, though intussusception with obstruction occurs rarely. Carcinoids may extend locally into the muscularis, serosa, and mesentery, where they engender a fibroblastic reaction with contraction and kinking of the bowel. This may lead to symptoms of partial small bowel obstruction with intermittent abdominal pain or obstruction. Small bowel barium studies may reveal kinking, but because the lesion is extraluminal the diagnosis may be overlooked for several years. Encasement of the mesenteric vessels can lead to bowel infarction. Further extension occurs to the local lymph nodes and to the liver. Abdominal CT may demonstrate a mesenteric mass with tethering of the bowel, lymphadenopathy, and hepatic metastasis. Carcinoid involvement of the heart (resulting in right-sided valvular lesions) is a late manifestation of metastatic disease. Carcinoid syndrome occurs in less than 10% of patients (see [Chapter 40](#)) and only in patients with hepatic metastasis. It is caused by tumor secretion of hormonal mediators that cause cramps, flushing, diarrhea, cyanosis, or bronchospasm. Virtually all patients with carcinoid syndrome have obvious signs of cancer with liver metastasis on abdominal imaging. The optimal initial hepatic imaging study is somatostatin receptor scintigraphy, which is positive in over 90% of patients with metastatic carcinoid. A urinary 5-HIAA > 10 mg/24 h or an elevated serum serotonin confirms the diagnosis of carcinoid syndrome.

Small intestinal carcinoids are extremely indolent tumors with slow spread. Patients with disease confined to the small intestine should have local excision, for which the cure rate exceeds 85%. In patients with resectable disease who have lymph node involvement, the 5-year disease-free survival is 80%; however, by 25 years, less than 25% remain disease-free. Even patients with hepatic metastases may have an indolent course with a median survival of 3 years. In patients with advanced disease, therapy should be deferred until the patient is symptomatic. Surgery should be directed toward palliation of obstructive symptoms. In patients with carcinoid syndrome or diarrhea, resection of hepatic metastases may provide dramatic improvement. The somatostatin analog octreotide (150-500 ug subcutaneously three times daily) inhibits hormone secretion from the carcinoid tumor, resulting in dramatic relief of diarrhea and symptoms of carcinoid syndrome in 90% of patients for a median period of 1 year. Thereafter, many patients escape from octreotide control. Hepatic artery occlusion and chemotherapy may provide symptomatic improvement in some patients with hepatic metastases.

Sarcoma

Malignant stromal tumors (commonly called leiomyosarcomas) occur most commonly in the jejunum. Histologically, they resemble smooth muscle cells, but most are believed to arise from precursors to the interstitial cell of Cajal. (See Malignant Tumors of the Stomach: Stromal Tumors.) Tumors may grow quite large before causing symptoms due to obstruction, intussusception, or bleeding due to central ulceration within the tumor. Surgery should be performed for symptomatic tumors and asymptomatic tumors more than 3-5 cm in size (in which the risk of malignancy is increased). Overall 5-year survival after surgical resection is 30%. The tyrosine kinase inhibitor imatinib induces partial remission and clinical improvement in patients with metastatic disease.

Kaposi's sarcoma was at one time a common complication in AIDS, but the incidence is declining with highly active antiretroviral therapy (HAART). It is strongly associated with infection with human herpesvirus 8. Lesions may be present anywhere in the intestinal tract. Visceral involvement usually is associated with cutaneous disease. Most lesions are clinically silent; however, large lesions may be symptomatic. Lesions of the gingiva, palate, and hypopharynx can lead to painful mastication and dysphagia. Lesions of the stomach or small intestine may lead to bleeding, obstruction, or even perforation. The diagnosis may be confirmed at endoscopy by the characteristic visual appearance and by biopsy. Oral complications can be treated with the CO₂ laser or radiation. Limited bleeding or obstructing lesions in the stomach or anus can be treated with the YAG laser or radiation therapy. Interferon alfa induces regression in up to one-third of patients who have a CD4 cell count of > 200/uL. Widespread involvement may be best treated by systemic chemotherapy using combinations of vincristine, bleomycin, or doxorubicin, to which the tumor is very responsive.

APPENDICITIS

Essentials of Diagnosis

- Early: periumbilical pain; later: right lower quadrant pain and tenderness.
- Anorexia, nausea and vomiting, obstipation.
- Tenderness or localized rigidity at McBurney's point.
- Low-grade fever and leukocytosis.

General Considerations

Appendicitis is the most common abdominal surgical emergency, affecting approximately 10% of the population. It occurs most commonly between the ages of 10 and 30 years. It is initiated by obstruction of the appendix by a fecalith, inflammation, foreign body, or neoplasm. Obstruction leads to increased intraluminal pressure, venous congestion, infection, and thrombosis of intramural vessels. If untreated, gangrene and perforation develop within 36 hours.

Clinical Findings

A. Symptoms and Signs

Appendicitis usually begins with vague, often colicky periumbilical or epigastric pain. Within 12 hours the pain shifts to the right lower quadrant, manifested as a steady ache that is worsened by walking or coughing. Almost all patients have nausea with one or two episodes of vomiting. Protracted vomiting or vomiting that begins before the onset of pain suggests another diagnosis. A sense of constipation is typical, and some patients administer cathartics in an effort to relieve their symptoms—though

some report diarrhea. Low-grade fever (< 38 °C) is typical; high fever or rigors suggest another diagnosis or appendiceal perforation.

On physical examination, localized tenderness with guarding in the right lower quadrant can be elicited with gentle palpation with one finger. When asked to cough, patients may be able to precisely localize the painful area, a sign of peritoneal irritation. Light percussion may also elicit pain. Although rebound tenderness is also present, it is unnecessary to elicit this finding if the above signs are present. The psoas sign (pain on passive extension of the right hip) and the obturator sign (pain with passive flexion and internal rotation of the right hip) are indicative of adjacent inflammation and strongly suggestive of appendicitis.

B. Laboratory Findings

Moderate leukocytosis (10,000-20,000/uL) with neutrophilia is common. Microscopic hematuria and pyuria are present in one-fourth of patients.

C. Imaging

No imaging studies are necessary in patients with typical appendicitis. Studies may be useful in patients in whom the diagnosis is uncertain. Abdominal or transvaginal ultrasound has a diagnostic accuracy of over 85% and is especially useful in the exclusion of adnexal disease in younger women. Abdominal CT is useful in cases of suspected appendiceal perforation to diagnose a periappendiceal abscess.

Atypical Presentations of Appendicitis

Owing to the variable location of the appendix, there are a number of "atypical" presentations. Because the retrocecal appendix does not touch the anterior abdominal wall, the pain remains less intense and poorly localized; abdominal tenderness is minimal and may be elicited in the right flank. The psoas sign may be positive. With pelvic appendicitis there is pain in the lower abdomen, often on the left, with an urge to urinate or defecate. Abdominal tenderness is absent, but tenderness is evident on pelvic or rectal examination; the obturator sign may be present. In the elderly, the diagnosis of appendicitis is often delayed because patients present with minimal, vague symptoms and mild abdominal tenderness. Appendicitis in pregnancy may present with pain in the right lower quadrant, periumbilical area, or right subcostal area owing to displacement of the appendix by the uterus.

Differential Diagnosis

Given its frequency and myriad presentations, appendicitis should be considered in the differential diagnosis of all patients with abdominal pain. It is difficult to reliably diagnose the disease in some cases. A several-hour period of close observation with reassessment usually clarifies the diagnosis. Absence of the classic migration of pain (from the epigastrium to the right lower abdomen), right lower quadrant pain, fever, or guarding makes appendicitis less likely. Ten to 20 percent of patients with suspected appendicitis have either a negative examination at laparotomy or an alternative surgical diagnosis. The widespread use of ultrasonography and CT has reduced the number of incorrect diagnoses. Still, in some cases diagnostic laparotomy or laparoscopy is required. The most common causes of diagnostic confusion are gastroenteritis and gynecologic disorders. Viral gastroenteritis presents with nausea, vomiting, low-grade fever, and diarrhea and can be difficult to distinguish from appendicitis. The onset of vomiting before pain makes appendicitis less likely. As a rule, the pain of gastroenteritis is more generalized and the tenderness less well localized. Acute salpingitis or tubo-ovarian abscess should be considered in young, sexually active women with fever and bilateral abdominal or pelvic tenderness. A twisted ovarian cyst may also cause sudden severe pain. The sudden onset of lower abdominal pain in the middle of the menstrual cycle suggests mittelschmerz. Sudden severe abdominal pain with diffuse pelvic tenderness and shock suggests a ruptured ectopic pregnancy. A positive pregnancy test and pelvic ultrasonography are diagnostic. Retrocecal or retroileal appendicitis (often associated with pyuria or hematuria) may be confused with ureteral colic or pyelonephritis. Other conditions that may resemble appendicitis are diverticulitis, Meckel's diverticulitis, carcinoid of the appendix, perforated colonic cancer, Crohn's ileitis, perforated peptic ulcer, cholecystitis, and mesenteric adenitis. It is virtually impossible to distinguish appendicitis from Meckel's diverticulitis, but both require surgical treatment.

Complications

Perforation occurs in 20% of patients and should be suspected in patients with pain persisting for over 36 hours, high fever, diffuse abdominal tenderness or peritoneal findings, a palpable abdominal mass, or marked leukocytosis. Localized perforation results in a contained abscess, usually in the pelvis. A free perforation leads to suppurative peritonitis with toxicity. Septic thrombophlebitis (pyelephlebitis) of the portal venous system is rare and suggested by high fever, chills, bacteremia, and jaundice.

Treatment

The treatment of uncomplicated appendicitis is surgical appendectomy. This may be performed through a laparotomy or by laparoscopy. Prior to surgery, patients should be given systemic antibiotics, which reduce the incidence of postoperative wound infections. Emergency appendectomy is also required in patients with perforated appendicitis with generalized peritonitis.

The optimal treatment of stable patients with perforated appendicitis and a contained abscess is controversial. Surgery in this setting can be difficult. Many recommend percutaneous CT-guided drainage of the abscess with intravenous fluids and antibiotics to allow the inflammation to subside. An interval appendectomy may be performed after 6 weeks to prevent recurrent appendicitis.

Prognosis

The mortality rate from uncomplicated appendicitis is extremely low. Even with perforated appendicitis, the mortality rate in most groups is only 0.2%, though it approaches 15% in the elderly.

INTESTINAL TUBERCULOSIS

Intestinal tuberculosis is common in underdeveloped countries. Previously rare in the United States, its incidence has been rising in immigrant groups and patients with AIDS. It is caused by both *Mycobacterium tuberculosis* and *M bovis*. Active pulmonary disease is present in less than 50% of patients. The most frequent site of involvement is the ileocecal region; however, any region of the gastrointestinal tract may be involved. Intestinal tuberculosis may cause mucosal ulcerations or scarring and fibrosis with narrowing of the lumen. Patients may complain of chronic abdominal pain, obstructive symptoms, weight loss, and diarrhea. An abdominal mass may be palpable. Complications include intestinal obstruction, hemorrhage, and fistula formation. The PPD skin test may be negative, especially in patients with weight loss or AIDS. Barium radiography may demonstrate mucosal ulcerations, thickening, or stricture formation. Colonoscopy may demonstrate an ulcerated mass, multiple ulcers with steep edges and adjacent small sessile polyps, or small diverticula, most commonly in the ileocecal region. The differential diagnosis includes Crohn's disease, carcinoma, and intestinal amebiasis. The diagnosis is established by either endoscopic or surgical biopsy revealing acid-fast bacilli, caseating granuloma, or positive cultures from the organism. Detection of tubercle bacilli in biopsy specimens by PCR is now the most sensitive means of diagnosis.

Treatment with standard antituberculous regimens is effective.

PROTEIN-LOSING ENTEROPATHY

Protein-losing enteropathy comprises a number of conditions that result in excessive loss of serum proteins into the gastrointestinal tract. The essential diagnostic features are hypoalbuminemia and an elevated fecal α_1 -antitrypsin level.

The normal intact gut epithelium prevents the loss of serum proteins. Proteins may be lost through one of three mechanisms: (1) mucosal disease with ulceration, resulting in the loss of proteins across the disrupted mucosal surface; (2) lymphatic obstruction, resulting in the loss of protein-rich chylous fluid from mucosal lacteals; and (3) idiopathic change in permeability of mucosal capillaries and conductance of interstitium, resulting in "weeping" of protein-rich fluid from the mucosal surface (Table 14-13).

Hypoalbuminemia is the sine qua non of protein-losing enteropathy. However, a number of other serum proteins such as α_1 -antitrypsin also are lost from the gut epithelium. In protein-losing enteropathy caused by lymphatic obstruction, loss of lym-phatic fluid commonly results in lymphocytopenia (< 1000/uL), hypoglobulinemia, and hypocholesterolemia.

In most cases, protein-losing enteropathy is recognized as a sequela of a known gastrointestinal disorder. In patients in whom the cause is unclear, evaluation is indicated and is guided by the clinical suspicion. Protein-losing enteropathy must be distinguished from other causes of hypoalbuminemia, which include liver disease

and nephrotic syndrome, and from congestive heart failure. Protein-losing enteropathy is confirmed by determining the gut α_1 -antitrypsin clearance (24-hour volume of feces $\times$ stool concentration of α_1 -antitrypsin $\div$ serum α_1 -antitrypsin concentration). A clearance of more than 13 mL/24 h is abnormal.

Laboratory evaluation of protein-losing enteropathy includes serum protein electrophoresis, lymphocyte count, and serum cholesterol to look for evidence of lymphatic obstruction. Serum ANA and C3 levels are useful to screen for autoimmune disorders. Stool samples should be examined for ova and parasites. Evidence of malabsorption is evaluated by means of a stool qualitative fecal fat determination. Intestinal imaging is performed with an upper endoscopy with small bowel biopsy and a small bowel barium series. Colonic diseases are excluded with barium enema or colonoscopy. A CT scan of the abdomen is performed to look for evidence of neoplasms or lymphatic obstruction. Rarely, lymphangiography is helpful. In some situations, laparotomy with full-thickness intestinal biopsy is required to establish a diagnosis.

Treatment is directed at the underlying cause. Patients with lymphatic obstruction benefit from low-fat diets supplemented with medium-chain triglycerides. Case reports suggest that octreotide may lead to symptomatic and nutritional improvement in some patients.

IRRITABLE BOWEL SYNDROME

Essentials of Diagnosis

- Chronic functional disorder characterized by abdominal pain or discomfort with alterations in bowel habits.
- Symptoms usually begin in late teens to early twenties.
- Limited evaluation to exclude organic causes of symptoms.

General Considerations

The functional gastrointestinal disorders are characterized by a variable combination of chronic or recurrent gastrointestinal symptoms *not explicable by the presence of structural or biochemical abnormalities*. Several clinical entities are included under this broad rubric, including chest pain of unclear origin (noncardiac chest pain), functional dyspepsia, and biliary dyskinesia (sphincter of Oddi dysfunction). There is a large overlap among these entities. For example, over half of patients with noncardiac chest pain and over one-third with functional dyspepsia also have symptoms compatible with irritable bowel syndrome. In none of these disorders is there a definitive diagnostic study. Rather, the diagnosis is a subjective one based upon the presence of a compatible profile and the exclusion of similar disorders.

Irritable bowel syndrome can be defined, therefore, as an idiopathic clinical entity characterized by some combination of chronic (more than 3 months) lower abdominal symptoms and bowel complaints that may be continuous or intermittent. Consensus definition of irritable bowel syndrome is abdominal discomfort or pain that has two of the following three features: (1) relieved with defecation, (2) onset associated with a change in frequency of stool, and (3) onset associated with a change in form (appearance) of stool. Other symptoms supporting the diagnosis include abnormal stool frequency (more than three bowel movements per day or fewer than three per week), abnormal stool form (lumpy or hard; loose or watery), abnormal stool passage (straining, urgency, or feeling of incomplete evacuation), passage of mucus; and bloating or a feeling of abdominal distention.

Patients may have other somatic or psychologic complaints such as dyspepsia, heartburn, chest pain, headaches, fatigue, myalgias, urologic dysfunction, gynecologic symptoms, anxiety, or depression.

The disorder is a common problem presenting to both gastroenterologists and primary care physicians. Up to 20% of the adult population have symptoms compatible with the diagnosis, but most never seek medical attention. Approximately two-thirds of patients with irritable bowel syndrome are women.

Pathogenesis

A number of pathophysiologic mechanisms have been identified and may have varying importance in different individuals.

A. Abnormal Motility

A variety of abnormal myoelectrical and motor abnormalities have been identified in the colon and small intestine. In some cases, these are temporally correlated with episodes of abdominal pain or emotional stress. Whether they represent a primary motility disorder or are secondary to psychosocial stress is debated. Differences between patients with constipation-predominant and diarrhea-predominant syndromes are reported.

B. Visceral Hypersensitivity

Patients often have a lower visceral pain threshold, reporting abdominal pain at lower volumes of colonic gas insufflation or colonic balloon inflation than controls. Although many patients complain of bloating and distention, their absolute intestinal gas volume is normal. Many patients report rectal urgency despite small rectal volumes of stool.

C. Enteric Infection

Up to 30% of patients develop symptoms compatible with irritable bowel syndrome after an episode of bacterial gastroenteritis. Women and patients with increased life stressors at the onset of gastroenteritis appear to be at increased risk of developing "postinfectious" irritable bowel syndrome. Increased inflammatory cells have been found in the mucosa, submucosa, and muscularis of some patients with irritable bowel syndrome, but their importance is unclear. Chronic inflammation is postulated by some investigators to contribute to alterations in motility or visceral hypersensitivity.

D. Psychosocial Abnormalities

More than half of patients with irritable bowel who seek medical attention have underlying depression, anxiety, or somatization. By contrast, those who do not seek medical attention are similar psychologically to normal individuals. Psychologic abnormalities may influence how the patient perceives or reacts to illness and minor visceral sensations. Chronic stress may alter intestinal motility or modulate pathways that affect central and spinal processing of visceral afferent sensation.

Clinical Findings

A. Symptoms and Signs

Irritable bowel is a chronic condition. Symptoms usually begin in the late teens to twenties. Symptoms should be present for at least 3 months before the diagnosis can be considered. The diagnosis is established in the presence of compatible symptoms and after the exclusion of organic disease.

Abdominal pain usually is intermittent, crampy, and in the lower abdominal region. As previously stated, the onset of pain typically is associated with a change in stool frequency or form and commonly is relieved by defecation. It does not usually occur at night or interfere with sleep. Patients with irritable bowel syndrome may be classified into one of three categories: those who have predominant problems with constipation, diarrhea, or alternating constipation and diarrhea. It is important to clarify what the patient means by these complaints. Patients with irritable bowel and constipation report infrequent bowel movements (less than three per week), hard or lumpy stools, or straining. Patients with irritable bowel syndrome with diarrhea refer to loose or watery stools, frequent stools (more than three per day), urgency, or fecal incontinence. Many patients report that they have a firm stool in the morning followed by progressively looser movements. Mucus is commonly seen. Complaints of visible distention and bloating are common, though these are not clinically evident.

The patient should be asked about "red flags" that suggest a diagnosis other than irritable bowel syndrome. The acute onset of symptoms raises the likelihood of organic disease, especially in patients aged > 40-50 years. Nocturnal diarrhea, severe constipation or diarrhea, hematochezia, weight loss, and fever are incompatible with a diagnosis of irritable bowel syndrome and warrant investigation for underlying disease. A family history of cancer, inflammatory bowel disease, or celiac disease may also warrant further investigation.

A physical examination should be performed to look for evidence of organic disease and to allay the patient's anxieties. The physical examination usually is normal. Abdominal tenderness, especially in the lower abdomen, is common but not pronounced. A new onset of symptoms in a patient over age 40 warrants further examination.

B. Laboratory Findings and Special Examinations

In a patient 20-50 years of age with a presumptive clinical diagnosis of irritable bowel syndrome, a limited series of examinations is warranted to screen for organic disease. Overtesting should be avoided. The complete blood count, serum albumin, erythrocyte sedimentation rate, thyroid function tests, and stool occult blood test all should be normal. In patients with diarrhea, serologic tests for celiac disease (anti-gliadin antibodies or tissue transglutaminase antibody) and stool examination for ova and parasites are performed. In patients under age 45 with diarrhea, flexible sigmoidoscopy should be considered to exclude ulcerative colitis; however, this is optional in young patients with constipation-predominant symptoms. In all patients over age 45 who have not had a previous evaluation, barium enema or colonoscopy should be considered to exclude malignancy.

Differential Diagnosis

A number of disorders may present with similar symptoms. Examples include colonic neoplasia, inflammatory bowel disease, hyper- or hypothyroidism, causes of chronic diarrhea (especially celiac disease, bacterial overgrowth, and lactase deficiency), and endometriosis. Psychiatric disorders such as depression and anxiety must be considered as well. Women with refractory symptoms have an increased incidence of prior sexual and physical abuse.

Treatment

A. General Measures

As with other functional disorders, the most important interventions the physician can offer are reassurance, education, and support. An ongoing therapeutic relationship may be the most important factor in successful management of this disorder. This includes identifying and responding to the patient's concerns, careful explanation of the pathophysiology and natural history of the disorder, setting realistic treatment goals, and involving the patient in the treatment process. Because irritable bowel symptoms are chronic, the patient's reasons for seeking consultation at this time should be determined. These may include major life events or recent psychosocial stressors, dietary or medication changes, concerns about serious underlying disease, or reduced quality of life and impairment of daily activities. In discussing with the patient the importance of the mind-gut interaction, it may be helpful to explain that alterations in visceral motility and sensitivity may be exacerbated by environmental, social, or psychologic factors such as foods, medications, hormones, and stress. Symptoms such as pain, bloating, and altered bowel habits may lead to anxiety and distress which in turn may further exacerbate bowel disturbances due to disordered communication between the gut and the central nervous system. A symptom diary in which patients record the time and severity of symptoms, food intake, and life events may help uncover aggravating dietary or psychosocial factors. Physicians will earn the confidence of their patients by being nonjudgmental and attentive. Fears that the symptoms will progress, require surgery, or degenerate into serious illness should be allayed. The patient should understand that irritable bowel syndrome is a chronic disorder characterized by periods of exacerbation and quiescence. The physician can help but cannot "cure" such a disorder. The emphasis should be shifted from finding the cause of the symptoms to finding a way to cope with them. Physicians must resist the temptation to chase chronic complaints with new or repeated diagnostic studies.

B. Dietary Therapy

Patients commonly report dietary intolerances, although a role for dietary triggers in irritable bowel syndrome has never been convincingly demonstrated. Fatty foods and caffeine are poorly tolerated by many patients with irritable bowel syndrome. In patients with diarrhea, lactose intolerance should be excluded with a breath hydrogen test or a trial of a lactose-free diet. Malabsorption of dietary fructose or sorbitol (contained in fruits and artificially sweetened foods) may exacerbate bloating, flatulence, and diarrhea. A variety of foods are flatulogenic, producing pain and distention in some patients. These include brown beans, Brussels sprouts, cabbage, cauliflower, raw onions, grapes, plums, raisins, coffee, garlic, red wine, and beer.

A high-fiber diet (20-30 g/d) may be tried in patients with predominant constipation but is of no value for the treatment of diarrhea. Many patients report increased gas and distention with high-fiber diets or from fiber supplementation with bran. Fiber supplements with psyllium, methylcellulose, or polycarbophil may be better tolerated (see section on constipation).

C. Pharmacologic Measures

More than two-thirds of patients with irritable bowel syndrome have mild symptoms that respond readily to education, reassurance, and dietary interventions. Drug therapy should be reserved for patients with moderate to severe symptoms that do not respond to conservative measures. These agents should be viewed as being adjunctive rather than curative. Given the wide spectrum of symptoms, no single agent is expected to provide relief in all or even most patients. Nevertheless, therapy targeted at the specific dominant symptom (pain, constipation, or diarrhea) may be beneficial.

1. Antispasmodic agents—Anticholinergic agents are used by some practitioners for treatment of acute episodes of pain or bloating. Available agents include dicyclomine, 10-20 mg orally three or four times daily, and hyoscyamine, 0.125 mg orally (or sublingually as needed) or sustained-release, 0.037 mg or 0.75 mg orally twice daily. Anticholinergic side effects are common, including urinary retention, constipation, tachycardia, and dry mouth. Hence, these agents should be used with caution in the elderly and in patients with constipation.

2. Antidiarrheal agents—Loperamide (2 mg orally three or four times daily) is effective for the treatment of patients with diarrhea, reducing stool frequency, liquidity, and urgency. It may best be used "prophylactically" in situations in which diarrhea is anticipated (such as stressful situations) or would be inconvenient (social engagements).

3. Anticonstipation agents—A trial of fiber supplementation with bran, psyllium, methylcellulose, or polycarbophil is helpful for treatment of constipation in some cases but may exacerbate intestinal gas, bloating, and abdominal discomfort. Treatment with osmotic laxatives (milk of magnesia or polyethylene glycol) may increase stool frequency, improve stool consistency, and reduce straining. Lactulose or sorbitol produces increased flatus and distention, which are poorly tolerated in patients with irritable bowel syndrome. Patients with intractable constipation should undergo further assessment for slow colonic transit and pelvic floor dysfunction (see Constipation, above).

4. Psychotropic agents—Patients with predominant symptoms of pain or bloating may benefit from low doses of tricyclic antidepressants, which are believed to have effects upon motility, visceral sensitivity, and central pain perception that are independent of their psychotropic effects. Because of their anticholinergic effects, these agents may be more useful in patients with diarrhea-predominant than constipation-predominant symptoms. Nortriptyline, desipramine, imipramine, or trazodone may be started at a low dosage of 10-25 mg at bedtime and increased gradually to 50-100 mg as tolerated. Side effects are common, and lack of efficacy with one agent does not preclude benefit from another. Improvement should be evident within 4 weeks. The efficacy of serotonin reuptake inhibitors (sertraline, 50-150 mg daily, or fluoxetine, 20-40 mg daily) for irritable bowel syndrome has not been established. Anxiolytics should not be used chronically in irritable bowel syndrome because of their habituation potential. Patients with major depression or anxiety disorders should be identified and treated with therapeutic doses of appropriate agents.

5. Serotonin receptor agonists and antagonists—Serotonin is an important mediator of gastrointestinal motility and sensation. Two agents approved for treatment of irritable bowel syndrome that modulate serotonin pathways are tegaserod and alosetron. Although both of these agents have some effect upon visceral sensation, they have very different effects upon intestinal motility.

Tegaserod is a selective partial 5-HT₄ receptor agonist that has been approved recently for treatment of women who have irritable bowel syndrome with predominant constipation. Through stimulation of neurons in the intestinal mucosa, tegaserod stimulates intestinal peristalsis, inhibits visceral afferents involved in pain sensation, and stimulates colonic chloride and water secretion. In humans it acts as a prokinetic agent, accelerating gastric emptying and small and large bowel transit. Tegaserod (6 mg twice daily) results in modest but significant improvement compared with placebo in global irritable bowel symptoms in women. Efficacy in men has not been established. Tegaserod leads to an increase in stool frequency, improvement of stool consistency, and a reduction in abdominal pain and bloating. Symptom improvement is evident within 1 week in responsive patients. Diarrhea occurs in about 10% but usually resolves with continued therapy. The drug is otherwise extremely well tolerated and without significant drug interactions. For patients who demonstrate symptomatic improvement, it may be continued for 4-12 weeks and used intermittently for symptomatic flares.

Alosetron is a 5-HT₃ antagonist that has been approved for the treatment of women with severe irritable bowel syndrome with predominant diarrhea. It appears to alter visceral sensation through blockade of peripheral 5-HT₃ receptors on enteric afferent neurons as well as central receptors. It also inhibits enteric cholinergic motor neurons, resulting in inhibition of colonic motility. In humans, it increases the pain threshold in response to intestinal distention and slows colonic transit time. Alosetron (1 mg twice daily) results in improvement in 50-60% of women compared with 30-40% treated with placebo. Alosetron reduces symptoms of pain, discomfort, cramps, urgency, and diarrhea. Efficacy in men has not been demonstrated. In contrast to the excellent safety profile of other 5-HT₃ antagonists (eg, ondansetron), alosetron may cause constipation in 30%, frequently requiring discontinuation. Severe constipation (requiring hospitalization) and ischemic colitis may occur in 4:1000 patients. Given the seriousness of these side effects, alosetron is restricted to women with severe irritable bowel syndrome with diarrhea who have failed conventional therapies and who have been educated about the relative risks and benefits of the agent. It should not be used in patients with constipation.

D. Other Therapies

Behavioral modification with relaxation techniques and hypnotherapy may be beneficial in some patients. Patients with underlying psychologic abnormalities may benefit from evaluation by a psychiatrist or psychologist. Patients with severe disability should be referred to a pain treatment center.

Prognosis

The majority of patients with irritable bowel syndrome learn to cope with their symptoms and lead productive lives.

ANTIBIOTIC-ASSOCIATED COLITIS

Essentials of Diagnosis

- Most cases of antibiotic-associated diarrhea are not attributable to *Clostridium difficile* and are usually mild and self-limited.
- Symptoms of antibiotic-associated colitis vary from mild to fulminant; almost all colitis is attributable to *C difficile*.
- Diagnosis in mild to moderate cases established by stool toxin assay.
- Flexible sigmoidoscopy provides most rapid diagnosis in severe cases.

General Considerations

Antibiotic-associated diarrhea is a common clinical occurrence. Characteristically, the diarrhea occurs during the period of antibiotic exposure, is dose-related, and resolves spontaneously after discontinuation of the antibiotic. In most cases, this diarrhea is mild, self-limited, and does not require any specific laboratory evaluation or treatment. Stool examination usually reveals no fecal leukocytes, and stool cultures reveal no pathogens. Although *C difficile* is identified in the stool of 15-25% of cases of antibiotic-associated diarrhea, it is also identified in 5-10% of patients treated with antibiotics who do not have diarrhea. Most cases of antibiotic-associated diarrhea are due to changes in colonic bacterial fermentation of carbohydrates and are not due to *C difficile*.

Antibiotic-associated colitis is a significant clinical problem almost always caused by *C difficile*. Hospitalized patients are most susceptible, especially those who are severely ill or malnourished or who are receiving chemotherapy. This anaerobic bacterium colonizes the colon of 5% of healthy adults. In hospitalized patients, however, it is present in over 20% of patients, most of whom have received antibiotics that disrupt the normal bowel flora and thus allow the bacterium to flourish. Most of these patients are asymptomatic. Recently, patients receiving enteral tube feedings have been found to have a higher risk for acquisition of *C difficile* and the development of *C difficile*-associated diarrhea. The organism is spread in a fecal-oral fashion. It is found throughout hospitals in patient rooms and bathrooms and is readily transmitted from patient to patient by hospital personnel. Fastidious hand washing and use of disposable gloves are helpful in minimizing transmission.

In one-third of colonized patients, *C difficile*-induced colitis may develop. *C difficile* colitis is the major cause of diarrhea in patients hospitalized for more than 3 days, affecting 7:1000 patients. Although virtually all antibiotics have been implicated, colitis most commonly develops after use of ampicillin, clindamycin, and third-generation cephalosporins. Symptoms usually begin during or shortly after antibiotic therapy but may be delayed for up to 8 weeks. All patients with acute diarrhea should be questioned about recent antibiotic exposure.

Clinical Findings

A. Symptoms and Signs

Most patients report mild to moderate greenish, foul-smelling watery diarrhea with lower abdominal cramps. Physical examination is normal or reveals mild left lower quadrant tenderness. With more serious illness, there is abdominal pain and profuse watery diarrhea with up to 30 stools per day. The stools may have mucus but seldom gross blood. There may be fever up to 40 °C, abdominal tenderness, and leukocytosis as high as 50,000/uL. *C difficile* colitis should be considered in all hospitalized patients with unexplained leukocytosis. In most patients, colitis is most severe in the distal colon and rectum. When colitis is more severe in the right side of the colon, there may be little or no diarrhea. In such cases, fever, abdominal distention, pain and tenderness, and leukocytosis suggest the presence of infection.

B. Special Examinations

1. Stool studies—Pathogenic strains of *C difficile* produce two toxins: toxin A is an enterotoxin, and toxin B a cytotoxin. In most patients, the diagnosis of antibiotic-associated colitis is established by the demonstration of *C difficile* toxins in the stool. A cytotoxicity assay (toxin B) performed in cell cultures has a specificity of 90% and a sensitivity of 95%. This is the definitive test, but it is expensive and takes at least 24 hours. Rapid enzyme immunoassays (EIA) (2-4 hours) for toxins A and B have been developed that have a 70-85% sensitivity with a single stool specimen but 90% with two specimens. Some toxic strains of *C difficile* do not produce a functional toxin A (and therefore have a negative EIA). When *C difficile* is suspected but the EIA is negative, a cytotoxicity assay should be performed. Culture for *C difficile* is the most sensitive test, but 25% of isolates are not pathogenic. Because it is slower (2-3 days), more costly, and less specific than toxin assays, it is not used in most clinical settings. Fecal leukocytes are present in only 50% of patients with colitis.

2. Flexible sigmoidoscopy—Flexible sigmoidoscopy is performed in patients with more severe symptomatology when a rapid diagnosis is desired so that therapy can be initiated. In patients with mild to moderate symptoms, there may be no abnormalities or only patchy or diffuse, nonspecific colitis indistinguishable from other causes. In patients with severe illness, true **pseudomembranous colitis** is seen. This has a characteristic appearance, with yellow adherent plaques 2-10 mm in diameter scattered over the colonic mucosa interspersed with hyperemic mucosa. Biopsies reveal epithelial ulceration with a classic "volcano" exudate of fibrin and neutrophils. In 10% of cases, pseudomembranous colitis is confined to the proximal colon and may be missed at sigmoidoscopy.

3. Imaging studies—Abdominal radiographs are obtained in patients with fulminant symptoms to look for evidence of toxic dilation or megacolon but are of no value in mild disease. Mucosal edema or "thumbprinting" may be evident. Abdominal CT scan may be very useful in detecting colonic edema, especially in patients with predominantly right-sided colitis or abdominal pain without significant diarrhea (in whom the diagnosis may be unsuspected). CT is also useful in the evaluation of possible complications.

Differential Diagnosis

In the hospitalized patient who develops acute diarrhea after admission, the differential diagnosis includes simple antibiotic-associated diarrhea (not related to *C difficile*), enteral feedings, medications, and ischemic colitis. Other infectious causes are unusual in hospitalized patients who develop diarrhea more than 72 hours after admission, and it is not cost-effective to obtain stool cultures unless tests for *C difficile* are negative. Rarely, other organisms (staphylococci, *Clostridium perfringens*) have been associated with pseudomembranous colitis.

Complications

Fulminant disease may result in dehydration, electrolyte imbalance, toxic megacolon, perforation, and death. Chronic untreated colitis may result in weight loss and protein-losing enteropathy.

Treatment

A. Acute Therapy

If possible, antibiotic therapy should be discontinued. In patients with mild symptoms, doing so may result in prompt resolution of symptoms without specific treatment. If diarrhea is severe or persistent, specific therapy is warranted. The drug of choice is metronidazole, 500 mg orally three times daily. The duration of therapy is usually 10-14 days. However, in patients requiring long-term systemic antibiotics, it may be appropriate to continue metronidazole therapy until the antibiotics can be discontinued. Vancomycin, 125 mg orally four times daily, is equally effective as metronidazole but significantly more expensive, and it promotes the emergence of vancomycin-resistant nosocomial infections. Therefore, metronidazole is the preferred first-line therapy in most patients. Vancomycin should be reserved for patients who are intolerant of metronidazole, pregnant women, and children. Symptomatic improvement occurs in most patients within 72 hours. For patients with severe disease who do not respond rapidly to initial metronidazole therapy, therapy should be switched to vancomycin, 125 mg orally four times daily, escalating the dose to 500 mg four times daily if diarrhea and leukocytosis fail to improve. In patients who are unable to take oral medications and those with toxic megacolon, intravenous metronidazole, 500-750 mg every 6 hours, should be given—sometimes supplemented by oral vancomycin administered per nasointestinal tube or enema. Intravenous vancomycin does not penetrate the bowel and should not be used. Total abdominal colectomy may be required in patients with toxic megacolon, perforation, sepsis, or hemorrhage.

B. Treatment of Relapse

Up to 20% of patients have a relapse of diarrhea from *C difficile* within 1 or 2 weeks after stopping initial therapy. This may be due to reinfection or failure to eradicate the organism. Most relapses respond promptly to a second course of metronidazole therapy. Some patients have recurrent relapses that can be difficult to treat. The optimal treatment regimen for recurrent relapses is unknown. Many authorities recommend a 6-week tapering regimen of vancomycin (125 mg orally four times daily for 7 days; twice daily for 7 days; once daily for 7 days; every other day for 7 days; and every third day for 2 weeks). Oral administration of a live yeast, *Saccharomyces boulardii*, has been shown to reduce the incidence of relapse by 50% in one United States trial. However, this agent is not yet available in the United States.

INFLAMMATORY BOWEL DISEASE

The term "inflammatory bowel disease" includes ulcerative colitis and Crohn's disease. Ulcerative colitis is a chronic, recurrent disease characterized by diffuse mucosal inflammation involving only the colon. Ulcerative colitis invariably involves the rectum and may extend proximally in a continuous fashion to involve part or all of the colon. Crohn's disease is a chronic, recurrent disease characterized by patchy transmural inflammation involving any segment of the gastrointestinal tract from the mouth to the anus.

Drug Therapies for Inflammatory Bowel Disease

Although ulcerative colitis and Crohn's disease appear to be distinct entities, the same pharmacologic agents are used to treat both. Despite extensive research, there are still no specific therapies for these diseases. The mainstays of therapy remain 5-aminosalicylic acid derivatives, corticosteroids, and mercaptopurine or azathioprine.

A. 5-Aminosalicylic Acid (5-ASA)

5-Aminosalicylic acid is a topically active agent that has a variety of anti-inflammatory effects. It is used in the active treatment of ulcerative colitis and Crohn's disease and during disease inactivity in order to maintain remission. It is readily absorbed from the small intestine but demonstrates minimal colonic absorption. A number of oral and topical compounds have been designed to target delivery of 5-ASA to the colon or small intestine while minimizing absorption. Commonly used formulations of 5-ASA are sulfasalazine, mesalamine, and azo compounds.

1. Sulfasalazine—Sulfasalazine consists of 5-aminosalicylic acid linked by an azo bond to a sulfapyridine moiety. It is largely unabsorbed in the small intestine. In the colon, bacterial azoreductases cleave 5-ASA from the sulfapyridine group. It is unclear whether the sulfapyridine group has any anti-inflammatory effects. One gram of sulfasalazine contains 400 mg of 5-ASA. The 5-ASA works topically and is largely unabsorbed. The sulfapyridine group, however, is absorbed and may cause side effects in 15-30% of patients. Dose-related side effects include nausea, headaches, leukopenia, oligospermia, and impaired folate metabolism. Allergic and idiosyncratic side effects are fever, rash, hemolytic anemia, neutropenia, worsened colitis, hepatitis, pancreatitis, and pneumonitis. Despite its side effects, sulfasalazine continues to be used because it is significantly less expensive than other 5-aminosalicylic acid agents. It should always be administered in conjunction with folate.

2. Oral mesalamine agents—These 5-ASA agents are coated in various pH-sensitive resins (Asacol) or packaged in timed-release capsules (Pentasa). Mesalamine tablets dissolve at pH 7.0, releasing 5-ASA in the terminal small bowel and proximal colon. Pentasa releases 5-ASA slowly throughout the small intestine and colon. Side effects of these compounds are uncommon but include nausea, headache, pancreatitis, and nephropathy. Eighty percent of patients intolerant of sulfasalazine can tolerate mesalamine.

3. Azo compounds—Balsalazide and olsalazine are 5-ASA prodrugs released almost entirely in the colon. They contain 5-ASA linked by an azo bond that requires cleavage by colonic bacterial azoreductases in order to release 5-ASA. Absorption of the prodrugs or 5-ASA from the small intestine is negligible. Compared with mesalamine, there is less systemic absorption of 5-ASA and lower systemic side effects. Balsalazide contains 5-ASA linked to an inert carrier (4-aminobenzoyl- β -alanine). It is as effective as or more effective than other 5-ASA compounds for the treatment of ulcerative colitis.

4. Topical mesalamine—5-Aminosalicylic acid is provided in the form of suppositories (500 mg) and enemas (Rowasa; 4 g/60 mL). These formulations can deliver much higher concentrations of 5-aminosalicylic acid to the distal colon than oral compounds. Side effects are uncommon.

B. Corticosteroids

A variety of intravenous, oral, and topical steroid formulations have been used in inflammatory bowel disease. They have utility in the short-term treatment of moderate to severe disease. However, long-term use is associated with serious, potentially irreversible side effects and is to be avoided. The agents, route of administration, duration of use, and tapering regimens employed are based more upon personal bias and experience than upon data from rigorous clinical trials. The most commonly used intravenous formulations have been hydrocortisone or methylprednisolone, which are given by continuous infusion or every 6 hours. Oral formulations are prednisone or methylprednisolone. Topical preparations are provided as hydrocortisone suppositories (100 mg), foam (90 mg), and enemas (100 mg). Budesonide is an oral glucocorticoid with high topical anti-inflammatory activity but low systemic activity due to high first-pass hepatic metabolism.

C. Mercaptopurine and Azathioprine

Mercaptopurine and azathioprine are used in 10-15% of patients with refractory Crohn's disease and, increasingly, in ulcerative colitis. Side effects occur in 10%, including pancreatitis, bone marrow suppression, infections, hepatitis or cholestatic jaundice, allergies, and, potentially, a higher risk of neoplasm. After therapy is initiated or dosages are increased, complete blood counts should be obtained weekly for 1 month. Thereafter, complete blood count and liver chemistries should be monitored every 1-2 months to monitor for myelosuppression and hepatitis. About one person in ten has a genetically acquired deficiency in the enzyme thiopurine methyltransferase (TPMT) that metabolizes these thiopurine medications, placing them at risk of profound immunosuppression. Levels of TPMT and mercaptopurine metabolites now are available clinically; their proper use is debated.

Social Support for Patients with Inflammatory Bowel Disease

Inflammatory bowel disease is a lifelong illness that can have profound emotional and social impacts on the individual. Patients should be encouraged to become involved in the Crohn's and Colitis Foundation of America (CCFA). National headquarters may be contacted at 444 Park Avenue South, 11th Floor, New York, NY 10016-7374; phone 212-685-3440. Internet address: <http://www.ccfa.org>.

1. Crohn's Disease

Essentials of Diagnosis

- Insidious onset.
- Intermittent bouts of low-grade fever, diarrhea, and right lower quadrant pain.
- Right lower quadrant mass and tenderness.
- Perianal disease with abscess, fistulas.
- Radiographic evidence of ulceration, stricturing, or fistulas of the small intestine or colon.

General Considerations

One-third of cases of Crohn's disease involve only the small bowel, most commonly the terminal ileum (ileitis). Half of cases involve the small bowel and colon, most often the terminal ileum and adjacent proximal ascending colon (ileocolitis). In 20% of cases, the colon alone is affected. Unlike ulcerative colitis, Crohn's disease is a transmural process that can result in mucosal inflammation and ulceration, stricturing, fistula development, and abscess formation.

Clinical Findings

A. Symptoms and Signs

Because of the variable location of involvement and severity of inflammation, Crohn's disease may present with a variety of symptoms and signs. In eliciting the history, the clinician should take particular note of fevers, the patient's general sense of well-being, the presence of abdominal pain, the number of liquid bowel movements per day, and prior surgical resections. Physical examination should focus upon the patient's temperature, weight, and nutritional status, the presence of abdominal tenderness or an abdominal mass, rectal examination, and extraintestinal manifestations. Most commonly, there is one or a combination of the following clinical constellations.

1. Chronic inflammatory disease—This is the most common presentation and is often seen in patients with ileitis or ileocolitis. Patients report low-grade fever, malaise, weight loss, and loss of energy. There may be diarrhea, which is nonbloody and often intermittent. Cramping or steady right lower quadrant or periumbilical pain is present. Physical examination reveals focal tenderness, usually in the right lower quadrant. A palpable, tender mass that represents thickened or matted loops of inflamed intestine may be present in the lower abdomen.

2. Intestinal obstruction—Narrowing of the small bowel may occur as a result of inflammation, spasm, or fibrotic stenosis. Patients report postprandial bloating, cramping pains, and loud borborygmi. This sometimes occurs in patients with active inflammatory symptoms (as above). More commonly, however, it occurs later in the disease from chronic fibrosis without other systemic symptoms or signs of inflammation.

3. Fistulization with or without infection—A subset of patients develop sinus tracts that penetrate through the bowel and form fistulas to a number of locations.

Fistulas to the mesentery are usually asymptomatic but can result in intra-abdominal or retroperitoneal abscesses manifested by fevers, chills, a tender abdominal mass, and leukocytosis. Fistulas from the colon to the small intestine or stomach can result in bacterial overgrowth with diarrhea, weight loss, and malnutrition. Fistulas to the bladder or vagina produce recurrent infections. Enterocutaneous fistulas usually occur at the site of surgical scars.

4. Perianal disease—One-third of patients with either large or small bowel involvement develop perianal disease manifested by anal fissures, perianal abscesses, and fistulas.

5. Extraintestinal manifestations—The extracolonic manifestations (described in the section on ulcerative colitis) may also be seen with Crohn's disease, particularly Crohn's colitis. Other problems may also arise. Oral aphthous lesions are common. There is an increased prevalence of gallstones due to malabsorption of bile salts from the terminal ileum. Nephrolithiasis with urate or calcium oxalate stones may occur.

B. Laboratory Findings

There is a poor correlation between laboratory studies and the patient's clinical picture. Laboratory values may reflect inflammatory activity or nutritional complications of disease. A complete blood count and serum albumin should be obtained in all patients. Anemia may reflect chronic inflammation, mucosal blood loss, iron deficiency, or vitamin B₁₂ malabsorption secondary to terminal ileal inflammation or resection. Leukocytosis may reflect inflammation or abscess formation or may be secondary to corticosteroid therapy. Hypoalbuminemia may be due to intestinal protein loss (protein-losing enteropathy), malabsorption, or chronic inflammation. The sedimentation rate or C-reactive protein level is elevated in many patients during active inflammation. Stool specimens are sent for examination for routine pathogens, ova and parasites, and *C difficile* toxin.

C. Special Diagnostic Studies

In most patients, the initial diagnosis of Crohn's disease is based upon a compatible clinical picture with supporting radiographic findings. An upper gastrointestinal series with small bowel follow-through is obtained in all patients. Suggestive findings include ulcerations, strictures, and fistulas. To evaluate the colon, a barium enema or colonoscopy is obtained. Colonoscopy offers the advantage of obtaining mucosal biopsies of the colon or terminal ileum. Typical endoscopic findings include aphthoid ulcers, linear or stellate ulcers, strictures, and segmental involvement with areas of normal-appearing mucosa adjacent to inflamed mucosa. In 10% of cases, it may be difficult to distinguish ulcerative colitis from Crohn's disease. When the diagnosis remains uncertain, two serologic tests may be useful in further distinguishing these two diseases. Antineutrophil cytoplasmic antibodies with perinuclear staining (p-ANCA) are found in 50-70% of patients with ulcerative colitis and 5-10% of patients with Crohn's disease. Antibodies to the yeast *S cerevisiae* (ASCA) are found in 60-70% of patients with Crohn's disease and 10-15% of patients with ulcerative colitis. A combination of p-ANCA negativity and ASCA positivity has a 95% positive predictive value and 92% specificity for a diagnosis of Crohn's disease. Conversely, p-ANCA positivity and ASCA negativity has an 88% positive predictive value and 98% specificity for the diagnosis of ulcerative colitis. The presence of granulomas on biopsy are seen in less than 25% of patients but are highly suggestive of Crohn's disease.

Complications

A. Abscess

The presence of a tender abdominal mass with fever and leukocytosis suggests an abscess. Emergent CT of the abdomen is necessary to confirm the diagnosis. Patients should be given broad-spectrum antibiotics and, if malnourished, maintained on TPN. Percutaneous drainage or surgery is usually required.

B. Obstruction

Small bowel obstruction may develop secondary to active inflammation or chronic fibrotic stricturing and is often acutely precipitated by dietary indiscretion. Patients should be given intravenous fluids with nasogastric suction for several days. Systemic steroids are indicated in patients with symptoms or signs of active inflammation but are unhelpful in patients with inactive, fixed disease. Patients unimproved on medical management require surgical resection of the stenotic area or stricturoplasty.

C. Fistulas

The majority of enteromesenteric and enteroenteric fistulas are asymptomatic and require no specific therapy. Most symptomatic fistulas require surgical therapy, particularly when there is evidence of intestinal stricturing below the fistula. Medical therapy is effective in a subset of patients and is usually tried before surgery. Although fistulas may close temporarily in response to TPN or oral elemental diets, they recur when oral feedings are resumed. Azathioprine or mercaptopurine heals fistulas in 30-40% of patients but requires 3-6 months. The anti-TNF antibody infliximab is the most effective medical therapy for chronic fistulizing Crohn's disease. Infliximab injections (5 mg/kg) given at 0, 2, and 6 weeks result in complete closure of fistulas (both perianal and abdominal) in up to half of patients and improvement in up to 75%. In patients treated with infliximab, it is recommended that mercaptopurine or azathioprine also be given to reduce the otherwise high likelihood of fistula recurrence. Rapid closure of perianal fistulas may lead to abscess in patients with active perianal infection. Although cyclosporine has demonstrated some value for fistulous disease, high relapse rates and the risk of toxicity have limited its use.

D. Perianal Disease

Patients with fissures, fistulas, and skin tags commonly have perianal discomfort. Severe pain should suggest a perianal abscess. The treatment of perianal problems can be very difficult. Initial conservative treatment with sitz baths, attempts to control diarrhea, and application of perianal cotton balls to absorb irritating drainage are warranted. Metronidazole, 250 mg three times daily, or ciprofloxacin, 500 mg twice daily, are commonly given but have not been proved to be efficacious. Aminosalicylates are of no benefit. Steroids are of no value and may retard healing. The role of mercaptopurine or azathioprine and infliximab is discussed in the section on fistulas. Patients with abscesses require conservative incision and drainage. Surgical fistulotomy should be avoided in the presence of active Crohn's disease because there is a risk of poor wound healing or incontinence. Patients may benefit from placement of noncutting drains, which allows drainage and improves comfort while medical treatment with antibiotics, azathioprine, or infliximab is instituted.

E. Carcinoma

Patients with extensive colonic Crohn's disease are at increased risk of developing colon carcinoma. Screening colonoscopy to detect dysplasia or cancer is recommended by most authorities for patients with a history of 8 or more years of Crohn's colitis.

F. Hemorrhage

Unlike ulcerative colitis, severe hemorrhage is unusual in Crohn's disease.

G. Malabsorption

Malabsorption may arise from bacterial overgrowth in patients with enterocolonic fistulas, strictures and stasis, extensive jejunal inflammation, and prior surgical resections.

Differential Diagnosis

Chronic cramping abdominal pain and diarrhea are typical of both irritable bowel syndrome and Crohn's disease, but x-ray examinations are normal in the former. Acute fever and right lower quadrant pain may resemble appendicitis or *Yersinia enterocolitica* enteritis. Intestinal lymphoma causes fever, pain, weight loss, and abnormal small bowel radiographs that may mimic Crohn's disease. Patients with undiagnosed AIDS may present with fever and diarrhea. Segmental colitis may be caused by tuberculosis, *Entamoeba histolytica*, chlamydia, or ischemic colitis. Diverticulitis with abscess formation may be difficult to distinguish acutely from Crohn's disease. NSAID-induced colitis may cause diarrhea with or without bleeding, abdominal pain, and anemia. NSAIDs cause strictures or colitis characterized by erosions or ulcers that tend to be most severe in the right colon.

Treatment of Active Disease

Crohn's disease is a chronic lifelong illness characterized by exacerbations and periods of remission. As no specific therapy exists, current treatment is directed toward symptomatic improvement and controlling the disease process. The treatment must address the specific problems of the individual patient.

A. Nutrition

1. Diet—Patients should eat a well-balanced diet with as few restrictions as possible. There is no convincing evidence of specific food allergy in disease pathogenesis. Because lactose intolerance is common, a trial off dairy products is warranted if flatulence or diarrhea is a prominent complaint. Patients with mainly colonic involvement benefit from fiber supplementation. Conversely, patients with obstructive symptoms should be placed on a low-roughage diet, ie, no raw fruits or vegetables, popcorn, nuts, etc. Resection of more than 100 cm of terminal ileum results in fat malabsorption. A low-fat diet with medium-chain triglyceride supplementation is used. Iron supplements may be necessary in patients with chronic intestinal blood loss. Parenteral vitamin B₁₂ (100 ug intramuscularly per month) commonly is needed for patients with previous ileal resection or extensive terminal ileal disease.

2. Enteral therapy—Enteral therapy for 4 weeks is less effective than corticosteroids in inducing remission, and the relapse rate after return to a normal diet is high. Nevertheless, it may be considered in patients (especially children) who are refractory in an attempt to avoid chronic corticosteroids.

3. Total parenteral nutrition—TPN is used short term in patients with active disease and progressive weight loss or those awaiting surgery who have malnutrition but cannot tolerate enteral feedings because of high-grade obstruction, high-output fistulas, severe diarrhea, or abdominal pain. It is required long term in a small subset of

patients with extensive intestinal resections resulting in short bowel syndrome with malnutrition.

B. Symptomatic Medications

1. Symptomatic treatment of diarrhea—There are several potential mechanisms by which diarrhea may occur in Crohn's disease in addition to active Crohn's disease. A rational empirical treatment approach often yields therapeutic improvement that may obviate the need for corticosteroids or immunosuppressive agents. Involvement of the terminal ileum with Crohn's disease or prior ileal resection may lead to reduced absorption of bile acids that may induce secretory diarrhea from the colon. This diarrhea commonly responds to cholestyramine 2-4 g or colestipol 5 g two or three times daily before meals to bind the malabsorbed bile salts. Patients with extensive ileal disease or more than 100 cm of ileal resection have such severe bile salt malabsorption that steatorrhea may arise. Such patients may benefit from a low-fat diet; bile salt binding agents will exacerbate the diarrhea and should not be given. Patients with Crohn's disease are at risk for the development of small intestinal bacterial overgrowth due to enteral fistulas, ileal resection, and impaired motility and may benefit from a course of broad-spectrum antibiotics (see Bacterial Overgrowth, above). Other causes of diarrhea include lactase deficiency and short bowel syndrome (described in other sections). Use of antidiarrheals may provide benefit in some patients. Loperamide (2-4 mg), diphenoxylate with atropine (one tablet), or tincture of opium (5-15 drops) may be given as needed up to four times daily. Because of the risk of toxic megacolon, these drugs should not be used in patients with active severe colitis.

C. Specific Drug Therapy

1. 5-Aminosalicylic acid agents—Aminosalicylates still are used for the treatment of mild to moderately active ileocolonic and colonic Crohn's disease; however, their use is declining as a result of the advent of more effective therapies. Remission rates of over 40% are reported in patients with mild to moderate small bowel and ileocecal disease compared with 20-30% in patients treated with placebo.

2. Antibiotics—For patients with mild disease who do not respond to aminosalicylates, antibiotic therapy with metronidazole (10 mg/kg/d) or ciprofloxacin (500 mg twice daily) appears to be as effective as aminosalicylates in controlled trials. Ciprofloxacin may be better for ileitis and metronidazole for ileocolitis or colitis.

3. Corticosteroids—Corticosteroids dramatically suppress the acute clinical symptoms or signs in most patients with both small and large bowel disease. However, steroids do not appear to alter the underlying disease. Prednisone, 40-60 mg/d, is generally administered to patients with an active flare-up of Crohn's disease. After improvement at 2-3 weeks, tapering proceeds at 5 mg/wk until a dosage of 20 mg/d is being given. Thereafter, slow tapering by 2.5 mg/wk is recommended. Some patients cannot be completely withdrawn from steroids without experiencing a symptomatic flare-up. Use of chronic low corticosteroid doses (2.5-10 mg/d) should be avoided, if possible, because of associated complications including aseptic necrosis of the hips, osteoporosis, cataracts, diabetes, and hypertension. Patients requiring chronic corticosteroid treatment should be given 5-ASA derivatives or immunomodulatory drugs (as described below) in an effort to wean them from corticosteroids. Calcium and vitamin D supplementation should be administered to all patients receiving chronic corticosteroid therapy. Bone densitometry and urinary calcium or N-telopeptide should be monitored. Alendronate should be considered to prevent osteoporosis in patients requiring chronic corticosteroids. An ileal-release preparation of the oral topically active compound budesonide, 9 mg once daily for 8 weeks, induces remission in 50-70% of patients with mild to moderate Crohn's disease involving the terminal ileum or ascending colon. It is superior to that of mesalamine and comparable to that of prednisone, with fewer acute steroid-related adverse effects and less suppression of the pituitary-adrenal axis; however, bone density loss associated with chronic use is similar to that reported with other steroids. Its role relative to other steroids for treatment of acute disease is unclear at present.

Patients with persisting symptoms despite oral steroids or those with high fever, persistent vomiting, evidence of intestinal obstruction, severe weight loss, severe abdominal tenderness, or suspicion of an abscess should be hospitalized. In patients with a tender, palpable inflammatory abdominal mass, CT scan of the abdomen should be obtained prior to administering steroids in order to rule out an abscess. If no abscess is identified, parenteral steroids should be administered (as described for ulcerative colitis). Nutritional support with enteral elemental feedings or parenteral nutrition is indicated for patients unable to tolerate an oral diet after 5 days.

4. Immunomodulatory drugs—Azathioprine (2-2.5 mg/kg) and mercaptopurine (1-1.5 mg/kg) are effective in the long-term treatment of Crohn's disease. They are most useful in the management of patients with unresponsive disease, those requiring repeat courses or chronic corticosteroids, and those with symptomatic fistulas. These agents permit elimination or reduction of steroids in over 75% and fistula closure in 30%. Blood counts should be monitored weekly for the first month, then monthly. Drug dosages should be monitored to maintain a white blood cell count > 3000/uL and platelet count > 120,000/uL. Side effects requiring withdrawal of the drug occur in about 10%. The mean time to symptomatic response is 4 months, so these agents are not useful for acute exacerbations. Once patients achieve remission, these drugs reduce the 3-year relapse rate from over 60% to less than 25%. Methotrexate (25 mg intramuscularly weekly for 12 weeks, followed by 12.5-15 mg intramuscularly once weekly) probably is less efficacious but is used in patients who are unresponsive to or intolerant of mercaptopurine or azathioprine. Other immunosuppressive agents have been investigated in the treatment of Crohn's disease, including cyclosporine and thalidomide; however, efficacy has been modest and toxicity greater than with the thiopurines.

A chimeric IgG anti-TNF antibody, infliximab, is used for the treatment of patients with active moderate to severe Crohn's disease with an inadequate response to corticosteroids or other immunomodulators (azathioprine or mercaptopurine), symptomatic flares when steroids are tapered, severe illness requiring hospitalization, or fistulizing disease. It is also used instead of corticosteroids to promote rapid initial improvement while other immunosuppressives (azathioprine, mercaptopurine) that take weeks to months to achieve therapeutic effect are being initiated. A three-dose induction regimen of 5 mg/kg administered at 0, 2, and 6 weeks is recommended. Improvement occurs in two-thirds of patients and remission in one-third. Maximal response is seen within 2 weeks in most patients and gradually diminishes over 3 months. Antinuclear antibodies and human antichimeric antibodies may develop, leading to a risk of infusion-related reactions, hypersensitivity reactions, reduced drug efficacy, and, rarely, a lupus-like syndrome. Concomitant therapy with other immunosuppressives reduces the development of these antibodies. Re-treatment with infliximab every 8 weeks is required in some patients. Serious infections may occur in patients taking infliximab, including pneumonia, sinusitis, sepsis, disseminated tuberculosis, invasive fungal infections, listeriosis, pneumocystosis, and other opportunistic infections. All patients should be evaluated with a tuberculin skin test prior to initiation of infliximab therapy.

Maintenance of Remission

Crohn's disease is characterized by exacerbations and remissions. Aminosalicylates have modest benefit in maintaining disease remission, lowering recurrence rates by approximately 6%. The benefit appears to be greatest in patients with ileal disease or recent surgical resection of active disease. Corticosteroids (including budesonide) should not be used in patients with inactive disease to maintain remission. The purine analogs (azathioprine, mercaptopurine) and methotrexate are beneficial and should be given to maintain remission in patients with frequent recurrences and in those who require chronic corticosteroid therapy. Maintenance therapy with infliximab (5 mg/kg every 8 weeks) should be considered for patients who fail maintenance therapy with other immunosuppressives.

Indications for Surgery

Over half of patients will require at least one surgical procedure. The main indications for surgery are intractability to medical therapy, intra-abdominal abscess, massive bleeding, and obstruction with fibrous stricture. Patients with active inflammation who are unresponsive to medical therapy or who require chronic prednisone in doses exceeding 15 mg/d may achieve dramatic relief from limited excision for 5-15 years before disease recurs.

Prognosis

With proper medical and surgical treatment, the majority of patients are able to cope with this chronic disease and its complications and lead productive lives. Few patients die as a direct consequence of the disease.

2. Ulcerative Colitis

Essentials of Diagnosis

- Bloody diarrhea.
- Lower abdominal cramps and fecal urgency.

- Anemia, low serum albumin.
- Negative stool cultures.
- Sigmoidoscopy is the key to diagnosis.

General Considerations

Ulcerative colitis is an idiopathic inflammatory condition that involves the mucosal surface of the colon, resulting in diffuse friability and erosions with bleeding. Approximately 50% of patients have disease confined to the rectosigmoid region (proctosigmoiditis); 30% extend to the splenic flexure (left-sided colitis); and less than 20% extend more proximally (extensive colitis). There is some correlation between disease extent and symptom severity. In the majority of patients, the extent of colonic involvement does not progress over time. In most patients, the disease is characterized by periods of symptomatic flare-ups and remissions. Ulcerative colitis is more common in nonsmokers and former smokers. Disease severity may be lower in active smokers and may worsen in patients who stop smoking. Appendectomy before the age of 20 for acute appendicitis is associated with a reduced risk of developing ulcerative colitis.

Clinical Findings

A. Symptoms and Signs

The clinical profile in ulcerative colitis is highly variable. Bloody diarrhea is the hallmark. On the basis of several clinical and laboratory parameters, it is clinically useful to classify patients as having mild, moderate, or severe disease ([Table 14-14](#)). Patients should be asked about stool frequency, the presence and amount of rectal bleeding, cramps, abdominal pain, fecal urgency, and tenesmus. Physical examination should focus upon the patient's volume status as determined by orthostatic blood pressure and pulse measurements and by nutritional status. On abdominal examination, the clinician should look for tenderness and evidence of peritoneal inflammation. Red blood may be present on digital rectal examination.

1. Mild to moderate disease—Patients with mild disease have a gradual onset of infrequent diarrhea (less than five movements per day) with intermittent rectal bleeding and mucus. Stools may be formed too loose in consistency. Because of rectal inflammation, there is fecal urgency and tenesmus. Left lower quadrant cramps relieved by defecation are common, but there is no significant abdominal tenderness. Patients with moderate disease have more severe diarrhea with frequent bleeding. Abdominal pain and tenderness may be present but are not severe. There may be mild fever, anemia, and hypoalbuminemia.

2. Severe disease—Patients with severe disease have more than six to ten bloody bowel movements per day, resulting in severe anemia, hypovolemia, and impaired nutrition with hypoalbuminemia. Abdominal pain and tenderness are present. "Fulminant colitis" is a subset of severe disease characterized by rapidly worsening symptoms with signs of toxicity.

3. Extracolonic manifestations—Ulcerative colitis is associated with extraintestinal manifestations in 25% of cases. Some extracolonic signs are associated with disease activity. These include erythema nodosum, pyoderma gangrenosum, episcleritis, thromboembolic events, and an oligoarticular, nondeforming arthritis. In patients who are HLA B27-seropositive, there may be anterior uveitis or ankylosing spondylitis which is independent of colitis activity. Sclerosing cholangitis can occur in colitis patients even after total colectomy. Patients with this entity are at higher risk of developing cholangiocarcinoma.

B. Laboratory Findings

The degree of abnormality of the hematocrit, sedimentation rate, and serum albumin reflect disease severity.

C. Endoscopy

In acute colitis, the diagnosis is readily established by sigmoidoscopy. The mucosal appearance is characterized by edema, friability, mucopus, and erosions. Colonoscopy should not be performed in patients with severe disease because of the risk of perforation. After patients have demonstrated improvement on therapy, colonoscopy is sometimes performed to determine the extent of disease, which will dictate the need for subsequent cancer surveillance.

D. Imaging

Plain abdominal radiographs are obtained in patients with severe colitis to look for significant colonic dilation. Barium enemas are of little utility in the evaluation of acute ulcerative colitis and may precipitate toxic megacolon in patients with severe disease.

Differential Diagnosis

The initial presentation of ulcerative colitis is indistinguishable from other causes of colitis, clinically as well as endoscopically. Thus, the diagnosis of idiopathic ulcerative colitis is reached after excluding other known causes of colitis. Infectious colitis should be excluded by sending stool specimens for routine bacterial cultures (to exclude salmonella, shigella, and campylobacter), ova and parasites (to exclude amebiasis), and stool toxin assay for *C difficile*. Mucosal biopsy can distinguish amebic colitis from ulcerative colitis. Enteroinvasive *E coli* and *E coli* O157:H7 will not be detected on routine bacterial cultures. CMV colitis occurs in immunocompromised patients (especially those with AIDS) and is diagnosed on mucosal biopsy. Gonorrhea, chlamydial infection, herpes, and syphilis are considerations in sexually active patients with proctitis. In elderly patients with cardiovascular disease, ischemic colitis may involve the rectosigmoid. A history of radiation to the pelvic region can result in proctitis months to years later. Crohn's disease involving the colon but not the small intestine may be confused with ulcerative colitis. In 10% of patients, a distinction between Crohn's disease and ulcerative colitis may not be possible. The utility of ANCA and ASCA antibodies in these difficult patients is discussed in the section on Crohn's disease.

Treatment ([Table 14-15](#))

There are two main treatment objectives: (1) to terminate the acute, symptomatic attack and (2) to prevent recurrence of attacks. The treatment of acute ulcerative colitis is dependent upon the extent of colonic involvement and the severity of illness.

Patients with mild to moderate disease should eat a regular diet but limit their intake of caffeine and gas-producing vegetables. Fiber supplements decrease diarrhea and rectal symptoms (psyllium, 3.4 g twice daily; methylcellulose, 2 g twice daily; bran powder, 1 tbsp twice daily). Antidiarrheal agents should not be given in the acute phase of illness but are safe and helpful in patients with mild chronic symptoms. Loperamide (2 mg), diphenoxylate with atropine (one tablet), or tincture of opium (8-15 drops) may be given up to four times daily. Such remedies are particularly useful at nighttime and when taken prophylactically for occasions when patients may not have reliable access to toilet facilities.

A. Distal Colitis

Patients with disease confined to the rectum or rectosigmoid region generally have mild but distressing symptoms. Acute therapy is best approached with topical agents. Topical mesalamine is the drug of choice and is superior to topical corticosteroids. Mesalamine is administered as a suppository, 500 mg twice daily for proctitis, and as an enema, 4 g at bedtime for proctosigmoiditis, for 3-12 weeks, with 75% of patients improving. Topical steroids are a less expensive alternative to mesalamine but are also less effective. Hydrocortisone suppository or foam is prescribed for proctitis and hydrocortisone enema (80-100 mg) for proctosigmoiditis. Systemic effects from short-term use are very slight. It is not known whether combination therapy with mesalamine and hydrocortisone is advantageous. Patients with distal disease who fail to improve with topical therapy should be considered for systemic steroids or immunosuppressives as described below.

Patients whose acute symptoms resolve with acute therapy have an 80-90% chance of a symptomatic relapse within 1 year. Maintenance therapy with mesalamine suppositories (500 mg daily) or with oral agents (see below) reduces the relapse rate to less than 20% per year.

B. Mild to Moderate Colitis

Disease extending above the sigmoid colon is best treated with oral agents. The currently available agents, derivatives of 5-aminosalicylic acid (sulfasalazine, mesalamine, balsalazide), result in symptomatic improvement in 50-75% of patients. Balsalazide, 2.25 g three times daily, appears to be as effective as or more effective than other 5-ASA agents and soon may become the drug of first choice for treatment of mild to moderate ulcerative colitis. Mesalamine, 800 mg three times daily (Asacol) or 1 g four times daily (Pentasa), is also approved for active disease. Higher doses (4-6 g daily) may be required in some patients. Because it is significantly less expensive than balsalazide or mesalamine, sulfasalazine is still commonly used as a first-line agent by many providers. To minimize side effects, sulfasalazine is begun at a dosage of 500 mg twice daily and increased gradually over 1-2 weeks to 2 g twice daily. Most patients improve within 3 weeks, though some require 2-3 months. Total doses of 5-6 g/d may have greater efficacy but are poorly tolerated. Folic acid, 1 mg/d, should be administered to all patients taking sulfasalazine. Balsalazide or mesalamine should be used in patients intolerant of sulfasalazine. It has been suggested that a nicotine patch (22 mg) is effective in symptom improvement in patients with mild to moderate ulcerative colitis, but this is not yet recommended for routine clinical use.

Patients with mild to moderate disease who fail to improve after 2-3 weeks of 5-ASA therapy should have the addition of corticosteroid therapy. Topical therapy with hydrocortisone foam or enemas (80-100 mg twice daily) may be tried first. Patients who fail to improve after 2 more weeks require systemic steroid therapy. Prednisone and methylprednisolone are most commonly used. Depending on the severity of illness, the initial oral dose of prednisone is 20-30 mg twice daily. Rapid improvement is observed in most cases. One can usually begin to taper prednisone after 2 weeks. Tapering of prednisone should proceed by no more than 5 mg/wk. After tapering to 15 mg/d, slower tapering is sometimes required. Complete tapering without symptomatic flare-ups is possible in the majority of patients.

C. Severe Colitis

About 10-15% of ulcerative colitis patients have a more severe course. Because they may deteriorate rapidly, hospitalization is generally required.

1. General measures—Discontinue all oral intake. Total parenteral nutrition is indicated in patients with poor nutritional status. Instruct the patient to avoid all opioid or anticholinergic agents. Restore circulating volume with fluids and blood as needed, and correct electrolyte abnormalities. Abdominal examinations should be repeated to look for evidence of worsening distention or pain. A plain abdominal radiograph should be ordered on admission to look for evidence of colonic dilation. Send stools for bacterial (including *C difficile*) culture and examination for ova and parasites. Surgical consultation should be sought for all patients with severe disease.

2. Corticosteroid therapy—Methylprednisolone, 48-64 mg, or hydrocortisone, 300 mg, is administered in four divided doses or by continuous infusion over 24 hours. Higher or "pulse" doses are of no benefit. Hydrocortisone enemas may also be administered twice daily as a drip, 100 mg over 30 minutes. In patients who have not previously received corticosteroids, administration of ACTH, 120 units/24 h, may be superior to corticosteroids. Approximately 50-75% of patients achieve remission with systemic steroids within 7-10 days. Once symptomatic improvement has occurred, oral fluids are reinstituted. If fluids are well tolerated, intravenous steroids are discontinued and the patient is started on oral prednisone (as described for moderate disease).

3. Cyclosporine—Intravenous cyclosporine (4 mg/ kg/d) benefits 60-75% of patients with severe colitis who have not improved after 7-10 days of corticosteroids. This therapy may be considered in patients with severe steroid-resistant colitis who are reluctant to undergo colectomy. Up to two-thirds of responders may be maintained in remission with a combination of oral cyclosporine for 3 months and long-term therapy with mercaptopurine or azathioprine.

4. Surgical therapy—Patients with severe disease who fail to improve after 7-10 days of corticosteroid or cyclosporine therapy are unlikely to respond to further medical therapy, and surgery is recommended.

D. Fulminant Colitis and Toxic Megacolon

A subset of patients with severe disease have a more fulminant course with rapid progression of symptoms over 1-2 weeks and signs of severe toxicity. These patients appear quite ill, with prominent hypovolemia, hemorrhage requiring transfusion, and abdominal distention with tenderness. They are at a higher risk of perforation or development of toxic megacolon and must be followed closely. Broad-spectrum antibiotics should be administered to cover anaerobes and gram-negative bacteria.

Toxic megacolon develops in less than 2% of cases of ulcerative colitis. It is characterized by colonic dilation of more than 6 cm on plain films with signs of toxicity. In addition to the therapies outlined above, nasogastric suction should be initiated. Patients should be instructed to roll from side to side and onto the abdomen in an effort to decompress the distended colon. Serial abdominal plain films should be obtained to look for worsening dilation or ischemia. Patients with fulminant disease or toxic megacolon who worsen or fail to improve within 48-72 hours should undergo surgery to prevent perforation. If operation is performed before perforation, the mortality rate should be low.

Maintenance of Remission

Without chronic therapy, 75% of patients who initially go into remission on medical therapy will experience a symptomatic relapse within 1 year. Chronic maintenance therapy with sulfasalazine, 1-1.5 g twice daily, olsalazine, 500 mg twice daily, and mesalamine, 800 mg three times daily or 500 mg four times daily has been shown to reduce relapse rates to less than 33%.

Refractory Disease

A subset of patients either do not respond to aminosalicylates or corticosteroids or have symptomatic flares during attempts at steroid tapering. Surgical resection is traditionally recommended for patients with refractory disease. However, some patients may wish to avoid surgery and others have moderately severe disease for which surgery might not otherwise be warranted. Limited trials suggest that immunosuppressive therapy with mercaptopurine or azathioprine is of benefit in 60% of patients, allowing tapering of steroids and maintenance of remission. The risks of these agents and chronic immunosuppression must be weighed against the certainty of cure with surgical resection. A single intravenous infusion of infliximab (5 mg/kg) has resulted anecdotally in rapid and sustained clinical and endoscopic improvement in 50-100% of patients with refractory ulcerative colitis.

Risk of Colon Cancer

In ulcerative colitis patients with disease proximal to the sigmoid colon, there is a markedly increased risk of developing colon carcinoma. In patients who have had colitis for more than 10 years, the risk of developing colon cancer increases approximately 0.5-1% per year. Ingestion of folic acid, 1 mg/d, is associated with a decreased risk of cancer development. Colonoscopies are recommended every 1-2 years in patients with extensive colitis, beginning 8-10 years after diagnosis. At colonoscopy, multiple (at least 32) random mucosal biopsies are taken throughout the colon at 10-cm intervals as well as biopsies of mass lesions to look for dysplasia or carcinoma. Because of the relatively high incidence of concomitant carcinoma in patients with dysplasia (either low- or high-grade) in flat mucosa or mass lesions, colectomy is recommended. When low-grade dysplasia is detected only in flat mucosa, some authorities recommend a repeat colonoscopy in 3-6 months to confirm the presence of dysplasia before proceeding with colectomy.

Surgery in Ulcerative Colitis

Surgery is required in 25% of patients. Severe hemorrhage, perforation, and documented carcinoma are absolute indications for surgery. Surgery is indicated also in patients with fulminant colitis or toxic megacolon that does not improve within 48-72 hours, in patients with dysplasia on surveillance colonoscopy, and in patients with refractory disease requiring chronic steroids to control symptoms.

Although total proctocolectomy (with placement of an ileostomy) provides complete cure of the disease, most patients seek to avoid it out of concern for the impact it may have upon their bowel function, their self-image, and their social interactions. After complete colectomy, patients may have a standard ileostomy with an external appliance, a continent ileostomy, or an internal ileal pouch which is anastomosed to the anal canal (ileoanal anastomosis). The latter maintains intestinal continuity, thereby obviating an ostomy. Under optimal circumstances, patients have five to seven loose bowel movements per day without incontinence. Endoscopic or histologic inflammation in the ileal pouch ("pouchitis") develops in over one-fourth of patients, resulting in increased stool frequency, fecal urgency, cramping, and bleeding, but usually resolves with a 2-week course of metronidazole (20 mg/kg/d) or ciprofloxacin (1000 mg/d). Oral therapy with nonpathogenic bacteria ("probiotics") is effective in maintaining remission in patients with recurrent pouchitis. Refractory cases of proctitis can be disabling and may require conversion to a standard ileostomy.

Prognosis

Ulcerative colitis is a lifelong disease characterized by exacerbations and remissions. For most patients, the disease is readily controlled by medical therapy without need for surgery. The majority never require hospitalization. A subset of patients with more severe disease will require surgery, which results in complete cure of the disease. Properly managed, most ulcerative colitis patients lead close to normal productive lives.

3. Microscopic Colitis

Microscopic colitis is an idiopathic condition in which patients have chronic watery diarrhea with normal-appearing mucosa at endoscopy. Histologic evaluation of mucosal biopsies, however, reveals lymphocytic inflammation in the lamina propria. It occurs much more commonly in women, especially in the fifth to sixth decades. Symptoms tend to be chronic or recurrent but may remit spontaneously after many years. Chronic NSAID therapy has been implicated as a causative factor in up to

half of cases. Microscopic colitis occurs in up to one-third of patients with celiac sprue and should be considered in patients with continued diarrhea after institution of a gluten-free diet. There appear to be two subtypes—lymphocytic colitis and collagenous colitis—the latter distinguished by the presence of a thickened band of collagen below the epithelium. Mild disease may be treated with bulking agents or antidiarrheal agents (loperamide, cholestyramine). NSAIDs should be discontinued. Treatment with 5-aminosalicylates (sulfasalazine, mesalamine) is of unproved benefit. Bismuth subsalicylate (two tablets four times daily) for 2 months is effective in many patients. Patients refractory to aminosalicylates or bismuth may be treated with corticosteroids or immunosuppressives. The natural history of microscopic colitis is variable, with spontaneous remission occurring in up to half of patients within 5 years after diagnosis.

DIVERTICULAR DISEASE OF THE COLON

Colonic diverticulosis increases with age, ranging from 5% in those under age 40, to 30% at age 60, to more than 50% over age 80 in Western societies. In contrast, it is very uncommon in developing countries with much lower life expectancies. Most are asymptomatic, discovered incidentally at endoscopy or on barium enema. Complications in one-third include lower gastrointestinal bleeding and diverticulitis.

Colonic diverticula may vary in size from a few millimeters to several centimeters and in number from one to several dozen. Almost all patients with diverticulosis have involvement in the sigmoid colon; however, only 15% have proximal colonic disease.

In most patients, diverticulosis is believed to arise after many years of a diet deficient in fiber. The undistended, contracted segments of colon have higher intraluminal pressures. Over time, the contracted colonic musculature, working against greater pressures to move small, hard stools, develops hypertrophy, thickening, rigidity, and fibrosis. Diverticula may develop more commonly in the sigmoid because intraluminal pressures are highest in this region. The extent to which abnormal motility and hereditary factors contribute to diverticular disease is unknown. Patients with diffuse diverticulosis may have an inherent weakness in the colonic wall. Patients with abnormal connective tissue are also disposed to development of diverticulosis, including Ehlers-Danlos syndrome, Marfan's syndrome, and scleroderma.

1. Uncomplicated Diverticulosis

More than two-thirds of patients with diverticulosis have uncomplicated disease and no specific symptoms. In some, diverticulosis may be an incidental finding detected during colonoscopic examination or barium enema examination. Some patients have nonspecific complaints of chronic constipation, abdominal pain, or fluctuating bowel habits. It is unclear whether these symptoms are due to alterations in the colonic musculature or underlying irritable bowel syndrome. Physical examination is usually normal but may reveal mild left lower quadrant tenderness with a thickened, palpable sigmoid and descending colon. Screening laboratory studies should be normal in uncomplicated diverticulosis.

There is no reason to perform imaging studies for the purpose of diagnosing uncomplicated disease. Diverticula are best seen on barium enema. Involved segments of colon may also be narrowed and deformed. Colonoscopy is a less sensitive means of detecting diverticula.

Asymptomatic patients in whom diverticulosis is discovered and patients with a history of complicated disease (see below) should be treated with a high-fiber diet or fiber supplements (bran powder, 1-2 tbsp twice daily; psyllium or methylcellulose) (see section on constipation). Retrospective studies suggest that such treatment may decrease the likelihood of subsequent complications.

2. Diverticulitis

Essentials of Diagnosis

- Acute abdominal pain and fever.
- Left lower abdominal tenderness and mass.
- Leukocytosis.

Clinical Findings

A. Symptoms and Signs

Perforation of a colonic diverticulum results in an intra-abdominal infection that may vary from microperforation (most common) with localized paracolic inflammation to macroperforation with either abscess or generalized peritonitis. Thus, there is a range from mild to severe disease. Most patients with localized inflammation or infection report mild to moderate aching abdominal pain, usually in the left lower quadrant. Constipation or loose stools may be present. Nausea and vomiting are frequent. In many cases, symptoms are so mild that the patient may not seek medical attention until several days after onset. Physical findings include a low-grade fever, left lower quadrant tenderness, and a palpable mass. Stool occult blood is common, but hematochezia is rare. Leukocytosis is mild to moderate. Patients with free perforation present with a more dramatic picture of generalized abdominal pain and peritoneal signs.

B. Imaging

Plain abdominal films are obtained in all patients to look for evidence of free abdominal air (signifying free perforation), ileus, and small or large bowel obstruction. In patients with mild symptoms and a presumptive diagnosis of diverticulitis, empirical medical therapy is started without further imaging in the acute phase. Patients who respond to acute medical management should undergo complete colonic evaluation with colonoscopy or barium enema after resolution of clinical symptoms to corroborate the diagnosis or exclude other disorders such as colonic neoplasms. In patients who do not improve rapidly after 2-4 days of empirical therapy and in those with severe disease, CT scan of the abdomen is obtained to look for evidence of diverticulitis, including colonic diverticula and wall thickening, pericolic fat infiltration, abscess formation, or extraluminal air or contrast. Endoscopy and barium enema are contraindicated during the initial stages of an acute attack because of the risk of free perforation, though sigmoidoscopy with minimal air insufflation is sometimes required to exclude other diagnoses.

Differential Diagnosis

Localized diverticulitis must be distinguished from perforated colonic carcinoma, Crohn's disease, appendicitis, ischemic colitis, *C difficile*-associated colitis, and gynecologic disorders (ectopic pregnancy, ovarian cyst or torsion).

Complications

Fistula formation may involve the bladder, ureter, vagina, uterus, bowel, and abdominal wall. Diverticulitis may result in stricturing of the colon with partial or complete obstruction.

Treatment

A. Medical Management

Most patients can be managed with conservative measures. Patients with mild symptoms and no peritoneal signs may be managed initially as outpatients on a clear liquid diet and broad-spectrum oral antibiotics with anaerobic activity. Reasonable regimens include amoxicillin and clavulanate potassium (875 mg/125 mg) twice daily, or metronidazole, 500 mg three times daily, plus either ciprofloxacin, 500 mg twice daily, or trimethoprim-sulfamethoxazole, 160/800 mg twice daily orally, for 7-10 days or until the patient is afebrile for 3-5 days. Symptomatic improvement usually occurs within 3 days, at which time the diet may be advanced. Patients with increasing pain, fever, or inability to tolerate oral fluids require hospitalization. Patients with severe diverticulitis (high fevers, leukocytosis, or peritoneal signs) and patients who are elderly or immunosuppressed or who have serious comorbid disease require hospitalization acutely. Patients should be given nothing by mouth and should receive intravenous fluids. If ileus is present, a nasogastric tube should be placed. Intravenous antibiotics should be given to cover anaerobic and gram-negative bacteria. Single-agent therapy with either a second-generation cephalosporin (eg, cefoxitin), piperacillin-tazobactam, or ticarcillin clavulanate appears to be as effective as combination therapy (eg, metronidazole or clindamycin plus an aminoglycoside or third-generation cephalosporin [eg, ceftazidime, cefotaxime]). Symptomatic improvement should be evident within 2-3 days. The antibiotics should be continued for 7-10 days, after which time elective evaluation with colonoscopy or barium enema should be performed.

B. Surgical Management

Approximately 20-30% of patients with diverticulitis will require surgical management. Surgical consultation should be obtained on all patients with severe disease or those who fail to improve after 72 hours of medical management. Indications for emergent surgical management include free peritonitis and large abscesses. Patients

with fistulas or colonic obstruction due to chronic disease will require elective surgery.

Patients with a localized abdominal abscess can be treated acutely with a percutaneous catheter drain placed by an interventional radiologist. This permits control of the infection and resolution of the immediate infectious inflammatory process. In this manner, a subsequent single-stage elective surgical operation can be performed in which the diseased segment of colon is removed and primary colonic anastomosis performed. In patients in whom catheter drainage is not possible or helpful or in cases requiring emergency surgery, it is necessary to perform surgery in two stages. In the first stage, the diseased colon is resected and the proximal colon brought out to form a temporary colostomy. The distal colonic stump is either closed (forming a Hartmann pouch) or exteriorized as a mucous fistula. Weeks later, after inflammation and infection have completely subsided, the colon can be reconnected electively.

Prognosis

Diverticulitis recurs in one-third of patients treated with medical management. Recurrent attacks warrant elective surgical resection, which carries a lower morbidity and mortality risk than emergency surgery.

Stollman NH et al: Diagnosis and management of diverticular disease of the colon in adults. Am J Gastroenterol 1999;94: 1310. [\[PMID: 10566700\]](#)

3. Diverticular Bleeding

Half of cases of acute lower gastrointestinal bleeding are attributable to diverticulosis. For a full discussion, see the section on Acute Lower Gastrointestinal Bleeding.

POLYPS OF THE COLON & SMALL INTESTINE

Polyps are discrete mass lesions that protrude into the intestinal lumen. Although most commonly sporadic, they may be inherited as part of familial polyposis syndrome. Polyps may be divided into three major pathologic groups: mucosal neoplastic (adenomatous) polyps, mucosal nonneoplastic polyps (hyperplastic, juvenile polyps, hamartomas, inflammatory polyps), and submucosal lesions (lipomas, lymphoid aggregates, carcinoids, pneumatosis cystoides intestinalis). The nonneoplastic mucosal polyps have no malignant potential and usually are discovered incidentally at colonoscopy or barium enema. Only the adenomatous polyps have significant clinical implications and will be considered further here. Of polyps removed at colonoscopy, over 70% are adenomatous; most of the remainder are hyperplastic. Hyperplastic polyps are generally small (< 5 mm) and of no consequence. Their only importance is that they cannot be reliably distinguished from adenomatous lesions except by biopsy.

NONFAMILIAL ADENOMATOUS POLYPS

Histologically, adenomas are classified as tubular, villous, or tubulovillous. They may be sessile or pedunculated (containing a stalk). They are present in 35% of adults over 50 years of age. Their significance is that over 95% of cases of adenocarcinoma of the colon are believed to arise from adenomas. It is proposed that there is an adenoma ? carcinoma sequence whereby colorectal cancer develops through a continuous process from normal mucosa to adenoma to carcinoma. Most adenomas are small (< 1 cm) and have a low risk of becoming malignant; fewer than 4% of these enlarge with time. Fifteen percent of adenomas are = 1 cm or contain villous features and have a much higher risk (> 10%) of harboring malignancy or high-grade dysplasia. It has been estimated from longitudinal studies that it takes an average of 5 years for a medium-sized polyp to develop from normal-appearing mucosa and 10 years for a gross cancer to arise. In an asymptomatic population of male veterans over age 50 undergoing screening with colonoscopy, invasive cancer was detected in 1%, adenomas containing high-grade dysplasia in 1.7%, and other adenomas = 1 cm in size in 7.2%.

Clinical Findings

A. Symptoms and Signs

Most patients with adenomatous polyps are completely asymptomatic. Chronic occult blood loss may lead to iron deficiency anemia. Large polyps may ulcerate, resulting in intermittent hematochezia.

B. Fecal Occult Blood Testing

Fecal occult blood tests are commonly performed as part of colorectal cancer screening programs. Unfortunately, these tests detect less than 40% of adenomas larger than 1 cm. Of patients with positive tests, approximately one-third have adenomas—only slightly higher than the expected prevalence in the adult population. (See section on colorectal cancer screening, below.) Thus, these tests are insensitive and nonspecific for adenomas.

C. Special Tests

Polyps are identified by means of barium enema examinations, flexible sigmoidoscopy, or colonoscopy. Barium enema examinations (either single- or double-contrast) as currently performed have unacceptable sensitivity and specificity for the detection of colorectal polyps. A recent comparative study with colonoscopy demonstrated that barium enemas failed to detect approximately half of polyps over 1 cm in size. Spiral CT colonography with computer-enabled luminal image reconstruction ("virtual colonoscopy") detects over 80-90% of clinically significant neoplasms. The clinical role of CT colonography is being defined in ongoing studies. At this time, barium enema and CT colonography may be best suited for patients with significant cardiac or pulmonary comorbidities—for whom colonoscopy is deemed unsafe—or in clinical settings in which endoscopic expertise is not readily available.

Flexible sigmoidoscopy is commonly performed as part of colorectal screening programs. Approximately one-half to two-thirds of colonic adenomas are within the reach of a flexible sigmoidoscope. Polyps are seen in 10-20% of patients undergoing screening sigmoidoscopy, and polyps less than 8 mm in size should be removed by excisional biopsy. Patients with hyperplastic polyps require no further evaluation. Patients with advanced neoplasms (as defined above) have an increased risk of harboring other advanced neoplasms in the proximal colon and should undergo colonoscopy. At present, the management of patients with small adenomas without villous features or high-grade dysplasia is controversial. Opinions are conflicting about whether such lesions found on sigmoidoscopy are predictive of finding an increased prevalence of advanced neoplasms (> 1 cm or containing villous features or high-grade dysplasia) in the colon proximal to the splenic flexure during colonoscopy. Some physicians have not routinely performed colonoscopy in patients found to have a single small (< 5-8 mm) polyp in the distal colon on screening sigmoidoscopy. However, most gastroenterologists routinely recommend colonoscopy for all patients with adenomas found in the distal colon at sigmoidoscopy irrespective of size. In patients with no adenomas detected in the distal colon, the prevalence of advanced proximal adenomas is 2.7%; among patients with a distal adenoma less than 10 mm in size, the prevalence of advanced proximal neoplasia was 6.8%.

Colonoscopy allows evaluation of the entire colon and is the best means of detecting and removing adenomatous polyps. It should be performed in all patients who have positive fecal occult blood tests or iron deficiency anemia (see Occult Gastrointestinal Bleeding, above), as the prevalence of colonic neoplasms is increased in these patients. Colonoscopy should also be performed in patients with polyps detected on radiologic imaging studies or adenomas detected on flexible sigmoidoscopy in order to remove these polyps and to fully evaluate the entire colon.

Treatment

A. Colonoscopic Polypectomy

Most adenomatous polyps are amenable to colonoscopic removal with biopsy forceps or snare cautery. Large sessile polyps (> 2-3 cm) may be removed in piecemeal fashion or may require primary surgical resection. Complications after colonoscopic polypectomy include perforation in 0.2% and clinically significant bleeding in 1%.

A malignant polyp is an adenoma that appears grossly benign at endoscopy but on histologic assessment is found to contain cancer that has penetrated through the muscularis mucosae into the submucosa. Malignant polyps may be considered to be adequately treated by polypectomy alone if (1) the polyp is completely excised and submitted for pathologic examination, (2) it is well differentiated, (3) the margin is not involved, and (4) there is no vascular or lymphatic invasion. The risk of residual cancer or nodal metastasis with these favorable histologic features is 0.3% for pedunculated polyps and 1.5% for sessile polyps. The excision site of these "favorable" malignant polyps should be checked in 3 months for residual tissue. In patients with malignant polyps that have unfavorable histologic features, cancer resection is advisable if the patient is a good operative candidate.

B. Postpolypectomy Surveillance

Adenomas can be found in 30-40% of patients when another colonoscopy is performed within 3 years after the initial examination. Periodic colonoscopic surveillance is therefore recommended to detect these "metachronous" adenomas, which either may be new or may have been overlooked during the initial examination. Most of these adenomas are small, without high-risk features, and of little immediate clinical significance. The probability of detecting advanced neoplasms at surveillance colonoscopy is increased significantly if the polyps found on initial (index) colonoscopy were advanced (= 1 cm, villous features, or high-grade dysplasia) or multiple (more than two polyps) or if the patient's family includes a first-degree member with colorectal cancer. In these higher-risk patients, repeat or "surveillance" colonoscopy should be performed 3 years after the initial colonoscopy and polypectomy. For patients with adenomatous polyps who had low-risk features on initial colonoscopy and polypectomy (ie, one or two polyps less than 10 mm in size without villous features or high-grade dysplasia) or for higher-risk patients whose follow-up surveillance colonoscopy is negative for further polyps after 3 years, repeat colonoscopy to check for metachronous adenomas should be performed in 5 years.

HEREDITARY COLORECTAL CANCER & POLYPOSIS SYNDROMES

Approximately 1-3% of all colorectal cancers are caused by germline genetic mutations that impose on carriers a high lifetime risk of developing colorectal cancer. Because the diagnosis of these disorders has important implications for treatment of affected members and for screening of family members, it is important to consider these disorders in patients with a family history of colorectal cancer that has affected more than one family member, those with a personal or family history of colorectal cancer developing at an early age (= 50 years), those with a personal or family history of multiple polyps (> 20), and those with a personal or family history of multiple extracolonic malignancies.

1. Familial Adenomatous Polyposis

Familial adenomatous polyposis is an autosomal dominant syndrome affecting 1:10,000 people and characterized by the development of multiple (> 100) colonic adenomatous polyps and by other extracolonic features. It is due to an inherited mutation in the adenomatous polyposis coli (*APC*) gene on chromosome 5q21 that leads to frameshifts or premature stop codons, most of which result in truncation of the APC gene product, a protein important in the regulation of cell adhesion and apoptosis. More than 300 different mutations have been reported. The location of the mutation affects the number of polyps formed and the type of extracolonic features seen. Approximately 25% of cases appear to involve spontaneous germline mutations, ie, to occur in the absence of a family history of inherited colon cancer.

Polyps develop by a mean age of 15 years, and almost all affected individuals develop adenomatous polyps by age 35. Unless prophylactic colectomy is performed, colorectal cancer is inevitable by age 50. An attenuated variant of familial adenomatous polyposis has been recognized in which affected family members develop an average of only 30 polyps and therefore have a lower risk of cancer that occurs an average of 12 years later than the classic disease. These families have mutations on either the 5' or 3' end of the *APC* gene.

Adenomatous polyps of the duodenum and periampullary area develop in over 90% of patients, resulting in a 5-8% lifetime risk of adenocarcinoma. Adenomas occur less frequently in the gastric antrum and small bowel and in those locations have a lower risk of malignant transformation. Gastric fundus gland polyps occur in over 50% but have no malignant potential.

In addition to gastrointestinal polyps, some patients with familial adenomatous polyposis develop a variety of other benign extraintestinal manifestations, including soft tissue tumors of the skin, desmoid tumors, osteomas, and congenital hypertrophy of the retinal pigment. They may also develop malignancies of the central nervous system (Turcot's syndrome) and tumors of the thyroid and liver (hepatoblastomas). These extraintestinal manifestations vary among families, depending in part upon the type or site of mutation in the *APC* gene.

Genetic counseling and testing should be offered to patients with a diagnosis of familial adenomatous polyposis established by endoscopy and to first-degree family members of patients with the disease; testing should be done also to confirm a diagnosis of attenuated disease in patients with 20 or more adenomas. First-degree relatives of patients with familial adenomatous polyposis should undergo genetic screening after age 10. Genetic testing is also commercially available for Ashkenazic Jews with a personal or family history of colorectal cancer (see Colorectal Cancer: Family History). A protein truncation assay is commercially available that has a sensitivity of 80% for the diagnosis of familial adenomatous polyposis. Therefore, a negative result can be considered to be a true negative only if an affected family member has a positive test result. If the assay cannot be done or is not informative, family members at risk should undergo yearly sigmoidoscopy beginning at 12 years of age. Once the diagnosis has been established, complete proctocolectomy with ileoanal anastomosis or colectomy with ileorectal anastomosis is recommended, usually before age 20. Ileorectal anastomosis affords superior bowel function but has a 10% risk of development of rectal cancer, and for that reason frequent sigmoidoscopy with fulguration of polyps is required. Sulindac and COX-2 selective agents (celecoxib, rofecoxib) have been shown to decrease the number and size of polyps in the rectal stump but not the duodenum. Upper endoscopic evaluation of the stomach, duodenum, and periampullary area should be performed every 1-3 years to look for adenomas or carcinoma. Large (> 2 cm) periampullary adenomas require surgical resection.

2. Hamartomatous Polyposis Syndromes

Hamartomatous polyposis syndromes are rare and account for less than 0.1% of colorectal cancers.

Peutz-Jeghers syndrome is an autosomal dominant condition characterized by hamartomatous polyps throughout the gastrointestinal tract (most notably in the small intestine) as well as mucocutaneous pigmented macules on the lips, buccal mucosa, and skin. The hamartomas may become large, leading to bleeding, intussusception, or obstruction. Although hamartomas are not malignant, up to 13% of patients develop malignancies (especially of the stomach and duodenum) of nonintestinal organs (breast, gonads, pancreas). The defect has been localized to the serine threonine kinase 11 gene, and genetic testing is available.

Familial juvenile polyposis is also autosomal dominant and characterized by several (more than 10) juvenile hamartomatous polyps located most commonly in the colon. There is an increased risk (up to 50%) of adenocarcinoma due to synchronous adenomatous polyps or mixed hamartomatous-adenomatous polyps. Genetic defects have been identified in several genes. Genetic testing is available.

Cowden's syndrome is characterized by juvenile and hamartomatous polyps throughout the gastrointestinal tract. An increased rate of malignancy has not been demonstrated, but the condition must be distinguished from other hamartomatous syndromes.

3. Hereditary Nonpolyposis Colorectal Cancer (HNPCC)

HNPCC is an autosomal dominant condition in which there is a markedly increased risk of developing colorectal cancer as well as a host of other cancers, including endometrial, ovarian, renal or vesical, hepatobiliary, gastric, and small intestinal cancers. It is estimated to account for 1-3% of all colorectal cancers. Affected individuals have a 70-80% lifetime risk of developing colorectal carcinoma and an over 30% lifetime risk of endometrial cancer. Unlike individuals with familial adenomatous polyposis, HNPCC patients develop only a few adenomas, which may be flat and more often contain villous features or high-grade dysplasia. In contrast to the traditional polyp ? cancer progression (which may take over 10 years), these polyps are believed to undergo rapid transformation from normal tissue ? adenoma ? cancer. HNPCC tends to develop at an earlier age than sporadic colorectal cancers (mean age: 44 years), and over two-thirds arise proximal to the splenic flexure. Compared with patients with sporadic tumors of similar pathologic stage, those with HNPCC tumors have markedly improved survival. Synchronous or metachronous cancers occur within 10 years in up to 45% of patients.

HNPCC is caused by a defect in one of several genes that are important in the detection and repair of DNA base-pair mismatches: *hMLH1*, *hMSH2*, *hMSH6*, *hPMS1*, and *hPMS2*. Germline mutations in *hMLH1* and *hMSH2* account for more than 90-95% of the known mutations in families with HNPCC. Mutations in any of these mismatch repair genes result in a characteristic phenotypic abnormality known as microsatellite instability. In over 90% of cancers in HNPCC patients, microsatellite instability is readily demonstrated by expansion or contraction of DNA microsatellites (short, repeated DNA sequences). Microsatellite instability also occurs in 15% of sporadic colorectal cancers, over 85% of which do not have demonstrated mutations in mismatch repair genes.

A thorough family cancer history is essential to identify families that may be affected with HNPCC so that appropriate genetic and colonoscopic screening can be offered. The ability to find mutations in one of the known HNPCC genes is not nearly as great as with the inherited polyposis syndromes. Owing to the limitations of genetic testing for HNPCC and the medical, psychologic, and social implications that such testing may have, families with suspected HNPCC should be evaluated first by a genetic counselor and should give informed consent in writing before genetic testing is performed. Patients whose families fulfill the "Amsterdam criteria" have a high likelihood (45- 64%) of harboring a germline mutation in one of the mismatch repair genes and should be considered for genetic testing: (1) three or more first-degree family members with colorectal cancer (or one of the other associated cancers), (2) colon cancer involving at least two generations, and (3) at least one colon cancer diagnosed before age 50. These stringent criteria may, however, fail to identify many families with HNPCC. Therefore, genetic testing should be considered also (4) for individuals with colorectal cancer or endometrial cancer diagnosed before age 50 years (especially if right-sided, undifferentiated, or signet ring) or adenoma before age 40 years, (5) for those with colorectal cancer who have a first-degree relative with colorectal cancer or extracolonic cancer diagnosed before age 50 years, and (6) for those with a personal history of two HNPCC-associated cancers. Before proceeding with germline testing of family members, tumor tissues of affected individuals or family members should be tested first for microsatellite instability. Individuals whose tumors do not have microsatellite instability are unlikely to have germline mutations in mismatch repair genes, and further genetic testing is not warranted. Germline testing for gene mutations is warranted in individuals whose tumors demonstrate a high level of microsatellite instability. Germline testing is also warranted in families with a strong history consistent with HNPCC when tumors are unavailable for assessment. If a mutation is detected in a patient with cancer in one of the known mismatch genes, genetic testing of other first-degree family members is indicated. If a mutation in one of the known HNPCC genes is not identified, further genetic testing is of no value and all family members must still be considered to be at increased risk of developing neoplasia and screened accordingly.

If genetic testing documents an HNPCC gene mutation, affected relatives should be screened with colonoscopy every 1-2 years beginning at age 25 (or 5 years

younger than the earliest diagnosed family cancer). In families that fulfill the Amsterdam criteria or that have tumors with proved microsatellite instability but who do not have a documented gene mutation in one of the known HNPCC genes, colonoscopic screening (as above) is recommended for all family members. If cancer is found, subtotal colectomy with ileorectal anastomosis (followed by annual surveillance of the rectal stump) should be performed. Women should undergo screening for endometrial cancer beginning at age 25-35 with endometrial aspiration or transvaginal ultrasound. Prophylactic hysterectomy and oophorectomy may be considered, especially in women of post-childbearing age.

COLORECTAL CANCER

Essentials of Diagnosis

- Symptoms or signs dependent upon tumor location.
- Proximal colon: fecal occult blood, anemia.
- Distal colon: change in bowel habits, hematochezia.
- Characteristic findings on barium enema.
- Diagnosis established with colonoscopy.

General Considerations

Colorectal cancer is the second leading cause of death due to malignancy in the United States. Approximately 6% of Americans will develop colorectal cancer and 40% of those will die of the disease. An estimated 134,000 new cases and 55,000 deaths occur annually. Colorectal cancers are almost all adenocarcinomas, which tend to form bulky exophytic masses or annular constricting lesions. Approximately half of cancers are located within the rectosigmoid region; one-fourth are located proximally in the cecum and ascending colon. It is currently believed that the majority of colorectal cancers arise from malignant transformation of an adenomatous polyp.

Risk Factors

A number of factors increase the risk of developing colorectal cancer. Recognition of these has impact upon screening strategies. However, 75% of all cases occur in people with no known predisposing factors.

A. Age

The incidence of colorectal cancer rises sharply after age 45, and 90% of cases occur in persons over the age of 50.

B. Personal History of Neoplasia

A personal history of colorectal cancer or adenomatous polyps increases the risk of developing metachronous adenomas or carcinoma and therefore requires periodic colonoscopic surveillance (see Adenomatous Polyps, above). Patients with a family or personal history of breast, uterine, or ovarian cancer have a slightly increased risk.

C. Family History

A family history of colorectal cancer is present in 25% of patients with colon cancer. Patients with a family history of colorectal cancer have a significantly increased risk of developing colorectal cancer and deserve more intensive screening. Approximately 3% of colorectal cancers are caused by inherited autosomal dominant germline mutations resulting in polyposis syndromes or hereditary nonpolyposis colorectal cancer, which are reviewed elsewhere in this chapter. Genetic testing is now available for the diagnosis of most of these syndromes. (See Hereditary Colorectal Cancer and Polyposis Syndromes, above.)

The reason for the familial risk in the remainder of patients is still not well understood. The risk of colon cancer is proportionate to the number and age of affected first-degree family members with colon cancer. A person with one family member with colon cancer has a twofold increased risk; if the affected member was under age 60 years at diagnosis, the risk is greater. People with two first-degree relatives have a fivefold—or 25-30% lifetime—risk of developing colon cancer. First-degree relatives of patients with adenomas diagnosed before age 60 are also at increased risk. Cancers arise at an earlier age in patients with a positive family history, meriting screening at an earlier age. The risk of a 40-year old person with a positive family history is comparable to that of an average-risk 50-year-old.

Approximately 6% of the Ashkenazic Jewish population has a missense mutation in the APC gene (*APC I1307K*) which confers a modestly increased lifetime risk of developing colorectal cancer (OR 1.4-1.9) but phenotypically resembles sporadic colorectal cancer rather than familial adenomatous polyposis. Genetic screening is available, and patients harboring the mutation merit intensive screening.

D. Inflammatory Bowel Disease

The risk of adenocarcinoma of the colon begins to rise 7-10 years after disease onset in patients with ulcerative colitis and Crohn's colitis. The cumulative risk approaches 5-10% after 20 years and 20% after 30 years.

E. Dietary Factors and Chemoprevention

In case-control studies, diets rich in fats and red meat are associated with an increased risk of colorectal adenomas and cancer, whereas diets high in fruits, vegetables, and fiber are associated with a decreased risk. However, two prospective, randomized controlled trials failed to demonstrate a risk reduction in the recurrence of adenomas after treatment with a diet low in fat and high in fiber, fruits, and vegetables or with fiber supplementation over a 3- to 4-year period. Both calcium carbonate (3 g/d) and folate therapy have been shown in prospective trials to yield a modest but significant reduction in the relative risk of developing colorectal neoplasia. In women, hormone replacement therapy may also be beneficial. The antioxidant vitamins A, C, and E have not been shown to be of benefit in prospective controlled studies.

Prolonged regular use of aspirin (at least 325 mg twice weekly) and NSAIDs is associated with a 30- 50% decrease in the incidence of colorectal cancer and adenomas. Pending the results of prospective, placebo- controlled studies of aspirin and other NSAIDs, the relative risks and benefits of these agents as chemopreventive agents for colorectal neoplasia are unclear. Chronic administration of these agents may be considered in patients with a personal or family history of colorectal cancer or advanced adenomas.

F. Race

The incidence of colon adenocarcinoma is higher in blacks than in whites. It is unclear whether this is due to genetic or socioeconomic factors (eg, diet or reduced access to screening).

Clinical Findings

A. Symptoms and Signs

Adenocarcinomas grow slowly and may be present for several years before symptoms appear. However, asymptomatic tumors may still be detected by the presence of fecal occult blood (see Colorectal Cancer Screening, below). Symptoms depend upon the location of the carcinoma. Chronic blood loss from right-sided colonic cancers may cause iron deficiency anemia, manifested by fatigue and weakness. Obstruction, however, is uncommon because of the large diameter of the right colon and the liquid consistency of the fecal material. Lesions of the left colon often involve the bowel circumferentially. Because the left colon has a smaller diameter and the fecal matter is solid, obstructive symptoms may develop with colicky abdominal pain and a change in bowel habits. Constipation may alternate with periods of increased frequency and loose stools. The stool may be streaked with blood, though marked bleeding is unusual. With rectal cancers, patients note tenesmus, urgency, and recurrent hematochezia. Physical examination is usually normal except in advanced disease. A mass may be palpable in the abdomen. The liver should be examined for hepatomegaly, suggesting metastatic spread.

B. Laboratory Findings

A complete blood count is obtained to look for evidence of anemia. Elevated liver function tests are suspicious for metastatic disease. Carcinoembryonic antigen (CEA) should be measured in all patients with proved colorectal cancer. Levels are elevated in 70% of patients but are poorly correlated with cancer stage. After complete

surgical resection, CEA levels should normalize; persistently elevated levels portend a poor prognosis. A rise in CEA levels that had normalized initially after surgery is suggestive of cancer recurrence.

C. Inspection of the Colon

Cancers may be detected with a high degree of reliability with either barium enema, CT colonography ("virtual colonoscopy"), or colonoscopy. Colonoscopy is the diagnostic procedure of choice in patients with a clinical history suggestive of colon cancer or in patients with an abnormality suspicious for cancer detected on barium enema. Colonoscopy permits biopsy for pathologic confirmation of malignancy. In patients in whom colonoscopy is unable to reach the cecum (5% of cases) or when a nearly obstructing tumor precludes passage of the colonoscope, barium enema or CT colonography examination should be performed.

D. Imaging

Chest x-ray is obtained to look for evidence of metastatic disease. Some clinicians prefer to obtain an abdominal CT scan to assist in preoperative staging. However, this seldom changes surgical management and is deemed unnecessary by most surgeons for the evaluation of colon cancer. Conversely, for rectal cancer, pelvic MRI and endorectal ultrasonography provide important accurate information about the depth of penetration of the cancer through the rectal wall and pararectal lymph nodes that may guide operative management.

Differential Diagnosis

The nonspecific symptoms of colon cancer may be confused with those of irritable bowel syndrome, diverticular disease, ischemic colitis, inflammatory bowel disease, infectious colitis, and hemorrhoids. Neoplasm must be excluded in any patient over age 45 who reports a change in bowel habits or hematochezia or who has an unexplained iron deficiency anemia or occult blood in the stools.

Staging

Determination of the stage of colorectal cancer is important not only because it correlates with the patient's long-term survival but also because it is used to determine which patients should receive adjuvant therapy ([Table 14-16](#)). Although the Dukes classification has been widely employed in the past, the TNM system is now more commonly used.

Treatment

Resection of the primary colonic or rectal cancer is the treatment of choice for virtually all patients who have resectable lesions and can tolerate general anesthesia. Regional lymph node dissection should be performed to determine staging, which guides decisions about adjuvant therapy. Even patients with extensive metastatic disease may benefit from resection of the colonic tumor to reduce the likelihood of intestinal obstruction or serious bleeding.

For rectal carcinoma, the operative approach depends upon the level of the tumor above the anal verge, the size and depth of penetration, and the patient's overall condition. In carefully selected patients with small (< 3 cm), well-differentiated rectal tumors that are less than 7.5 cm from the anal verge and that appear on endosonography to be localized to the rectal wall, transanal excision may be performed. This approach avoids laparotomy and spares the rectum and anal sphincter, preserving normal bowel continence. All other patients will require either a low anterior resection with a colorectal anastomosis or an abdominoperineal resection with a colostomy, depending upon how far above the anal verge the tumor is located and the extent of local tumor spread. With unresectable rectal cancer, the patient may be palliated with a diverting colostomy, laser fulguration, or placement of an expandable wire stent.

A. Adjuvant Therapy for Colon Cancer

Adjuvant chemotherapy and radiotherapy have been demonstrated to improve overall and tumor-free survival in selected patients with colorectal cancer.

1. Stage I—Because of the excellent 5-year survival rate (80-100%), no adjuvant therapy is recommended.

2. Stage II (node-negative disease)—The expected 5-year survival rate is 50-75%. A benefit from adjuvant chemotherapy has not been demonstrated in controlled trials for stage II colon cancer. Patients with advanced local stage II disease (T3-T4) should be considered for study protocols looking at the role of adjuvant chemotherapy or radiotherapy for control of local recurrence.

3. Stage III (node-positive) disease—The expected 5-year survival rate is 30-50%. Patients with one to three involved nodes have better survival than those with more than three involved nodes. Postoperative adjuvant chemotherapy reduces mortality by 33% and is recommended for all patients. Currently, a combination of fluorouracil and leucovorin for 6 months may be recommended and improves 5-year disease-free survival to 64%. Alternatively, a combination of fluorouracil and levamisole for 1 year may be used, though one trial has shown this to be an inferior strategy. Selected patients with locally advanced (T₃ or T₄) cancer may benefit from radiotherapy to reduce the risk of local recurrence.

4. Stage IV (metastatic disease)—Approximately 20% of patients have metastatic disease at the time of initial diagnosis, and another 30% eventually develop metastasis. The long-term survival of these patients is only 5%. Resection of isolated (one to three) liver or lung metastases may result in long-term (over 5 years) survival in 20-40% of cases. For those with unresectable hepatic metastases, local ablative techniques (cryosurgery, embolization) may provide long-term tumor control. Chemotherapy with fluorouracil with or without leucovorin has been widely used for palliation but does not improve survival. Combination therapy with fluorouracil, leucovorin, and irinotecan (a topoisomerase inhibitor) provides significant improvement in tumor response rate (40%) and overall survival (mean: 15 months) compared with fluorouracil and leucovorin alone but is associated with significantly higher toxicity (diarrhea and neutropenia).

B. Adjuvant Therapy for Rectal Cancer

In the United States, combined postoperative adjuvant therapy with pelvic radiation and chemotherapy with fluorouracil is recommended for both stage II and stage III rectal cancers. Such therapy has been shown to improve both the overall and the disease-free survival rate and to decrease pelvic recurrences. In Europe, radiation is used preoperatively and chemotherapy typically is not used. The merits of these approaches are debated. Preoperative radiation may shrink tumor, permitting low anterior resection or transanal excision of some cases previously thought to need abdominoperineal resection with colostomy. However, it may lead to higher surgical complication rates and unnecessary treatment of some patients who are "over-staged" by clinical criteria. Postoperative therapy allows accurate staging but may lead to inadvertent radiation of small intestines as well as the surgical anastomosis. To date, therapy is individualized. Preoperative radiotherapy may be warranted in patients with known extensive disease or lymph node involvement. When staging suggests stage I or stage II disease, surgery may be performed first, followed by postoperative radiotherapy in patients found to have transmural extension or lymph node involvement. Where possible, patients should be enrolled in clinical trials that seek to identify the optimal combined-modality regimen.

Follow-Up After Surgery

Patients who have undergone resections for cure are followed closely to look for evidence of tumor recurrence. The optimal cost-effective strategy is not clear and varies in different medical centers. Two randomized trials reported that intense follow-up with yearly colonoscopy, abdominal CT, and chest radiography did not improve overall outcome compared with most standard follow-up protocols. In the absence of consensus guidelines, the following may be recommended. Patients should be evaluated every 3-6 months for 3-5 years with history, physical examination, fecal occult blood testing, liver function tests, and CEA determinations. Colonoscopy is performed within 6-12 months after operation to look for evidence of recurrence and then every 3-5 years to look for metachronous polyps or cancer. Because of the high incidence of local tumor recurrence in patients with rectal cancer, sigmoidoscopy should be performed every 6-12 months for 3 years. A change in the patient's clinical picture, abnormal liver function tests, or a rising CEA warrant investigation with chest radiography and abdominal CT to look for recurrent or metastatic disease that may be amenable to therapy.

Prognosis

The stage of disease at presentation is the most important determinant of long-term survival: stage I, > 90%; stage II, > 70%; stage III with fewer than four positive lymph nodes, 67%; stage III with more than four positive lymph nodes, 33%; and stage IV, < 5%. For each stage, rectal cancers have a worse prognosis. Although molecular markers (eg, *P53* mutation, 18q deletion, *Ki-ras* mutation) may be independent risk factors for the development of metastatic disease, these are not yet used clinically to guide therapy or follow-up. Tumors that have microsatellite instability, suggesting inactivation of mismatch repair genes (HNPCC and 15% of sporadic cancers), appear to have a more favorable prognosis.

For those patients whose disease progresses despite therapy, meticulous efforts at palliative care are essential (see [Chapter 5](#)).

Screening for Colorectal Neoplasms

Colorectal cancer is ideal for screening because it is a common disease affecting 6% of men and women which is fatal in almost half of cases yet is curable if detected at an earlier stage. Furthermore, the vast majority of cases arise from benign adenomas that progress over many years to cancer, and removal of adenomas has been shown to prevent the vast majority of cancers. Colorectal cancer screening has now been endorsed by the United States Preventive Services Task Force, the Agency

for Health Care Policy and Research, the American Cancer Society, and every professional gastroenterology and colorectal surgery society. Although there is continued debate about the optimal cost-effective means of providing population screening, there is unanimous consent that screening of *some kind* should be offered to every patient over the age of 50. Several analyses suggest that the cost of screening is approximately \$25,000 per year of life saved for all recommended screening strategies, which is well below the range of \$40,000-\$50,000 per year generally considered to be cost-effective.

A number of options for screening are available and reimbursed by third-party payers and by Medicare. The recommendations of a multidisciplinary consensus panel are listed in [Table 14-17](#) for patients at average risk of developing colorectal cancer. Patients with first-degree relatives with colorectal cancer are at increased risk, and for these individuals more intensive screening recommendations are recommended. Recommendations for screening in families with inherited cancer syndromes or inflammatory bowel disease are provided in separate sections. (See Hereditary Colorectal Cancer and Polyposis Syndromes; Inflammatory Bowel Disease.) The advantages and disadvantages of the various options are discussed below. It is important for primary care providers to understand the relative merits of various options and to discuss them with their patients. Despite growing awareness of the importance of screening on the part of medical professionals and the public, less than half of patients have undergone screening of any kind. Discussion and encouragement by the primary care provider are the most important factors in achieving patient compliance with screening programs.

A. Fecal Occult Blood Test (FOBT)

Most colorectal cancers and some large adenomas result in increased chronic blood loss that may be detectable. A variety of tests have been developed that have varying sensitivities for fecal occult blood, some of which are in clinical testing. A guaiac-based test (Hemoccult II) has undergone the most extensive testing and has had the greatest clinical use. Two slides must be prepared from three consecutive bowel movements. To reduce the likelihood of false-positive tests, patients should abstain from aspirin (in doses greater than 325 mg/d), NSAIDs, red meat, poultry, fish, and vegetables with peroxide activity (turnips, horseradish) for 72 hours. Vitamin C may cause a false-negative test. Slides should be developed within 7 days after preparation.

When fecal occult blood testing is administered to the general population as part of a screening program, 1-5% of tests are positive. Patients with positive tests should undergo colonoscopy accompanied by removal of any polyps identified. If colonoscopy reveals no colorectal neoplasm, further screening for colorectal cancer can be deferred for 10 years. Of those with positive tests, 5-18% have colorectal cancer, more likely to be at an earlier stage (Dukes A or B). Adenomatous polyps are identified in 25-50% of patients with positive tests. Finding these polyps is somewhat fortuitous since most are less than 1 cm in size and unlikely to cause occult bleeding. The estimated sensitivity of a fecal occult blood test for colorectal cancer is only 30-50%—ie, a negative test does not exclude the possibility of a significant neoplasm. Sensitivity may be increased in patients who are compliant with annual testing. In several large prospective studies, fecal occult blood testing has been demonstrated to reduce mortality from colorectal cancer by 15-33%. Higher risk reductions are obtained with annual versus biennial testing.

B. Flexible Sigmoidoscopy

Use of a 60-cm flexible sigmoidoscope permits visualization of the rectosigmoid and descending colon. It requires no sedation and in many centers is performed by a nurse specialist or physician's assistant. Adenomatous polyps are identified in 10-20% and colorectal cancers in 1% of patients. Polyps less than 5-8 mm in diameter should be removed by biopsy to determine the histology. Patients found to have adenomatous polyps should undergo pancolonoscopy to look for synchronous neoplasms in the proximal colon. (See Adenomatous Polyps, above.) Up to 80% of cases of advanced neoplasia will be detected in flexible sigmoidoscopy screening programs provided that all patients in whom an adenoma is identified at sigmoidoscopy undergo subsequent colonoscopy. The risk of serious complications (perforation) associated with flexible sigmoidoscopy is less than 1:10,000 patients.

C. Screening Colonoscopy

Colonoscopy permits examination of the entire colon. Approximately 40% of advanced neoplasms (cancer, adenomas = 1 cm, polyps with villous histology, or high-grade dysplasia) are proximal to the splenic flexure, ie, above the reach of a flexible sigmoidoscopic examination. Up to 50-60% of such patients do not have an adenomatous polyp distal to the splenic flexure at sigmoidoscopy. Therefore, screening programs that employ flexible sigmoidoscopy will miss approximately 20-30% of patients with advanced colonic neoplasia. To alleviate discomfort, intravenous sedation is used for most patients. For this reason, screening colonoscopy is the preferred screening test in patients deemed to be at higher risk due to a positive family history of colorectal cancer. Colonoscopy has been advocated by the American College of Gastroenterology as the preferred screening modality in average-risk patients as well. In a population of asymptomatic veterans between the ages of 50 and 75 years of age undergoing screening colonoscopy, the prevalence of advanced adenomas or cancer was 10.7%. The incidence of serious complications after colonoscopy (perforation, bleeding, cardiopulmonary events) is 0.3%.

D. Double Contrast Barium Enema

Like colonoscopy, barium enema permits examination of the entire colon. However, the sensitivity of barium enema is 70-90% for polyps = 1 cm and only 55-85% for early-stage colorectal cancers. Therefore, most authorities do not recommend this examination for screening of asymptomatic patients. It may be used when screening of the entire colon is desired and the patient is unable or unwilling to undergo colonoscopy, or when colonoscopic expertise is unavailable.

E. CT Colonography (Virtual Colonoscopy)

Using computer-assisted image reconstruction and rapid helical CT, three-dimensional views can be generated of the colon lumen that simulate the view of colonoscopy. This technique is performed rapidly, requires no sedation or intravenous contrast, and is without risk. Compared with conventional colonoscopy, the sensitivity of virtual colonoscopy for the detection of polyps = 1 cm is 90%. Virtual colonoscopy is costly, not available at most centers, and not as yet recommended for routine screening.

■ ANORECTAL DISEASES

HEMORRHOIDS

Essentials of Diagnosis

- Bright red blood per rectum
- Protrusion, discomfort
- Characteristic findings on external anal inspection and anoscopic examination

General Considerations

Internal hemorrhoids are a plexus of superior hemorrhoidal veins located above the dentate line which are covered by mucosa. They are a normal anatomic entity, occurring in all adults. Internal hemorrhoids form a vascular cushion in the lower rectum that may contribute to normal continence. They occur in three primary locations—right anterior, right posterior, and left lateral—though smaller hemorrhoids may occur between these primary locations. External hemorrhoids arise from the inferior hemorrhoidal veins located below the dentate line and are covered with squamous epithelium of the anal canal or perianal region.

Hemorrhoids may become symptomatic as a result of activities that increase venous pressure, resulting in distention and engorgement. Straining at stool, constipation, prolonged sitting, pregnancy, obesity, and low-fiber diets all may contribute. With time, redundancy and enlargement of the venous cushions may develop and result in bleeding or protrusion.

Clinical Findings

A. Symptoms and Signs

Patients often attribute a variety of perianal complaints to "hemorrhoids." However, the principal problems attributable to internal hemorrhoids are bleeding and mucoid discharge. Bleeding is manifested by bright red blood that may range from streaks of blood visible on toilet paper or stool to bright red blood that drips into the toilet bowl after a bowel movement. Rarely is bleeding severe enough to result in anemia. Initially, internal hemorrhoids are confined to the anal canal (stage I). Over time, the internal hemorrhoids may gradually enlarge and protrude from the anal opening. At first, this prolapse occurs during straining and reduces spontaneously (stage II). With progression over time, the prolapsed hemorrhoids may require manual reduction after bowel movements (stage III) or may remain chronically protruding (stage IV). Chronically prolapsed hemorrhoids may result in mucoid perianal discharge, resulting in irritation and soiling of underclothes. Discomfort and pain are unusual with internal hemorrhoids, occurring only when there is extensive inflammation and thrombosis of irreducible tissue or with thrombosis of an external hemorrhoid (see below).

B. Examination

External hemorrhoids are readily visible on perianal inspection. Nonprolapsed internal hemorrhoids are not visible but may protrude through the anus with gentle straining while the physician spreads the buttocks. Prolapsed hemorrhoids are visible as protuberant purple nodules covered by mucosa. The perianal region should also be examined for other signs of disease such as fistulas, fissures, skin tags, or dermatitis. On digital examination, uncomplicated internal hemorrhoids are neither palpable nor painful. Anoscopic evaluation, best performed in the prone jackknife position, provides optimal visualization of internal hemorrhoids.

Differential Diagnosis

Rectal bleeding may be caused by colorectal neoplasms, ulcerative colitis or Crohn's colitis, infectious proctitis, and diverticular disease. Rectal prolapse, in which a full thickness of rectum protrudes concentrically from the anus, is readily distinguished from mucosal hemorrhoidal prolapse. Proctosigmoidoscopy should be performed in all patients with hematochezia to exclude disease in the rectum or sigmoid colon that could be misinterpreted in the presence of hemorrhoidal bleeding. Patients with iron deficiency anemia should undergo colonoscopy or barium enema to exclude disease proximal to the sigmoid colon.

Treatment

A. Conservative Measures

Most patients with early (stage I and stage II) disease can be managed with conservative treatment. To decrease straining with defecation, patients should be given instructions for a high-fiber diet and told to increase fluid intake with meals. Dietary fiber may be supplemented with bran powder (1-2 tbsp twice daily added to food or in 8 oz of liquid) or with commercial psyllium bulk laxatives (eg, Metamucil, Citrucel). Suppositories and rectal ointments have no demonstrated utility in the management of mild disease. Mucoid discharge may be treated effectively by the local application of a cotton ball tucked next to the anal opening after bowel movements. For edematous, prolapsed hemorrhoids, gentle manual reduction may be supplemented by suppositories (eg, Anusol with or without hydrocortisone) that have anesthetic and astringent properties and by warm sitz baths.

B. Surgical Treatment

Patients with stage I or stage II hemorrhoids and recurrent bleeding despite conservative measures may be treated with injection sclerotherapy or rubber band ligation. However, recurrence is common unless patients alter their dietary habits. Surgical excision (hemorrhoidectomy) is reserved for patients with chronic severe bleeding due to stage III or stage IV hemorrhoids or patients with acute thrombosed stage IV hemorrhoids.

Thrombosed External Hemorrhoid

Thrombosis of the external hemorrhoidal plexus results in a perianal hematoma. It most commonly occurs in otherwise healthy young adults and may be precipitated by coughing, heavy lifting, or straining at stool. The condition is characterized by the relatively acute onset of an exquisitely painful, tense and bluish perianal nodule covered with skin that may be up to several centimeters in size. Pain is most severe within the first few hours but gradually eases over 2-3 days as edema subsides. Symptoms may be relieved with warm sitz baths, analgesics, and ointments. If the patient is evaluated in the first 24-48 hours, removal of the clot may hasten symptomatic relief. With the patient in the lateral position, the skin around and over the lump is injected subcutaneously with 1% lidocaine using a tuberculin syringe with a 30-gauge needle. An ellipse of skin is then excised and the clot evacuated. A dry gauze dressing is applied for 12-24 hours, and daily sitz baths are then begun.

ANORECTAL INFECTIONS

A number of organisms can cause inflammation of the anal and rectal mucosa. Proctitis is defined as inflammation of the distal 15 cm of rectum and is characterized by anorectal discomfort, tenesmus, constipation, and discharge. Most cases of proctitis are sexually transmitted, especially by anal-receptive intercourse. Proctocolitis implies inflammation that extends above the rectum to the sigmoid colon or more proximally and is caused by entirely different organisms such as campylobacter, *Entamoeba histolytica*, shigella, and enteroinvasive *E coli*. These organisms are discussed earlier in the section on diarrhea. Symptoms include frequent, small-volume, bloody or watery diarrhea, urgency, cramps, and tenesmus.

Etiology & Management

Several organisms may cause infectious proctitis.

A. Neisseria gonorrhoeae

Gonorrhea may cause itching, burning, tenesmus, and a mucopurulent discharge. Blind swabs of the anal canal have a sensitivity of less than 60%. Swabs should be taken for Gram staining and culture during anoscopy, expressing mucopus from the anal crypts. Cultures should also be taken from the urethra and pharynx in men and from the cervix in women. Complications of untreated infections include strictures, fissures, fistulas, and perirectal abscesses.

B. Treponema pallidum

Anal syphilis may be asymptomatic or may lead to perianal pain and discharge. With primary syphilis, the chancre may be at the anal margin or within the anal canal and may mimic a fissure, fistula, or ulcer. Proctitis or inguinal lymphadenopathy may be present. With secondary syphilis, condylomata lata (pale-brown, flat verrucous lesions) may be seen, with secretion of foul-smelling mucus. The diagnosis is established with dark-field microscopy of scrapings from the chancre or condylomas. The VDRL test is positive in 75% of primary cases and in 99% of secondary cases.

C. Chlamydia trachomatis

Chlamydial infection may cause proctitis similar to gonorrheal proctitis or may cause lymphogranuloma venereum, characterized by proctocolitis with fever and bloody diarrhea, painful perianal ulcerations, anorectal strictures and fistulas, and inguinal adenopathy (buboes). The diagnosis is established by culture of rectal discharge or rectal biopsy, which is over 80% sensitive.

D. Herpes Simplex Type 2

HSV is a common cause of anorectal infection. Symptoms occur 4-21 days after exposure and include severe pain, itching, constipation, tenesmus, urinary retention, and radicular pain from involvement of lumbar or sacral nerve roots. Small vesicles or ulcers may be seen in the perianal area or anal canal. Sigmoidoscopy is not usually necessary but may reveal vesicular or ulcerative lesions in the distal rectum. Diagnosis is established by viral culture or antigen detection assays of vesicular fluid. Symptoms resolve within 2 weeks, but viral shedding may continue for several weeks. Patients may remain asymptomatic with or without viral shedding or may have recurrent mild relapses. Treatment of acute infection with acyclovir, 400 mg orally five times daily for 5-10 days, has been shown to reduce the duration of symptoms and viral shedding. Patients with AIDS and recurrent relapses may benefit from chronic suppressive therapy (see [Chapter 32](#)).

E. Condylomata Acuminata

Condylomata acuminata are a significant cause of anorectal symptoms. Caused by the human papillomavirus, they are seen in up to 25% of homosexual men. HIV-positive individuals with condylomas have a higher relapse rate after therapy and a higher rate of progression to high-grade dysplasia or anal cancer. The warts

are located on the perianal skin and extend within the anal canal up to 2 cm above the dentate line. Patients may have no symptoms or may report itching, bleeding, and pain. The warts may form a confluent mass that may obscure the anal opening. Treatment can be difficult. Sexual partners should also be examined and treated. Topical application of podophyllum resin, imiquimod cream, and 5% fluorouracil cream is effective for small external perianal lesions. Anal canal lesions may require topical application of bichloroacetic acid, cryotherapy, or electrocautery. Refractory or large lesions may be treated with local injection of alpha interferon beneath the lesions or surgical excision. HIV-positive individuals with condylomas who have detectable serum HIV RNA levels should have anoscopic surveillance every 3-6 months.

RECTAL PROLAPSE & SOLITARY RECTAL ULCER SYNDROME

Rectal prolapse is protrusion through the anus of some or all of the layers of the rectum. It is most commonly seen in the elderly. Although surgical and traumatic injuries are causative in some patients, in most cases rectal prolapse arises from chronic, excessive straining at stool in conjunction with weakening of pelvic support structures. Although prolapse initially reduces spontaneously after defecation, with time the rectal mucosa becomes chronically prolapsed, resulting in mucous discharge, bleeding, incontinence, and sphincteric damage. Patients with complete prolapse require surgical correction.

The term solitary rectal ulcer syndrome is a misnomer. The syndrome is characterized by anal pain, excessive straining at stool, and passage of mucus and blood. It is most commonly seen in young adults, especially women. Proctoscopic examination reveals either shallow ulcerations (single or multiple) or a nodular mass located anteriorly 6-10 cm above the anal verge. Biopsy is diagnostic. The disorder may be caused by rectal intussusception with straining. Treatment is directed at decreasing straining through education of the patient and use of bulking agents.

Malouf A et al: Results of behavioral treatment (biofeedback) for solitary rectal ulcer syndrome. *Dis Colon Rectum* 2001; 44:72. [\[PMID: 11805566\]](#)

FECAL INCONTINENCE

There are five general requirements for bowel continence: (1) solid or semisolid stool (even healthy young adults have difficulty maintaining continence with liquid rectal contents), (2) a distensible rectal reservoir (as sigmoid contents empty into the rectum, the vault must expand to accommodate), (3) a sensation of rectal fullness (if the patient cannot sense this, overflow may occur before the patient can take appropriate action), (4) intact pelvic nerves and muscles, and (5) the ability to reach a toilet in a timely fashion.

Minor Incontinence

Many patients complain of inability to control flatus or slight soilage of undergarments that tends to occur after bowel movements or with straining or coughing. This may be due to local anal problems such as hemorrhoids and skin tags that make it difficult to form a tight anal seal, especially if stools are somewhat loose. Patients should be treated with fiber supplements to provide greater stool bulk. Loose application of a cotton ball near the anal opening may absorb small amounts of fecal leakage. Control of flatus and seepage may be improved by Kegel perineal strengthening exercises. Conditions such as ulcerative proctitis that cause tenesmus and urgency, chronic diarrheal conditions, and irritable bowel syndrome may result in difficulty in maintaining complete continence, especially if a toilet is not readily available. Similarly, the elderly may require more time or assistance to reach a toilet, which may lead to incontinence. Elderly patients with chronic constipation may develop stool impaction leading to "overflow" incontinence.

Major Incontinence

Complete uncontrolled loss of stool reflects a significant problem with sphincteric or neurologic damage. Causes of sphincteric damage include traumatic childbirth (especially forceps delivery), episiotomy, prolapse, prior anal surgery, and physical trauma. Neurologic disruption may be caused by obstetric trauma (with pudendal nerve damage), aging, diabetes mellitus, dementia, multiple sclerosis, spinal cord injury, and cauda equina syndrome.

Physical examination should include careful inspection of the perianal area for hemorrhoids, rectal prolapse, fissures, fistulas, and either gaping or a keyhole defect of the anal sphincter (indicating severe sphincteric injury). The perianal skin should be stimulated to confirm an intact anocutaneous reflex. Digital examination during relaxation and squeezing gives valuable information about resting tone (due to the internal sphincter) and external sphincter function and excludes fecal impaction. Anoscopy is required to evaluate for hemorrhoids, fissures, and fistulas. Proctosigmoidoscopy is useful to exclude rectal carcinoma or proctitis. Anal ultrasonography is the most reliable test for definition of anatomic defects in the external and internal anal sphincters. Anal manometry and surface electromyography may also be useful to define the severity of weakness, to diagnose nerve injury, and to predict response to biofeedback training.

Patients who are incontinent only of loose or liquid stools are treated with bulking agents and antidiarrheal drugs (eg, loperamide, 2 mg before meals and prophylactically before social engagements, shopping trips, etc). Patients with incontinence of solid stool benefit from scheduled toilet use after glycerin suppositories or tap water enemas. Biofeedback training with anal sphincter (Kegel) exercises is helpful in motivated patients to lower the threshold for awareness of rectal filling—or to improve anal sphincter squeeze function—or both. Operative management is seldom needed but should be considered in patients with major incontinence due to prior injury to the anal sphincter who have failed medical therapy

OTHER ANAL CONDITIONS

Anal Fissures

Anal fissures are linear or rocket-shaped ulcers that are usually less than 5 mm in length. They occur most commonly in the posterior midline, but 10% occur anteriorly. Fissures are believed to arise from trauma to the anal canal during defecation, perhaps caused by straining, constipation, or high internal sphincter tone. Patients complain of severe, tearing pain during defecation followed by throbbing discomfort that may lead to constipation due to fear of recurrent pain. There may be mild associated hematochezia, with blood on the stool or toilet paper. Anal fissures are confirmed by visual inspection of the anal verge while gently separating the buttocks. Acute fissures look like cracks in the epithelium. Chronic fissures result in fibrosis and the development of a skin tag at the outermost edge (sentinel pile). Digital and anoscopic examinations may cause severe pain and may not be possible. Medical management is directed at promoting effortless, painless bowel movements. Fiber supplements and sitz baths should be prescribed. Suppositories are of no benefit. Topical 0.2-0.4% nitroglycerin ointment (1 cm of ointment) applied twice daily just inside the anus with the tip of a finger for 6-8 weeks results in healing in 50-80% of patients with chronic anal fissure; however, headaches occur in up to 40%. Injection of botulinum toxin (20 units) into the internal anal sphincter has been shown to cause healing in over 80% of patients with chronic anal fissure. Fissures may recur in up to 40% of patients treated with either nitrates or botulinum toxin. Chronic or recurrent fissures benefit from lateral internal sphincterotomy; however, minor incontinence may complicate this procedure.

Perianal Abscess & Fistula

The anal glands located at the base of the anal crypts at the dentate line may become infected, leading to abscess formation. Other causes of abscess include anal fissure and Crohn's disease. Abscesses may extend upward or downward through the intersphincteric plane. Symptoms of perianal abscess are throbbing, continuous perianal pain. Erythema, fluctuance, and swelling may be found in the perianal region on external examination or in the ischiorectal fossa on digital rectal examination. Perianal abscesses are treated with local incision and drainage, while ischiorectal abscesses require drainage in the operating room. After drainage of an abscess, most patients are found to have a fistula in ano.

Fistula in ano most often arises in an anal crypt and is usually preceded by an anal abscess. In patients with fistulas that connect to the rectum, other disorders such as Crohn's disease, lymphogranuloma venereum, rectal tuberculosis, and cancer should be considered. Fistulas are associated with purulent discharge that may lead to itching, tenderness, and pain. Treatment is by surgical incision or excision under anesthesia. Care must be taken to preserve the anal sphincters.

Pruritus Ani

Pruritus ani is characterized by perianal itching and discomfort. It may be caused by poor anal hygiene associated with fistulas, fissures, prolapsed hemorrhoids, skin tags, and minor incontinence. Conversely, overzealous cleansing with soaps may contribute to local irritation or contact dermatitis. Pinworms, candidal infection (especially in diabetics), scabies, and condylomata acuminata must be excluded. In patients with idiopathic pruritus ani, examination may reveal erythema, excoriations, or lichenified, eczematous skin. Education is vital to successful therapy. After bowel movements, the perianal area should be cleansed with nonscented wipes premoistened with lanolin followed by gentle drying. A piece of cotton ball should be tucked next to the anal opening to absorb perspiration or fecal seepage. Anal ointments and lotions may exacerbate the condition and should be avoided.

CARCINOMA OF THE ANUS

These tumors are relatively rare, comprising only 1-2% of all cancers of the anus and large intestine. Squamous cancers make up the majority of anal cancers. Squamous cancer involving the anal canal may be subclassified as transitional and cloacogenic carcinoma; however, these are treated similarly. Anal cancer is increased among people practicing receptive anal intercourse and those with a history of other sexually transmitted diseases. In over 80% of cases, human papillomavirus (HPV) may be detected, suggesting that this virus may be a causal factor. Anal cancer is increased in HIV-infected individuals. Combined HIV and HPV infection markedly increases the risk of anal carcinoma. Bleeding, pain, and local tumor are the commonest symptoms. The lesion is often confused with hemorrhoids or other common anal disorders. These tumors tend to become annular, invade the sphincter, and spread upward via the lymphatics into the perirectal mesenteric lymphatic nodes.

Treatment depends upon the tumor stage. MR scan and endoluminal ultrasound assist in determining the depth of penetration and local spread. Small (< 3 cm) superficial lesions of the perianal skin may be treated with wide local excision. Squamous cancer of the anal canal and large perianal tumors invading the sphincter or rectum are treated with combined-modality therapy that includes external radiation with simultaneous chemotherapy (fluorouracil and either mitomycin or cisplatin). Local control is achieved in 80% of patients. Radical surgery (abdominoperineal resection) is reserved for patients who fail chemotherapy and radiation therapy. The 5-year survival rate is 60-70% for localized tumors and over 25% for metastatic (stage IV) disease.

Calcium polycarbophil	1 or 2 tablets once or twice	12-24 hours	
Stool surfactants			
Docusate sodium	100 mg once or twice daily	12-72 hours	(Colace) Marginal benefit
Mineral oil	15-45 mL once or twice daily	6-8 hours	May cause lipoid pneumonia, if aspirated
Osmotic laxatives			
Magnesium hydroxide; magnesium sulfate	15-30 mL orally once or twice	3-12 hours	(Milk of magnesia; Epsom salts)
Lactulose or 70% sorbitol	15-60 mL orally once daily to three times daily	24-48 hours	Cramps, bloating flatulence
PEG 3350	17 g in 8 oz liquid once or twice daily	3-24 hours	(Miralax) Less bloating than lactulose, sorbitol
Stimulant laxatives			
Bisacodyl	5-15 mg orally as needed	6-8 hours	May cause cramps; avoid daily use, if possible
Bisacodyl	10 mg per rectum as needed	1 hour	
Cascara	4-8 mL or 2 tablets as needed	8-12 hours	(Nature's Remedy); may cause cramps; avoid daily use, if possible
Senna	5-15 mg orally up to threetimes daily	8-12 hours	
Enemas			
Tap Water	500 mL per rectum	5-15 minutes	Commonly used for acute constipation or to induce movement prior to medical procedures
Phosphate enema	120 mL per rectum	5-15 minutes	
Soapsuds enema	Up to 1500 mL per rectum	5-15 minutes	Impaction
Mineral oil enema	100-250 mL per rectum	Up to hours	To soften and lubricate fecal impaction
Agents used to clean bowel prior to medical procedures			
Polyethylene glycol (PEG)	4L orally administered over 2-4 hours	< 4 hours	(GoLyte; CoLyte; NuLyte) Used to cleanse bowel before colonoscopy
Sodium phosphate	45 mL in 12 oz water May repeat in 10-12 hours	1-6 hours	Used before colonoscopy.
Magnesium citrate	10 oz	3-6 hours	Lemon flavored
Combination kits: sodium phosphate and bisacodyl			(Fleet); commonly used prior to barium enema

- TABLES
 - Table 14-6. Fecal leukocytes in intestinal disorders.
-

Table 14-7. Causes of chronic diarrhea.

Osmotic diarrhea

CLUES: Stool volume decreases with fasting; increased stool osmotic gap

- 1. Medications: antacids, lactulose, sorbitol
- 2. Disaccharidase deficiency: lactose intolerance
- 3. Factitious diarrhea: magnesium (antacids, laxatives)

Secretory diarrhea

CLUES: Large volume (> 1 L/d); little change with fasting; normal stool osmotic gap

- 1. Hormonally mediated: VIPoma, carcinoid, medullary carcinoma of thyroid (calcitonin), Zollinger-Ellison syndrome (gastrin)
- 2. Factitious diarrhea (laxative abuse); phenolphthalein, cascara, senna
- 3. Villous adenoma
- 4. Bile salt malabsorption (ileal resection; Crohn's ileitis; postcholecystectomy)
- 5. Medications

Inflammatory conditions

CLUES: Fever, hematochezia, abdominal pain

- 1. Ulcerative colitis
- 2. Crohn's disease
- 3. Microscopic colitis
- 4. Malignancy: lymphoma, adenocarcinoma (with obstruction and pseudodiarrhea)
- 5. Radiation enteritis

¹MAI = *Mycobacterium avium-intracellulare*.

Malabsorption syndromes

CLUES: Weight loss, abnormal laboratory values; fecal fat > 10 g/24 h

- 1. Small bowel mucosal disorders: celiac sprue, tropical sprue, Whipple's disease, eosinophilic gastroenteritis, small bowel resection (short bowel syndrome), Crohn's disease
- 2. Lymphatic obstruction: lymphoma, carcinoid, infectious (tuberculosis, MAI),¹ Kaposi's sarcoma, sarcoidosis, retroperitoneal fibrosis
- 3. Pancreatic disease: chronic pancreatitis, pancreatic carcinoma
- 4. Bacterial overgrowth: motility disorders (diabetes, vagotomy), scleroderma, fistulas, small intestinal diverticula

Motility disorders

CLUES: Systemic disease or prior abdominal surgery

- 1. Postsurgical: vagotomy, partial gastrectomy, blind loop with bacterial overgrowth
- 2. Systemic disorders: scleroderma, diabetes mellitus, hyperthyroidism
- 3. Irritable bowel syndrome

Chronic infections

- 1. Parasites: *Giardia lamblia*, *Entamoeba histolytica*
- 2. AIDS-related:

Viral: Cytomegalovirus, HIV infection (?)

Bacterial: *Clostridium difficile*, *Mycobacterium avium* complex

Protozoal: Microsporida (*Enterocytozoon bieneusi*), cryptosporidium, *Isospora belli*)

•

Table 14-8. Causes of ascites.

NORMAL PERITONEUM

Portal hypertension (SAAG = 1.1 g/dL)

1. Hepatic congestion¹

- Congestive heart failure
- Constrictive pericarditis
- Tricuspid insufficiency
- Budd-Chiari syndrome
- Veno-occlusive disease

2. Liver disease²

- Cirrhosis
- Alcoholic hepatitis
- Fulminant hepatic failure
- Massive hepatic metastases
- Hepatic fibrosis
- Acute fatty liver of pregnancy

3. Portal vein occlusion

Hypoalbuminemia (SAAG < 1.1 g/dL)

- Nephrotic syndrome
- Protein-losing enteropathy
- Severe malnutrition with anasarca

Miscellaneous conditions (SAAG < 1.1 g/L)

- Chylous ascites
- Pancreatic ascites
- Bile ascites
- Nephrogenic ascites
- Urine ascites
- Myxedema (SAAG = 1.1 g/dL)
- Ovarian disease

DISEASED PERITONEUM (SAAG < 1.1 G/DL²)

Infections

- Bacterial peritonitis
- Tuberculous peritonitis
- Fungal peritonitis
- HIV-associated peritonitis

Malignant conditions

- Peritoneal carcinomatosis
- Primary mesothelioma
- Pseudomyxoma peritonei
- Massive hepatic metastases
- Hepatocellular carcinoma

Other conditions

- Familial Mediterranean fever
- Vasculitis
- Granulomatous peritonitis
- Eosinophilic peritonitis
- SAAG = serum-ascites albumin gradient.

¹Hepatic congestion usually associated with SAAG = 1.1 g/dL and ascitic fluid total protein > 2.5 g/dL.

²There may be cases of "mixed ascites" in which portal hypertensive ascites is complicated by a secondary process such as infection. In these cases, the SAAG is = 1.1 g/dL.

Table 14-11. Treatment options for peptic ulcer disease.
Active <i>Helicobacter pylori</i>-associated ulcer:
1. Treat with anti- <i>H pylori</i> regimen for 10-14 days. Treatment options:
Proton pump inhibitor twice daily ¹ Clarithromycin 500 mg twice daily Amoxicillin 1 g twice daily (OR metronidazole 500 mg twice daily, if penicillin allergic)
Proton pump inhibitor twice daily ¹ Bismuth subsalicylate two tablets four times daily Tetracycline 500 mg four times daily Metronidazole 250 mg four times daily
Ranitidine bismuth citrate 400 mg twice daily Clarithromycin 500 mg twice daily Amoxicillin 1 g OR tetracycline 500 mg OR metronidazole 500 mg twice daily
(Proton pump inhibitors administered before meals. Avoid metronidazole regimens in areas of known high resistance or in patients who have failed a course of treatment that included metronidazole).
2. After completion of 10-14 day course of <i>H pylori</i> eradication therapy, continue treatment with proton pump inhibitor ¹ once daily or H ₂ receptor antagonist (as below) for 4-8 weeks to promote healing.
Active ulcer not attributable to <i>H pylori</i>:
1. Consider other causes: NSAIDs, Zollinger-Ellison syndrome, gastric malignancy. Treatment options:
Proton pump inhibitors ¹ : Uncomplicated duodenal ulcer: treat for 4 weeks Uncomplicated gastric ulcer: treat for 8 weeks H ₂ receptor antagonists: Uncomplicated duodenal ulcer: cimetidine 800 mg, ranitidine or nizatidine 300 mg, famotidine 40 mg, once daily at bedtime for 6 weeks Uncomplicated gastric ulcer: cimetidine 400 mg, ranitidine or nizatidine 150 mg, famotidine 20 mg, twice daily for 8 weeks Complicated ulcers: proton pump inhibitors are preferred drugs
Prevention of ulcer relapse:
1. NSAID-induced ulcer: prophylactic therapy for high-risk patients (prior ulcer disease or ulcer complications, use of corticosteroids or anticoagulants, age > 70 with serious comorbid illnesses). Treatment options:
Proton pump inhibitor once daily COX-2 selective NSAID (rofecoxib, celecoxib) (In special circumstances: misoprostol 200 µg 3-4 times daily)
2. Chronic "maintenance" therapy indicated in patients with recurrent ulcers who either are <i>H pylori</i> -negative or who have failed attempts at eradication therapy: once daily proton pump inhibitor ¹ or H ₂ receptor antagonist at bedtime (cimetidine 400-800 mg, nizatidine or ranitidine 150-300 mg, famotidine 20-40 mg)
¹ Proton pump inhibitors: omeprazole 20 mg, rabeprazole 20 mg, lansoprazole 30 mg, pantoprazole 40 mg.

Table 14-12. Clinical and laboratory manifestations of malabsorption.¹

Manifestation	Laboratory Findings	Malabsorbed Nutrients
Steatorrhea (bulky, light-colored stools)	Increased fecal fat; decreased serum cholesterol	Fat
Diarrhea (increased fecal water)	Increased fecal fat or positive bile salt breath test	Fatty acids or bile salts
Weight loss; malnutrition (muscle wasting); weakness, fatigue, abdominal distention	Increased fecal fat and nitrogen; decreased glucose and xylose absorption	Calories (fat, protein, carbohydrates)
Iron deficiency anemia	Hypochromic anemia; low serum iron	Iron
Megaloblastic anemia	Macrocytosis; decreased vitamin B ₁₂ absorption (⁶⁷ Co-labeled B ₁₂); decreased serum vitamin B ₁₂ and red cell folate	Vitamin B ₁₂ or folic acid
Paresthesia; tetany; positive Trousseau and Chvostek signs	Decreased serum calcium, magnesium, and potassium	Calcium, vitamin D, magnesium, potassium
Bone pain; pathologic fractures; skeletal deformities	Osteoporosis on x-ray; osteomalacia on biopsy	Calcium, protein
Bleeding tendency (ecchymoses, melena, hematuria)	Prolonged prothrombin time	Vitamin K
Edema	Decreased serum albumin; increased fecal loss of a ₁ -antitrypsin (antiprotease)	Protein (or protein-losing enteropathy)
Nocturia; abdominal distention	Increased small bowel fluid on x-ray	Water
Milk intolerance (cramps, bloating, diarrhea)	Flat lactose tolerance test; decreased mucosal lactase levels	Lactose

JAUNDICE (ICTERUS)

Jaundice results from the accumulation of bilirubin—a reddish pigment product of heme metabolism—in the body tissues; the cause may be hepatic or nonhepatic. Hyperbilirubinemia may be due to abnormalities in the formation, transport, metabolism, and excretion of bilirubin. Total serum bilirubin is normally 0.2-1.2 mg/dL, and jaundice may not be recognizable until levels are about 3 mg/dL.

Jaundice is caused by predominantly unconjugated or conjugated bilirubin in the serum ([Table 15-1](#)). Unconjugated hyperbilirubinemia may result from overproduction of bilirubin because of hemolysis; impaired hepatic uptake of bilirubin due to certain drugs; or impaired conjugation of bilirubin by glucuronide, as in Gilbert's syndrome, due to mild decreases in glucuronyl transferase, or Crigler-Najjar syndrome, caused by moderate decreases or absence of glucuronyl transferase. In the absence of liver disease, hemolysis rarely elevates the serum bilirubin level to more than 7 mg/dL. Predominantly conjugated hyperbilirubinemia may result from impaired excretion of bilirubin from the liver due to hepatocellular disease, drugs, sepsis, hereditary disorders such as Dubin-Johnson syndrome, or extrahepatic biliary obstruction. Features of some hyperbilirubinemic syndromes are summarized in [Table 15-2](#). The term "cholestasis" denotes retention of bile in the liver, and the term "cholestatic jaundice" is often used when conjugated hyperbilirubinemia results from impaired bile flow.

Manifestations of Diseases Associated with Jaundice

A. Unconjugated Hyperbilirubinemia

Stool and urine color are normal, and there is mild jaundice and indirect (unconjugated) hyperbilirubinemia with no bilirubin in the urine. Splenomegaly occurs in hemolytic disorders except in sickle cell anemia. Abdominal or back pain may occur with acute hemolytic crises.

B. Conjugated Hyperbilirubinemia

1. Hereditary cholestatic syndromes or intrahepatic cholestasis—The patient may be asymptomatic; intermittent cholestasis is often accompanied by pruritus, light-colored stools, and, occasionally, malaise.

2. Hepatocellular disease—Malaise, anorexia, low-grade fever, and right upper quadrant discomfort are frequent. Dark urine, jaundice, and, in women, amenorrhea occur. An enlarged tender liver, vascular spiders, palmar erythema, ascites, gynecomastia, sparse body hair, fetor hepaticus, and asterixis may be present, depending on the cause, severity, and chronicity of liver dysfunction.

C. Biliary Obstruction

There may be right upper quadrant pain, weight loss (suggesting carcinoma), jaundice, dark urine, and light-colored stools. Symptoms and signs may be intermittent if caused by stone, carcinoma of the ampulla, or cholangiocarcinoma. Pain may be absent early in pancreatic cancer. Occult blood in the stools suggests cancer of the ampulla. Hepatomegaly and a palpable gallbladder (Courvoisier's sign) are characteristic, but neither specific nor sensitive of pancreatic head tumor. Fever and chills are far more common in benign obstruction and associated cholangitis.

Diagnostic Methods for Evaluation of Liver Disease & Jaundice ([Table 15-3](#))

A. Laboratory Studies

Elevated serum aspartate and alanine aminotransferase levels (AST, ALT) result from hepatocellular necrosis or inflammation, as in hepatitis; ALT is more specific for the liver than AST, but an AST level at least twice that of the ALT is typical of alcoholic liver injury. In contrast, the ALT level is greater than the AST level in nonalcoholic fatty liver disease prior to the development of cirrhosis. In addition to signaling underlying liver disease, an isolated elevation of the serum ALT level may be the only clue to the diagnosis of celiac disease. Elevated alkaline phosphatase levels are seen in cholestasis or infiltrative liver disease (such as tumor or granuloma). Alkaline phosphatase elevations of hepatic rather than bone, intestinal, or placental origin are confirmed by concomitant elevation of γ -glutamyl transpeptidase or 5'-nucleotidase levels. The differential diagnosis of any liver test elevation includes toxicity caused by drugs, herbal remedies, and toxins.

B. Liver Biopsy

Percutaneous liver biopsy is the definitive study for determining the cause and histologic severity of hepatocellular dysfunction or infiltrative liver disease. In patients with suspected metastatic disease or a hepatic mass, it is performed under ultrasound or CT guidance. A transjugular route can be used in patients with coagulopathy or ascites.

C. Imaging

Demonstration of dilated bile ducts by ultrasonography or CT scan indicates biliary obstruction (90-95% sensitivity). Ultrasonography, CT scan, and MRI may also demonstrate hepatomegaly, intrahepatic tumors, and portal hypertension. Spiral arterial-phase and multislice CT scanning, in which the liver is imaged during peak hepatic enhancement while the patient holds one or two breaths, improves diagnostic accuracy. Dual-phase or triphasic spiral or multislice CT, CT arterial portography, in which imaging follows intravenous contrast infusion via a catheter placed in the superior mesenteric artery, MRI with use of ferumoxides as contrast agents, and intraoperative ultrasonography are the most sensitive techniques for detection of individual small hepatic lesions in patients eligible for resection of metastases. Use of color Doppler ultrasound or contrast agents that produce microbubbles increases the sensitivity of transcutaneous ultrasound for detecting small neoplasms. MRI is the most accurate technique for identifying isolated liver lesions such as hemangiomas, focal nodular hyperplasia, or focal fatty infiltration and for detecting hepatic iron overload. Because of its much lower cost, ultrasonography (\$350) is preferable to CT (\$1200-\$1400) or MRI (\$2000) as a screening test. Ultrasonography can detect gallstones with a sensitivity of 95%.

Endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography (PTC) identifies the cause, location, and extent of biliary obstruction. Magnetic resonance cholangiopancreatography (MRCP) appears to be a sensitive, noninvasive method of detecting bile duct stones, strictures, and dilation. ERCP requires a skilled endoscopist and may be utilized to demonstrate pancreatic or ampullary causes of jaundice, to carry out papillotomy and stone extraction, or to insert a stent through an obstructing lesion. Complications of ERCP include pancreatitis (5%) and, less commonly, cholangitis, bleeding, or duodenal perforation after papillotomy. Severe complications of PTC occur in 3% and include fever, bacteremia, bile peritonitis, and intraperitoneal hemorrhage. Endoscopic ultrasonography is the most sensitive test for detecting small lesions of the ampulla or pancreatic head and for detecting portal vein invasion by pancreatic cancer. It is also accurate in detecting or excluding bile duct stones.

■ DISEASES OF THE LIVER

VIRAL HEPATITIS

Essentials of Diagnosis

- Prodrome of anorexia, nausea, vomiting, malaise, aversion to smoking.
- Fever, enlarged and tender liver, jaundice.
- Normal to low white cell count; abnormal liver tests, especially markedly elevated aminotransferases early in the course.
- Liver biopsy shows hepatocellular necrosis and mononuclear infiltrate but is rarely indicated.

General Considerations

Hepatitis can be caused by many drugs and toxic agents as well as by numerous viruses, the clinical manifestations of which may be quite similar. Viruses causing hepatitis are (1) hepatitis A virus (HAV), (2) hepatitis B virus (HBV), (3) hepatitis C virus (HCV), (4) hepatitis D virus (delta agent), and (5) hepatitis E virus (an enterically transmitted hepatitis seen in epidemic form in Asia, North Africa, and Mexico). The designation hepatitis G virus (HGV) applies to an agent that rarely, if ever, causes frank hepatitis. A DNA virus designated the TT virus (TTV) has been identified in up to 7.5% of blood donors and found to be transmitted readily by blood transfusions, but an association between this virus and liver disease has not been established. A related virus known as SEN-V has been found in 2% of United States blood donors, is transmitted by transfusion, and may account for some cases of transfusion-associated non-ABCDE hepatitis. In immunocompromised and rare immunocompetent hosts, cytomegalovirus, Epstein-Barr virus, and herpes simplex virus should be considered in the differential diagnosis of hepatitis. As yet unidentified agents account for a small percentage of cases of apparent acute viral hepatitis.

A. Hepatitis A

([Figure 15-1](#)) HAV is a 27-nm RNA hepatovirus (in the picornavirus family) causing epidemics or sporadic cases of hepatitis. Transmission is by the fecal-oral route, and spread is favored by crowding and poor sanitation. Common source outbreaks result from contaminated water or food. The incubation period averages 30 days. Hepatitis A virus is excreted in feces for up to 2 weeks before clinical illness but rarely after the first week of illness. The mortality rate for hepatitis A is low, and fulminant hepatitis A is uncommon save for rare instances in which it occurs in a patient with chronic hepatitis C. Chronic hepatitis A does not occur, and there is no carrier state. Clinical illness is more severe in adults than in children, in whom it is typically asymptomatic. It is the only viral hepatitis causing spiking fevers.

Antibody to hepatitis A (anti-HAV) appears early in the course of the illness. Both IgM and IgG anti-HAV are detectable in serum soon after the onset. Peak titers of IgM anti-HAV occur during the first week of clinical disease and disappear within 3-6 months. Detection of IgM anti-HAV is an excellent test for diagnosing acute hepatitis A. Titers of IgG anti-HAV peak after 1 month of the disease and may persist for years. IgG anti-HAV indicates previous exposure to HAV, noninfectivity, and immunity. In the United States, about 30% of the population have serologic evidence of previous infection.

B. Hepatitis B

([Figure 15-2](#)) Hepatitis B virus (HBV) is a 42-nm hepadnavirus with a partially double-stranded DNA genome, inner core protein (hepatitis B core antigen, HBcAg) and outer surface coat (hepatitis B surface antigen, HBsAg). There are seven different genotypes. HBV is usually transmitted by inoculation of infected blood or blood products or by sexual contact and is present in saliva, semen, and vaginal secretions. HBsAg-positive mothers may transmit HBV at delivery; the risk of chronic infection in the infant is as high as 90%.

Hepatitis B virus (HBV) is prevalent in homosexuals and intravenous drug users, but the greatest number of cases result from heterosexual transmission; the incidence has decreased by 75% since the 1980s. Groups at risk include patients and staff at hemodialysis centers, physicians, dentists, nurses, and personnel working in clinical and pathology laboratories and blood banks. The risk of HBV infection from a blood transfusion is less than one in 60,000 units transfused in the United States. The incubation period of hepatitis B is 6 weeks to 6 months (average 12-14 weeks).

The onset of hepatitis B is more insidious and the aminotransferase levels higher than in HAV infection. The risk of fulminant hepatitis is less than 1%, with a mortality rate of up to 60%. Following acute hepatitis B, HBV infection persists in 1-2% of immunocompetent adults but in a higher percentage of immunocompromised adults or children. Persons with chronic hepatitis B, particularly when HBV infection is acquired early in life and viral replication persists, are at substantial risk of cirrhosis and hepatocellular carcinoma (up to 25-40%). Men are more at risk. Infection caused by HBV may be associated with serum sickness, glomerulonephritis, and polyarteritis nodosa.

There are three distinct antigen-antibody systems that relate to HBV infection and circulating markers that are useful in diagnosis. Interpretation of common serologic patterns is shown in [Table 15-4](#).

1. HBsAg—The appearance of HBsAg is the first evidence of infection, appearing before biochemical evidence of liver disease, and persists throughout the clinical illness. Persistence of HBsAg after the acute illness may be associated with clinical and laboratory evidence of chronic hepatitis for variable periods of time. The detection of HBsAg establishes infection with HBV and implies infectivity.

2. Anti-HBs—Specific antibody to HBsAg (anti-HBs) appears in most individuals after clearance of HBsAg and after successful vaccination against hepatitis B. Disappearance of HBsAg and the appearance of anti-HBs signals recovery from HBV infection, noninfectivity, and immunity.

3. Anti-HBc—IgM anti-HBc appears shortly after HBsAg is detected. (HBcAg alone does not appear in serum.) Its presence in the setting of acute hepatitis indicates a diagnosis of acute hepatitis B, and it fills the serologic gap in patients who have cleared HBsAg but do not yet have detectable anti-HBs. IgM anti-HBc can persist for 3-6 months or more. IgM anti-HBc may also reappear during flares of previously inactive chronic hepatitis B. IgG anti-HBc also appears during acute hepatitis B but persists indefinitely, whether the patient recovers (with the appearance of anti-HBs in serum) or develops chronic hepatitis B (with persistence of HBsAg). In asymptomatic blood donors, an isolated anti-HBc with no other positive HBV serologic results may represent a falsely positive result or latent infection in which HBV DNA is detectable only by polymerase chain reaction testing.

4. HBeAg—HBeAg is a soluble protein found only in HBsAg-positive serum. It is a secretory form of HBcAg appearing during the incubation period shortly after the detection of HBsAg. HBeAg indicates viral replication and infectivity. Persistence of HBeAg in serum beyond 3 months indicates an increased likelihood of chronic hepatitis B. Its disappearance is often followed by the appearance of anti-HBe, signifying diminished viral replication and decreased infectivity.

5. HBV DNA—The presence of HBV DNA in serum generally parallels the presence of HBeAg, though HBV DNA is a more sensitive and precise marker of viral replication and infectivity. Very low levels of HBV DNA, detectable only by PCR, may persist in serum after a patient has recovered from acute hepatitis B, but the HBV DNA is bound to IgG and rarely infectious. In some patients with chronic hepatitis B, HBV DNA is present at high levels without HBeAg in serum because of a mutation that prevents synthesis of HBeAg in infected hepatocytes. This "pre-core mutant" appears during the course of chronic wild-type HBV infection, presumably as a result of immune pressure. When additional mutations in the core gene are present, the pre-core mutant enhances the severity of HBV and increases the risk of cirrhosis.

C. Hepatitis D (Delta Agent)

Hepatitis D virus (HDV) is a defective RNA virus that causes hepatitis only in association with hepatitis B infection and specifically only in the presence of HBsAg; it is cleared when the latter is cleared.

HDV may co-infect with HBV or may superinfect a person with chronic hepatitis B, usually by percutaneous exposure. When acute hepatitis D is coincident with acute HBV infection, the infection is generally similar in severity to acute hepatitis B alone. In chronic hepatitis B, superinfection by HDV appears to carry a worse short-term prognosis, often resulting in fulminant hepatitis or severe chronic hepatitis that progresses rapidly to cirrhosis. In the 1970s and early 1980s, HDV was endemic in some areas, such as the Mediterranean countries, where up to 80% of HBV carriers were superinfected with it. In the United States, HDV occurred primarily among intravenous drug users. However, new cases of hepatitis D are now infrequent, and cases seen today are usually from cohorts infected years ago who survived the initial impact of hepatitis D and now have inactive cirrhosis. These patients have a threefold increased risk of hepatocellular carcinoma. Diagnosis is made by detection of antibody to hepatitis D antigen (anti-HDV) or, where available, HDV RNA in serum.

Hepatitis D is best prevented by prevention of hepatitis B (eg, with HBV vaccine).

D. Hepatitis C (HCV)

([Figure 15-3](#)) The hepatitis C virus is a single-stranded RNA virus (hepacivirus) with properties similar to those of flavivirus. At least six major genotypes of HCV have been identified. In the past, HCV was responsible for over 90% of cases of posttransfusion hepatitis, yet only 4% of cases of hepatitis C were attributable to blood transfusions. Over 50% of cases are transmitted by intravenous drug use. Intranasal cocaine use and body piercing also are risk factors. The risk of sexual and maternal-neonatal transmission is low and may be greatest in a subset of patients with high circulating levels of HCV RNA. Having multiple sexual partners may increase the risk of HCV infection. Transmission via breast feeding has not been documented. An outbreak of hepatitis C in patients with immune deficiencies occurred in some recipients of intravenous immune globulin, and nosocomial transmission via multidose vials of saline used to flush Portacaths has occurred. Coinfection with HCV is found in 30-50% of persons infected with HIV; HIV infection leads to more rapid progression of chronic hepatitis C to cirrhosis. Covert transmission during bloody fisticuffs has even been reported. In many patients, the source of infection is unknown. There are more than 2.7 million HCV carriers in the United States and another 1.3 million previously exposed persons who have cleared the virus.

The incubation period averages 6-7 weeks, and clinical illness is often mild, usually asymptomatic, and characterized by waxing and waning aminotransferase elevations and a high rate (> 80%) of chronic hepatitis. In pregnant patients, serum aminotransferase levels frequently normalize despite persistence of viremia, only to increase again after delivery. HCV is a pathogenetic factor in cryoglobulinemia and membranoproliferative glomerulonephritis and may be related to lichen planus, autoimmune thyroiditis, lymphocytic sialadenitis, idiopathic pulmonary fibrosis, sporadic porphyria cutanea tarda, monoclonal gammopathies, and probably lymphoma. The risk of type 2 diabetes mellitus may be increased in persons with chronic hepatitis C. Hepatic steatosis is a particular feature of infection with HCV genotype 3.

Diagnosis of hepatitis C is based on an enzyme immunoassay that detects antibodies to HCV. Anti-HCV is not protective, and in patients with acute or chronic hepatitis its presence in serum generally signifies that HCV is the cause. Limitations of the enzyme immunoassay include moderate sensitivity (false-negatives) for the diagnosis

of acute hepatitis C early in the course and in healthy blood donors and low specificity (false-positives) in some persons with elevated gamma globulin levels. In these situations, a diagnosis of hepatitis C may be confirmed by use of an assay for HCV RNA and, in some cases, a supplemental recombinant immunoblot assay (RIBA) for anti-HCV. Most RIBA-positive persons are potentially infectious, as confirmed by use of polymerase chain reaction-based tests to detect HCV RNA. Occasional persons are found to have anti-HCV in serum, confirmed by RIBA, without HCV RNA in serum, suggesting recovery from HCV infection in the past. Testing of donated blood for HCV has helped reduce the risk of transfusion-associated hepatitis C from 10% a decade ago to about one case per 2 million units today.

E. Hepatitis E (HEV)

HEV is a 29- to 32-nm RNA virus similar to calicivirus and responsible for waterborne hepatitis outbreaks in India, Burma, Afghanistan, Algeria, and Mexico. It is rare in the United States but should be considered in patients with acute hepatitis after a trip to an endemic area. Illness is self-limited (no carrier state), with a high mortality rate (10-20%) in pregnant women and an increased risk of hepatic decompensation in patients with underlying chronic liver disease.

F. Hepatitis G

The designation hepatitis G virus (HGV) has been applied to a flavivirus that is percutaneously transmitted and associated with chronic viremia lasting at least 10 years. HGV has been detected in 1.5% of blood donors, 50% of intravenous drug users, 30% of hemodialysis patients, 20% of hemophiliacs, and 15% of patients with chronic hepatitis B or C, but it does not appear to cause important liver disease or affect the response of patients with chronic hepatitis B or C to antiviral therapy. HGV coinfection may improve survival in patients with HIV infection.

Clinical Findings

The clinical picture of viral hepatitis is extremely variable, ranging from asymptomatic infection without jaundice to a fulminating disease and death in a few days.

A. Symptoms

1. Prodromal phase—The onset may be abrupt or insidious, with general malaise, myalgia, arthralgia, easy fatigability, upper respiratory symptoms, and anorexia. A distaste for smoking, paralleling anorexia, may occur early. Nausea and vomiting are frequent, and diarrhea or constipation may occur. Serum sickness may be seen early in acute hepatitis B. Fever is generally present but is low-grade save in occasional cases of hepatitis A. Defervescence and a fall in pulse rate often coincide with the onset of jaundice.

Abdominal pain is usually mild and constant in the right upper quadrant or epigastrium, often aggravated by jarring or exertion, and rarely may be severe enough to simulate cholecystitis.

2. Icteric phase—Jaundice occurs after 5-10 days but may appear at the same time as the initial symptomatology. Many never develop it. With the onset of jaundice, there is often worsening of the prodromal symptoms, followed by progressive clinical improvement.

3. Convalescent phase—There is an increasing sense of well-being, return of appetite, and disappearance of jaundice, abdominal pain and tenderness, and fatigability.

4. Course and complications—The acute illness usually subsides over 2-3 weeks with complete clinical and laboratory recovery by 9 weeks in hepatitis A and by 16 weeks in hepatitis B. In 5-10% of cases, the course may be more protracted, but less than 1% will have a fulminant course. In some cases of acute hepatitis A, clinical, biochemical, and serologic recovery may be followed by one or two relapses, but recovery is the rule. A protracted course of hepatitis A has been reported to be associated with HLA *DRB1*1301*. Hepatitis B, D, and C (and G) may become chronic (see below).

B. Signs

Hepatomegaly—rarely marked—is present in over half of cases. Liver tenderness is usually present. Splenomegaly is reported in 15% of patients, and soft, enlarged lymph nodes—especially in the cervical or epitrochlear areas—may occur. Systemic toxicity is most often encountered in hepatitis A. Slight neurocognitive impairment has been described in patients with chronic hepatitis C.

C. Laboratory Findings

The white blood cell count is normal to low, especially in the preicteric phase. Large atypical lymphocytes may occasionally be seen. Rarely, aplastic anemia follows an episode of acute hepatitis not caused by any of the known hepatitis viruses. Mild proteinuria is common, and bilirubinuria often precedes the appearance of jaundice. Acholic stools are often present during the icteric phase. Strikingly elevated AST or ALT occurs early, followed by elevations of bilirubin and alkaline phosphatase; in a minority of patients, the latter persist after aminotransferase levels have normalized. Cholestasis is occasionally marked in acute hepatitis A. Marked prolongation of the prothrombin time in severe hepatitis correlates with increased mortality.

Differential Diagnosis

The differential diagnosis includes other viral diseases such as infectious mononucleosis, cytomegalovirus infection, and herpes simplex virus infection; spirochetal diseases such as leptospirosis and secondary syphilis; brucellosis; rickettsial diseases such as Q fever; drug-induced liver disease; and shock liver (ischemic hepatitis). Occasionally, autoimmune hepatitis (see below) may have an acute onset mimicking acute viral hepatitis. Rarely, metastatic cancer of the liver may present with a hepatitis-like picture.

The prodromal phase of viral hepatitis must be distinguished from other infectious disease such as influenza, upper respiratory infections, and the prodromal stages of the exanthematous diseases. Cholestasis may mimic obstructive jaundice.

Prevention

Strict isolation of patients is not necessary, but hand washing after bowel movements is required. Thorough hand washing by medical staff who may contact contaminated utensils, bedding, or clothing is essential. Careful handling of disposable needles—including not recapping used needles—is routine for medical personnel. Screening of donated blood for HBsAg, anti-HBc, and anti-HCV has reduced the risk of transfusion-associated hepatitis markedly. All pregnant women should undergo testing for HBsAg. HBV- and HCV-infected persons should practice safe sex, but there is little evidence that HCV is spread easily by sexual contact. Vaccination against HAV (after prescreening for prior immunity) and HBV is recommended for patients with chronic hepatitis C, and vaccination against HAV is recommended for patients with chronic hepatitis B.

A. Hepatitis A

Immune globulin should be given to all *close* (eg, household) personal contacts of patients with hepatitis A. The recommended dose of 0.02 mL/kg intramuscularly is protective if administered during incubation. Two effective inactivated hepatitis A vaccines are available and recommended for persons living in or traveling to endemic areas (including military personnel), patients with chronic liver disease upon diagnosis, persons with clotting-factor disorders who are treated with concentrates, homosexual and bisexual men, animal handlers, illicit drug users, sewage workers, food handlers, and children and caregivers in day care centers and institutions. Routine vaccination of all children has been recommended in states with a high incidence of hepatitis A. HAV vaccine is also effective in the prevention of secondary spread to household contacts of primary cases. The recommended dose for adults is 1 mL (1440 ELISA units) of Havrix (GlaxoSmithKline) or 0.5 mL (50 units) of Vaqta (Merck) intramuscularly, followed by a booster dose at 6-12 months. A combined hepatitis A and B vaccine (Twinrix, GlaxoSmithKline) is available.

B. Hepatitis B

Hepatitis B immune globulin (HBIG) may be protective—or may attenuate the severity of illness—if given in large doses within 7 days after exposure (adult dose is 0.06 mL/kg body weight) followed by initiation of the HBV vaccine series (see below). This approach is currently recommended for individuals exposed to hepatitis B surface antigen-contaminated material via mucous membranes or through breaks in the skin and for individuals who have had sexual contact with persons with HBV infection. HBIG is also indicated for newborn infants of HBsAg-positive mothers followed by initiation of the vaccine series (see below).

The currently used vaccines are recombinant-derived. Initially, the vaccine was targeted to persons at high risk, including renal dialysis patients and attending personnel, patients requiring repeated transfusions, spouses of HBsAg-positive individuals, men who have sex with men, intravenous drug users, newborns of HBsAg-positive mothers, beginning medical and nursing students, and all medical technologists. Because this strategy failed to lower the incidence of hepatitis B, the CDC recommended universal vaccination of infants and children in the United States. Over 90% of recipients of the vaccine mount protective antibody to hepatitis B; immunocompromised persons respond poorly. The standard regimen for adults is 10-20 ug initially (depending on the formulation) repeated again at 1 and 6 months, but alternative schedules have been approved. For greatest reliability of absorption, the deltoid muscle is the preferred site. Vaccine formulations free of the mercury-containing preservative thimerosal are given in infants less than 6 months of age. When documentation of seroconversion is considered desirable, postimmunization anti-HBs titers may be checked. Protection appears to be excellent even if the titer wanes—at least for 15 years—and booster reimmunization is not routinely recommended but is advised for immunocompromised persons in whom anti-HBs titers fall below 10 mIU/mL. For vaccine nonresponders, three additional vaccine doses may elicit seroprotective anti-HBs levels in 30-50% of persons. Universal vaccination of neonates in countries endemic for HBV reduces the incidence of hepatocellular carcinoma.

Treatment

Bed rest is recommended only if symptoms are marked. If nausea and vomiting are pronounced or if oral intake is substantially decreased, intravenous 10% glucose is indicated. Encephalopathy or severe coagulopathy indicates impending acute hepatic failure, and hospitalization is mandatory (see below).

Dietary management consists of palatable meals as tolerated, without overfeeding; breakfast is usually best tolerated. Strenuous physical exertion, alcohol, and hepatotoxic agents are avoided. Small doses of oxazepam are safe, as metabolism is not hepatic; morphine sulfate is avoided.

Corticosteroids have no benefit in patients with viral hepatitis, including those with fulminant disease. Treatment of acute hepatitis C patients with interferon alfa for 6-24 weeks appreciably decreases the risk of chronic hepatitis. Because 20% of patients with acute hepatitis C clear the virus without such treatment, reserving it for patients in whom serum HCV RNA levels fail to clear after 1-2 months may be advisable.

Prognosis

In the majority, clinical recovery is complete in 3-6 weeks. Laboratory evidence of liver dysfunction may persist for a longer period, but most patients recover completely. The overall mortality rate is less than 1%, but the rate is reportedly higher in older people.

Hepatitis A does not cause chronic liver disease, though it may persist for up to 1 year, and clinical and biochemical relapses may occur before full recovery. The mortality rate is less than 0.2%. The mortality rate for acute hepatitis B is 0.1-1%, but higher with superimposed hepatitis D. Fulminant hepatitis C is rare in the United States. For unknown reasons, the mortality rate for hepatitis E is especially high in pregnant women (10-20%).

Chronic hepatitis, characterized by elevated aminotransferase levels for more than 6 months, develops in 1-2% of immunocompetent adults with acute hepatitis B but in as many as 90% of infected neonates and infants and a substantial proportion of immunocompromised adults. As many as 80% of all persons with acute hepatitis C develop chronic hepatitis, which in many cases progresses very slowly. Ultimately, cirrhosis develops in up to 30% of those with chronic hepatitis C and 40% of those with chronic hepatitis B; the risk of cirrhosis is even higher in patients coinfecting with both viruses or with HIV. Patients with cirrhosis are at risk of hepatocellular carcinoma at a rate of 3-5% per year. Even in the absence of cirrhosis, patients with chronic hepatitis B—particularly those with active viral replication—are at increased risk.

ACUTE HEPATIC FAILURE

Acute hepatic failure may be fulminant or subfulminant. Fulminant hepatic failure is characterized by the development of hepatic encephalopathy within 8 weeks after the onset of acute liver disease. Coagulopathy is invariably present. Subfulminant hepatic failure occurs when these findings appear between 8 weeks and 6 months after the onset of acute liver disease and carries an equally poor prognosis.

Acetaminophen toxicity is now the most common cause of acute hepatic failure in the United States, as it has been in England for some time, accounting for up to 40% of cases. Other causes include idiosyncratic drug reactions (now the second most common cause), viral hepatitis, poisonous mushrooms, shock, hyper- or hypothermia, Budd-Chiari syndrome, malignancy (most commonly lymphomas), Wilson's disease, Reye's syndrome, fatty liver of pregnancy and other disorders of fatty acid oxidation, and parvovirus B19 infection.

Until recently, about 70% of all cases of acute hepatic failure in the United States were caused by acute viral hepatitis, with up to 50% of cases due to hepatitis B—in some cases detectable only by polymerase chain reaction (PCR) methodology—and most of the remainder due to hepatitis A or unknown (non-ABCDE) viruses. In endemic areas, hepatitis D and hepatitis E cause acute hepatic failure. Hepatitis C appears to be a rare cause of acute hepatic failure in the United States, but acute hepatitis A or B superimposed on chronic hepatitis C is associated with a high risk of fulminant hepatitis.

In acute hepatic failure due to hepatitis or drug toxicity, extensive necrosis of large areas of the liver gives a typical pathologic picture of acute liver atrophy. A systemic inflammatory response, gastrointestinal symptoms, and hemorrhagic phenomena are common. Jaundice may be absent or minimal early, but laboratory tests show severe hepatocellular damage. In acute hepatic failure due to microvesicular steatosis (eg, Reye's syndrome), serum aminotransferase elevations may be modest (< 300 units/L).

The treatment of acute hepatic failure is directed toward correcting metabolic abnormalities. These include coagulation defects, electrolyte and acid-base disturbances, renal failure, hypoglycemia, and encephalopathy. Prophylactic antibiotic therapy decreases the risk of infection, observed in up to 90%, but has no effect on survival and is not routinely recommended. For suspected sepsis, broad coverage is indicated. Early administration of acetylcysteine (140 mg/kg orally followed by 70 mg/kg orally every 4 hours for an additional 17 doses) is indicated for acetaminophen toxicity and improves cerebral blood flow and oxygenation in patients with fulminant hepatic failure due to any cause. (Acetylcysteine treatment can prolong the prothrombin time, leading to the erroneous assumption that liver failure is worsening.) Early transfer to a liver transplantation center is essential. Extradural sensors are placed to monitor intracranial pressure for impending cerebral edema.

Mannitol, 100-200 mL of a 20% solution by intravenous infusion over 10 minutes, may decrease cerebral edema but should be used with caution in patients with renal failure. The value of hyperventilation, intravenous prostaglandin E₁, and hypothermia is uncertain. Indeed, patients may already be hypothermic. Hepatic-assist devices using living hepatocytes, extracorporeal whole liver perfusion, hepatocyte transplantation, and liver xenografts have shown promise experimentally. The artificial system undergoing the most extensive evaluation in the United States is the Molecular Adsorbents Recirculating System (MARS), which is based on extracorporeal albumin dialysis. The mortality rate of fulminant hepatitis with severe encephalopathy is as high as 80%. The outlook is especially poor in patients younger than 10 and older than 40 years of age and in those with an idiosyncratic drug reaction. Other adverse prognostic factors are a serum bilirubin level > 18 mg/dL, INR > 6.5, onset of encephalopathy more than 7 days after the onset of jaundice, and a low factor V level (< 20% of normal). For acetaminophen-induced fulminant hepatic failure, indicators of a poor outcome (which is less common than for other causes) are acidosis (pH < 7.3), INR > 6.5, and azotemia (serum creatinine = 3.4 mg/dL). Hyperphosphatemia (> 1.2 mmol/L) and an elevated blood lactate level (> 3.5 mmol/L) also predict poor survival outcomes. Emergency liver transplantation is considered for patients with stage II to stage III encephalopathy and is associated with an 80% survival rate at 1 year. Compared with chronic hepatitis B, liver transplantation for fulminant hepatitis B is less likely to result in reinfection of the graft with HBV.

CHRONIC VIRAL HEPATITIS

Chronic hepatitis is defined as a chronic inflammatory reaction of the liver of more than 3-6 months' duration, demonstrated by persistently abnormal serum aminotransferase levels and characteristic histologic findings. In many cases, the diagnosis of chronic hepatitis may be made on initial presentation. The causes of chronic hepatitis include HBV, HCV, and HDV as well as autoimmune hepatitis, chronic hepatitis associated with certain medications (particularly isoniazid), Wilson's

disease, and α_1 -antiprotease deficiency. Traditionally, chronic hepatitis has been categorized histologically as chronic persistent hepatitis and chronic active hepatitis. However, with improved serologic and autoimmune markers, more specific categorization is possible, based on etiology; the grade of portal, periportal, and lobular inflammation (minimal, mild, moderate, or severe); and the stage of fibrosis (none, mild, moderate, severe, cirrhosis).

Clinical Findings & Diagnosis

A. Chronic Hepatitis B

Chronic hepatitis B afflicts nearly 400 million people worldwide and 1.25 million (predominantly males) in the United States. It may be noted as a continuum of acute hepatitis or diagnosed because of persistently elevated aminotransferase levels.

Early in the course, HBeAg and HBV DNA are present in serum, indicative of active viral replications and necroinflammatory activity in the liver. These persons are at risk for progression to cirrhosis and for hepatocellular carcinoma. Low-level IgM anti-HBc is also present in about 70%. In some patients, clinical and biochemical improvement coincides with disappearance of HBeAg and HBV DNA from serum, appearance of anti-HBe, and integration of the HBV genome into the host genome in infected hepatocytes. If cirrhosis has not yet developed, such persons are at a lower risk for cirrhosis and hepatocellular carcinoma. As noted, infection by a pre-core mutant of HBV or spontaneous mutation of the pre-core or pre-core promoter region of the HBV genome during the course of chronic hepatitis caused by wild-type HBV may result in particularly severe chronic hepatitis with rapid progression to cirrhosis, particularly when additional mutations in the core gene of HBV are present. HIV coinfection is also associated with an increased frequency of cirrhosis when the CD4 count is low.

B. Hepatitis D

Acute hepatitis D infection superimposed on chronic HBV infection may result in severe chronic hepatitis, which may progress rapidly to cirrhosis and may be fatal. Patients with long-standing chronic hepatitis D and B often have inactive cirrhosis. The diagnosis is confirmed by detection of anti-HDV in serum.

C. Chronic Hepatitis C

Up to 80% of patients with acute hepatitis C develop chronic hepatitis C. It is clinically indistinguishable from chronic hepatitis due to other causes and may be the most common. In approximately 40% of cases, serum aminotransferase levels are persistently normal. The diagnosis is confirmed by detection of anti-HCV by enzyme immunoassay (EIA). In rare cases of suspected chronic hepatitis C but a negative EIA, HCV RNA is detected by PCR. Progression to cirrhosis occurs in 20% of affected patients after 20 years, with an increased risk in men, those who drink more than 50 g of alcohol daily, and possibly those who acquire HCV infection after age 40. Immunosuppressed persons—including patients with hypogammaglobulinemia, HIV infection with a low CD4 count, or organ transplants receiving immunosuppressants—appear to progress more rapidly to cirrhosis than immunocompetent persons with chronic hepatitis C. Affected persons with persistently normal serum aminotransferase levels usually have mild chronic hepatitis with slow or absent progression to cirrhosis; however, cirrhosis is present in 10% of these patients.

Treatment

A. Chronic Hepatitis B

Patients with active viral replication (HBeAg and HBV DNA in serum; elevated aminotransferase levels) may be treated with recombinant human interferon alfa-2b in a dose of 5 million units a day or 10 million units three times a week intramuscularly for 4 months. About 40% of treated patients will respond with sustained normalization of aminotransferase levels, disappearance of HBeAg and HBV DNA from serum, appearance of anti-HBe, and improved survival. A response is most likely in patients with an HBV DNA level under 200 pg/mL and high aminotransferase levels. Moreover, over 60% of these responders may eventually clear HBsAg from serum and liver, develop anti-HBs in serum, and thus be cured. Relapses are uncommon in such complete responders. Patients with HBeAg-negative chronic hepatitis B (pre-core mutant) have a durable sustained response rate of only 15-25% after 12 months of interferon therapy. The response to interferon is poor in patients with HIV coinfection.

The nucleoside analog lamivudine, 100 mg orally daily as a single dose, may be used instead of interferon for the treatment of chronic hepatitis B and is much better tolerated. This agent reliably suppresses HBV DNA in serum, improves liver histology in 60% of patients, and leads to normal ALT levels in over 40% and HBeAg seroconversion in 20% of patients after 1 year of therapy. However, 15-30% of responders experience a generally mild relapse during treatment as a result of mutation in the polymerase gene of HBV DNA that confers resistance to lamivudine. Moreover, hepatitis activity may recur when the drug is stopped, and long-term, perhaps indefinite treatment despite a high rate of resistance over time may be required to suppress the disease when HBeAg seroconversion does not ensue. Rates of complete response—as well as resistance to lamivudine—increase with increasing duration of therapy. The drug is well tolerated even in patients with decompensated cirrhosis and may be effective in patients with rapidly progressive hepatitis B ("fibrosing cholestatic hepatitis") following organ transplantation. Although lamivudine therapy leads to biochemical, virologic, and histologic improvement in patients with HBeAg-negative chronic hepatitis B (pre-core mutant), relapse is frequent when therapy is stopped, and long-term treatment is associated with a high rate of viral resistance. Combined use of interferon and lamivudine offers no advantage over the use of either drug alone.

A nucleotide analog, adefovir dipivoxil, has activity against wild-type and lamivudine-resistant HBV. The standard dose is 10 mg orally once a day. Resistance to this drug has not been reported. Patients with underlying renal dysfunction are at risk of nephrotoxicity from adefovir. Tenofovir, a drug used for HIV infection, also has activity against HBV. Other antiviral agents such as emtricitabine and entecavir are under study, and strategies employing multiple drugs are likely to be studied. Nucleoside analogs are now also recommended for inactive HBV carriers prior to the initiation of immunosuppressive therapy or cancer chemotherapy to prevent reactivation.

Recombinant interferon alfa-2a (9 million units three times a week for 48 weeks) may lead to normalization of serum aminotransferase levels, histologic improvement, and elimination of HDV RNA from serum in about 50% of patients with chronic hepatitis D, but relapse is common after therapy is stopped. Lamivudine and adefovir are not effective in chronic hepatitis D.

B. Chronic Hepatitis C

Treatment of chronic hepatitis C is generally considered in patients under age 70 with more than minimal fibrosis on liver biopsy. Because of high response rates to treatment in patients infected with HCV genotype 2 or 3, treatment may be initiated in these patients without a liver biopsy. Until recently, standard therapy was with a combination of interferon alfa and ribavirin. A combination of "pegylated" interferon (peginterferon) and ribavirin is now standard therapy.

Recombinant human interferon alfa-2b or alfa-2a in a dose of 3 million units three times a week for 24 weeks and "consensus" interferon (a synthetic recombinant interferon derived by assigning the most commonly observed amino acid at each position of several alpha interferon subtypes) in a dose of 9 mg three times a week were previously shown to induce biochemical, virologic, and histologic improvement in up to 50% of patients—return of ALT to normal, loss of HCV RNA from serum for at least 6 months after therapy is stopped, decrease in hepatic inflammation, and occasionally regression of fibrosis. Factors predicting an increased chance of response include the absence of cirrhosis on liver biopsy (though treatment is not contraindicated by compensated cirrhosis), low serum HCV RNA levels as assessed by quantitative assays, and infection by genotypes of HCV other than 1a, 1b, or 4. After stopping the medication at 24 weeks, only 30-50% of the treated responders maintained the improvement. More prolonged treatment (eg, for 12-18 months) was shown to increase the durability of remission. The use of higher doses of interferon alfa-2b (eg, 6 million units three times a week) increases toxicity and does not appear to increase the rate of sustained responses substantially. Response rates among blacks appear to be lower than those among whites, in part because of a higher rate of genotype 1 among infected black patients.

Slow-release, long-acting pegylated interferon (pegin-terferon) taken only once a week is more effective than standard interferon—presumably because of sustained high blood levels—and is now the preferred form of interferon for treatment of chronic hepatitis C. Two formulations are available: Pegintron (peginterferon alfa-2b), with a 12-kD polyethylene glycol (PEG), and Pegasys (peginterferon alfa-2a), with a 40-kD PEG. Whether there are clinically important differences between the two formulations is unclear. With peginterferon alfa-2a administered in a dose of 180 mg once per week for 48 weeks, a sustained biochemical and virologic response was achieved in 38% of patients with chronic hepatitis C compared with 17% of those treated with standard interferon. Peginterferon alfa-2b yields similar results but is given according to the patient's weight in a dose of 1.5 mg/kg weekly.

Addition of the nucleoside analog ribavirin, 1000-1200 mg daily in two divided doses, results in higher sustained response rates than interferon or peginterferon alone in previously untreated patients with chronic hepatitis C or patients who have had a relapse after an initial response to interferon alfa alone. Long-term response rates are 40% and 50%, respectively, following combination therapy consisting of standard interferon and ribavirin. Rates with a combination of peginterferon and ribavirin are as high as 55% (and up to 80% for HCV genotypes 2 or 3). For nonresponders to standard interferon and ribavirin, sustained response rates to re-treatment with peginterferon and ribavirin are only 10-15%. When used with peginterferon alfa-2b, the dose of ribavirin is also based on the patient's weight and may range from 800 mg to 1400 mg daily in two divided doses. When used with peginterferon alfa-2a, the daily ribavirin dose is 1000 mg or 1200 mg depending on whether the patient's weight is less than or greater than 75 kg. Patients infected with genotype 1a or 1b are treated for 48 weeks if viral clearance has been achieved by 12-24 weeks. Patients with cirrhosis or a high viral level in serum (> 850,000 IU/mL) may also require 48 weeks of treatment. Those infected with genotype 2 or 3, without cirrhosis, and with low levels of viremia are treated for 24 weeks and require a ribavirin dose of only 800 mg.

Peginterferon alfa with ribavirin may be beneficial in the treatment of cryoglobulinemia associated with chronic hepatitis C. On the other hand, treatment of asymptomatic "chronic carriers" with normal serum aminotransferase levels is of uncertain benefit since such patients usually have mild disease that progresses slowly. Patients with both HCV and HIV infections may benefit from treatment of HCV if the CD4 count is not low. Treatment with peginterferon alfa plus ribavirin is costly (\$12,000 for a 24-week supply), and side effects, which include flu-like symptoms, are almost universal; more serious toxicity includes psychiatric symptoms (irritability, depression), thyroid dysfunction, and bone marrow suppression. A blood count is obtained at weeks 1, 2, and 4 after therapy is started and monthly thereafter.

Interferon is contraindicated in patients with decompensated cirrhosis, profound cytopenias, severe psychiatric disorders, and autoimmune diseases. Patients taking ribavirin must be monitored for hemolysis, and, because of teratogenic effects in animals, men and women taking the drug must practice strict contraception until 6 months after conclusion of therapy. Ribavirin should be avoided in persons over age 65 and in others in whom hemolysis could pose a risk of angina or stroke. Rash, itching, headache, cough, and shortness of breath also occur with the drug. Lactic acidosis is a concern in patients also taking highly active antiretroviral therapy for HIV infection. Rarely, erythropoietin (epoetin alfa) and granulocyte colony-stimulating factor are used to treat therapy-induced anemia and leukopenia. Interferon is generally contraindicated in heart, lung, and renal transplant recipients because of an increased risk of organ rejection. Selected liver transplant recipients with recurrent hepatitis C may be treated with peginterferon and ribavirin, but response rates are low.

In nonresponders to interferon-based therapy, treatment with interleukin-10 may normalize aminotransferase levels, improve liver histology, and even reduce fibrosis, but further study of this and other strategies, such as long-term maintenance interferon, is required.

Prognosis

The course of chronic viral hepatitis is variable and unpredictable. The sequelae of chronic hepatitis secondary to hepatitis B include cirrhosis, liver failure, and hepatocellular carcinoma. Up to 40-50% of patients with chronic hepatitis B and cirrhosis die within 5 years after the onset of symptoms, though treatment may improve the prognosis in responders. Chronic hepatitis C is an indolent, often subclinical disease that may lead to cirrhosis and hepatocellular carcinoma after decades. Indeed, the mortality rate from transfusion-associated hepatitis C may be no different from that of an age-matched control population. Nevertheless, mortality rates clearly rise once cirrhosis develops, and mortality from cirrhosis and hepatocellular carcinoma due to hepatitis C is expected to triple in the next 10-20 years. Peginterferon plus ribavirin appears to have a beneficial effect on survival and quality of life, is cost-effective, appears to retard and even reverse fibrosis, and in responders may reduce the risk of hepatocellular carcinoma.

AUTOIMMUNE HEPATITIS

Clinical Findings & Diagnosis

Though usually a disease of young women, autoimmune hepatitis can occur in either sex at any age. Affected younger persons are often positive for HLA-B8 and HLA-DR3; in older patients, HLA-DR4. The principal susceptibility allele among white Americans and northern Europeans is HLA *DRB1*0301*; HLA *DRB1*0401* is a secondary but independent risk factor. The onset is usually insidious, but up to 40% present with an acute attack of hepatitis and some cases follow a viral illness such as hepatitis A, Epstein-Barr infection, or measles or exposure to a drug or toxin such as nitrofurantoin. The serum bilirubin is usually increased, but 20% of patients are anicteric. Typically, examination reveals a healthy-appearing young woman with multiple spider nevi, cutaneous striae, acne, hirsutism, and hepatomegaly. Amenorrhea may be a presenting feature. Extrahepatic features include arthritis, Sjogren's syndrome, thyroiditis, nephritis, ulcerative colitis, and Coombs-positive hemolytic anemia. In classic (type I) autoimmune hepatitis, antinuclear antibody (ANA) or smooth muscle antibody (either or both) is detected in serum. Serum gamma globulin levels are typically elevated (up to 5-6 g/dL). In patients with the latter, the enzyme immunoassay for antibody to HCV may be falsely positive. Other antibodies, including antineutrophil cytoplasmic antibodies (ANCA), may be found. A second type, seen more often in Europe, is characterized by circulating antibody to liver-kidney microsomes (anti-LKM1)—directed against cytochrome P450 2D6—without anti-smooth muscle antibody or ANA. This type can be seen in patients with autoimmune polyglandular syndrome type 1. A third variant is characterized by antibodies to soluble liver antigen-liver pancreas (anti-SLA/LP) and may represent a variant of type I autoimmune hepatitis characterized by severe disease, a high relapse rate after treatment, and absence of the usual antibodies (ANA and smooth muscle antibody). Anti-SLA/LP appears to be directed against a transfer RNA complex responsible for incorporating selenocysteine into peptide chains. Concurrent primary biliary cirrhosis or primary sclerosing cholangitis has been recognized in up to 15% of patients with autoimmune hepatitis. Liver biopsy is indicated to help establish the diagnosis, evaluate disease severity, and determine the need for treatment.

Treatment

Prednisone with or without azathioprine improves symptoms; decreases the serum bilirubin, aminotransferase, and gamma globulin levels; and reduces hepatic inflammation. Symptomatic patients with aminotransferase levels elevated tenfold (or fivefold if the serum globulins are elevated at least twofold) are optimal for therapy, and asymptomatic patients with modest enzyme elevations may be considered for therapy depending on the clinical circumstances.

Prednisone or an equivalent drug is given initially in doses of 30 mg orally daily with azathioprine or mercaptopurine, 50 mg/d orally, which are generally well tolerated and permit the use of lower corticosteroid doses. Blood counts are monitored weekly for the first 2 months of therapy and monthly thereafter because of the small risk of bone marrow suppression. The dose of prednisone is lowered from 30 mg/d after 1 week to 20 mg/d and again after 2 or 3 weeks to 15 mg/d. Ultimately, a maintenance dose of 10 mg/d is achieved. While symptomatic improvement is often prompt, biochemical improvement is more gradual, with normalization of serum aminotransferase levels after several months in many cases. Histologic resolution of inflammation may require 18-24 months, the time at which repeat liver biopsy is recommended. Failure of aminotransferase levels to normalize invariably predicts lack of histologic resolution.

The response rate to therapy with prednisone and azathioprine is 80%. Cirrhosis, however, does not reverse with therapy and may even develop after apparent biochemical and histologic remission. Once remission is achieved, therapy may be withdrawn, but the subsequent relapse rate is 50-90%. Relapses may again be treated in the same manner as the initial episode, with the same remission rate. After successful treatment of a relapse, the patient may be kept indefinitely on azathioprine (up to 2 mg/kg) and the lowest dose of prednisone needed to maintain aminotransferase levels as close to normal as possible—though another attempt at withdrawing therapy may be considered in patients remaining in remission long term (eg, = 4 years). Budesonide, a corticosteroid with less toxicity than prednisone, does not appear to be effective in maintaining remission. Nonresponders to prednisone and azathioprine may be considered for a trial of cyclosporine, tacrolimus, or methotrexate. Mycophenolate mofetil is an effective alternative to azathioprine in patients who cannot tolerate or do not respond to it. Bone density should be monitored—particularly in patients being maintained on corticosteroids—and measures undertaken to prevent or treat osteoporosis. Liver transplantation may be required for treatment failures, and the disease has been recognized to recur in up to one-third of transplanted livers (and rarely to develop de novo) as immunosuppression is reduced.

ALCOHOLIC HEPATITIS

Alcoholic hepatitis is characterized by acute or chronic inflammation and parenchymal necrosis of the liver induced by alcohol. While alcoholic hepatitis is often a reversible disease, it is the most common precursor of cirrhosis in the United States and is associated with four to five times the number of hospitalizations and deaths as hepatitis C, which is the second most common cause of cirrhosis.

The frequency of alcoholic cirrhosis is estimated to be 10-15% among persons who consume over 50 g of alcohol (4 oz of 100-proof whiskey, 15 oz of wine, or four 12-oz cans of beer) daily for over 10 years (although the risk of cirrhosis may be lower for wine than for a comparable intake of beer or spirits). The risk of cirrhosis is lower (5%) in the absence of other cofactors such as chronic viral hepatitis. Genetic factors may also account in part for differences in susceptibility, and there are

associations with polymorphisms of the genes encoding for tumor necrosis factor- α and cytochrome P450 2E1. Women appear to be more susceptible than men, in part because of lower gastric mucosal alcohol dehydrogenase levels. Although alcoholic hepatitis may not develop in many patients even after several decades of alcohol abuse, it appears in a few individuals within a year after onset of excessive drinking. In general, over 80% of patients with alcoholic hepatitis have been drinking 5 years or more before developing any symptoms that can be attributed to liver disease; the longer the duration of drinking (10-15 or more years) and the larger the alcoholic consumption, the greater the probability of developing alcoholic hepatitis and cirrhosis. In individuals who drink alcohol excessively, the rate of ethanol metabolism can be sufficiently high to permit the consumption of large quantities without raising the blood alcohol level over 80 mg/dL.

The role of deficiencies in vitamins and calories in the development of alcoholic hepatitis or in the progression of this lesion to cirrhosis remains controversial but is at least contributory. Ethanol-induced elevation of circulating endotoxin levels is thought to play a critical role in the pathogenesis of alcoholic liver disease by inducing release of tumor necrosis factor- α and other cytokines by Kupffer cells. Many of the adverse effects of alcohol on the liver are thought to be mediated by the oxidative metabolite acetaldehyde, which contributes to lipid peroxidation and induction of an immune response following covalent binding to proteins in the liver. Concurrent HBV or HCV infection and heterozygosity for the *HFE* gene mutation for hemochromatosis increase the severity of alcoholic liver disease.

Clinical Findings

A. Symptoms and Signs

The clinical presentation of alcoholic hepatitis can vary from an asymptomatic patient with an enlarged liver to a critically ill individual who dies quickly. A recent period of heavy drinking, complaints of anorexia and nausea, and the demonstration of hepatomegaly and jaundice strongly suggest the diagnosis. Abdominal pain and tenderness, splenomegaly, ascites, fever, and encephalopathy may be present.

B. Laboratory Findings

Anemia (usually macrocytic) may be present. Leukocytosis with shift to the left is common in patients with severe disease. Leukopenia is occasionally seen and disappears after cessation of drinking. About 10% of patients have thrombocytopenia related to a direct toxic effect of alcohol on megakaryocyte production or to hypersplenism.

AST is usually elevated but rarely above 300 units/L. AST is greater than ALT, usually by a factor of 2 or more. Serum alkaline phosphatase is generally elevated, but seldom more than three times the normal value. Serum bilirubin is increased in 60-90% of patients. Serum bilirubin levels greater than 10 mg/dL and marked prolongation of the prothrombin time (= 6 seconds above control) indicate severe alcoholic hepatitis with a mortality rate as high as 50%. The serum albumin is depressed, and the gamma globulin level is elevated in 50-75% of individuals, even in the absence of cirrhosis. Increased transferrin saturation and hepatic iron stores are found in many alcoholic patients due to sideroblastic anemia. Folic acid deficiency may coexist.

C. Liver Biopsy

Liver biopsy, if done, demonstrates macrovesicular fat, PMN infiltration with hepatic necrosis, Mallory bodies (alcoholic hyaline), and perivenular and perisinusoidal fibrosis. Micronodular cirrhosis may be present as well. The findings are identical to those of nonalcoholic steatohepatitis.

D. Other Studies

Imaging studies are generally not helpful in the diagnosis of alcoholic hepatitis. Ultrasound helps exclude biliary obstruction and identifies subclinical ascites. CT scanning with intravenous contrast or MRI may be indicated in selected cases to evaluate patients for collateral vessels, space-occupying lesions of the liver, or concomitant disease of the pancreas.

Differential Diagnosis

Alcoholic hepatitis may be closely mimicked by cholecystitis and cholelithiasis and by drug toxicity. Other causes of hepatitis or chronic liver disease may be excluded by serologic or biochemical testing, by imaging studies, or by liver biopsy.

Treatment

A. General Measures

Abstinence from alcohol is essential. Every effort should be made to provide sufficient amounts of carbohydrates and calories in anorectic patients to reduce endogenous protein catabolism, promote gluconeogenesis, and prevent hypoglycemia. Nutritional support (40 kcal/kg with 1.5-2 g/kg as protein) improves survival in patients with malnutrition. Use of liquid formulas rich in branched-chain amino acids does not improve survival beyond that achieved with less expensive caloric supplementation. The administration of vitamins, particularly folic acid and thiamine, is indicated, especially when deficiencies are noted; glucose administration increases the vitamin B₁ requirement and can precipitate Wernicke-Korsakoff syndrome if thiamine is not coadministered.

B. Corticosteroids

Methylprednisolone, 32 mg/d for 1 month or the equivalent, may reduce short-term mortality in patients with alcoholic hepatitis and either encephalopathy or a greatly elevated bilirubin concentration and prolonged prothrombin time (specifically, when a discriminant function defined by the patient's prothrombin time minus the control prothrombin time times 4.6 plus the total bilirubin in mg/dL is > 32). No benefit has been demonstrated in patients with concomitant gastrointestinal bleeding.

C. Experimental Therapies

Pentoxifylline—an inhibitor of tumor necrosis factor—400 mg orally three times daily for 4 weeks, may reduce 1-month mortality rates in patients with severe alcoholic hepatitis, primarily by decreasing the risk of hepatorenal syndrome. Other experimental therapies include propylthiouracil, oxandrolone, and S-adenosyl-*L*-methionine.

Prognosis

A. Short-Term

When the prothrombin time is short enough to permit liver biopsy (< 3 seconds above control), the 1-year mortality rate is 7%, rising to 20% if there is progressive prolongation of the prothrombin time during hospitalization. Individuals in whom the prothrombin time prohibits liver biopsy have a 42% mortality rate at 1 year. Other unfavorable prognostic factors are a serum bilirubin greater than 10 mg/dL, hepatic encephalopathy, and azotemia.

B. Long-Term

In the United States, the 3-year mortality rate of persons who recover from acute alcoholic hepatitis is ten times greater than that of control individuals of comparable age. Histologically severe disease is associated with continued excessive mortality rates after 3 years, whereas the death rate is not increased after the same period in those whose liver biopsies show only mild alcoholic hepatitis. Complications of portal hypertension (ascites, variceal bleeding, hepatorenal syndrome), coagulopathy, and severe jaundice following recovery from acute alcoholic hepatitis also suggest a poor long-term prognosis.

The most important prognostic consideration is continued excessive drinking. A 6-month period of abstinence is generally required before liver transplantation can be considered.

DRUG- & TOXIN-INDUCED LIVER DISEASE

The continuing synthesis, testing, and introduction of new drugs into clinical practice has resulted in an increase in toxic reactions of many types. Many widely used therapeutic agents, including over-the-counter "natural" and "herbal" products, may cause hepatic injury. Drug-induced liver disease can mimic viral hepatitis, biliary tract obstruction, or other types of liver disease. In any patient with liver disease, the clinician must inquire carefully about the use of potentially hepatotoxic drugs or exposure to hepatotoxins. In some cases, coadministration of a second agent may increase the toxicity of the first (eg, isoniazid and rifampin, acetaminophen and alcohol). Drug toxicity may be categorized on the basis of pathogenesis or histologic appearance.

Direct Hepatotoxic Group

The liver lesion caused by this group of drugs is characterized by (1) dose-related severity, (2) a latent period following exposure, and (3) susceptibility in all individuals. Examples include acetaminophen, alcohol, carbon tetrachloride, chloroform, heavy metals, mercaptopurine, niacin, plant alkaloids, phosphorus, tetracyclines, valproic

acid, and vitamin A.

Idiosyncratic Reactions

Reactions of this type are sporadic, not related to dose, and occasionally associated with features suggesting an allergic reaction, such as fever and eosinophilia. In some, toxicity results directly from a metabolite that is produced only in certain individuals on a genetic basis. Examples include amiodarone, aspirin, carbamazepine, chloramphenicol, diclofenac, flutamide, halothane, isoniazid, ketoconazole, lamotrigine, methyl-dopa, oxacillin, phenytoin, pyrazinamide, quinidine, streptomycin, troglitazone (withdrawn from the market in the United States), and less commonly other thiazolidinediones, and perhaps tacrine.

Cholestatic Reactions

A. Noninflammatory

Direct effect of agent on bile secretory mechanisms: azathioprine, estrogens, or anabolic steroids containing an alkyl or ethinyl group at carbon 17, indinavir, mercaptopurine, methyltestosterone, and cyclosporine.

B. Inflammatory

Inflammation of portal areas with bile duct injury (cholangitis), often with allergic features such as eosinophilia: amoxicillin-clavulanic acid, azithromycin, chlorothiazide, chlorpromazine, chlorpropamide, erythromycin, penicillamine, prochlorperazine, semisynthetic penicillins (eg, cloxacillin), and sulfadiazine.

Acute or Chronic Hepatitis

Histologically and in some cases clinically indistinguishable from autoimmune hepatitis: aspirin, isoniazid (increased risk in HBV carriers), methyldopa, minocycline, nitrofurantoin, nonsteroidal anti-inflammatory drugs, and propylthiouracil. Hepatitis also can occur with cocaine, ecstasy, efavirenz, nevirapine, ritonavir, sulfonamides, troglitazone (withdrawn from the market in the United States), and zafirlukast as well as a variety of alternative remedies (eg, chaparral, germander, jin bu huan, skullcap).

Other Reactions

A. Fatty Liver

1. Macrovesicular—Alcohol, amiodarone, corticosteroids, methotrexate.

2. Microvesicular (often resulting from mitochondrial injury)—Didanosine, stavudine, tetracyclines, valproic acid, zidovudine.

B. Granulomas

Allopurinol, quinidine, quinine, phenylbutazone, phenytoin.

C. Fibrosis and Cirrhosis

Methotrexate, vitamin A.

D. Peliosis Hepatis (Blood-Filled Cavities)

Anabolic steroids, azathioprine, oral contraceptive steroids.

E. Neoplasms

Oral contraceptive steroids, estrogens (hepatic adenoma but not focal nodular hyperplasia); vinyl chloride (angiosarcoma).

ALCOHOLIC & NONALCOHOLIC FATTY LIVER DISEASE

Ethanol can cause hepatic steatosis (fatty liver) in the absence of malnutrition, although inadequate diets—specifically those deficient in choline, methionine, and protein—can contribute to liver damage caused by ethanol. Other nonalcoholic causes of steatosis, or nonalcoholic fatty liver disease (NAFLD), are obesity (present in = 40%), diabetes mellitus (in = 20%), hypertriglyceridemia (in = 20%), corticosteroids, amiodarone, diltiazem, tamoxifen, highly active antiretroviral therapy, poisons (carbon tetrachloride and yellow phosphorus), endocrinopathies such as Cushing's syndrome, hypobetalipoproteinemia and other metabolic disorders, starvation and refeeding syndrome, and total parenteral nutrition. Steatosis is nearly universal in obese alcoholics and is a hallmark of "syndrome X" (insulin resistance syndrome), characterized by obesity, diabetes, hypertriglyceridemia, and hypertension). In addition to macrovesicular steatosis, histologic features may include focal infiltration by polymorphonuclear neutrophils and Mallory's hyalin, a picture indistinguishable from that of alcoholic hepatitis and referred to as nonalcoholic steatohepatitis (NASH). In patients with nonalcoholic fatty liver disease, older age, obesity, and diabetes are risk factors for advanced hepatic fibrosis and cirrhosis.

Microvesicular steatosis is seen with Reye's syndrome, valproic acid toxicity, high-dose tetracycline, or acute fatty liver of pregnancy and may result in fulminant hepatic failure.

There are several factors, presumably resulting from impaired responsiveness of fat cells to insulin, that are responsible for the accumulation of fat in the liver in patients with nonalcoholic fatty liver disease: (1) increased mobilization of fatty acids from peripheral adipose depots, (2) decreased utilization or oxidation of fatty acids by the liver, (3) increased hepatic fatty acid synthesis, (4) increased esterification of fatty acids into triglycerides, and (5) decreased secretion or liberation of fat from the liver. High serum leptin levels in obese persons may contribute to hepatic steatosis by promoting insulin resistance and altering insulin signaling in hepatocytes. There is controversy over whether leptin also stimulates proinflammatory cytokines and thereby influences progression from hepatic steatosis to steatohepatitis.

The exact stimulus that causes progression of steatosis to steatohepatitis and fibrosis is unclear. The leading possibility is lipid peroxidation and oxidative stress. Some patients with nonalcoholic fatty liver disease have hepatic iron overload, and some of these patients are heterozygous for the C282Y gene for hemochromatosis (*HFE*); increased hepatic iron as well as severe steatosis (both attributed to insulin resistance) have been associated with hepatic fibrosis in some studies. Hepatic concentrations of cytochrome P450 2E1 are increased in patients with nonalcoholic steatohepatitis, as they are in alcoholic liver disease, and patients with nonalcoholic steatohepatitis appear to replenish depleted hepatic adenosine triphosphate (ATP) stores more slowly than healthy subjects after an ATP-depleting challenge. Increased circulating levels of tumor necrosis factor- α due to obesity and to impaired macrophage function may contribute to the development of nonalcoholic steatohepatitis. Mitochondrial structural abnormalities are associated with nonalcoholic steatohepatitis but not nonalcoholic fatty liver disease alone. Women in whom fatty liver of pregnancy develops often have a defect in fatty acid oxidation due to reduced long-chain 3-hydroxyacyl-CoA dehydrogenase activity.

Hepatomegaly is present in up to 75% of patients with nonalcoholic fatty liver disease, but the stigmas of chronic liver disease are uncommon. Rare instances of subacute liver failure caused by previously unrecognized nonalcoholic steatohepatitis have been described.

Laboratory studies may show mildly elevated aminotransferase and alkaline phosphatase levels. In contrast to alcoholic liver disease, the ratio of ALT to AST is almost always greater than 1 in nonalcoholic fatty liver disease, but it decreases to less than 1 as advanced fibrosis and cirrhosis develop. An AST/ALT ratio > 2.0 is highly suggestive of alcoholic liver disease. Macrovascular steatosis may be demonstrated on ultrasound, CT, or MRI. Percutaneous liver biopsy is diagnostic and is the only way to assess the degree of fibrosis. The risks of the procedure must be balanced against the impact of the added information on management decisions and assessment of prognosis.

Treatment consists of removing or modifying the offending factors. Weight loss, dietary fat restriction, and exercise often lead to improvement in liver tests and steatosis in obese patients with fatty liver, but the benefit of such measures is less clear in patients with steatohepatitis. Ursodeoxycholic acid, 13-15 mg/kg/d, may also improve liver function test results and liver histologic features, but the long-term benefit requires further study. Hepatic steatosis due to total parenteral nutrition may be ameliorated—and perhaps prevented—with supplemental choline. Vitamin E (to reduce oxidative stress), thiazolidinediones (to reverse insulin resistance), and betaine (a methyl donor) may have some benefit and are under study. Metformin has been shown to reduce insulin resistance and reverse fatty liver in obese leptin-deficient mice and—in preliminary clinical trials—in humans. Gastric bypass may be considered in patients with a body mass index > 35.

Fatty liver is readily reversible with discontinuation of alcohol or treatment of other underlying conditions. Nonalcoholic steatohepatitis may be associated with hepatic fibrosis in 40% of cases; cirrhosis develops in 10-15%; and decompensated cirrhosis occurs in 2-5% of patients. Instances of hepatocellular carcinoma in patients with cirrhosis caused by nonalcoholic steatohepatitis have been reported. Nonalcoholic steatohepatitis may account for a substantial percentage of cases labeled as cryptogenic cirrhosis and can recur following liver transplantation.

CIRRHOSIS

Cirrhosis is the end result of hepatocellular injury that leads to both fibrosis and nodular regeneration throughout the liver. Cirrhosis is a serious and generally irreversible disease and is the eighth leading cause of death in the United States. The clinical features result from hepatic cell dysfunction, portosystemic shunting, and portal hypertension.

The most common histologic classification divides cirrhosis into micronodular, macronodular, and mixed forms. These are descriptive terms rather than separate diseases, and each form may be seen in the same patient at different stages of the disease. In micronodular cirrhosis—typical of alcoholic liver disease (Laennec's cirrhosis)—the regenerating nodules are no larger than the original lobules, ie, approximately 1 mm in diameter or less.

Macronodular cirrhosis is characterized by larger nodules, which can measure several centimeters in diameter and may contain central veins. This form corresponds more or less to postnecrotic (posthepatic) cirrhosis but does not necessarily follow episodes of massive necrosis and stromal collapse.

Clinical Findings

A. Symptoms and Signs

Cirrhosis may cause no symptoms for long periods. The onset of symptoms may be insidious or, less often, abrupt. Weakness, fatigability, disturbed sleep, muscle cramps, and weight loss are common. In advanced cirrhosis, anorexia is usually present and may be extreme, with associated nausea and occasional vomiting. Abdominal pain may be present and is related either to hepatic enlargement and stretching of Glisson's capsule or to the presence of ascites. Menstrual abnormalities (usually amenorrhea), impotence, loss of libido, sterility, and gynecomastia in men may occur. Hematemesis is the presenting symptom in 15-25%.

In 70% of cases, the liver is enlarged, palpable, and firm if not hard and has a sharp or nodular edge; the left lobe may predominate. Skin manifestations consist of spider nevi (invariably on the upper half of the body), palmar erythema (mottled redness of the thenar and hypothenar eminences), and Dupuytren's contractures. Evidence of vitamin deficiencies (glossitis and cheilosis) is common. Weight loss, wasting, and the appearance of chronic illness are present. Jaundice—usually not an initial sign—is mild at first, increasing in severity during the later stages of the disease. Ascites, pleural effusions, peripheral edema, and ecchymotic lesions are late findings. Encephalopathy characterized by day-night reversal, asterixis, tremor, dysarthria, delirium, drowsiness, and ultimately coma also occur late except when precipitated by an acute hepatocellular insult or an episode of gastrointestinal bleeding. Fever may be a presenting symptom in up to 35% of patients and usually reflects associated alcoholic hepatitis, spontaneous bacterial peritonitis, or intercurrent infection. Splenomegaly is present in 35-50% of cases. The superficial veins of the abdomen and thorax are dilated, reflecting the intrahepatic obstruction to portal blood flow, as do rectal varices. The veins fill from below when compressed.

B. Laboratory Findings

Laboratory abnormalities are either absent or minimal in latent or quiescent cirrhosis. Anemia, a frequent finding, is often macrocytic; causes include suppression of erythropoiesis by alcohol as well as folate deficiency, hemolysis, hypersplenism, and insidious or overt blood loss from the gastrointestinal tract. The white blood cell count may be low, reflecting hypersplenism, or high, suggesting infection; thrombocytopenia is secondary to alcoholic marrow suppression, sepsis, folate deficiency, or splenic sequestration. Prolongation of the prothrombin time may result from failure of hepatic synthesis of clotting factors.

Blood chemistries reflect hepatocellular injury and dysfunction, manifested by modest elevations of AST and alkaline phosphatase and progressive elevation of the bilirubin. Serum albumin is low; gamma globulin is increased and may be as high as in autoimmune hepatitis. The risk of diabetes mellitus is increased in patients with cirrhosis, particularly when associated with HCV infection, alcoholism, hemochromatosis, and nonalcoholic fatty liver disease. Patients with alcoholic cirrhosis may have elevated serum cardiac troponin I levels of uncertain significance.

Liver biopsy may show inactive cirrhosis (fibrosis with regenerative nodules) with no specific features to suggest the underlying cause. Alternatively, there may be additional features of alcoholic liver disease, chronic hepatitis, or other specific causes of cirrhosis.

C. Imaging

Plain films of the abdomen are seldom helpful. Barium studies of the upper gastrointestinal tract may reveal the presence of esophageal or gastric varices, though endoscopy is more sensitive. Ultrasound is helpful for assessing liver size and detecting ascites or hepatic nodules, including small hepatocellular carcinomas. Together with Doppler studies, it may establish patency of the splenic, portal, and hepatic veins. Hepatic nodules are characterized further by contrast-enhanced CT scan or MRI. Nodules suspicious for malignancy may be biopsied under ultrasound or CT guidance.

D. Special Examinations

Esophagogastroduodenoscopy confirms the presence of varices and detects specific causes of bleeding in the esophagus, stomach, and proximal duodenum. Liver biopsy may be performed by laparoscopy or, in patients with coagulopathy and ascites, by a transjugular approach. In selected cases, wedged hepatic vein pressure measurement may establish the presence and cause of portal hypertension.

Differential Diagnosis

Determining the cause of cirrhosis is important prognostically and therapeutically. The most common causes of cirrhosis are chronic hepatitis C and B and alcohol. Many cases of cirrhosis are "cryptogenic," in which unrecognized nonalcoholic fatty liver disease may play a role. Mutations in the keratin 8 gene have been associated with some cases of cryptogenic cirrhosis. In advanced cases, hemochromatosis may be associated with bronzing of the skin, arthritis, heart failure, and diabetes; however, most patients have no symptoms or signs. Diagnostic features include greater than 60% saturation of serum transferrin or serum ferritin level above the upper limit of normal, detection of the mutated *HFE* gene (see below), and increased staining for iron and quantitation of the iron on liver biopsy. Other metabolic diseases that may lead to cirrhosis include Wilson's disease and α_1 -antiprotease (α_1 -antitrypsin) deficiency. Primary biliary cirrhosis occurs more frequently in women and is associated with pruritus, significant elevation of alkaline phosphatase, elevated immunoglobulin (IgM) and hypercholesterolemia, and antimitochondrial antibody. Secondary biliary cirrhosis may result from chronic biliary obstruction due to a stone, stricture, or neoplasm and is not associated with antimitochondrial antibody. Congestive heart failure and constrictive pericarditis may lead to hepatic fibrosis ("cardiac cirrhosis") complicated by ascites and may be mistaken for other causes of cirrhosis. Hereditary hemorrhagic telangiectasia can lead to portal hypertension because of portosystemic shunting and nodular transformation of the liver.

Complications

Upper gastrointestinal tract bleeding may occur from varices, portal hypertensive gastropathy, or gastroduodenal ulcer (see [Chapter 14](#)). Hemorrhage may be massive, resulting in fatal exsanguination or encephalopathy. Varices may also result from portal vein thrombosis. Liver failure may be precipitated by alcoholism, surgery, and infection. The risk of carcinoma of the liver is increased in patients with cirrhosis. Hepatic Kupffer cell (reticuloendothelial) dysfunction and decreased opsonic activity lead to an increased risk of systemic infection.

Treatment

A. General Measures

The most important principle of treatment is abstinence from alcohol. The diet should be palatable, with adequate calories (25-35 kcal/kg body wt/d in those with compensated cirrhosis and 35-40 kcal/kg/d in those with malnutrition) and protein (1-1.2 g/kg/d in those with compensated cirrhosis and 1.5 g/kg/d in those with malnutrition) and, if there is fluid retention, sodium restriction. In the presence of hepatic encephalopathy, protein intake should be reduced to 60-80 g/d. Vitamin supplementation is desirable.

B. Treatment of Complications

1. Ascites and edema—Diagnostic paracentesis is indicated for new ascites. It is rarely associated with serious complications such as bleeding, infection, or bowel perforation even in patients with severe coagulopathy. In addition to a cell count and culture, the ascitic albumin level should be determined; a serum-ascites albumin gradient (serum albumin minus ascitic albumin) > 1.1 suggests portal hypertension. An elevated ascitic adenosine deaminase level is suggestive of tuberculous peritonitis, but the sensitivity of the test is reduced in patients with portal hypertension. Occasionally, cirrhotic ascites is chylous (rich in triglycerides); other causes of

chylous ascites are malignancy, tuberculosis, and recent abdominal surgery or trauma.

Ascites in patients with cirrhosis results from portal hypertension (increased hydrostatic pressure); hypoalbuminemia (decreased oncotic pressure); peripheral vasodilation, perhaps mediated by endotoxin-induced release of nitric oxide from splanchnic and systemic vasculature, with resulting increases in renin and angiotensin levels and sodium retention by the kidneys; impaired liver inactivation of aldosterone; and increased aldosterone secretion secondary to increased renin production. Free water excretion is also impaired in cirrhosis, and hyponatremia may develop.

In all patients with cirrhotic ascites, dietary sodium intake may initially be restricted to 400-800 mg/d; the intake of sodium may be liberalized slightly after diuresis ensues. Restriction of fluid intake (800-1000 mL/d) is required for patients with hyponatremia (serum sodium < 125 meq/L). In some patients, there is a rapid diminution of ascites on bed rest and dietary sodium restriction alone. In individuals with ascites, the urinary excretion of sodium is usually less than 10 meq/L.

a. Diuretics—Spironolactone, generally in combination with furosemide, should be used in patients who do not respond to salt restriction. The initial dose of spironolactone is 100 mg daily and may be increased by 100 mg every 3-5 days (up to a maximal conventional daily dose of 400 mg/d, though higher doses have been used) until diuresis is achieved, typically preceded by a rise in the urinary sodium concentration. Monitoring for hyperkalemia is important. In patients who cannot tolerate spironolactone because of side effects such as painful gynecomastia, amiloride, another potassium-sparing diuretic, may be used in a dose of 5-10 mg daily. Diuresis is augmented by the addition of a loop diuretic such as furosemide. This potent diuretic, however, will maintain its effect even with a falling glomerular filtration rate, with resultant prerenal azotemia. The dose of furosemide ranges from 40 to 160 mg/d, and the drug should be administered while monitoring blood pressure, urine output, mental status, and serum electrolytes, especially potassium.

The goal of weight loss in the ascitic patient without associated peripheral edema should be no more than 1-1.5 lb/d (0.5-0.7 kg/d).

b. Large-volume paracentesis—In patients with massive ascites and respiratory compromise, ascites refractory to diuretics, or intolerable diuretic side effects, large-volume paracentesis (4-6 L) is effective. Intravenous albumin concomitantly at a dosage of 10 g/L of ascites fluid removed protects the intravascular volume, though the utility of this practice is debated. Moreover, use of albumin at approximately \$15 per gram adds considerable expense to the procedure. Large-volume paracentesis can be repeated daily until ascites is largely resolved and may decrease the need for hospitalization. If possible, diuretics should be continued in the hope of preventing recurrent ascites.

c. Transjugular intrahepatic portosystemic shunt (TIPS)—TIPS has emerged as an alternative to surgical portosystemic shunting in selected cases of variceal bleeding refractory to standard therapy (eg, endoscopic band ligation or sclerotherapy) and has shown benefit in the treatment of severe refractory ascites. The technique involves insertion of an expandable metal stent between a branch of the hepatic vein and portal vein over a catheter inserted via the internal jugular vein. Increased renal sodium excretion and control of ascites refractory to diuretics can be achieved in about 75% of selected cases. The success rate is lower in patients with underlying renal insufficiency. TIPS appears to be the treatment of choice for refractory hepatic hydrothorax (translocation of ascites across the diaphragm to the pleural space), although pleurodesis using talc may also be effective. Complications include hepatic encephalopathy in 20-30% of cases, infection, shunt stenosis in up to 60%, and shunt occlusion in up to 30% of cases. Long-term patency usually requires periodic shunt revisions. In most cases, patency can be maintained by balloon dilation, local thrombolysis, or placement of an additional stent. Because of the complications associated with TIPS and uncertainty about its long-term efficacy (reduced hepatic perfusion as a result of TIPS may conceivably shorten a patient's survival), it is currently preferred in patients who require short-term control of variceal bleeding or ascites until liver transplantation can be performed—as opposed to patients in need of definitive control of bleeding or ascites but in whom liver transplantation is not a consideration. In patients with refractory ascites, TIPS results in lower rates of ascites recurrence and hepatorenal syndrome but a higher rate of hepatic encephalopathy than occur with repeated large-volume paracentesis, but a benefit in survival has not been demonstrated.

d. Peritoneovenous shunts—In the past, peritoneovenous shunts were advocated for use in patients with refractory ascites. These shunts may be effective but carry a considerable complication rate: disseminated intravascular coagulation in 65% of patients (25% symptomatic; 5% severe), bacterial infections in 4-8%, congestive heart failure in 2-4%, and variceal bleeding from sudden expansion of intravascular volume. TIPS is now preferred for refractory ascites.

2. Spontaneous bacterial peritonitis—Spontaneous bacterial peritonitis is heralded by abdominal pain, increasing ascites, fever, and progressive encephalopathy in a patient with cirrhotic ascites; symptoms are typically mild. Paracentesis reveals an ascitic fluid with, most commonly, a total white cell count of up to 500 cells/uL with a high percentage of PMNs and a protein concentration of 1 g/dL or less, corresponding to decreased ascitic opsonic activity. Cultures of ascites give the highest yield—80-90% positive—using blood culture bottles inoculated at the bedside. Common isolates are *E coli* and pneumococci. (Gram-positive cocci are the most common isolates in patients who have undergone invasive procedures such as central venous line placement.) Anaerobes are rare. Pending culture results, if there are 250 or more PMN/uL, intravenous antibiotic therapy should be initiated with cefotaxime, 2 g intravenously every 8-12 hours for at least 5 days. Ceftriaxone or amoxicillin-clavulanic acid are alternatives. A 2-day course of intravenous ciprofloxacin, 200 mg twice daily, followed by oral ciprofloxacin, 500 mg twice daily for 5 days, may be effective in selected patients. Supplemental administration of intravenous albumin may reduce mortality. Response to therapy can be documented, if necessary, by a decrease in the PMN count of at least 50% on repeat paracentesis 48 hours after initiation of therapy. The overall mortality rate is high—up to 70% by 1 year. In survivors, the risk of recurrent peritonitis may be decreased by long-term norfloxacin, 400 mg orally daily (although in recurrence the causative organism is often resistant to quinolones). In high-risk cirrhotics (eg, ascitic protein < 1 g/dL, acute variceal bleeding), first episodes of peritonitis may be prevented by prophylactic norfloxacin, ciprofloxacin (500 mg twice a day), or trimethoprim-sulfamethoxazole (one double-strength tablet five times a week).

3. Hepatorenal syndrome—Hepatorenal syndrome is characterized by azotemia in the absence of shock or significant proteinuria in a patient with end-stage liver disease in whom renal function fails to improve following intravenous infusion of 1.5 L of isotonic saline. Oliguria, hyponatremia, and low urinary sodium are typical features. Hepatorenal syndrome is diagnosed only when other causes of renal failure have been excluded. Type I hepatorenal syndrome is characterized by doubling of the serum creatinine to a level greater than 2.5 mg/dL or by halving of the creatinine clearance to less than 20 mL/min in less than 2 weeks. Type II hepatorenal syndrome is more slowly progressive and chronic. The cause is unknown, but the pathogenesis involves intense renal vasoconstriction, possibly because of impaired synthesis of renal vasodilators such as prostaglandin E₂ and decreased total renal blood flow; histologically, the kidneys are normal. Treatment is generally ineffective. Improvement may follow intravenous infusion of the long-acting vasoconstrictor ornipressin and albumin (but with a high rate of ischemic side effects), ornipressin and dopamine, terlipressin (a long-acting vasopressin analog) and albumin, norepinephrine, and albumin, or administration of the somatostatin analog octreotide subcutaneously and midodrine, an alpha-adrenergic drug, orally. Prolongation of survival has been associated with use of the molecular adsorbent recirculating system (MARS), a modified dialysis method that selectively removes albumin-bound substances. Improvement may also follow placement of a TIPS. Mortality is high without liver transplantation, death being due to complicating infection or hemorrhage.

4. Hepatic encephalopathy—Hepatic encephalopathy is a state of disordered central nervous system function resulting from failure of the liver to detoxify noxious agents of gut origin because of hepatocellular dysfunction and portosystemic shunting. Ammonia is the most readily identified toxin but is not solely responsible for the disturbed mental status. Pathogenic factors may include production of false neurotransmitters, increased sensitivity of central nervous system neurons to the inhibitory neurotransmitter γ-aminobutyric acid (GABA), an increase in circulating levels of endogenous benzodiazepines, decreased activity of urea-cycle enzymes due to zinc deficiency, decreased brain levels of myoinositol, deposition of manganese in the basal ganglia, and swelling of astrocytes in the brain. Bleeding into the intestinal tract may significantly increase the amount of protein in the bowel and precipitate rapid development of encephalopathy. Other precipitants include constipation, alkalosis, potassium deficiency induced by diuretics, opioids, hypnotics, and sedatives; medications containing ammonium or amino compounds; paracentesis with attendant hypovolemia; hepatic or systemic infection; and portosystemic shunts (including TIPS).

Dietary protein should be withheld during acute episodes. When the patient resumes oral intake, protein intake is started at 20 g/d and increased by 10 g every 3-5 days to 60-80 g/d as tolerated, and vegetable protein is better tolerated than meat protein. Gastrointestinal bleeding should be controlled and blood purged from the gastrointestinal tract. This can be accomplished with 120 mL of magnesium citrate by mouth or nasogastric tube every 3-4 hours until the stool is free of gross blood, or by administration of lactulose.

Lactulose, a nonabsorbable synthetic disaccharide, is digested by bacteria in the colon to short-chain fatty acids, resulting in acidification of colon contents. This acidification favors the formation of ammonium ion in the $\text{NH}_4^+ \rightleftharpoons \text{NH}_3 + \text{H}^+$ equation; NH_4^+ is not absorbable, whereas NH_3 is absorbable and thought to be neurotoxic. Lactulose also leads to a change in bowel flora so that less ammonia-forming organisms are present. When given orally, the initial dose of lactulose for acute hepatic encephalopathy is 30 mL three or four times daily. The dose should then be titrated so that two or three soft stools per day are produced. When rectal use is indicated because of the patient's inability to take medicines orally, the dose is 300 mL of lactulose in 700 mL of saline or sorbitol as a retention enema for 30-60 minutes; it may be repeated every 4-6 hours.

The ammonia-producing intestinal flora may also be controlled with neomycin sulfate, 0.5-1 g orally every 6 or 12 hours for 7 days. Side effects of neomycin include diarrhea, malabsorption, superinfection, ototoxicity, and nephrotoxicity, usually only after prolonged use. Alternative antibiotics are vancomycin, 1 g orally twice daily, or metronidazole, 250 mg orally three times daily. Patients who do not respond to lactulose alone may improve with a 1-week course of an antibiotic in addition to lactulose.

Opioids and sedatives metabolized or excreted by the liver are avoided. If agitation is marked, oxazepam, 10-30 mg, which is not metabolized by the liver, may be given cautiously by mouth or by nasogastric tube. Zinc deficiency should be corrected, if present, with oral zinc sulfate, 600 mg/d in divided doses. There is limited evidence that eradication of *Helicobacter pylori*, which generates ammonia in the stomach, may improve encephalopathy. Sodium benzoate, 10 g daily, and ornithine aspartate, 9 g three times daily, may lower blood ammonia levels, but there is less experience with these drugs than with lactulose. The benzodiazepine competitive

antagonist flumazenil is effective in about 30% of patients with severe hepatic encephalopathy, but the drug is short-acting and intravenous administration is required. Use of special dietary supplements enriched with branched-chain amino acids is usually unnecessary except in occasional patients who are intolerant of standard protein supplements.

5. Anemia—For iron deficiency anemia, ferrous sulfate, 0.3-g enteric-coated tablets, one tablet three times daily after meals, is effective. Folic acid, 1 mg/d orally, is indicated in the treatment of macrocytic anemia associated with alcoholism. Transfusions with packed red blood cells may be necessary to replace blood loss.

6. Hemorrhagic tendency—Severe hypoprothrombinemia may be treated with vitamin K (eg, phytonadione, 5 mg orally or subcutaneously daily). This treatment is ineffective when synthesis of coagulation factors is impaired because of severe hepatic disease. In such cases, correcting the prolonged prothrombin time requires large volumes of fresh frozen plasma. Because the effect is transient, plasma infusions are not indicated except for active bleeding or before an invasive procedure. Use of recombinant factor VII may be an alternative.

7. Hemorrhage from esophageal varices—See [Chapter 14](#).

8. Hepatopulmonary syndrome—The hepatopulmonary syndrome is the triad of chronic liver disease, an increased alveolar-arterial gradient while the patient is breathing room air, and intrapulmonary vascular dilations or arteriovenous communications that result in a right-to-left intrapulmonary shunt. The syndrome is presumed to result from failure of the diseased liver to clear circulating pulmonary vasodilators. Patients often have dyspnea and arterial deoxygenation in the upright position (orthodeoxia) and relieved by recumbency. The diagnosis should be suspected in a cirrhotic patient with a pulse oximetry level = 92%. Contrast-enhanced echocardiography is a sensitive screening test for detecting pulmonary vascular dilations, whereas macroaggregated albumin lung perfusion scanning is more specific and is used to confirm the diagnosis. High-resolution CT may be useful for detecting dilated pulmonary vessels in affected patients and is under study. Medical therapy has been disappointing; however, intravenous methylene blue may improve oxygenation in patients by inhibiting nitric oxide-induced vasodilation. The syndrome may reverse with liver transplantation, although postoperative mortality is increased in patients with a preoperative arterial oxygen tension < 50 mm Hg or with substantial intrapulmonary shunting. Liver transplantation is contraindicated in patients with moderate to severe pulmonary hypertension (mean pulmonary pressure > 35 mm Hg), though in some cases treatment with epoprostenol may reduce pulmonary hypertension and thereby facilitate liver transplantation. TIPS may provide palliation in patients with hepatopulmonary syndrome awaiting transplantation.

C. Liver Transplantation

Liver transplantation is indicated in selected cases of irreversible, progressive chronic liver disease, acute hepatic failure, and certain metabolic diseases in which the metabolic defect is in the liver. Absolute contraindications include malignancy (except small hepatocellular carcinomas in a cirrhotic liver), advanced cardiopulmonary disease (except pulmonary arteriovenous shunting due to portal hypertension and cirrhosis), and sepsis. Relative contraindications include age over 70, portal and mesenteric vein thrombosis, active alcohol or drug abuse, HIV infection, severe malnutrition, and lack of patient understanding. Alcoholics should be abstinent for 6 months. Liver transplantation should be considered in patients with worsening functional status, rising bilirubin, decreasing albumin, worsening coagulopathy, refractory ascites, recurrent variceal bleeding, or worsening encephalopathy. The major impediment to more widespread use of liver transplantation is a shortage of donor organs. Increasingly, adult living donor liver transplantation is an option for some patients. Five-year survival rates as high as 80% are now reported. Hepatocellular carcinoma, hepatitis B and C, and some cases of Budd-Chiari syndrome and autoimmune liver disease may recur in the transplanted liver. The incidence of recurrence of hepatitis B can be reduced by pre- and postoperative treatment with lamivudine or adefovir dipivoxil and perioperative administration of hepatitis B immune globulin. Immunosuppression is achieved with a combination of cyclosporine or tacrolimus, corticosteroids, azathioprine, and mycophenolate mofetil and may be complicated by infections, renal failure, neurologic disorders, and drug toxicity as well as graft rejection, vascular occlusion, or bile leaks. Patients are at risk of obesity, diabetes, and hyperlipidemia.

Prognosis

The prognosis of cirrhosis has shown little change over the years. Factors determining survival include the patient's ability to stop the intake of alcohol as well as the Child-Turcotte-Pugh class ([Table 15-5](#)). Other prognostic scoring systems have been devised, and there is current interest in the Model for End-Stage Liver Disease (MELD), which incorporates the serum bilirubin and creatinine levels, and the international normalized ratio (INR) as a measure of mortality risk in patients with end-stage liver disease and as a tool for determining allocation priorities for donor livers. Hematemesis, jaundice, and ascites are unfavorable signs. In established cases with severe hepatic dysfunction (serum albumin < 3 g/dL, bilirubin > 3 mg/dL, ascites, encephalopathy, cachexia, and upper gastrointestinal bleeding), only 50% survive 6 months. The risk of death in this subgroup of patients with advanced cirrhosis is associated with renal insufficiency, cognitive dysfunction, ventilatory insufficiency, age = 65 years, and prothrombin time = 16 seconds. Liver transplantation has markedly improved the outlook for patients who are acceptable candidates and are referred for evaluation early.

PRIMARY BILIARY CIRRHOSIS

Primary biliary cirrhosis is a chronic disease of the liver characterized by autoimmune destruction of intrahepatic bile ducts and cholestasis. It is insidious in onset, occurs usually in women aged 40-60, and is often detected by the chance finding of elevated alkaline phosphatase levels. Estimated incidence and prevalence rates in the United States are 4.5 and 65.4 per 100,000, respectively, in women, and 0.7 and 12.1 per 100,000, respectively, in men. The disease is progressive and is complicated by steatorrhea, xanthomas, xanthelasma, osteoporosis, osteomalacia, and portal hypertension. It may be associated with Sjogren's syndrome, autoimmune thyroid disease, Raynaud's syndrome, scleroderma, hypothyroidism, and celiac disease. Infection with *Chlamydia pneumoniae* may be a triggering or causative agent in primary biliary cirrhosis; viral triggers are also suspected.

Clinical Findings

A. Symptoms and Signs

Many patients are asymptomatic for years. The onset of clinical illness is insidious and is heralded by fatigue and pruritus. With progression, physical examination reveals hepatosplenomegaly. Xanthomatous lesions may occur in the skin and tendons and around the eyelids. Jaundice and signs of portal hypertension are late findings. The risk of osteoporosis is increased in patients with primary biliary cirrhosis, as in patients with other forms of chronic liver disease.

B. Laboratory Findings

Blood counts are normal early in the disease. Liver biochemical tests reflect cholestasis with elevation of alkaline phosphatase, cholesterol (especially high-density lipoproteins), and, in later stages, bilirubin. Antimitochondrial antibodies (directed against pyruvate dehydrogenase or other 2-oxo-acid enzymes in mitochondria) are present in 95% of patients, and serum IgM levels are elevated.

Diagnosis

The diagnosis of primary biliary cirrhosis is based on the detection of cholestatic liver chemistries (often an isolated elevation of the alkaline phosphatase) and antimitochondrial antibodies in serum in combination with characteristic histology on liver biopsy. Liver biopsy also permits histologic staging: I, portal inflammation with granulomas; II, bile duct proliferation, periportal inflammation; III, interlobular fibrous septa; and IV, cirrhosis.

Differential Diagnosis

The disease must be differentiated from chronic biliary tract obstruction (stone or stricture), carcinoma of the bile ducts, primary sclerosing cholangitis, sarcoidosis, cholestatic drug toxicity (eg, chlorpromazine), and in some cases chronic hepatitis. Patients with a clinical and histologic picture of primary biliary cirrhosis but no antimitochondrial antibodies are said to have "autoimmune cholangitis," which has been associated with lower serum IgM levels and a greater frequency of smooth muscle and antinuclear antibodies. Some patients have overlapping features of primary biliary cirrhosis and autoimmune hepatitis.

Treatment

Treatment is primarily symptomatic. Cholestyramine (4 g) or colestipol (5 g) in water or juice three times daily may be beneficial for the pruritus. Rifampin, 150-300 mg orally twice daily, is inconsistently beneficial. Opioid antagonists (eg, naloxone, 0.2 ug/kg/ min by intravenous infusion, or naltrexone, 50 mg/d by mouth) show promise

in the treatment of pruritus. The 5-HT₃ serotonin receptor antagonist ondansetron may also provide some benefit. Deficiencies of vitamins A, K, and D may occur if steatorrhea is present and is aggravated when cholestyramine or colestipol is administered. Calcium supplementation (500 mg three times daily) may help prevent osteomalacia but is of uncertain benefit in osteoporosis.

Because of its lack of toxicity, ursodeoxycholic acid (10-15 mg/kg/d in one or two doses) is the preferred medical treatment and has been shown to slow the progression of disease, improve long-term survival, reduce the risk of developing esophageal varices, and delay the need for liver transplantation. Colchicine (0.6 mg twice daily) and methotrexate (15 mg/wk) have had some reported benefit in improving symptoms and serum levels of alkaline phosphatase and bilirubin. Methotrexate may also improve liver histology. Penicillamine, corticosteroids, and azathioprine have proved to be of no benefit. Mycophenolate mofetil is under study. For patients with advanced disease, liver transplantation is the treatment of choice.

Prognosis

Without liver transplantation, survival averages 7-10 years once symptoms develop. In advanced disease, adverse prognostic markers are older age, high serum bilirubin, edema, low serum albumin, prolonged prothrombin time, and variceal hemorrhage. Among asymptomatic patients, at least one-third will become symptomatic within 15 years. The risk of hepatobiliary malignancies appears to be increased in patients with primary biliary cirrhosis. Liver transplantation for advanced primary biliary cirrhosis is associated with a 1-year survival rate of 85-90%. The disease recurs in the graft in 20% of patients by 3 years, but this does not seem to affect survival.

HEMOCHROMATOSIS

Hemochromatosis is an autosomal recessive disease with linkage in many cases to HLA-A3. The principal genetic defect has been identified as a mutation in the *HFE* gene on chromosome 6. The alteration leads to substitution of tyrosine for cysteine at position 282 (*C282Y*) in a region of the gene product involved in interaction with β_2 -microglobulin. The HFE protein is thought to play an important role in the process by which duodenal crypt cells sense body iron stores. The presence of the mutation apparently reduces surface expression of an HFE- β_2 microglobulin complex on duodenal crypt cells, decreasing the affinity of the transferrin receptor for transferrin. This impairs transferrin-mediated uptake of iron from the circulation into crypt cells and results in up-regulation of duodenal metal-transporter-1 and ferroportin-1 expression on the luminal side of villous cells, leading in turn to increased iron absorption from the intestine. About 85% of persons with well-established hemochromatosis are homozygous for the *C282Y* mutation. The frequency of the gene mutation averages 7% in Northern European and North American white populations, resulting in a 0.5% frequency of homozygotes (of whom 40-70% will develop iron overload and even fewer will develop clinical symptoms). By contrast, the gene mutation and hemochromatosis are uncommon in African-American and Asian-American populations. A second genetic mutation leading to substitution of aspartic acid for histidine at position 63 (*H63D*) of the same protein may contribute to the development of hemochromatosis in a small percentage (1.5%) of persons who are compound heterozygotes for *C282Y* and *H63D*. A third *HFE* mutation, *S65C*, appears to lead to mild-to-moderate hepatic iron overload without fibrosis in some cases. Rare instances of hemochromatosis result from mutations in the transferring receptor, ferroportin-1, and other modifier genes.

The disorder is characterized by increased accumulation of iron as hemosiderin in the liver, pancreas, heart, adrenals, testes, pituitary, and kidneys. Eventually the patient may develop hepatic and pancreatic insufficiency, congestive heart failure, and hypogonadism. The disease is rarely recognized clinically before the fifth decade. Heterozygotes do not develop cirrhosis in the absence of associated disorders such as viral hepatitis or nonalcoholic fatty liver disease.

Clinical Findings

The onset is usually after age 50—earlier in men than in women; however, because of widespread liver biochemical testing and iron screening, the diagnosis can be made long before symptoms develop. Early symptoms are nonspecific (eg, fatigue, arthralgias). Later clinical manifestations include arthropathy, hepatomegaly and evidence of hepatic insufficiency (late finding), skin pigmentation (combination of slate-gray due to iron and brown due to melanin, sometimes resulting in bronze color), cardiac enlargement with or without heart failure or conduction defects, diabetes mellitus with its complications, and impotence in men. Bleeding from esophageal varices may occur, and in patients who develop cirrhosis, there is a 15-20% incidence of hepatocellular carcinoma. Affected patients are at increased risk of infection with *Vibrio vulnificus*, *Listeria monocytogenes*, *Yersinia enterocolitica*, and other siderophilic organisms. A variant presentation in young patients is characterized by cardiac dysfunction, hypogonadotropic hypogonadism, and a high mortality rate and is not associated with the *C282Y* mutation.

Laboratory findings include mildly abnormal liver tests (AST, alkaline phosphatase), an elevated plasma iron with greater than 50% saturation of the transferrin (after an overnight fast), and an elevated serum ferritin (although a normal iron saturation and normal ferritin does not exclude the diagnosis). CT and MRI may show changes consistent with iron overload of the liver, but these techniques are not sensitive enough for screening. Testing for *HFE* mutations is indicated in any patient with evidence of iron overload and in siblings of patients with confirmed hemochromatosis. In patients who are homozygous for *C282Y*, liver biopsy is often indicated to determine whether cirrhosis is present. Biopsy can be deferred, however, in patients under age 40 in whom the serum ferritin level is < 1000 ug/L, serum AST level is normal, and no hepatomegaly is present. The likelihood of cirrhosis is low in these individuals. Liver biopsy is also indicated when iron overload is suspected even though the patient is not homozygous for *C282Y*. In patients with hemochromatosis, the liver biopsy characteristically shows extensive iron deposition in hepatocytes and in bile ducts and the hepatic iron index—hepatic iron content per gram of liver converted to micromoles and divided by the patient's age—is generally greater than 1.9.

Treatment

Early diagnosis and treatment in the precirrhotic phase of hemochromatosis is of great importance. Affected patients should avoid foods rich in iron (such as red meat), alcohol, vitamin C, raw shellfish, and supplemental iron. Treatment consists initially of weekly phlebotomies of 500 mL of blood (about 250 mg of iron), continued for up to 2-3 years to achieve depletion of iron stores. This process is monitored by hematocrit and serum iron determinations. When iron store depletion is achieved (iron saturation < 50% and serum ferritin level < 50 ug/L), maintenance phlebotomies (every 2-4 months) are continued. The chelating agent deferoxamine is indicated for patients with hemochromatosis and anemia or in those with secondary iron overload due to thalassemia who cannot tolerate phlebotomies. The drug is administered intravenously or subcutaneously in a dose of 20-40 mg/kg/d infused over 24 hours and can mobilize 30 mg of iron per day. However, treatment is painful and time-consuming. Complications of hemochromatosis—arthropathy, diabetes, heart disease, portal hypertension, and hypopituitarism—also require treatment.

The course of the disease is favorably altered by phlebotomy therapy. In precirrhotic patients, cirrhosis may be prevented. Cardiac conduction defects and insulin requirements improve with treatment. In patients with cirrhosis, varices may reverse, and the risk of variceal bleeding declines. However, cirrhotic patients must be monitored for the development of hepatocellular carcinoma. Liver transplantation for advanced cirrhosis associated with severe iron overload, including hemochromatosis, has been reported to lead to survival rates that are lower than those for other types of liver disease because of cardiac complications and an increased risk of infections. Genetic testing is recommended for all first-degree family members of the proband; children of an affected person (*C282Y* homozygote) need be screened only if the patient's spouse carries the *C282Y*? or *H63D* mutation. Screening all white men over age 30 or all adults over age 20 by measurement of the transferrin saturation or perhaps the unbound iron-binding capacity has been recommended by some, but the value of screening has been questioned on the basis of recent observations that morbidity and mortality from hemochromatosis are lower than expected.

WILSON'S DISEASE

Wilson's disease (hepatolenticular degeneration) is a rare autosomal recessive disorder that usually occurs between the first and third decades. The condition is characterized by excessive deposition of copper in the liver and brain. The genetic defect, localized to chromosome 13, has been shown to affect a copper-transporting adenosine triphosphatase (ATP7B) in the liver and leads to oxidative damage of hepatic mitochondria. Over 200 different mutations in the Wilson disease gene have been identified, making genetic diagnosis impractical.

The major physiologic aberration in Wilson's disease is excessive absorption of copper from the small intestine and decreased excretion of copper by the liver, resulting in increased tissue deposition, especially in the liver, brain, cornea, and kidney. Serum ceruloplasmin, the plasma copper-carrying protein, is low. Urinary excretion of copper is high.

Clinical Findings

Wilson's disease tends to present as liver disease in adolescents and neuropsychiatric disease in young adults, but there is great variability. The diagnosis should always be considered in any child or young adult with hepatitis, splenomegaly with hypersplenism, hemolytic anemia, portal hypertension, and neurologic or psychiatric abnormalities. Wilson's disease should also be considered in persons under 40 years of age with chronic or fulminant hepatitis.

Hepatic involvement may range from elevated liver tests (although the alkaline phosphatase may be low) to cirrhosis and portal hypertension. The neurologic manifestations are related to basal ganglia dysfunction and include a resting, postural, or kinetic tremor and dystonia of the bulbar musculature with resulting dysarthria and dysphagia. Psychiatric features include behavioral and personality changes and emotional lability. The pathognomonic sign of the condition is the brownish or gray-green Kayser-Fleischer ring, which represents fine pigmented granular deposits in Descemet's membrane in the cornea close to the endothelial surface. The ring is usually most marked at the superior and inferior poles of the cornea. It can frequently be seen with the naked eye and almost invariably by slit-lamp examination. It may be absent in patients with hepatic manifestations only but is usually present in those with neuropsychiatric disease. Renal calculi, the Fanconi defect, renal tubular acidosis, hypoparathyroidism, and hemolytic anemia may occur in patients with Wilson's disease.

The diagnosis can be challenging and is based on demonstration of increased urinary copper excretion ($> 100 \text{ ug}/24 \text{ h}$) or low serum ceruloplasmin levels ($< 20 \text{ ug}/\text{dL}$), and elevated hepatic copper concentration ($> 250 \text{ ug}/\text{g}$ of dry liver). However, increased urinary copper and low serum ceruloplasmin levels are not specific for Wilson's disease. In equivocal cases (when the serum ceruloplasmin level is normal), the diagnosis may require demonstration of low radiolabeled copper incorporation into ceruloplasmin or urinary copper determination after a penicillamine challenge. Liver biopsy may show acute or chronic hepatitis or cirrhosis.

Treatment

Early treatment to remove excess copper is essential before it can produce neurologic or hepatic damage. Early in the treatment phase, restriction of dietary copper (shellfish, organ foods, and legumes) may be of value. Oral penicillamine ($0.75\text{--}2 \text{ g}/\text{d}$ in divided doses) is the drug of choice, making possible urinary excretion of chelated copper. Pyridoxine, 50 mg per week, is added, since penicillamine is an antimetabolite of this vitamin. If penicillamine treatment cannot be tolerated because of gastrointestinal, hypersensitivity, or autoimmune reactions, consider the use of trientine, 250-500 mg three times a day. Oral zinc acetate, 50 mg three times a day, promotes fecal copper excretion and may be used as maintenance therapy after decoppering with a chelating agent or as first-line therapy in presymptomatic or pregnant patients. Ammonium tetrathiomolybdate has shown promise as initial therapy for neurologic Wilson's disease.

Treatment should continue indefinitely. Once the serum nonceruloplasmin copper level is within the normal range, the dose of chelating agent can be reduced to the minimum necessary for maintaining that level. The prognosis is good in patients who are effectively treated before liver or brain damage has occurred. Liver transplantation is indicated for fulminant hepatitis (often after plasma exchange as a stabilizing measure), end-stage cirrhosis, and, in selected cases, intractable neurologic disease. Family members, especially siblings, require screening with serum ceruloplasmin, liver function tests, and slit-lamp examination.

HEPATIC VEIN OBSTRUCTION (BUDD-CHIARI SYNDROME)

Occlusion of the hepatic veins may occur from a variety of causes. Many cases are associated with polycythemia vera or other myeloproliferative diseases, which may be subclinical. Hepatovenous obstructions may be associated with caval webs, right-sided heart failure or constrictive pericarditis, neoplasms causing hepatic vein occlusions, paroxysmal nocturnal hemoglobinuria, Behcet's syndrome, blunt abdominal trauma, use of birth control pills, and pregnancy. In some cases, an underlying predisposition to thrombosis (eg, hyperprothrombinemia [factor II G20210A mutation], activated protein C resistance [factor V Leiden mutation], protein C or S or antithrombin deficiency, antiphospholipid antibodies) can be identified. Some cytotoxic agents and pyrrolizidine alkaloids ("bush teas") may cause hepatic veno-occlusive disease (occlusion of terminal venules), which mimics Budd-Chiari syndrome clinically. Veno-occlusive disease is common in patients who have undergone bone marrow transplantation, particularly those with pretransplant aminotransferase elevations or fever during cytoreductive therapy with cyclophosphamide, azathioprine, carmustine, busulfan, or etoposide or those receiving high-dose cytoreductive therapy or high-dose total body irradiation. In India, China, and South Africa, Budd-Chiari syndrome is often the result of occlusion of the hepatic portion of the inferior vena cava, presumably due to prior thrombosis, and the clinical presentation is mild but the course is frequently complicated by hepatocellular carcinoma.

Clinical manifestations may include tender, painful hepatic enlargement, jaundice, splenomegaly, and ascites. With advanced disease, bleeding varices and hepatic coma may be evident; hepatopulmonary syndrome may occur. Hepatic imaging studies may show a prominent caudate lobe, since its venous drainage may not be occluded. The screening test of choice is duplex Doppler ultrasonography, which has a sensitivity of 85% for detecting evidence of hepatic venous or inferior vena caval thrombosis. Caval venography can delineate caval webs and occluded hepatic veins. Percutaneous liver biopsy frequently shows a characteristic centrilobular congestion.

Ascites should be treated with fluid and salt restriction and diuretics. Treatable causes of Budd-Chiari syndrome should be sought. Prompt recognition and treatment of an underlying hematologic disorder may avoid the need for surgery. Surgical decompression (side-to-side portacaval, mesocaval, or mesoatrial shunt) of the congested liver may be required to relieve persistent hepatic congestion. In some cases, placement of a transjugular intrahepatic portosystemic shunt (TIPS) may be feasible, although late TIPS dysfunction is common. Balloon angioplasty, in some cases with placement of an intravascular metallic stent, is preferred in patients with an inferior vena caval web and may be feasible in patients with a short segment of thrombosis in the hepatic vein. Rarely, thrombolytic therapy may be attempted within 2 weeks of acute hepatic vein thrombosis. Liver transplantation is considered in patients with cirrhosis and hepatocellular dysfunction. Patients often require lifelong anticoagulation and treatment of the underlying myeloproliferative disease; antiplatelet therapy with aspirin and hydroxyurea has been suggested as an alternative to warfarin in patients with a myeloproliferative disorder.

THE LIVER IN HEART FAILURE

Shock liver, or ischemic hepatopathy, results from an acute fall in cardiac output due, for example, to acute myocardial infarction or arrhythmia, usually in a patient with passive congestion of the liver. Clinical hypotension may be absent (or unwitnessed). In some cases, the precipitating event is arterial hypoxemia due to respiratory failure. The hallmark is a rapid and striking elevation of serum aminotransferase levels (often $> 5000 \text{ units}/\text{L}$); an early rapid rise in the serum lactate dehydrogenase level is also typical, but elevations of serum alkaline phosphatase and bilirubin are usually mild. The prothrombin time may be prolonged, and encephalopathy may develop. The mortality rate due to the underlying disease is high, but in patients who recover, the aminotransferase levels return to normal quickly, usually within 1 week—in contrast to viral hepatitis.

In patients with passive congestion of the liver due to right-sided heart failure, the serum bilirubin level may be elevated, occasionally as high as 40 mg/dL, due in part to hypoxia of perivenular hepatocytes. Serum alkaline phosphatase levels are normal or slightly elevated. Hepatojugular reflux is present, and with tricuspid regurgitation the liver may be pulsatile. Ascites may be out of proportion to peripheral edema, with a high serum ascites-albumin gradient (> 1.1) and a protein content

of more than 2.5 g/dL. In severe cases, signs of encephalopathy may develop.

Rosenberg PM, Friedman LS: The liver in circulatory failure. In: *Schiff's Diseases of the Liver*, 9th ed. Schiff ER et al (editors). Lippincott Williams & Wilkins, 2003.

NONCIRRHOTIC PORTAL HYPERTENSION

Noncirrhotic portal hypertension must be considered in the differential diagnosis of splenomegaly or upper gastrointestinal bleeding due to esophageal or gastric varices in patients with little if any liver dysfunction. This syndrome may be due to portal vein thrombosis (with so-called cavernous transformation), splenic vein obstruction (presenting as gastric varices without esophageal varices), schistosomiasis, noncirrhotic intrahepatic portal sclerosis, nodular regenerative hyperplasia, or arterial-portal vein fistula. Aside from splenomegaly, the physical findings are not remarkable, though hepatic decompensation can follow severe gastrointestinal bleeding or a concurrent hepatic disorder. Endoscopy shows esophageal or gastric varices. The liver tests are usually normal, but there may be findings of hypersplenism. Magnetic resonance angiography (MRA) of the portal system is generally confirmatory. Needle biopsy of the liver may be indicated to diagnose schistosomiasis and noncirrhotic intrahepatic portal sclerosis. An underlying hypercoagulable state is found in many patients; these include mutation G20210A of prothrombin, factor V Leiden mutation, protein C and S deficiency, antiphospholipid syndrome, mutation TT677 of methylenetetrahydrofolate reductase, and myeloproliferative disorders. It is possible, however, that deficiency of protein C and S—as well as of antithrombin—is a secondary phenomenon due to portosystemic shunting and reduced hepatic blood flow.

If splenic vein thrombosis is the cause, splenectomy is curative. In other cases, band ligation or sclerotherapy is initiated for variceal bleeding and portosystemic shunting is reserved for failures of endoscopic therapy. Anticoagulation may be indicated for isolated acute portal vein thrombosis if a hypercoagulable disorder is identified.

PYOGENIC HEPATIC ABSCESS

The liver can be invaded by bacteria via (1) the portal vein (pylephlebitis); (2) the common duct (ascending cholangitis); (3) the hepatic artery, secondary to bacteremia; (4) direct extension from an infectious process; and (5) traumatic implantation of bacteria through the abdominal wall.

Ascending cholangitis resulting from biliary obstruction due to a stone, stricture, or neoplasm is the most common identifiable cause of hepatic abscess in the United States. In 10% of cases, liver abscess is secondary to appendicitis or diverticulitis. Up to 40% of abscesses have no demonstrable cause and are classified as cryptogenic. A dental source is identified in some such cases. The most frequently encountered organisms are *Escherichia coli*, *Proteus vulgaris*, *Enterobacter aerogenes*, *Klebsiella pneumoniae*, and multiple anaerobic species. *Staphylococcus aureus* is usually the causative organism in patients with chronic granulomatous disease. Hepatic candidiasis is seen in immunocompromised patients and those with hematologic malignancies. Rarely, hepatocellular carcinoma can present as a pyogenic abscess because of tumor necrosis, biliary obstruction, and superimposed bacterial infection. The possibility of an amebic liver abscess must always be considered (see [Chapter 35](#)).

Clinical Findings

The presentation is often insidious. Fever is almost always present and may antedate other symptoms or signs. Pain may be a prominent complaint and is localized to the right hypochondrium or epigastric area. Jaundice, tenderness in the right upper abdomen, and either steady or swinging fever are the chief physical findings.

Laboratory examination reveals leukocytosis with a shift to the left. Liver function studies are nonspecifically abnormal. Chest roentgenograms usually reveal elevation of the diaphragm if the abscess is on the right side. Ultrasound, CT, or MRI may reveal the presence of intrahepatic defects. On MRI, characteristic findings include high signal intensity on T2-weighted images and rim enhancement. Hepatic candidiasis is seen usually in the setting of systemic candidiasis, and on CT scan the characteristic appearance is that of multiple "bulls-eyes," but imaging studies may be negative in neutropenic patients.

Treatment

Treatment should consist of antimicrobial agents (a third-generation cephalosporin and metronidazole) that are effective against coliform organisms and anaerobes. If the abscess is at least 5 cm in diameter or the response to antibiotic therapy is not rapid, catheter or surgical (eg, laparoscopic) drainage should be undertaken. The mortality rate is still substantial (= 8%) and is highest in patients with underlying biliary malignancy or severe multiorgan dysfunction. Hep-atic candidiasis often responds to intravenous amphotericin B (total dose of 2-9 g). Fungal abscesses are associated with mortality rates of up to 50% and are treated with intravenous amphotericin B and drainage.

NEOPLASMS OF THE LIVER

1. Hepatocellular Carcinoma

Malignant neoplasms of the liver that arise from parenchymal cells are called hepatocellular carcinomas; those that originate in the ductular cells are called cholangiocarcinomas.

Hepatocellular carcinomas are associated with cirrhosis in general and hepatitis B or C in particular. Incidence rates are rising in the United States and other Western countries, presumably because of the high prevalence of chronic hepatitis C infection over the past 2-3 decades. In Africa and most of Asia, hepatitis B is of major etiologic significance, whereas in Western countries and Japan hepatitis C and alcoholic cirrhosis are the most common causes. Other associations include hemochromatosis, aflatoxin exposure (associated with mutation of the *p53* gene), α_1 -antiprotease (α_1 -antitrypsin) deficiency, and tyrosinemia. Increasingly, cirrhosis resulting from nonalcoholic fatty liver disease has been associated with hepatocellular carcinomas. The fibrolamellar variant of hepatocellular carcinoma occurs in young women and is characterized by a distinctive histologic picture, absence of risk factors, and indolent course.

Histologically, hepatocellular carcinoma is made up of cords or sheets of cells that roughly resemble the hepatic parenchyma. Blood vessels such as portal or hepatic veins are commonly involved by tumor.

The presence of a hepatocellular carcinoma may be unsuspected until there is deterioration in the condition of a cirrhotic patient who was formerly stable. Cachexia, weakness, and weight loss are associated symptoms. The sudden appearance of ascites, which may be bloody, suggests portal or hepatic vein thrombosis by tumor or bleeding from the necrotic tumor.

Physical examination may show tender enlargement of the liver, with an occasionally palpable mass. In Africa, young patients typically present with a rapidly expanding abdominal mass. Auscultation may reveal a bruit over the tumor or a friction rub when the process has extended to the surface of the liver.

Laboratory tests may reveal leukocytosis, as opposed to the leukopenia that is frequently encountered in cirrhotic patients. Anemia is common, but a normal or elevated hematocrit may be found in up to one-third of patients owing to elaboration of erythropoietin by the tumor. Sudden and sustained elevation of the serum alkaline phosphatase in a patient who was formerly stable is a common finding. Hepatitis B surface antigen is present in a majority of cases in endemic areas, whereas in the United States anti-HCV is found in up to 40% of cases. Alpha-fetoprotein levels are elevated in up to 70% of patients with hepatocellular carcinoma in Western countries (though the sensitivity is lower in blacks); however, mild elevations are also often seen in patients with chronic hepatitis. Serum levels of des-gamma-carboxy prothrombin are elevated in up to 90% of patients with hepatocellular carcinoma, but they may also be elevated in patients with vitamin K deficiency, chronic hepatitis, and metastatic cancer. Cytologic study of ascitic fluid rarely reveals malignant cells.

Arterial phase helical CT scanning with and without intravenous contrast or MRI is the preferred imaging study to characterize the location and vascularity of the tumor. Ultrasound is less sensitive but is used to screen for hepatic nodules in high-risk patients. Contrast-enhanced ultrasound has a sensitivity and specificity approaching those of arterial phase helical CT. Liver biopsy is diagnostic, though seeding of the needle tract by tumor is a potential risk (= 5%), and biopsy can be deferred if

imaging studies and alpha-fetoprotein levels are diagnostic or if surgical resection is planned. Staging in the TNM classification includes the following definitions: T0: no evidence of primary tumor; T1: solitary tumor without vascular invasion; T2: solitary tumor with vascular invasion or multiple tumors none more than 5 cm; T3: multiple tumors more than 5 cm or tumor involving a major branch of the portal or hepatic vein; and T4: tumors with direct invasion of adjacent organs other than the gallbladder or with perforation of the visceral peritoneum. Alternative staging systems are under study that also incorporate liver function, tumor aggressiveness and growth rate, general health of the patient, and treatment.

In the United States, overall 1- and 5-year survival rates for patients with hepatocellular carcinoma are 23% and 5%, respectively. Attempts at surgical resection are usually fruitless if concomitant cirrhosis is present and if the tumor is multifocal. Surgical resection of solitary hepatocellular carcinomas may result in cure if liver function is preserved (Child class A or possibly B). Five-year survival rates rise to 56% for patients with localized resectable disease (T1, T2, T3, selected T4; N0; M0) but are virtually nil for those with localized unresectable or advanced disease. Adaptive immunotherapy and treatment of underlying chronic viral hepatitis may lower postsurgical recurrence rates. Laparoscopic liver resection has been performed in selected cases. Liver transplantation may be appropriate for small unresectable tumors in a patient with advanced cirrhosis, with reported 5-year survival rates of up to 75%. Liver transplantation may achieve a better recurrence-free survival than resection in patients with well-compensated cirrhosis and small tumors (one tumor < 5 cm or three or fewer tumors each < 3 cm in diameter) but is often impractical because of the donor organ shortage; living donor liver transplantation may be considered in these cases. Chemotherapy, hormonal therapy with tamoxifen, and long-acting octreotide have not been shown to prolong life, but chemoembolization via the hepatic artery may be palliative and may prolong survival. Injection of absolute ethanol into, radiofrequency ablation of, or cryotherapy of small tumors (< 3 cm) may prolong survival; these are reasonable alternatives to surgical resection in some patients and may provide a "bridge" to liver transplantation. For patients whose disease progresses despite treatment, meticulous efforts at palliative care are essential (see [Chapter 5](#)). Such patients may develop severe pain due to expansion of the liver capsule by the tumor and require concerted efforts at pain management, including the use of opioids (see [Chapter 1](#)).

In the patient with chronic hepatitis B or cirrhosis caused by HCV or alcohol, surveillance for the development of hepatocellular carcinoma should be considered with regular (eg, every 6 months) alpha-fetoprotein testing and ultrasonography. The risk of hepatocellular carcinoma in a patient with cirrhosis is 3-5% a year. Mass vaccination programs against HBV in developing countries are leading to reduced rates of hepatocellular carcinoma, whereas in the United States and western Europe the incidence of hepatocellular carcinoma is rising.

2. Benign Liver Neoplasms

Two distinct benign entities with characteristic clinical, radiologic, and histopathologic features have been described in women taking oral contraceptives. **Focal nodular hyperplasia** occurs at all ages but is probably not caused by oral contraceptives. It is often asymptomatic and appears as a hypervascular mass, occasionally with a central hypodense "stellate" scar on CT scan or MRI. Microscopically, focal nodular hyperplasia consists of hyperplastic units of hepatocytes with a central stellate scar containing proliferating bile ducts. It is not a true neoplasm but a nonspecific reaction to vascular abnormalities. **Liver cell adenoma** occurs most commonly in the third and fourth decades of life and is usually caused by oral contraceptives; the clinical presentation is often one of acute abdominal pain due to necrosis of the tumor with hemorrhage. The tumor is hypovascular and reveals a cold defect on liver scan. Grossly, the cut surface appears structureless. As seen microscopically, the liver cell adenoma consists of sheets of hepatocytes without portal tracts or central veins. The only physical finding in focal nodular hyperplasia or liver cell adenoma is a palpable abdominal mass in a minority of cases. Liver function is usually normal. Arterial phase helical CT and MRI can distinguish an adenoma from focal nodular hyperplasia in 80-90% of cases.

Treatment of focal nodular hyperplasia is resection only in the symptomatic patient. The prognosis is excellent. Liver cell adenoma often undergoes necrosis and rupture, and resection is advised even in asymptomatic persons. In selected cases, laparoscopic resection may be feasible. Regression of benign hepatic tumors may follow cessation of oral contraceptives.

The most common benign neoplasm of the liver is the **cavernous hemangioma**, often an incidental finding on ultrasound or CT scan. This lesion must be differentiated from other space-occupying intrahepatic lesions, usually by MRI. Rarely, fine-needle biopsy is necessary to differentiate these lesions and does not appear to carry an increased risk of bleeding. Cavernous hemangiomas rarely require treatment.

■ DISEASES OF THE BILIARY TRACT

CHOLELITHIASIS (Gallstones)

Gallstones are more common in women than in men and increase in incidence in both sexes and all races with aging. In the United States, over 10% of men and 20% of women have gallstones by age 65; the total exceeds 20 million people. Although cholesterol gallstones are less common in black people, cholelithiasis attributable to hemolysis occurs in over a third of individuals with sickle cell anemia. Native Americans of both the Northern and Southern Hemispheres have a high rate of cholesterol cholelithiasis, probably because of a predisposition resulting from "thrifty" (*LITH*) genes that promote efficient calorie utilization and fat storage. As many as 75% of Pima and other American Indian women over the age of 25 years have cholelithiasis. Obesity is a risk factor for gallstones, especially in women. Rapid weight loss also increases the risk of symptomatic gallstone formation. There is evidence that glucose intolerance and elevated serum insulin levels (insulin resistance syndrome) are risk factors for gallstones. A low-carbohydrate diet and physical activity may help prevent gallstones, and consumption of caffeinated coffee appears to protect against gallstones in women. The incidence of gallstones is high in individuals with Crohn's disease; approximately one-third of those with inflammatory involvement of the terminal ileum have gallstones due to disruption of bile salt resorption that results in decreased solubility of the bile. The incidence of cholelithiasis is also increased in patients with diabetes mellitus and in those with cirrhosis. Drugs such as clofibrate, octreotide, and ceftriaxone can cause gallstones. In contrast, aspirin and other nonsteroidal anti-inflammatory drugs may protect against gallstones. Prolonged fasting (over 5-10 days) can lead to formation of biliary "sludge" (microlithiasis), which usually resolves with refeeding but can lead to gallstones or biliary symptoms. Pregnancy is associated with an increased risk of gallstones and of symptomatic gallbladder disease. Hormone replacement therapy appears to have only a slight risk for biliary tract surgery.

Pathogenesis of Gallstones

Gallstones are classified according to their predominant chemical composition as cholesterol or calcium bilirubinate stones. The latter comprise less than 20% of the stones found in Europe or the United States but 30-40% of stones found in Japan.

Three compounds comprise 80-95% of the total solids dissolved in bile: conjugated bile salts, lecithin, and cholesterol. Cholesterol is a neutral sterol, and lecithin is a phospholipid; both are almost completely insoluble in water. However, bile salts in combination with lecithin are able to form multimolecular aggregates (and micelles) or vesicles that solubilize cholesterol in an aqueous solution. Precipitation of cholesterol microcrystals may come about because of increased biliary secretion of cholesterol, defective formation of vesicles, an excess of factors promoting the nucleation of cholesterol crystals (or deficiency of antinucleating factors), or delayed emptying of the gallbladder.

Presentation (Table 15-6)

Cholelithiasis is frequently asymptomatic and is discovered in the course of routine radiographic study, operation, or autopsy. There is generally no need for prophylactic cholecystectomy in an asymptomatic person unless the gallbladder is calcified or gallstones are over 3 cm in diameter. Ultimately, symptoms (biliary colic) develop in 10-25% of patients by 10 years. "Symptomatic" cholelithiasis usually means characteristic right upper quadrant or epigastric discomfort or pain (biliary colic). Occasional patients present with small intestinal obstruction due to "gallstone ileus" as the initial manifestation of cholelithiasis.

Treatment

Laparoscopic cholecystectomy is the treatment of choice for symptomatic gallbladder disease. The minimal trauma to the abdominal wall makes it possible for patients to go home within 2 days after the procedure and to return to work within 7 days (instead of weeks for those undergoing standard open cholecystectomy). In selected cases, the procedure may even be performed on an outpatient basis. This procedure is suitable in most patients, including those with acute cholecystitis. If problems are encountered, the surgery can be converted to a conventional open cholecystectomy. Bile duct injuries occur in 0.1% of cases done by experienced surgeons. Emerging data suggest that cholecystectomy may increase the risk of esophageal and proximal small intestinal adenocarcinoma because of increased duodenogastric reflux and changes in intestinal exposure to bile, respectively. A conservative approach to biliary colic is advised in pregnant patients, but for patients with repeated

attacks of biliary colic or acute cholecystitis, cholecystectomy can be performed—even by the laparoscopic route—preferably in the second trimester. Enterolithotomy alone is considered adequate treatment in most patients with gallstone ileus.

Persistence of symptoms after removal of the gallbladder (postcholecystectomy syndrome) implies either mistaken diagnosis, functional bowel disorder, technical error, retained or recurrent common bile duct stone, or spasm of the sphincter of Oddi (see below).

Cheno- and ursodeoxycholic acids are bile salts that when given orally for up to 2 years dissolve some cholesterol stones and may be considered in selected patients who refuse cholecystectomy. The dose is 7 mg/kg/d of each or 8-13 mg/kg of ursodeoxycholic acid in divided doses daily. They are most effective in patients with a functioning gallbladder, as determined by gallbladder visualization on oral cholecystography, and multiple small "floating" gallstones (representing not more than 15% of patients with gallstones). In half of patients, gallstones recur within 5 years after treatment is stopped.

Lithotripsy in combination with bile salt therapy for single radiolucent stones less than 20 mm in diameter was an option in the past but is no longer generally employed in the United States.

ACUTE CHOLECYSTITIS

Essentials of Diagnosis

- Steady, severe pain and tenderness in the right hypochondrium or epigastrium.
- Nausea and vomiting.
- Fever and leukocytosis.

General Considerations

Cholecystitis is associated with gallstones in over 90% of cases. It occurs when a stone becomes impacted in the cystic duct and inflammation develops behind the obstruction. Acalculous cholecystitis should be considered when unexplained fever or right upper quadrant pain occurs within 2-4 weeks of major surgery or in a critically ill patient who has had no oral intake for a prolonged period. Primarily as a result of ischemic changes secondary to distention, gangrene may develop, resulting in perforation. Although generalized peritonitis is possible, the leak usually remains localized and forms a chronic, well-circumscribed abscess cavity. Acute cholecystitis caused by infectious agents (eg, cytomegalovirus, cryptosporidiosis, or microsporidiosis) may occur in patients with AIDS.

Clinical Findings

A. Symptoms and Signs

The acute attack is often precipitated by a large or fatty meal and is characterized by the sudden appearance of steady pain localized to the epigastrium or right hypochondrium, which may gradually subside over a period of 12-18 hours. Vomiting occurs in about 75% of patients and in half of instances affords variable relief. Right upper quadrant abdominal tenderness is almost always present and is usually associated with muscle guarding and rebound pain. A palpable gallbladder is present in about 15% of cases. Jaundice is present in about 25% of cases and, when persistent or severe, suggests the possibility of choledocholithiasis. Fever is typical.

B. Laboratory Findings

The white blood cell count is usually high (12,000-15,000/uL). Total serum bilirubin values of 1-4 mg/dL may be seen even in the absence of common duct obstruction. Serum aminotransferase and alkaline phosphatase are often elevated—the former as high as 300 units/mL, or even higher when associated with ascending cholangitis. Serum amylase may also be moderately elevated.

C. Imaging

Plain films of the abdomen may show radiopaque gallstones in 15% of cases. ^{99m}Tc hepatobiliary imaging (using iminodiacetic acid compounds), also known as the HIDA scan, is useful in demonstrating an obstructed cystic duct, which is the cause of acute cholecystitis in most patients. This test is reliable if the bilirubin is under 5 mg/dL (98% sensitivity and 81% specificity for acute cholecystitis). Right upper quadrant abdominal ultrasound may show the presence of gallstones but is not sensitive for acute cholecystitis (67% sensitivity, 82% specificity).

Differential Diagnosis

The disorders most likely to be confused with acute cholecystitis are perforated peptic ulcer, acute pancreatitis, appendicitis in a high-lying appendix, perforated colonic carcinoma or diverticulum of the hepatic flexure, liver abscess, hepatitis, and pneumonia with pleurisy on the right side, and even myocardial ischemia. Definite localization of pain and tenderness in the right hypochondrium, with radiation around to the infrascapular area, strongly favors the diagnosis of acute cholecystitis. True cholecystitis without stones suggests the rare possibility of polyarteritis nodosa affecting the cystic artery.

Complications

A. Gangrene of the Gallbladder

Continuation or progression of right upper quadrant abdominal pain, tenderness, muscle guarding, fever, and leukocytosis after 24-48 hours suggests severe inflammation and possible gangrene of the gallbladder. Necrosis may occasionally develop without definite signs in the obese, diabetic, elderly, or immunosuppressed patient.

B. Cholangitis

Cholangitis classically presents with Charcot's triad, namely, fever and chills, right upper quadrant pain, and jaundice. Although 95% of patients who present with this picture will have common duct stones, only a minority of patients with acute cholecystitis have common duct stones that will present in this manner.

C. Chronic Cholecystitis and Other Complications

Chronic cholecystitis results from repeated episodes of acute cholecystitis or chronic irritation of the gallbladder wall by stones and is characterized pathologically by varying degrees of chronic inflammation of the gallbladder. Calculi are usually present. In about 4-5% of cases, the villi of the gallbladder undergo polypoid enlargement due to deposition of cholesterol that may be visible to the naked eye ("strawberry gallbladder," cholesterosis). In other instances, adenomatous hyperplasia of all or part of the gallbladder wall may be so marked as to give the appearance of a myoma (pseudotumor). Hydrops of the gallbladder results when acute cholecystitis subsides but cystic duct obstruction persists, producing distention of the gallbladder with a clear mucoid fluid. Occasionally, a stone in the neck of the gallbladder may compress the bile duct and cause jaundice (Mirizzi's syndrome). Xanthogranulomatous cholecystitis is a rare variant of chronic cholecystitis characterized by grayish-yellow nodules or streaks, representing lipid-laden macro-phages, in the wall of the gallbladder.

Cholelithiasis with chronic cholecystitis may be associated with acute exacerbations of gallbladder inflammation, common duct stone, fistulization to the bowel, pancreatitis, and, rarely, carcinoma of the gallbladder. Calcified (porcelain) gallbladder has generally been thought to have a high association with gallbladder carcinoma and to be an indication for cholecystectomy, though the risk of gallbladder cancer may be higher when calcification is mucosal rather than intramural.

Treatment

Acute cholecystitis will usually subside on a conservative regimen (withholding of oral feedings, intravenous alimentation, analgesics, and antibiotics). Meperidine may be preferable to morphine for pain because of less spasm of the sphincter of Oddi. Because of the high risk of recurrent attacks (up to 10% by 1 month and over 30% by 1 year), cholecystectomy—generally laparoscopically—should generally be performed within 2-3 days after hospitalization. If nonsurgical treatment has been elected, the patient (especially if diabetic or elderly) should be watched carefully for recurrent symptoms, evidence of gangrene of the gallbladder, or cholangitis. In high-risk patients, ultrasound-guided aspiration of the gallbladder or percutaneous cholecystostomy may postpone or even avoid the need for surgery. Cholecystectomy is mandatory when there is evidence of gangrene or perforation.

Surgical treatment of chronic cholecystitis is the same as for acute cholecystitis. If indicated, cholangiography can be performed during laparoscopic cholecystectomy. Choledocholithiasis can also be excluded by either pre- or postoperative ERCP or MRCP.

Prognosis

The overall mortality rate of cholecystectomy is less than 1%, but hepatobiliary tract surgery is a more formidable procedure in the elderly, in whom the mortality rate is 5-10%. A technically successful surgical procedure in an appropriately selected patient is generally followed by complete resolution of symptoms.

PRE- & POSTCHOLECYSTECTOMY SYNDROMES

Precholecystectomy

In a small group of patients (mostly women) with biliary colic, conventional radiographic studies of the upper gastrointestinal tract and gallbladder—including cholangiography—are unremarkable. However, emptying of the gallbladder is markedly reduced on gallbladder scintigraphy following injection of cholecystokinin. Cholecystectomy is curative. Anatomic and histologic examination of the operative specimen may reveal obstruction of the cystic duct because of fibrotic stenosis or adhesions and kinking. Additional diagnostic considerations are ampullary spasm and biliary dyskinesia (see below).

Postcholecystectomy

Following cholecystectomy, some patients complain of continuing symptoms, ie, right upper quadrant pain, flatulence, and fatty food intolerance. The persistence of symptoms in this group of patients suggests the possibility of an incorrect diagnosis prior to cholecystectomy, eg, esophagitis, pancreatitis, radiculopathy, or functional bowel disease. It is important to rule out the possibility of choledocholithiasis or common duct stricture as a cause of persistent symptoms in the postoperative period.

Pain has been associated with dilation of the cystic duct remnant, neuroma formation in the ductal wall, foreign body granuloma, or traction on the common duct by a long cystic duct. The clinical presentation of colicky pain, chills, fever, or jaundice should suggest biliary tract disease. Biliary colic associated with elevated liver tests or amylase suggests the possibility of spasm or stenosis of the sphincter of Oddi. Abdominal or endoscopic ultrasonography or retrograde cholangiography may be necessary to demonstrate or exclude biliary tract disease. Biliary manometry may be useful in documenting elevated baseline sphincter of Oddi pressures typical of sphincter dysfunction. Biliary scintigraphy shows promise as a screening test for sphincter dysfunction. In some such cases, treatment with calcium channel blockers, long-acting nitrates, or possibly injection of the sphincter with botulinum toxin may be beneficial. Endoscopic sphincterotomy is most likely to relieve symptoms when they are associated with elevated liver chemistry tests, a dilated common duct, or an elevated sphincter of Oddi pressure. In some cases, surgical sphincteroplasty or removal of the cystic duct remnant may be necessary.

Cicala M et al: Outcome of endoscopic sphincterotomy in post cholecystectomy patients with sphincter of Oddi dysfunction as predicted by manometry and quantitative choledochoscintigraphy. Gut 2002;50:665. [PMID: 11950813]

CHOLEDOCHOLITHIASIS & CHOLANGITIS

Essentials of Diagnosis

- Often a history of biliary colic or jaundice.
- Sudden onset of severe right upper quadrant or epigastric pain, which may radiate to the right scapula or shoulder.
- Occasional patients present with painless jaundice.
- Nausea and vomiting.
- Fever, which may be followed by hypothermia and gram-negative shock, jaundice, and leukocytosis.
- Abdominal films may reveal gallstones.

General Considerations

About 15% of patients with gallstones have choledocholithiasis (common bile duct stones). The percentage rises with age, and the frequency in elderly people with gallstones may be as high as 50%. Common duct stones usually originate in the gallbladder but may also form spontaneously in the common duct after cholecystectomy. The stones are frequently "silent" as no symptoms result unless there is obstruction.

Clinical Findings

A. Symptoms and Signs

A history suggestive of biliary colic or prior jaundice may be obtained. Biliary colic results from rapid increases in common bile duct pressure due to obstructed bile flow. The additional features that suggest the presence of a common duct stone are (1) frequently recurring attacks of right upper abdominal pain that is severe and persists for hours, (2) chills and fever associated with severe colic, and (3) a history of jaundice associated with episodes of abdominal pain. The combination of pain, fever (and chills), and jaundice represents **Charcot's triad** and denotes the classic picture of cholangitis. The presence of altered sensorium, lethargy, and septic shock connotes acute suppurative cholangitis and represents an endoscopic or surgical emergency.

Hepatomegaly may be present in calculous biliary obstruction, and tenderness is usually present in the right upper quadrant and epigastrium.

B. Laboratory Findings

Bilirubinuria and elevation of serum bilirubin are present if the common duct is obstructed; levels commonly fluctuate. Serum alkaline phosphatase elevation is especially suggestive of obstructive jaundice. Not uncommonly, serum amylase elevations are present because of secondary pancreatitis. On occasion, acute obstruction of the bile duct produces a transient striking increase in serum aminotransferase levels (> 1000 units/L). Prolongation of the prothrombin time can result from the obstructed flow of bile to the intestine. When extrahepatic obstruction persists for more than a few weeks, differentiation of obstruction from chronic cholestatic liver disease becomes progressively more difficult.

C. Imaging

Ultrasonography, CT scan, and radionuclide imaging may demonstrate dilated bile ducts and impaired bile flow. Endoscopic ultrasonography, helical CT, and MR cholangiography have been found to be accurate in demonstrating common duct stones and, if available, may be used in patients thought to be at low or intermediate risk for choledocholithiasis. Endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography provides the most direct and accurate means of determining the cause, location, and extent of obstruction. If the likelihood that obstruction is caused by a stone is high, ERCP is the procedure of choice because it permits papillotomy or balloon dilation of the papilla with stone extraction or stent placement.

Differential Diagnosis

The most common cause of obstructive jaundice is common duct stone. Next in frequency is carcinoma of the pancreas, ampulla of Vater, or common duct. Extrinsic compression of the common duct may result from metastatic carcinoma (usually from the gastrointestinal tract or breast) involving porta hepatis lymph nodes or, rarely, from a large duodenal diverticulum. Gallbladder cancer extending into the common duct often presents as obstructive jaundice. Chronic cholestatic liver diseases

(primarily biliary cirrhosis, sclerosing cholangitis, drug-induced) must be considered. Hepatocellular jaundice can usually be differentiated by the history, clinical findings, and liver tests, but liver biopsy is necessary on occasion. Recurrent pyogenic cholangitis should be considered in persons from Asia (and occasionally elsewhere) with intrahepatic biliary stones (particularly in the left ductal system) and with recurrent cholangitis.

Complications

A. Biliary Cirrhosis

Common duct obstruction lasting longer than 30 days results in liver damage leading to cirrhosis. Hepatic failure with portal hypertension occurs in untreated cases.

B. Hypoprotrombinemia

Patients with obstructive jaundice or liver disease may bleed excessively as a result of prolonged prothrombin times. In contrast to hepatocellular dysfunction, hypoprotrombinemia due to obstructive jaundice will respond to 10 mg of parenteral vitamin K or water-soluble oral vitamin K (phytonadione, 5 mg) within 24-36 hours.

Treatment

Common duct stone in a patient with cholelithiasis and cholecystitis is usually treated by endoscopic papillotomy and stone extraction followed by laparoscopic cholecystectomy. For the poor-risk patient, however, cholecystectomy may be deferred because the risk of subsequent cholecystitis is low. ERCP should be performed before cholecystectomy in patients with gallstones and jaundice (serum total bilirubin > 2 mg/dL), a dilated common bile duct (> 7 mm), or stones in the bile duct seen on ultrasound or computed tomography. When biliary pancreatitis resolves rapidly, the stone usually passes into the intestine, and ERCP prior to cholecystectomy is not necessary if an intraoperative cholangiogram is done.

Choledocholithiasis discovered at laparoscopic cholecystectomy may be managed via laparoscopic removal or, if necessary, conversion to open surgery or by postoperative endoscopic sphincterotomy. In the postcholecystectomy patient with choledocholithiasis, endoscopic papillotomy with stone extraction is preferable to transabdominal surgery. Lithotripsy (endoscopic or external), direct cholangioscopy, or biliary stenting may be a therapeutic consideration for large stones. For the patient with a T tube and common duct stone, the stone may be extracted via the T tube (see below). Urgent ERCP, sphincterotomy, and stone extraction are generally indicated for choledocholithiasis complicated by ascending cholangitis. Before ERCP, liver function should be evaluated thoroughly. Prothrombin time should be restored to normal by parenteral administration of vitamin K (see above). Nutrition should be restored by a high-carbohydrate, high-protein diet and vitamin supplementation. Ciprofloxacin, 250 mg intravenously every 12 hours, penetrates well into bile and is effective treatment for cholangitis. An alternative regimen in severely ill patients is mezlocillin, 3 g intravenously every 4 hours, plus either metronidazole or gentamicin (or both). The dose of metronidazole is 500 mg intravenously every 6 hours (if there has been no prior manipulation of the duct); the dose of gentamicin is 2 mg/kg intravenously as loading dose, plus 1.5 mg/kg every 8 hours adjusted for renal function. Aminoglycosides should not be given for more than a few days because the risk of aminoglycoside nephrotoxicity is increased in patients with cholestasis. Emergent decompression of the bile duct, generally by ERCP, is required for patients who are septic or fail to improve on antibiotics within 12-24 hours. Medical therapy alone is most likely to fail in patients with tachycardia, serum albumin < 3 g/dL, marked hyperbilirubinemia, and prothrombin time > 14 seconds on admission. If sphincterotomy cannot be performed, decompression by a biliary stent or nasobiliary catheter can be done. Once decompression is achieved, antibiotics are generally continued for another three days.

At cholecystectomy, operative cholangiography via the cystic duct should be considered. Operative findings of choledocholithiasis are palpable stones in the common duct, dilation or thickening of the wall of the common duct, and gallbladder stones small enough to pass through the cystic duct. If stones in the common duct are found, common duct exploration can be performed or a postoperative ERCP and sphincterotomy can be planned.

Following operative choledochostomy, a simple catheter or T tube is placed in the common duct for decompression. A properly placed tube should drain bile at the operating table and continuously thereafter; otherwise, it should be considered blocked or dislocated. The volume of bile drainage varies from 100 mL to 1000 mL daily (average, 200-400 mL). Above-average drainage may be due to obstruction at the ampulla (usually by edema).

Postoperative antibiotics are not administered routinely after biliary tract surgery. Cultures of the bile are always taken at operation. If biliary tract infection was present preoperatively or is apparent at operation, ampicillin (500 mg every 6 hours intravenously) with gentamicin (1.5 mg/kg every 8 hours) and metronidazole (500 mg every 6 hours) or ciprofloxacin (250 mg intravenously every 12 hours) or a third-generation cephalosporin (eg, cefoperazone, 1-2 g intravenous every 12 hours) is administered postoperatively until the results of sensitivity tests on culture specimens are available.

A T-tube cholangiogram should be done before the tube is removed, usually about 3 weeks after surgery. A small amount of bile frequently leaks from the tube site for a few days.

BILIARY STRICTURE

Benign biliary strictures are the result of surgical anastomosis or injury in about 95% of cases. The remainder are caused by blunt external injury to the abdomen, pancreatitis, erosion of the duct by a gallstone, or prior endoscopic sphincterotomy.

Signs of injury to the duct may or may not be recognized in the immediate postoperative period. If complete occlusion has occurred, jaundice will develop rapidly; more often, however, a tear has been accidentally made in the duct, and the earliest manifestation of injury may be excessive or prolonged loss of bile from the surgical drains. Bile leakage may predispose to localized infection, which in turn accentuates scar formation and the ultimate development of a fibrous stricture.

Cholangitis is the most common complication of stricture. Typically, the patient experiences episodes of pain, fever, chills, and jaundice within a few weeks to months after cholecystectomy. Physical findings may include jaundice during an attack of cholangitis and right upper quadrant abdominal tenderness.

Serum alkaline phosphatase is usually elevated. Hyperbilirubinemia is variable, fluctuating during exacerbations and usually remaining in the range of 5-10 mg/dL. Blood cultures may be positive during an episode of cholangitis. Endoscopic retrograde cholangiopancreatography or percutaneous transhepatic cholangiography can be valuable in demonstrating the stricture, permitting biopsy and cytologic specimens, and allowing dilation and stent placement, thereby avoiding surgical repair in some cases. Placement of multiple plastic stents may be more effective than placement of a single stent. Metal stents, which cannot be removed endoscopically, are generally avoided in benign strictures. When malignancy cannot be excluded with certainty, additional endoscopic diagnostic approaches may be considered—if available—including intraductal ultrasound and choledochoscopy (cholangioscopy).

Differentiation from cholangiocarcinoma may ultimately require surgical exploration. Significant hepatocellular disease due to secondary biliary cirrhosis will inevitably occur if a biliary stricture is not treated. Operative treatment of a stricture frequently necessitates performance of an end-to-end ductal repair, choledochojejunostomy, or hepaticojejunostomy to reestablish bile flow into the intestine.

PRIMARY SCLEROSING CHOLANGITIS

Primary sclerosing cholangitis is an uncommon disease characterized by a diffuse inflammation of the biliary tract leading to fibrosis and strictures of the biliary system. The disease is most common in men aged 20-40 and is closely associated with ulcerative colitis (and occasionally Crohn's colitis), which is present in approximately two-thirds of patients with primary sclerosing cholangitis; however, only 1-4% of patients with ulcerative colitis develop clinically significant sclerosing cholangitis. As in ulcerative colitis, smoking is associated with a decreased risk of primary sclerosing cholangitis. Primary sclerosing cholangitis is associated with the histocompatible antigens HLA-B8 and -DR3 or -DR4, suggesting that genetic factors may play an etiologic role. Antineutrophil cytoplasmic antibodies (ANCA), with fluorescent staining

characteristics and target antigens distinct from those found in patients with Wegener's granulomatosis or vasculitis, are found in 70% of patients. In patients with AIDS, sclerosing cholangitis may result from infections caused by CMV, cryptosporidium, or microsporium.

Primary sclerosing cholangitis presents as progressive obstructive jaundice, frequently associated with malaise, pruritus, anorexia, and indigestion. Patients may be diagnosed in the presymptomatic phase because of an elevated alkaline phosphatase level. Complications of chronic cholestasis, such as osteoporosis and malabsorption of fat-soluble vitamins, may occur.

The diagnosis of primary sclerosing cholangitis is generally made by endoscopic retrograde cholangiography; increasingly, magnetic resonance cholangiography is being used as a noninvasive diagnostic approach, but it is less sensitive than ERCP for visualizing the intrahepatic ducts. Biliary obstruction by a stone or tumor should be excluded. The disease may be confined to small intrahepatic bile ducts, in which case ERCP is normal and the diagnosis is suggested by liver biopsy. These patients have a longer survival and lower rate of cholangiocarcinoma than patients with involvement of the large ducts. Liver biopsy is also needed for staging, which is based on the degree of inflammation and fibrosis. In addition to ANCA, patients may have serum antinuclear, anticardiolipin, and antithyroperoxidase antibodies and rheumatoid factor. Occasional patients have clinical and histologic features of both sclerosing cholangitis and autoimmune hepatitis. Even more rarely, an association with chronic pancreatitis (sclerosing pancreaticholangitis) is seen, and this entity is often responsive to corticosteroids. In general, the diagnosis of primary sclerosing cholangitis is difficult to make after biliary surgery or intrahepatic artery chemotherapy, which may result in bile duct injury. Primary sclerosing cholangitis must be distinguished from idiopathic adulthood ductopenia, a rare disorder affecting young to middle-aged adults who manifest cholestasis resulting from loss of interlobular and septal bile ducts yet who have a normal cholangiogram.

Cholangiocarcinoma may complicate the course of primary sclerosing cholangitis in at least 10% of cases and may be difficult to diagnose by cytologic examination or biopsy because of false-negative results. A serum CA 19-9 level > 100 units/mL is suggestive but not diagnostic of cholangiocarcinoma.

Treatment with corticosteroids and broad-spectrum antimicrobial agents has been employed with inconsistent and unpredictable results. Episodes of acute bacterial cholangitis may be treated with ciprofloxacin. Ursodeoxycholic acid in standard doses (10-15 mg/kg/d) may improve liver function test results but does not appear to alter the natural history. However, recent experience suggests that high-dose ursodeoxycholic acid (20 mg/kg/d) may reduce cholangiographic progression and liver fibrosis. Careful endoscopic evaluation of the biliary tree may permit balloon dilation of localized strictures. If there is a major stricture, short-term placement of a stent may relieve symptoms and improve biochemical abnormalities with sustained improvement after the stent is removed. Repeated balloon dilation of a recurrent dominant bile duct stricture may improve survival. However, long-term stenting may increase the rate of complications such as cholangitis. In patients without cirrhosis, surgical resection of a dominant bile duct stricture may lead to longer survival than endoscopic therapy by decreasing the subsequent risk of cholangiocarcinoma. In patients with ulcerative colitis, primary sclerosing cholangitis is an independent risk factor for the development of colorectal dysplasia and cancer, and strict adherence to a colonoscopic surveillance program is advisable. For patients with cirrhosis and clinical decompensation, liver transplantation is the procedure of choice.

Survival of patients with primary sclerosing cholangitis averages 10 years once symptoms appear. Adverse prognostic markers are older age, higher serum bilirubin and aspartate aminotransferase levels, lower albumin levels, and a history of variceal bleeding. Actuarial survival rates with liver transplantation are as high as 85% at 3 years, but rates are much lower once cholangiocarcinoma has developed. Following transplantation, patients have an increased risk of nonanastomotic biliary strictures and—in those with ulcerative colitis—colon cancer. Those patients who are unable to undergo liver transplantation will ultimately require high-quality palliative care (see [Chapter 5](#)).

CARCINOMA OF THE BILIARY TRACT

Carcinoma of the gallbladder occurs in approximately 2% of all people operated on for biliary tract disease. It is notoriously insidious, and the diagnosis is often made unexpectedly at surgery. Cholelithiasis (often large, symptomatic stones) is usually present. Other risk factors are chronic infection of the gallbladder with *Salmonella typhi*, gallbladder polyps over 1 cm in diameter, mucosal calcification of the gallbladder (porcelain gallbladder), and anomalous pancreaticobiliary ductal junction. Spread of the cancer—by direct extension into the liver or to the peritoneal surface—may be the initial manifestation. The TNM classification includes the following stages: Tis, carcinoma in situ; T1a, tumor invades lamina propria, and T1b, tumor invades muscle layer; T2, tumor invades perimuscular connective tissue, no extension beyond serosa (visceral peritoneum) or into liver; T3, tumor perforates the serosa or directly invades the liver or adjacent organ or structure; T4, tumor invades main portal vein or hepatic artery or invades multiple extrahepatic organs or structures; N1, regional lymph node metastasis; and M1, distant metastasis.

Carcinoma of the bile ducts (cholangiocarcinoma) accounts for 3% of all cancer deaths in the United States, and the incidence and mortality rates have increased dramatically in the past 2 decades. It affects both sexes equally but is more prevalent in individuals aged 50-70. Two-thirds arise at the confluence of the hepatic ducts (Klatskin tumors), and one-fourth arise in the distal extrahepatic bile duct; the remainder are intrahepatic. Staging is similar to that for carcinoma of the gallbladder. The frequency of carcinoma in persons with choledochal cysts has been reported to be over 14% at 20 years, and surgical excision is recommended. There is an increased incidence in patients with ulcerative colitis, especially those with primary sclerosing cholangitis. In southeast Asia, infection of the bile ducts with helminths (*Clonorchis sinensis*, *Opisthorchis viverrini*, *Fasciola hepatica*) is associated with chronic cholangitis and an increased risk of cholangiocarcinoma.

Clinical Findings

Progressive jaundice is the most common and usually the first sign of obstruction of the extrahepatic biliary system. Pain in the right upper abdomen with radiation into the back is usually present early in the course of gallbladder carcinoma, but this occurs later in the course of bile duct carcinoma. Anorexia and weight loss are common and often associated with fever and chills due to cholangitis. Rarely, hematemesis or melena results from erosion of tumor into a blood vessel (hemobilia). Fistula formation between the biliary system and adjacent organs may also occur. The course is usually one of rapid deterioration, with death occurring within a few months.

Physical examination reveals profound jaundice. A palpable gallbladder with obstructive jaundice usually is said to signify malignant disease (Courvoisier's law); however, this clinical generalization has been proved to be accurate only about 50% of the time. Hepatomegaly is usually present and is associated with liver tenderness. Ascites may occur with peritoneal implants. Pruritus and skin excoriations are common.

Laboratory examination reveals predominantly conjugated hyperbilirubinemia, with total serum bilirubin values ranging from 5 to 30 mg/dL. There is usually concomitant elevation of the alkaline phosphatase and serum cholesterol. AST is normal or minimally elevated. An elevated CA 19-9 level may help distinguish cholangiocarcinoma from a benign biliary stricture (in the absence of cholangitis).

Ultrasonography and CT may show a gallbladder mass in gallbladder carcinoma and intrahepatic mass or biliary dilation in carcinoma of the bile ducts. CT may also show involved regional lymph nodes. MRI with MRCP permits visualization of the biliary tree and detection of vascular invasion and obviates the need for angiography. Preliminary observations suggest that positron emission tomography (PET) can detect cholangiocarcinomas as small as 1 cm. The most helpful diagnostic studies before surgery are either percutaneous transhepatic or endoscopic retrograde cholangiography with biopsy and cytologic specimens, though false-negative biopsy and cytology results are common. Fine-needle aspiration of tumors under endoscopic ultrasonographic guidance, choledochoscopy, and intraductal ultrasonography also have potential roles in the diagnosis of cholangiocarcinoma.

Treatment

In young and fit patients, curative surgery may be attempted if the tumor is well localized. The 5-year survival rate for localized carcinoma of the gallbladder (stage 1, T1a, N0, M0) is as high as 80% with laparoscopic cholecystectomy but drops to 15%, even with a more extended open resection, if there is muscular invasion (T1b). If the tumor is unresectable at laparotomy, cholecystoduodenostomy or T-tube drainage of the common duct can be performed. Carcinoma of the bile ducts is curable by surgery in less than 10% of cases. Palliation can be achieved by placement of a self-expandable metal stent via the endoscopic or percutaneous transhepatic route. Plastic stents are less expensive but more prone to occlude than metal ones; they are suitable for patients expected to survive only a few months. Preliminary experience supports a palliative role for photodynamic therapy. Radiotherapy may relieve pain and contribute to biliary decompression. There is limited response to chemotherapy such as with gemcitabine. In general, the prognosis is poor, with few patients surviving for more than 12 months after surgery. Although cholangiocarcinoma is generally considered to be a contraindication to liver transplantation because of rapid tumor recurrence, a 62% 5-year survival rate has been reported in patients with a single peripheral cholangiocarcinoma undergoing either transplantation or resection, with clear resection margins and no lymph node involvement.

For those patients whose disease progresses despite treatment, meticulous efforts at palliative care are essential (see [Chapter 5](#)).

■ DISEASES OF THE PANCREAS

ACUTE PANCREATITIS

- Abrupt onset of deep epigastric pain, often with radiation to the back.
- Nausea, vomiting, sweating, weakness.
- Abdominal tenderness and distention, fever.
- Leukocytosis, elevated serum amylase, elevated serum lipase.
- History of previous episodes, often related to alcohol intake.

General Considerations

Acute pancreatitis is thought to result from "escape" of activated pancreatic enzymes from acinar cells into surrounding tissues. Most cases are related to biliary tract disease (a passed gallstone, usually < 5 mm in diameter) or heavy alcohol intake. The exact pathogenesis is not known but may include edema or obstruction of the ampulla of Vater, resulting in reflux of bile into pancreatic ducts, or direct injury to the acinar cells. Among the numerous other causes or associations are hypercalcemia, hyperlipidemias (chylomicronemia, hypertriglyceridemia, or both), abdominal trauma (including surgery), drugs (including azathioprine, mercaptopurine, asparaginase, pentamidine, didanosine, valproic acid, tetracyclines, estrogen [by raising serum triglycerides] sulfonamides, thiazides, and possibly glucocorticoids), vasculitis, viral infections (eg, mumps), peritoneal dialysis, cardiopulmonary bypass, and ERCP. In patients with pancreas divisum, a congenital anomaly in which the dorsal and ventral pancreatic ducts fail to fuse, acute pancreatitis may result from stenosis of the minor papilla with obstruction to flow from the accessory pancreatic duct. Rarely, acute pancreatitis may be the presenting manifestation of a pancreatic or ampullary neoplasm. Apparently "idiopathic" acute pancreatitis is often caused by occult biliary microlithiasis.

Pathologic changes vary from acute edema and cellular infiltration to necrosis of the acinar cells, hemorrhage from necrotic blood vessels, and intra- and extrapancreatic fat necrosis. All or part of the pancreas may be involved.

Clinical Findings

A. Symptoms and Signs

Epigastric abdominal pain, generally abrupt in onset, is steady, boring, and severe and often made worse by walking and lying supine and better by sitting and leaning forward. The pain usually radiates into the back but may radiate to the right or left. Nausea and vomiting are usually present. Weakness, sweating, and anxiety are noted in severe attacks. There may be a history of alcohol intake or a heavy meal immediately preceding the attack, or a history of milder similar episodes or biliary colic in the past.

The abdomen is tender mainly in the upper abdomen, most often without guarding, rigidity, or rebound. The abdomen may be distended, and bowel sounds may be absent with associated paralytic ileus. Fever of 38.4-39°C, tachycardia, hypotension (even true shock), pallor, and cool clammy skin are often present. Mild jaundice is common. Occasionally, an upper abdominal mass due to the inflamed pancreas or a pseudocyst may be palpated. Acute renal failure (usually prerenal) may occur early in the course of acute pancreatitis.

B. Assessment of Severity

Ranson's criteria are generally used in assessing the severity of acute alcoholic pancreatitis on presentation (pancreatitis due to other causes is assessed by similar criteria).

1. When three or more of the following are present on admission, a severe course complicated by pancreatic necrosis can be predicted with a sensitivity of 60-80%:

- Age over 55 years.
- White blood cell count over 16,000/uL.
- Blood glucose over 200 mg/dL.
- Serum LDH over 350 units/L.
- AST over 250 units/L.

2. Development of the following in the first 48 hours indicates a worsening prognosis:

- Hematocrit drop of more than ten percentage points.
- BUN rise greater than 5 mg/dL.
- Arterial PO₂ of less than 60 mm Hg.
- Serum calcium of less than 8 mg/dL.
- Base deficit over 4 meq/L.
- Estimated fluid sequestration of more than 6 L.

3. Mortality rates correlate with the number of criteria present:

Number of criteria	Mortality rate
0-2	1%
3-4	16%
5-6	40%
7-8	100%

C. Laboratory Findings

Serum amylase and lipase are elevated—usually more than three times the upper limit of normal—within 24 hours in 90% of cases; their return to normal is variable depending on the severity of disease; lipase remains elevated longer than amylase. Leukocytosis (10,000-30,000/uL), proteinuria, granular casts, glycosuria (10-20% of cases), hyperglycemia, and elevated serum bilirubin may be present. Blood urea nitrogen and serum alkaline phosphatase may be elevated and coagulation tests abnormal. In patients with clear evidence of acute pancreatitis, a serum ALT level of more than 80 units/L suggests biliary pancreatitis. Decrease in serum calcium may reflect saponification and correlates well with severity of disease. Levels lower than 7 mg/dL (when serum albumin is normal) are associated with tetany and an unfavorable prognosis. An early rise in the hematocrit value above 47% suggests hemoconcentration and is thought to predict severe disease. An elevated C-reactive protein concentration after 48 hours also suggests the development of pancreatic necrosis.

Other tests that offer the possibility of simplicity, rapidity, ease of use, and low cost—including urinary trypsinogen-2, trypsinogen activation peptide, and carboxypeptidase B—are under study. In patients who develop ascites or left pleural effusions, fluid amylase content is high. Electrocardiography may show ST-T wave changes.

D. Imaging

Plain radiographs of the abdomen may show gallstones, a "sentinel loop" (a segment of air-filled small intestine most commonly in the left upper quadrant), the "colon cutoff sign"—a gas-filled segment of transverse colon abruptly ending at the area of pancreatic inflammation—or linear focal atelectasis of the lower lobe of the lungs with or without pleural effusion. CT scan is useful in demonstrating an enlarged pancreas when the diagnosis of pancreatitis is uncertain, in detecting pseudocysts, and

in differentiating pancreatitis from other possible intra-abdominal catastrophes. Dynamic intravenous contrast-enhanced CT is of particular value after the first 3 days of severe acute pancreatitis to identify areas of necrotizing pancreatitis and assessing prognosis ([Table 15-7](#)), though the use of intravenous contrast may increase the risk of complications of pancreatitis and of renal failure and should be avoided when the serum creatinine level is greater than 1.5 mg/dL. The presence of a fluid collection in the pancreas correlates with an increased mortality rate. CT-guided needle aspiration of areas of necrotizing pancreatitis may disclose infection, usually by enteric organisms, which invariably leads to death unless surgical debridement is performed. The presence of gas bubbles on CT scan implies that infection by gas-forming organisms is present. Ultrasonography is less reliable, because the echoes are deflected by the gas-distended small intestine frequently associated with pancreatitis but is the initial imaging study required when pancreatitis is thought to be caused by gallstones. Endoscopic ultrasonography is useful in identifying occult biliary disease (eg, small stones, sludge, microlithiasis) in a majority of patients with apparently idiopathic acute pancreatitis. ERCP is generally not indicated after a first attack of acute pancreatitis unless there is associated cholangitis or jaundice. However, aspiration of bile for crystal analysis may confirm the suspicion of microlithiasis in patients with apparently idiopathic acute pancreatitis.

Differential Diagnosis

Acute pancreatitis must be differentiated from an acutely perforated duodenal ulcer, acute cholecystitis, acute intestinal obstruction, leaking aortic aneurysm, renal colic, and acute mesenteric vascular insufficiency or thrombosis. Serum amylase may also be elevated in high intestinal obstruction, in gastroenteritis, in mumps not involving the pancreas (salivary amylase), in ectopic pregnancy, after administration of opioids, and after abdominal surgery. Serum lipase may also be elevated in many of these conditions.

Complications

Intravascular volume depletion secondary to leakage of fluids in the pancreatic bed and ileus with fluid-filled loops of bowel may result in prerenal azotemia and even acute tubular necrosis without overt shock. This usually occurs within 24 hours of the onset of acute pancreatitis and lasts 8-9 days. Some patients require peritoneal dialysis or hemodialysis.

As mentioned above, sterile or infected necrotizing pancreatitis may complicate the course of 5-10% of cases and accounts for most of the deaths. The risk of infection does not correlate with the extent of necrosis. Pancreatic necrosis is often associated with fever, leukocytosis, and, in some cases, shock and is associated with organ failure (eg, pulmonary, renal, gastrointestinal bleeding) in 50% of cases. Because infected pancreatic necrosis is an absolute indication for operative treatment, fine-needle aspiration of necrotic tissue under CT guidance should be performed (if necessary, repeatedly) for Gram stain and culture.

A serious complication of acute pancreatitis is acute respiratory distress syndrome (ARDS); cardiac dysfunction may be superimposed. It usually occurs 3-7 days after the onset of pancreatitis in patients who have required large volumes of fluid and colloid to maintain blood pressure and urine output. Most patients with ARDS require assisted respiration with positive end-expiratory pressure.

Pancreatic abscess is a suppurative process characterized by rising fever, leukocytosis, and localized tenderness and epigastric mass usually 6 or more weeks into the course of acute pancreatitis. This may be associated with a left-sided pleural effusion or an enlarging spleen secondary to splenic vein thrombosis. In contrast to infected necrosis, the mortality rate is low following drainage.

Pseudocysts, encapsulated fluid collections with high enzyme content, commonly appear in pancreatitis when CT scans are used to monitor the evolution of an acute attack. Although the natural history of pseudocysts is still not well delineated, it appears that those less than 6 cm in diameter often resolve spontaneously. They most commonly are within or adjacent to the pancreas but can present anywhere (eg, mediastinal, retrorectal), by extension along anatomic planes. Pseudocysts are multiple in 14% of cases. Pseudocysts may become secondarily infected, necessitating drainage as for an abscess. Erosion of the inflammatory process into a blood vessel can result in a major hemorrhage into the cyst.

Pancreatic ascites may present after recovery from acute pancreatitis as a gradual increase in abdominal girth and persistent elevation of the serum amylase level in the absence of frank abdominal pain. Marked elevations in the ascitic protein (> 3 g/dL) and amylase (> 1000 units/L) concentrations are typical. The condition results from rupture of the pancreatic duct or drainage of a pseudocyst into the peritoneal cavity.

Rare complications of acute pancreatitis include hemorrhage caused by erosion of a blood vessel to form a pseudoaneurysm and colonic necrosis. Chronic pancreatitis develops in about 10% of cases. Permanent diabetes mellitus and exocrine pancreatic insufficiency occur uncommonly after a single acute episode.

Treatment

A. Management of Acute Disease

In most patients, acute pancreatitis is a mild disease that subsides spontaneously within several days. The pancreatic rest program includes withholding food and liquids by mouth, bed rest, and, in patients with moderately severe pain or ileus and abdominal distention or vomiting, nasogastric suction. Pain is controlled with meperidine, up to 100-150 mg intramuscularly every 3-4 hours as necessary. In those with severe hepatic or renal dysfunction, the dose may need to be reduced. (Morphine has been thought to cause sphincter of Oddi spasm but is probably an acceptable alternative.) No fluid or foods should be given orally until the patient is largely free of pain and has bowel sounds. Clear liquids are then given, and gradual advancement to a regular low-fat diet is prescribed, guided by the patient's tolerance and by the absence of pain. Following recovery from acute biliary pancreatitis, laparoscopic cholecystectomy is generally performed, although in selected cases endoscopic sphincterotomy alone may be done. In patients with recurrent pancreatitis associated with pancreas divisum, insertion of a stent in the minor papilla (or minor papilla sphincterotomy) may reduce the frequency of subsequent attacks.

In more severe pancreatitis—particularly necrotizing pancreatitis—there may be considerable leakage of fluids, necessitating large amounts of intravenous fluids to maintain intravascular volume. Calcium gluconate must be given intravenously if there is evidence of hypocalcemia with tetany. Infusions of fresh frozen plasma or serum albumin may be necessary in patients with coagulopathy or hypoalbuminemia. With colloid solutions, there may be an increased risk of developing acute respiratory distress syndrome. If shock persists after adequate volume replacement (including packed red cells), pressors may be required. For the patient requiring a large volume of parenteral fluids, central venous pressure and blood gases should be monitored at regular intervals. Total parenteral nutrition (including lipids) should be considered in patients who have severe pancreatitis and ileus and will be without oral nutrition for at least 7-10 days. Enteral nutrition via a jejunal feeding tube is preferable in the absence of ileus. Imipenem (500 mg every 8 hours intravenously) or possibly cefuroxime (1.5 g intravenously three times daily, then 250 mg orally twice daily) administered to patients with sterile pancreatic necrosis may also reduce the risk of pancreatic infection. The role of intravenous somatostatin in severe acute pancreatitis is uncertain, but octreotide is thought to have no benefit. There is some evidence that the risk of pancreatitis after ERCP can be reduced by the administration of somatostatin or gabexate mesilate, a protease inhibitor. In preliminary trials, lexipafant, an antagonist of platelet-activating factor, was reported to reduce rates of multiple organ failure and mortality in patients with severe acute pancreatitis, but a subsequent larger trial failed to demonstrate benefit.

The patient with severe pancreatitis requires attention in an intensive care unit. Close follow-up of white blood count, hematocrit, serum electrolytes, serum calcium, serum creatinine, BUN, serum AST and LDH, and arterial blood gases is mandatory. Cultures of blood, urine, sputum, and pleural effusion (if present) and needle aspirations of areas of pancreatic necrosis (with CT guidance) should be obtained.

B. Treatment of Complications and Follow-Up

A surgeon should be consulted in all cases of severe acute pancreatitis. If the diagnosis is in doubt and investigations indicate a strong possibility of a serious surgically correctable lesion (eg, perforated peptic ulcer), exploration is indicated. When acute pancreatitis is unexpectedly found on exploratory laparotomy, it is usually wise to close without intervention. If the pancreatitis appears mild and cholelithiasis is present, cholecystostomy or cholecystectomy may be justified. When severe pancreatitis results from choledocholithiasis—particularly if jaundice (serum total bilirubin > 5 mg/dL) or cholangitis is present—ERCP with endoscopic sphincterotomy and stone extraction is indicated. The role of MRCP in this setting is evolving; eventually, MRCP may be useful in selecting patients for therapeutic ERCP.

Operation may improve survival in patients with necrotizing pancreatitis and clinical deterioration with multiorgan failure or lack of resolution by 4-6 weeks. Surgery is always indicated for infected necrosis. The goal of surgery is to debride necrotic pancreas and surrounding tissue and establish adequate drainage. In selected cases, nonsurgical drainage of necrotizing pancreatitis under radiologic or endoscopic guidance may be feasible depending on local expertise. Peritoneal lavage has not been shown to improve survival in severe acute pancreatitis, in part because the risk of late septic complications is not reduced.

The development of a pancreatic abscess is an indication for prompt percutaneous or surgical drainage. Chronic pseudocysts require endoscopic, percutaneous catheter, or surgical drainage when infected or associated with persisting pain, pancreatitis, or common duct obstruction. For pancreatic infections, imipenem, 500 mg every 8 hours intravenously, is a good antibiotic because it achieves bactericidal levels in pancreatic tissue for most causative organisms.

Prognosis

Mortality rates for acute pancreatitis have declined from at least 10% to around 5% in the past 20 years, but the mortality rate for severe acute pancreatitis (more than three Ranson criteria) remains at least 20%, especially when hepatic, cardiovascular, or renal impairment is present in association with pancreatic necrosis. Recurrences are common in alcoholic pancreatitis.

CHRONIC PANCREATITIS

Chronic pancreatitis occurs most often in patients with alcoholism (70-80% of all cases). The risk of chronic pancreatitis increases with the duration and amount of alcohol consumed, but only 5-10% of heavy drinkers develop pancreatitis. Ethanol is thought to cause secretion of insoluble pancreatic proteins that calcify and occlude the pancreatic duct. Progressive fibrosis and destruction of functioning glandular tissue then occur, perhaps as a result of repeated episodes of necroinflammation and activation of pancreatic stellate cells. About 2% of patients with hyperparathyroidism develop pancreatitis. In tropical Africa and Asia, tropical pancreatitis, related in part to malnutrition, is the most common cause of chronic pancreatitis. A stricture, stone, or tumor obstructing the pancreas can lead to obstructive chronic pancreatitis. Rare cases of autoimmune chronic pancreatitis associated with hypergammaglobulinemia and responsive to corticosteroids have been reported. About 10-20% of cases are idiopathic. Genetic factors may predispose to chronic pancreatitis in some of these cases. For example, a mutant trypsinogen gene (*PRSS1*) for hereditary pancreatitis, transmitted as an autosomal dominant trait with variable penetrance, has been identified on chromosome 7. Furthermore, mutations of the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene have been identified in as many as 50% of patients with idiopathic chronic pancreatitis and no other clinical features of cystic fibrosis. Mutations of the pancreatic secretory trypsin inhibitory gene (*PSTI*, *SPINK1*) have also been associated with idiopathic chronic pancreatitis. A useful mnemonic for the predisposing factors to chronic pancreatitis is TIGAR-O: toxic-metabolic, idiopathic, genetic; autoimmune, recurrent and severe acute pancreatitis, or obstructive.

In many cases, chronic pancreatitis is a self-perpetuating disease characterized by chronic pain or recurrent episodes of acute pancreatitis and ultimately by pancreatic exocrine or endocrine insufficiency. After many years, chronic pain may resolve spontaneously or as a result of surgery tailored to the cause of pain. Over 80% of adults develop diabetes 25 years after the clinical onset of chronic pancreatitis.

Clinical Findings

A. Symptoms and Signs

Persistent or recurrent episodes of epigastric and left upper quadrant pain with referral to the upper left lumbar region are typical. Anorexia, nausea, vomiting, constipation, flatulence, and weight loss are common. Abdominal signs during attacks consist chiefly of tenderness over the pancreas, mild muscle guarding, and paralytic ileus. Attacks may last only a few hours or as long as 2 weeks; pain may eventually be almost continuous. Steatorrhea (as indicated by bulky, foul, fatty stools) may occur late in the course.

B. Laboratory Findings

Serum amylase and lipase may be elevated during acute attacks; normal amylase does not exclude the diagnosis, however. Serum alkaline phosphatase and bilirubin may be elevated owing to compression of the common duct. Glycosuria may be present. Excess fecal fat may be demonstrated on chemical analysis of the stool; pancreatic insufficiency may be confirmed by response to therapy with pancreatic enzyme supplements, or by a bentiromide (NBT-PABA) test or secretin stimulation test if available. Where available, detection of decreased fecal chymotrypsin or elastase levels may be used to diagnose pancreatic insufficiency, though the tests lack sensitivity and specificity. Vitamin B₁₂ malabsorption is detectable in about 40% of patients, but clinical deficiency of vitamin B₁₂ and fat-soluble vitamins is rare.

C. Imaging

Plain films show calcifications due to pancreaticolithiasis in 30% of affected patients. CT may show calcifications not seen on plain films as well as ductal dilation and heterogeneity or atrophy of the gland. Endoscopic ultrasonography also can detect changes of chronic pancreatitis. Endoscopic retrograde cholangiopancreatography is the most sensitive imaging study for chronic pancreatitis and may show dilated ducts, intraductal stones, strictures, or pseudocyst, but the results may be normal in patients with so-called minimal change pancreatitis. Magnetic resonance cholangiopancreatography (MRCP) and endoscopic ultrasonography (with pancreatic tissue sampling) are promising alternatives to endoscopic retrograde cholangiopancreatography.

Complications

Opioid addiction is common. Other frequent complications include often brittle diabetes mellitus, pancreatic pseudocyst or abscess, cholestatic liver enzymes with or without jaundice, common bile duct stricture, steatorrhea, malnutrition, and peptic ulcer. Pancreatic cancer develops in 4% of patients after 20 years; the risk may relate to tobacco and alcohol use.

Treatment

Correctable coexistent biliary tract disease should be treated surgically.

A. Medical Measures

A low-fat diet should be prescribed. Alcohol is forbidden because it frequently precipitates attacks. Narcotics should be avoided if possible. Steatorrhea is treated with pancreatic supplements that are selected on the basis of their high lipase activity. A total dose of 30,000 units of lipase in capsules is given before, during, and after meals ([Chapter 27](#)).

B. Surgical and Endoscopic Treatment

Surgery may be indicated in chronic pancreatitis to drain persistent pseudocysts, treat other complications, or attempt to relieve pain. The objectives of surgical intervention are to eradicate biliary tract disease, ensure a free flow of bile into the duodenum, and eliminate obstruction of the pancreatic duct. Liver fibrosis may regress after biliary drainage. When obstruction of the duodenal end of the duct can be demonstrated by endoscopic retrograde cholangiopancreatography, dilation of the duct or resection of the tail of the pancreas with implantation of the distal end of the duct by pancreaticojejunostomy may be successful. When the pancreatic duct is diffusely dilated, anastomosis between the duct after it is split longitudinally and a defunctionalized limb of jejunum (modified Puestow procedure), in some cases combined with local resection of the head of the pancreas, is associated with relief of pain in 80% of cases. In advanced cases, subtotal or total pancreatectomy may be considered as a last resort but has variable efficacy and is associated with a high rate of pancreatic insufficiency and diabetes. Perioperative administration of somatostatin or octreotide may reduce the risk of postoperative pancreatic fistulas. Endoscopic or surgical drainage is indicated for symptomatic pseudocysts and, in many cases, those over 6 cm in diameter. Endoscopic ultrasound may facilitate selection of an optimal site for endoscopic drainage. Pancreatic ascites or pancreaticopleural fistulas due to a disrupted pancreatic duct can be managed by endoscopic placement of a stent across the disrupted duct. Fragmentation of stones in the pancreatic duct by lithotripsy and endoscopic removal of stones from the duct, pancreatic sphincterotomy, or pseudocyst drainage may relieve pain in selected patients. For patients with chronic pain and nondilated ducts, a percutaneous celiac plexus nerve block may be considered under either CT or endoscopic ultrasound guidance, with pain relief in approximately 50% of patients.

Prognosis

This is a serious disease and often leads to chronic disability. The prognosis is best in patients with recurrent acute pancreatitis caused by a remediable condition such as cholelithiasis, choledocholithiasis, stenosis of the sphincter of Oddi, or hyperparathyroidism. Medical management of the hyperlipidemia frequently associated with the condition may also prevent recurrent attacks of pancreatitis. In alcoholic pancreatitis, pain relief is most likely when a dilated pancreatic duct can be decompressed. In patients with disease not amenable to decompressive surgery, addiction to narcotics is a frequent outcome of treatment.

CARCINOMA OF THE PANCREAS & THE PERIAMPULLARY AREA

Essentials of Diagnosis

- Obstructive jaundice (may be painless).
- Enlarged gallbladder (may be painful).
- Upper abdominal pain with radiation to back, weight loss, and thrombophlebitis are usually late manifestations.

General Considerations

Carcinoma is the commonest neoplasm of the pancreas. About 75% are in the head and 25% in the body and tail of the organ. Carcinomas involving the head of the pancreas, the ampulla of Vater, the distal common bile duct, and the duodenum are considered together, because they are usually indistinguishable clinically; of these, carcinomas of the pancreas constitute over 90%. They comprise 2% of all cancers and 5% of cancer deaths. Risk factors include age, obesity, tobacco use, chronic pancreatitis, prior abdominal radiation, and family history. About 7-8% of patients with pancreatic cancer have a family history of pancreatic cancer in a first-degree relative, compared with 0.6% of control subjects. Neuroendocrine tumors account for 2-5% of pancreatic neoplasms. Cystic neoplasms account for only 1% of pancreatic cancers, but they are important because they are often mistaken for pseudocysts. A cystic neoplasm should be suspected when a cystic lesion in the pancreas is found in the absence of a history of pancreatitis. Whereas serous cystadenomas are benign, mucinous cystadenomas, intraductal papillary mucinous tumors, and papillary cystic neoplasms are premalignant, though their prognoses are better than the prognosis of adenocarcinoma of the pancreas, unless the neoplasm is locally advanced.

Clinical Findings

A. Symptoms and Signs

Pain is present in over 70% of cases and is often vague, diffuse, and located in the epigastrium or left upper quadrant when the lesion is in the tail. Radiation of pain into the back is common and sometimes predominates. Sitting up and leaning forward may afford some relief, and this usually indicates that the lesion has spread beyond the pancreas and is inoperable. Diarrhea, perhaps due to maldigestion, is an occasional early symptom. Migratory thrombophlebitis is a rare sign. Weight loss is a common but late finding and may be associated with depression. Occasionally a patient presents with acute pancreatitis in the absence of an alternative cause. Jaundice is usually due to biliary obstruction by a cancer in the pancreatic head. A palpable gallbladder is also indicative of obstruction by neoplasm (Courvoisier's law), but there are frequent exceptions. A hard, fixed, occasionally tender mass may be present. In advanced cases, a hard periumbilical (Sister Joseph's) nodule may be palpable.

B. Laboratory Findings

There may be mild anemia. Glycosuria, hyperglycemia, and impaired glucose tolerance or true diabetes mellitus are found in 10-20% of cases. The serum amylase or lipase level is occasionally elevated. Liver function tests may suggest obstructive jaundice. Steatorrhea in the absence of jaundice is uncommon. Occult blood in the stool is suggestive of carcinoma of the ampulla of Vater (the combination of biliary obstruction and bleeding may give the stools a distinctive silver appearance). CA 19-9, with a sensitivity of 70% and a specificity of 87%, has not proved sensitive enough for early detection; increased values are also found in acute and chronic pancreatitis and cholangitis. Point mutations in codon 12 of the K-ras oncogene are found in 70-100%, and inactivation of the tumor suppressor genes *P16* on chromosome 9, *P53* on chromosome 17, and *DCP4* on chromosome 18 are found in 95%, 50-70%, and 50% of pancreatic cancers, respectively.

C. Imaging

With carcinoma of the head of the pancreas, the upper gastrointestinal series may show a widening of the duodenal loop, mucosal abnormalities in the duodenum ranging from edema to invasion or ulceration, or spasm or compression. Ultrasound is not reliable because of interference by intestinal gas. Dual-phase spiral CT and MRI detect a mass in over 80% of cases and are helpful in delineating the extent of the tumor and allowing for percutaneous fine-needle aspiration for cytologic studies and tumor markers. Preliminary experience suggests that positron emission tomography is a sensitive technique for detecting pancreatic cancer and metastases. Selective celiac and superior mesenteric arteriography may demonstrate vessel invasion by tumor, a finding that would interdict attempts at surgical resection, but it is less widely used since the advent of dual-phase spiral CT. Endoscopic ultrasonography, if available, is useful for diagnosing pancreatic cancer and for demonstrating venous or gastric invasion. Endoscopic ultrasonography may also be used to guide fine-needle aspiration for tissue diagnosis and tumor markers. ERCP may clarify an ambiguous CT or MRI study by delineating the pancreatic duct system or confirming an ampullary or biliary neoplasm. MRCP appears to be at least as sensitive as ERCP in diagnosing pancreatic cancer. In some centers, pancreatoscopy or intraductal ultrasonography can be used to evaluate filling defects in the pancreatic duct and assess resectability of intraductal papillary mucinous tumors. With obstruction of the splenic vein, splenomegaly or gastric varices are present, the latter delineated by endoscopy, endoscopic ultrasonography, or angiography.

Staging by the TNM classification includes the following definitions: Tis: carcinoma in situ; T1: tumor limited to the pancreas, 2 cm or less in greatest dimension; T2: tumor limited to the pancreas, more than 2 cm in greatest dimension; T3: tumor extends beyond the pancreas but without involvement of the celiac axis or the superior mesenteric artery; T4, tumor involves the celiac axis or the superior mesenteric artery (unresectable primary tumor).

Treatment

Abdominal exploration is usually necessary when cytologic diagnosis cannot be made or if resection is to be attempted, which includes about 30% of patients. In a patient with a localized mass in the head of the pancreas and without jaundice, laparoscopy may detect tiny peritoneal or liver metastases and thereby avoid resection in 4-13% of patients. Radical pancreaticoduodenal (Whipple) resection is indicated for lesions strictly limited to the head of the pancreas, periampullary zone, and duodenum (T1, N0, M0). Five-year survival rates are 20-25% in this group and as high as 40% in those with negative resection margins and without lymph node involvement. Adjuvant radiation therapy and fluorouracil-based chemotherapy or gemcitabine are of potential benefit. When resection is not feasible, cholecystojejunostomy or endoscopic stenting of the bile duct is performed to relieve jaundice. A gastrojejunostomy is also done if duodenal obstruction is expected to develop later; alternatively, endoscopic placement of a self-expandable duodenal stent may be feasible. Combined irradiation and chemotherapy may be used for palliation of unresectable cancer confined to the pancreas. Chemotherapy has been disappointing in metastatic pancreatic cancer, though improved response rates have been reported with gemcitabine. Celiac plexus nerve block or thoracoscopic splanchnicectomy may improve pain control. Photodynamic therapy is under study.

Surgical resection is indicated for all mucinous cystic neoplasms, symptomatic serous cystadenomas, and cystic tumors that remain undefined after helical CT, endoscopic ultrasound, and diagnostic aspiration. In the absence of locally advanced disease, survival is higher than for adenocarcinoma. Endoscopic resection or ablation may be feasible for ampullary adenomas.

Prognosis

Carcinoma of the pancreas, especially in the body or tail, has a poor prognosis. Reported 5-year survival rates range from 2% to 5%. Lesions of the ampulla have a better prognosis, with reported 5-year survival rates of 20-40% after resection. In carefully selected patients, resection of cancer of the pancreatic head is feasible and results in reasonable survival. In persons with a family history of pancreatic cancer, screening with spiral CT and endoscopic ultrasonography should be considered beginning 10 years before the age at which pancreatic cancer was diagnosed in a family member.

For those patients whose disease progresses despite treatment, meticulous efforts at palliative care are essential (see [Chapter 5](#)).

Table 15-2. Hyperbilirubinemic disorders.

	Nature of Defect	Type of Hyper-bilirubinemia	Clinical and Pathologic Characteristics
Gilbert's syndrome	Glucuronyl transferase deficiency	Unconjugated (indirect bilirubin)	Benign, asymptomatic hereditary jaundice. Hyperbilirubinemia increased by 24- to 36-hour fast. No treatment required. Prognosis excellent.
Dubin-Johnson syndrome (familial chronic idiopathic jaundice) ¹	Faulty excretory function of hepatocytes	Conjugated (direct) bilirubin	Benign, asymptomatic hereditary jaundice. Gallbladder does not visualize on oral cholecystography. Liver darkly pigmented on gross examination. Biopsy shows centrilobular brown pigment. Prognosis excellent.
Rotor's syndrome			Similar to Dubin-Johnson syndrome, but liver is not pigmented and the gallbladder is visualized on oral cholecystography. Prognosis excellent.
Benign recurrent intrahepatic cholestasis ²	Cholestasis, often on a familial basis	Unconjugated plus conjugated (total) bilirubin	Episodic attacks of jaundice, itching and malaise. Onset in early life and may persist for a lifetime. Alkaline phosphatase increased. Cholestasis found on liver biopsy. (Biopsy is normal during remission.) Prognosis excellent.
Recurrent jaundice of pregnancy			Benign cholestatic jaundice of unknown cause, usually occurring in the third trimester of pregnancy. Itching, gastrointestinal symptoms, and abnormal liver excretory function tests. Cholestasis noted on liver biopsy. Prognosis excellent, but recurrence with subsequent pregnancies or use of birth control pills is characteristic.

¹The Dubin-Johnson syndrome is caused by a point mutation in the gene coding for an organic anion transporter in bile canaliculi on chromosome 10q23-24.

²Mutations in genes which control hepatocellular transport systems that are involved in the formation of bile and inherited as autosomal recessive traits are on chromosomes 18q21-22, 2q24, and 7q21 in families with progressive familial intrahepatic cholestasis. A gene mutation on chromosome 18q21-22 alters a P-type ATPase expressed in the small intestine and liver and causes benign recurrent intrahepatic cholestasis.

■ BENIGN BREAST DISORDERS

FIBROCYSTIC DISEASE

Essentials of Diagnosis

- Painful, often multiple, usually bilateral masses in the breast.
- Rapid fluctuation in the size of the masses is common.
- Frequently, pain occurs or increases and size increases during premenstrual phase of cycle.
- Most common age is 30-50. Rare in postmenopausal women not receiving hormonal replacement.

General Considerations

This disorder is the most frequent lesion of the breast. It is common in women 30-50 years of age but rare in postmenopausal women who are not taking hormonal replacement medications. Estrogen hormone is considered a causative factor. Fibrocystic disease encompasses a wide variety of pathologic entities. These lesions are always associated with benign changes in the breast epithelium, some of which are found so commonly in normal breasts that they are probably variants of normal breast histology but have nonetheless been termed a "disease."

The microscopic findings of fibrocystic disease include cysts (gross and microscopic), papillomatosis, adenosis, fibrosis, and ductal epithelial hyperplasia. Although fibrocystic disease has generally been considered to increase the risk of subsequent breast cancer, only the variants in which proliferation (especially with atypia) of epithelial components is demonstrated represent true risk factors.

Clinical Findings

A. Symptoms and Signs

Fibrocystic disease may produce an asymptomatic lump in the breast that is discovered by accident, but pain or tenderness often calls attention to the mass. There may be discharge from the nipple. In many cases, discomfort occurs or is increased during the premenstrual phase of the cycle, at which time the cysts tend to enlarge. Fluctuation in size and rapid appearance or disappearance of a breast mass are common in cystic disease. Multiple or bilateral masses are common, and many patients will give a history of a transient lump in the breast or cyclic breast pain.

B. Diagnostic Tests

Because a mass due to fibrocystic disease is frequently indistinguishable from carcinoma on the basis of clinical findings, suspicious lesions should be biopsied. Fine-needle aspiration cytology may be used, but if a suspicious mass that is nonmalignant on cytologic examination does not resolve over several months, it must be excised. Surgery should be conservative, since the primary objective is to exclude cancer. Occasionally, core needle biopsy will suffice. Simple mastectomy or extensive removal of breast tissue is rarely, if ever, indicated for fibrocystic disease.

Differential Diagnosis

Pain, fluctuation in size, and multiplicity of lesions are the features most helpful in differentiation from carcinoma. If a dominant mass is present, the diagnosis of cancer should be assumed until disproved by biopsy. Final diagnosis often depends on excisional biopsy. Mammography may be helpful, but the breast tissue in these young women is usually too radiodense to permit a worthwhile study. Sonography is useful in differentiating a cystic from a solid mass.

Treatment

When the diagnosis of fibrocystic disease has been established by previous biopsy or is likely because the history is classic, aspiration of a discrete mass suggestive of a cyst is indicated in order to alleviate pain and, more importantly, to confirm the cystic nature of the mass. The patient is reexamined at intervals thereafter. If no fluid is obtained or if fluid is bloody, if a mass persists after aspiration, or if at any time during follow-up a persistent lump is noted, biopsy is performed.

Breast pain associated with generalized fibrocystic disease is best treated by avoiding trauma and by wearing (night and day) a brassiere that gives good support and protection. Hormone therapy is not advisable, because it does not cure the condition and has undesirable side effects. Danazol (100-200 mg twice daily orally), a synthetic androgen, has been used for patients with severe pain. This treatment suppresses pituitary gonadotropins, but androgenic effects (acne, edema, hirsutism) usually make this treatment intolerable; in practice, it is rarely used. Postmenopausal women receiving hormone replacement therapy may stop hormones to reduce pain.

The role of caffeine consumption in the development and treatment of fibrocystic disease is controversial. Some studies suggest that eliminating caffeine from the diet is associated with improvement. Many patients are aware of these studies and report relief of symptoms after giving up coffee, tea, and chocolate. Similarly, many women find vitamin E (400 IU daily) helpful. However, these observations remain anecdotal.

Prognosis

Exacerbations of pain, tenderness, and cyst formation may occur at any time until the menopause, when symptoms usually subside, except in patients receiving hormonal replacement therapy. The patient should be advised to examine her own breasts each month just after menstruation and to inform her physician if a mass appears. The risk of breast cancer in women with fibrocystic disease showing proliferative or atypical changes in the epithelium is higher than that of women in general. These women should be followed carefully with physical examinations and mammography.

FIBROADENOMA OF THE BREAST

This common benign neoplasm occurs most frequently in young women, usually within 20 years after puberty. It is somewhat more frequent and tends to occur at an earlier age in black women. Multiple tumors are found in 10-15% of patients.

The typical fibroadenoma is a round or ovoid, rubbery, discrete, relatively movable, nontender mass 1-5 cm in diameter. It is usually discovered accidentally. Clinical diagnosis in young patients is generally not difficult. In women over 30, cystic disease of the breast and carcinoma of the breast must be considered. Cysts can be identified by aspiration or ultrasonography. Fibroadenoma does not normally occur after the menopause, but may occasionally develop after administration of hormones.

No treatment is usually necessary if the diagnosis can be made by needle biopsy or cytologic examination. Excision with pathologic examination of the specimen is performed if the diagnosis is uncertain. Cryoablation is being attempted as an alternative to excision. It is usually not possible to distinguish a large fibroadenoma from a phyllodes tumor on the basis of needle biopsy results.

Phyllodes tumor is a fibroadenoma-like tumor with cellular stroma that grows rapidly. It may reach a large size and if inadequately excised will recur locally. The lesion can be benign or malignant. If benign, phyllodes tumor is treated by local excision with a margin of surrounding breast tissue. The treatment of malignant phyllodes tumor is more controversial, but complete removal of the tumor with a rim of normal tissue avoids recurrence. Since these tumors may be large, simple mastectomy is sometimes necessary. Lymph node dissection is not performed, since the sarcomatous portion of the tumor metastasizes to the lungs and not the lymph nodes.

NIPPLE DISCHARGE

In order of decreasing frequency, the following are the commonest causes of nipple discharge in the nonlactating breast: duct ectasia, intraductal papilloma, and carcinoma. The important characteristics of the discharge and some other factors to be evaluated by history and physical examination are as follows:

1. Nature of discharge (serous, bloody, or other).
2. Association with a mass.
3. Unilateral or bilateral.
4. Single or multiple duct discharge.
5. Discharge is spontaneous (persistent or intermittent) or must be expressed.
6. Discharge produced by pressure at a single site or by general pressure on the breast.
7. Relation to menses.
8. Premenopausal or postmenopausal.
9. Patient taking contraceptive pills or estrogen.

Unilateral, spontaneous serous or serosanguineous discharge from a single duct is usually caused by an intraductal papilloma or, rarely, by an intraductal cancer. A mass may not be palpable. The involved duct may be identified by pressure at different sites around the nipple at the margin of the areola. Bloody discharge is suggestive of cancer but is more often caused by a benign papilloma in the duct. Cytologic examination may identify malignant cells, but negative findings do not rule out cancer, which is more likely in women over age 50. In any case, the involved duct—and a mass if present—should be excised. Ductography is of limited value since excision of the bloody duct system is indicated regardless of findings. Ductoscopy is being evaluated as a means of identifying intraductal lesions.

In premenopausal women, spontaneous multiple duct discharge, unilateral or bilateral, most marked just before menstruation, is often due to mammary dysplasia. Discharge may be green or brownish. Papillomatosis and ductal ectasia are usually seen on biopsy. If a mass is present, it should be removed.

Milky discharge from multiple ducts in the nonlactating breast occurs in certain endocrine syndromes, as a result of hyperprolactinemia. Serum prolactin levels should be obtained to search for a pituitary tumor. TSH helps exclude causative hypothyroidism. Numerous antipsychotic drugs and other drugs may also cause milky discharge that ceases on discontinuance of the medication.

Oral contraceptive agents or estrogen replacement therapy may cause clear, serous, or milky discharge from a single duct, but multiple duct discharge is more common. The discharge is more evident just before menstruation and disappears on stopping the medication. If it does not and is from a single duct, exploration should be considered.

Purulent discharge may originate in a subareolar abscess and require removal of the abscess and related lactiferous sinus.

When localization is not possible, no mass is palpable, and the discharge is nonbloody, the patient should be reexamined every 2 or 3 months for a year, and mammography should be done. Cytologic examination of nipple discharge for exfoliated cancer cells may rarely be helpful in diagnosis. However, the duct may be catheterized and lavage performed to evaluate cells for atypia. Recently, a small scope has been developed to examine the ductal system (ductoscopy), and its use may identify an intraductal tumor.

FAT NECROSIS

Fat necrosis is a rare lesion of the breast but is of clinical importance because it produces a mass, often accompanied by skin or nipple retraction, that is indistinguishable from carcinoma. Trauma is presumed to be the cause, though only about half of patients give a history of injury. Ecchymosis is occasionally present. If untreated, the mass effect gradually disappears. The safest course is to obtain a biopsy. Needle biopsy is often adequate, but frequently the entire mass must be excised, primarily to exclude carcinoma. Fat necrosis is common after segmental resection, radiation therapy, or flap reconstruction after mastectomy.

Meric F et al: Long-term complications associated with breast-conservation surgery and radiotherapy. Ann Surg Oncol 2002;9:543. [\[PMID: 12095969\]](#)

BREAST ABSCESS

During nursing, an area of redness, tenderness, and induration may develop in the breast. The organism most commonly found in these abscesses is *Staphylococcus aureus*. In the early stages, the infection can often be treated while nursing is continued from that breast by administering an antibiotic such as dicloxacillin or oxacillin, 250 mg four times daily for 7-10 days (see Puerperal Mastitis, [Chapter 18](#)). If the lesion progresses to form a localized mass with local and systemic signs of infection, surgical drainage is performed and nursing is discontinued.

A subareolar abscess may develop (rarely) in young or middle-aged women who are not lactating. These infections tend to recur after incision and drainage unless the area is explored during a quiescent interval, with excision of the involved lactiferous duct or ducts at the base of the nipple. Otherwise, infection in the breast is very rare unless the patient is lactating. In the nonlactating breast, inflammatory carcinoma is always considered. Thus, findings suggestive of abscess or cellulitis in the nonlactating breast are an indication for incision and biopsy of any indurated tissue. If the abscess can be percutaneously drained and completely resolves, the patient may be followed conservatively.

DISORDERS OF THE AUGMENTED BREAST

At least 4 million American women have had breast implants. Breast augmentation is performed by placing implants usually under the pectoralis muscle or, less desirably, in the subcutaneous tissue of the breast. Most implants are made of an outer silicone shell filled with a silicone gel, saline, or some combination of the two. About 15-25% of the patients develop capsule contraction or scarring around the implant, leading to a firmness and distortion of the breast that can be painful. Some require removal of the implant and capsule.

Implant rupture may occur in as many as 5-10% of women, and bleeding of gel through the capsule is noted even more commonly. While silicone gel may be an immunologic stimulant, there is no increase in autoimmune disorders in patients with such implants. The FDA has advised symptomatic women with ruptured implants to discuss possible surgical removal with their physicians. However, women who are asymptomatic and have no evidence of rupture of a silicone gel prosthesis should probably not undergo removal of the implant. Women with symptoms of autoimmune illnesses should address the possibility of removal.

Studies have failed to show any association between implants and an increased incidence of breast cancer. However, breast cancer may develop in a patient with a silicone gel prosthesis, as it does in women without them. Detection in patients with implants is made more difficult since mammography is less able to detect early lesions. However, local recurrence after breast reconstruction for cancer is usually cutaneous or subcutaneous and is easily palpated. If a cancer develops, it should be treated in the same manner as in women without implants. Such women should be offered the option of mastectomy or breast-conserving therapy, which may require removal or replacement of the implant. Radiotherapy of the augmented breast often results in marked capsular contracture. Adjuvant treatments should be given for the same indications as for women who have no implants.

■ CARCINOMA OF THE FEMALE BREAST

Essentials of Diagnosis

- Risk factors include delayed childbearing, positive family history of breast cancer or genetic mutations (BRCA-1, BRCA-2), and personal history of breast cancer or some types of mammary dysplasia.
- Most women with breast cancer do not have identifiable risk factors.
- Early findings: Single, nontender, firm to hard mass with ill-defined margins; mammographic abnormalities and no palpable mass.
- Later findings: Skin or nipple retraction; axillary lymphadenopathy; breast enlargement, redness, edema, pain; fixation of mass to skin or chest wall.

INCIDENCE & RISK FACTORS

Aside from skin cancer, the breast is the most common site of cancer in women, and cancer of the breast is second only to lung cancer as a cause of death from cancer among women. The probability of developing breast cancer increases throughout life. The mean and the median age of women with breast cancer is between 60 and 61 years.

There will be about 211,300 new cases of breast cancer and about 40,200 deaths from this disease in women in the United States in the year 2003. An additional 56,000 cases of ductal carcinoma in situ will be detected, principally by screening mammography. One out of every eight or nine American women will develop breast cancer during her lifetime. The incidence of breast cancer continues to increase, but mortality has stayed the same. Women whose mothers or sisters had breast cancer are three to four times more likely to develop the disease. Risk is further increased in patients whose mothers' or sisters' breast cancers occurred before menopause or were bilateral and in those with a family history of breast cancer in two or more first-degree relatives. However, there is no history of breast cancer among female relatives in over 75% of patients. Nulliparous women and women whose first full-term pregnancy was after age 35 have a 1.5 times higher incidence of breast cancer than multiparous women. Late menarche and artificial menopause are associated with a lower incidence, whereas early menarche (under age 12) and late natural menopause (after age 50) are associated with a slight increase in risk. Fibrocystic disease, when accompanied by proliferative changes, papillomatosis, or atypical epithelial hyperplasia, is associated with an increased incidence. A woman who has had cancer in one breast is at increased risk of developing cancer in the other breast. Such women develop a contralateral cancer at the rate of 1% or 2% per year. Women with cancer of the uterine corpus have a breast cancer risk significantly higher than that of the general population, and women with breast cancer have a comparably increased endometrial cancer risk. In the United States, breast cancer is more common in whites. The incidence of the disease among nonwhites (mostly blacks) is increasing, especially in younger women. In general, rates reported from developing countries are low, whereas rates are high in developed countries, with the notable exception of Japan. Some of the variability may be due to underreporting in the developing countries, but a real difference probably exists. Dietary factors, particularly increased fat consumption, may account for some differences in incidence. Oral contraceptives do not appear to increase the risk of breast cancer. There is evidence that administration of estrogens to postmenopausal women may result in a slightly increased risk of breast cancer, but only with higher, long-term doses of estrogens. Concomitant administration of progesterone and estrogen may markedly increase the incidence of breast cancer compared with the use of estrogen alone. The Women's Health Initiative prospective randomized study of hormone replacement therapy stopped treatment with estrogen and progesterone early because of an increased risk of breast cancer compared with untreated controls or women treated with estrogen alone. Alcohol consumption increases the risk slightly. Some inherited breast cancers have been found to be associated with a gene on chromosome 17. This gene, *BRCA1*, is mutated in families with early-onset breast cancer and ovarian cancer. As many as 85% of women with *BRCA1* gene mutations will develop breast cancer in their lifetime. Other genes are associated with increased risk of breast and other cancers, such as *BRCA2*, ataxia-telangiectasia mutation, and *TP53*, the tumor suppressor gene. *TP53* mutations have been found in approximately 1% of breast cancers in women under 40 years of age. Genetic testing is now commercially available for women at high risk of breast cancer. Women with genetic mutations who develop breast cancer may be treated in the same way as women who do not have mutations (ie, lumpectomy), though data are emerging to suggest an increased recurrence rate for these women. Such women with mutations often elect bilateral mastectomy as treatment. Some states have enacted legislation to prevent insurance companies from considering mutations as "preexisting conditions" preventing insurability.

Women at greater than normal risk of developing breast cancer ([Table 16-1](#)) should be identified by their physicians, taught the techniques of breast self-examination, and followed carefully. Those with an exceptional family history should be counseled and given the option of genetic testing. Some of these high-risk women may consider prophylactic mastectomy or tamoxifen.

The NSABP conducted the Breast Cancer Prevention Trial (BCPT), which studied the efficacy of tamoxifen as a preventive agent in women who had never had breast cancer but were at high risk for developing the disease. Women who received tamoxifen for 5 years had about a 50% reduction in noninvasive and invasive cancers compared with women taking placebo. However, women above the age of 50 who received the drug had an increased incidence of endometrial cancer and deep venous thrombosis. Unfortunately, no survival data will be produced from this trial. The estrogen replacement raloxifene, effective in preventing osteoporosis, may also prevent breast cancer. Several large studies to examine this hypothesis are under way.

EARLY DETECTION OF BREAST CANCER

Screening Programs

A number of mass screening programs consisting of physical and mammographic examination of the breasts of asymptomatic women have been conducted. Such programs frequently identify about ten cancers per 1000 women older than age 50 and about two cancers per 1000 women younger than age 50. About 80% of these women have negative axillary lymph nodes at the time of surgery, whereas only 50% of nonscreened women found in the course of usual medical practice have uninvolved axillary nodes. Detecting breast cancer before it has spread to the axillary nodes greatly increases the chance of survival, and about 85% of such women will survive at least 5 years.

Both physical examination and mammography are necessary for maximum yield in screening programs, since about 35-50% of early breast cancers can be discovered only by mammography and another 40% can be detected only by palpation. About one-third of the abnormalities detected on screening mammograms will be found to be malignant when biopsy is performed. Women 20-40 years of age should have a breast examination as part of routine medical care every 2-3 years. Women over age 40 should have yearly breast examinations. The sensitivity of mammography varies from approximately 60% to 90%. This sensitivity depends on several factors, including patient age (breast density), tumor size, location, and mammographic appearance. In young women with dense breasts, mammography is less sensitive than in older woman with fatty breasts, in whom mammography can detect at least 90% of malignancies. Smaller tumors, particularly those without calcifications, are more difficult to detect, especially in dense breasts. The lack of sensitivity and the low incidence of breast cancer in young women has led to questions concerning the value of mammography for screening in women 40-50 years of age. The specificity of mammography in women under 50 varies from about 30% to 40% for nonpalpable mammographic abnormalities to 85% to 90% for clinically evident malignancies.

Doubt exists about the beneficial effect of screening, especially in women under age 50. Questions such as the potential harmful effects of x-rays in a large population of young women and the general value of early detection were raised and largely ignored as various groups supported screening between ages 40 and 50. While the Health Insurance Plan Project study did show a beneficial effect of screening in such women, reducing breast cancer mortality 25% between 10 and 18 years after entry into the study, a Canadian trial demonstrated an unexplained shortening of survival from time of random assignment to death in the screening group. The small number of patients in this study experienced no beneficial effect, but the 95% confidence interval included a potential lifesaving effect as well as a potential harmful effect. A very large number of patients is necessary to show a beneficial effect of screening among patients age 40-49, where the incidence of breast cancer is low. In addition, the problems of crossover of patients in the control group with women undergoing physician examination and nonscreening mammograms, problems with mammography quality, and problems in recruitment, randomization, and compliance make the interpretation of such trials difficult. The beneficial effect of screening in women aged 50-69 is undisputed and has been confirmed by all clinical trials. The efficacy of screening in older women—those older than 70—is inconclusive and is difficult to determine because of the few women screened.

More recent studies showing a beneficial effect of screening young women and the recommendation of a Swedish consensus panel led the NCI to reconsider its position on screening mammography for women in their 40s. Two Swedish trials that had shown a 13% decrease in breast cancer mortality (not statistically significant) now showed a statistical advantage for screening women in their 40s, and a meta-analysis similarly revealed a statistical survival advantage for screened women with longer follow-up. In March 1997, the National Cancer Advisory Board recommended that women with average risk factors should have screening mammography every 1-2 years in their 40s and that women at higher risk should seek medical advice on when to begin screening. The American Cancer Society then recommended screening every year for asymptomatic women starting at age 40. Studies continue to support the value of screening mammography.

Self-Examination

Breast self-examination has not been shown to improve survival; however, it is a useful technique since many patients do detect their own cancer, and women often feel more in control and proactive by using the procedure. All women over age 20 should be advised to examine their breasts monthly. Premenopausal women should perform the examination 7-8 days after the menstrual period. The breasts should be inspected initially while standing before a mirror with the hands at the sides, overhead, and pressed firmly on the hips to contract the pectoralis muscles. Masses, asymmetry of breasts, and slight dimpling of the skin may become apparent as a result of these maneuvers. Next, in a supine position, each breast should be carefully palpated with the fingers of the opposite hand. Some women discover small breast lumps more readily when their skin is moist while bathing or showering. Physicians should instruct women in the technique of self-examination and advise them to report a mass or other abnormality.

Mammography

Mammography is the most useful technique for the detection of early breast cancer. Film screen mammography delivers less than 0.4 cGy to the mid breast per view and has largely replaced the older xeromammographic technique, which delivers more radiation.

Mammography is the only reliable means of detecting breast cancer before a mass can be palpated. Slowly growing cancers can be identified by mammography at least 2 years before reaching a size detectable by palpation.

Calcifications are the most easily recognized mammographic abnormality. The most common findings associated with carcinoma of the breast are clustered polymorphic microcalcifications. Such calcifications are usually at least five to eight in number, aggregated in one part of the breast and differing from each other in size and shape, often including branched or V- or Y-shaped configurations. There may be an associated mammographic mass density or, at times, only a mass density with no calcifications. Such a density usually has irregular or ill-defined borders and may lead to architectural distortion within the breast. A small mass or architectural distortion, particularly in a dense breast, may be subtle and difficult to detect.

Indications for mammography are as follows: (1) to screen at regular intervals women at high risk for developing breast cancer (see above); (2) to evaluate each breast when a diagnosis of potentially curable breast cancer has been made, and at yearly intervals thereafter; (3) to evaluate a questionable or ill-defined breast mass or other suspicious change in the breast; (4) to search for an occult breast cancer in a woman with metastatic disease in axillary nodes or elsewhere from an unknown primary; (5) to screen women prior to cosmetic operations or prior to biopsy of a mass, to examine for an unsuspected cancer; and (6) to follow those women with breast cancer who have been treated with breast-conserving surgery and radiation.

Patients with a dominant or suspicious mass must undergo biopsy despite mammographic findings. The mammogram should be obtained prior to biopsy so that other suspicious areas can be noted and the contralateral breast can be checked. Mammography is never a substitute for biopsy because it may not reveal clinical cancer in a very dense breast, as may be seen in young women with fibrocystic changes, and may not reveal medullary cancers.

Communication and documentation between the patient, the referring physician, and the interpreting physician are critical for high-quality screening and diagnostic mammography. The patient should be told about *how* she will receive timely results of her mammogram; that mammography does not "rule out" cancer; and that she may receive a correlative examination such as ultrasound at the mammography facility if referred for a suspicious lesion. She should also be aware of the technique and need for breast compression and that this may be uncomfortable. The mammography facility should be informed *in writing* of abnormal physical examination findings. It is strongly recommended in the AHCPR Clinical Practice Guidelines that all mammography reports be communicated with the patient as well as the health care provider in writing. Additional phone communication about any abnormal findings should take place between the interpreting and referring physicians. MRI and PET may play a role in imaging atypical lesions but only after diagnostic mammography has been performed.

Clinical Clues to Early Detection of Breast Cancer

A. Symptoms and Signs

The presenting complaint in about 70% of patients with breast cancer is a lump (usually painless) in the breast. About 90% of breast masses are discovered by the patient herself. Less frequent symptoms are breast pain; nipple discharge; erosion, retraction, enlargement, or itching of the nipple; and redness, generalized hardness, enlargement, or shrinking of the breast. Rarely, an axillary mass or swelling of the arm may be the first symptom. Back or bone pain, jaundice, or weight loss may be the result of systemic metastases, but these symptoms are rarely seen on initial presentation.

The relative frequency of carcinoma in various anatomic sites in the breast is shown in [Figure 16-1](#).

Inspection of the breast is the first step in physical examination and should be carried out with the patient sitting, arms at sides and then overhead. Abnormal variations in breast size and contour, minimal nipple retraction, and slight edema, redness, or retraction of the skin can be identified. Asymmetry of the breasts and retraction or dimpling of the skin can often be accentuated by having the patient raise her arms overhead or press her hands on her hips in order to contract the pectoralis muscles. Axillary and supraclavicular areas should be thoroughly palpated for enlarged nodes with the patient sitting ([Figure 16-2](#)). Palpation of the breast for masses or other changes should be performed with the patient both seated and supine with the arm abducted ([Figure 16-3](#)). Some authorities recommend palpation with a rotary motion of the examiner's fingers as well as a horizontal stripping motion.

Breast cancer usually consists of a nontender, firm or hard mass with poorly delineated margins (caused by local infiltration). Slight skin or nipple retraction is an important sign. Minimal asymmetry of the breast may be noted. Very small (1-2 mm) erosions of the nipple epithelium may be the only manifestation of Paget's carcinoma. Watery, serous, or bloody discharge from the nipple is an occasional early sign but is more often associated with benign disease.

A lesion smaller than 1 cm in diameter may be difficult or impossible for the examiner to feel and yet may be discovered by the patient. She should always be asked to demonstrate the location of the mass; if the physician fails to confirm the patient's suspicions, the examination should be repeated in 2-3 months, preferably 1-2 weeks after the onset of menses. During the premenstrual phase of the cycle, increased innocuous nodularity may suggest neoplasm or may obscure an underlying lesion. If there is any question regarding the nature of an abnormality under these circumstances, the patient should be asked to return after her period. Ultrasound is often valuable and mammography essential when an area is felt by the patient to be abnormal but the physician feels no mass.

Metastases tend to involve regional lymph nodes, which may be palpable. One or two movable, nontender, not particularly firm axillary lymph nodes 5 mm or less in diameter are frequently present and are generally of no significance. Firm or hard nodes larger than 1 cm are typical of metastases. Axillary nodes that are matted or fixed to skin or deep structures indicate advanced disease (at least stage III). Microscopic metastases are present in about 30% of patients with clinically negative nodes. On the other hand, if the examiner thinks that the axillary nodes are involved, that impression will be borne out by histologic section in about 85% of cases. The incidence of positive axillary nodes increases with the size of the primary tumor. Noninvasive cancers do not metastasize.

In most cases no nodes are palpable in the supraclavicular fossa. Firm or hard nodes of any size in this location or just beneath the clavicle are suggestive of metastatic cancer and should be biopsied. Ipsilateral supraclavicular or infraclavicular nodes containing cancer indicate that the tumor is in an advanced stage (stage IV). Edema of the ipsilateral arm, commonly caused by metastatic infiltration of regional lymphatics, is also a sign of advanced cancer.

B. Laboratory Findings

A consistently elevated sedimentation rate may be the result of disseminated cancer. Liver or bone metastases may be associated with elevation of serum alkaline phosphatase. Hypercalcemia is an occasional important finding in advanced cancer of the breast. Carcinoembryonic antigen (CEA) and CA 15-3 or CA 27-29 may be used as markers for recurrent breast cancer but are not helpful in diagnosis of early lesions.

C. Imaging for Metastases

Chest x-ray may show pulmonary metastases. CT scanning of the liver and brain is of value only when metastases are suspected in these areas. Bone scans utilizing technetium Tc 99m-labeled phosphates or phosphonates are more sensitive than skeletal x-rays in detecting metastatic breast cancer. Bone scanning has not proved to be of clinical value as a routine preoperative test in the absence of symptoms, physical findings, or abnormal alkaline phosphatase or calcium levels. The frequency of abnormal findings on bone scan parallels the status of the axillary lymph nodes on pathologic examination. Positron emission tomography (PET) may prove to be an effective single scan for bone and soft tissue or visceral metastases in patients with symptoms or signs of metastatic disease.

D. Diagnostic Tests

1. Biopsy—The diagnosis of breast cancer depends ultimately upon examination of tissue or cells removed by biopsy. Treatment should never be undertaken without an unequivocal histologic or cytologic diagnosis of cancer. The safest course is biopsy examination of all suspicious masses found on physical examination and of suspicious lesions demonstrated by mammography. About 60% of lesions clinically thought to be cancer prove on biopsy to be benign, and about 30% of lesions believed to be benign are found to be malignant. These findings demonstrate the fallibility of clinical judgment and the necessity for biopsy. A breast mass should not be followed without histologic diagnosis, except perhaps in the premenopausal woman with a nonsuspicious mass presumed to be fibrocystic disease. A lesion such as this could be observed through one or two menstrual cycles. However, if the mass does not completely resolve during this time, it must be biopsied. [Figures 16-4](#) and [16-5](#) present algorithms for management of breast masses in pre- and postmenopausal patients.

The simplest method is needle biopsy, either by aspiration of tumor cells (fine-needle aspiration cytology) or by obtaining a small core of tissue with a hollow needle.

Fine-needle aspiration cytology is a useful technique whereby cells are aspirated with a small needle and examined by the pathologist. This technique can be performed easily with no morbidity and is much less expensive than excisional or open biopsy. The main disadvantages are that it requires a pathologist skilled in the cytologic diagnosis of breast cancer and that it is subject to sampling problems, particularly because deep lesions may be missed. Furthermore, noninvasive cancers usually cannot be distinguished from invasive cancers. The incidence of false-positive diagnoses is extremely low, perhaps 1-2%. The false-negative rate is as high as 10%. Most experienced clinicians would not leave a suspicious dominant mass in the breast even when fine-needle aspiration cytology is negative unless the clinical diagnosis, breast imaging studies, and cytologic studies were all in agreement.

Large-needle (core needle) biopsy removes a core of tissue with a large cutting needle. Hand-held biopsy devices make large-core needle biopsy of a palpable mass easy and cost-effective in the office with local anesthesia. As in the case of any needle biopsy, the main problem is sampling error due to improper positioning of the needle, giving rise to a false-negative test result.

Open biopsy under local anesthesia as a separate procedure prior to deciding upon definitive treatment is the most reliable means of diagnosis. Needle biopsy or aspiration, when positive, offers a more rapid approach with less expense and morbidity, but when nondiagnostic it must be followed by excisional biopsy.

Additional evaluation for metastatic disease and therapeutic options can be discussed with the patient after the histologic or cytologic diagnosis of cancer has been established. This approach has the advantage of avoiding unnecessary procedures, since cancer is found in the minority of patients biopsied for a breast lump. In situ cancers are not easily diagnosed cytologically and usually require excisional biopsy.

As an alternative in highly suspicious circumstances, the patient may be admitted to the hospital, where the diagnosis is made on frozen section of tissue obtained by open biopsy under general anesthesia. If the frozen section is positive, the surgeon can proceed immediately with operation. This one-step method is rarely used today except when cytologic study has suggested cancer but is not diagnostic and there is a high clinical suspicion of malignancy.

In general, the two-step approach—outpatient biopsy followed by definitive operation at a later date—is preferred in the diagnosis and treatment of breast cancer, because patients can be given time to adjust to the diagnosis of cancer, can consider alternative forms of therapy, and can seek a second opinion if they wish. There is no adverse effect from the short (1-2 weeks) delay of the two-step procedure, and this is the current recommendation of the National Cancer Institute.

2. Ultrasonography—Ultrasonography is performed chiefly to differentiate cystic from solid lesions. Though not diagnostic, ultrasound may reveal features highly suggestive of malignancy such as irregular margins on a new solid mass. Ultrasonography may show an irregular mass within a cyst in the rare case of intracystic carcinoma. If a tumor is palpable and feels like a cyst, an 18-gauge needle can be used to aspirate the fluid and make the diagnosis of cyst. If a cyst is aspirated and the fluid is nonbloody, it does not have to be examined cytologically. If the mass does not recur, no further diagnostic test is necessary. Nonpalpable mammographic densities that appear benign should be investigated with ultrasound to determine whether the lesion is cystic or solid. These may even be needle-biopsied with ultrasound guidance.

3. Mammography—When a suspicious abnormality is identified by mammography alone and cannot be palpated by the clinician, the lesion should be biopsied by **computerized stereotactic guided core needle** technique. These units have been added to mammographic suites in order to localize abnormalities and perform needle biopsy without surgery. Under mammographic guidance, a biopsy needle can be inserted into the lesion by the mammographer, and a core of tissue for histologic examination of cells for cytology can then be examined.

Mammographic localization biopsy is performed by obtaining a mammogram in two perpendicular views and placing a needle or hook-wire near the abnormality so that the surgeon can use the metal needle or wire as a guide during operation to locate the lesion. After mammography confirms the position of the needle in relation to the lesion, an incision is made and the subcutaneous tissue is dissected until the needle is identified. Using the films as a guide, the abnormality can then be localized and excised. It often happens that the abnormality cannot even be palpated through the incision—this is the case with microcalcifications—and thus it is essential to obtain a mammogram of the specimen to document that the lesion was excised. At that time, a second marker needle can further localize the lesion for the pathologist. Stereotactic core needle biopsies have proved equivalent to mammographic localization biopsies. Core biopsy is preferable to mammographic localization for accessible lesions.

4. Other imaging modalities—Other modalities of breast imaging have been investigated. Automated breast ultrasonography is useful in distinguishing cystic from

solid lesions but should be used only as a supplement to physical examination and mammography. Ductography may be useful to define the site of a lesion causing a bloody discharge, but since biopsy is always indicated, ductography may be omitted and the blood-filled nipple system excised. MRI is highly sensitive but not specific and should not be used for screening, but it may be of value in highly selective cases. It is useful, for example, in differentiating scar from recurrence post lumpectomy. PET scanning may prove to be of use in evaluating the breast and regional lymphatics.

5. Cytology—Cytologic examination of nipple discharge or cyst fluid may be helpful on rare occasions. As a rule, mammography (or ductography) and breast biopsy are required when nipple discharge or cyst fluid is bloody or cytologically questionable. Ductal lavage, a technique that washes individual duct systems with saline and loosens epithelial cells for cytologic evaluation, is being evaluated as a diagnostic technique among women with discharge or serious risk factors for malignancy.

DIFFERENTIAL DIAGNOSIS

The lesions to be considered most often in the differential diagnosis of breast cancer are the following, in descending order of frequency: mammary dysplasia (cystic disease of the breast), fibroadenoma, intraductal papilloma, lipoma, and fat necrosis.

STAGING

Currently, the American Joint Committee on Cancer and the International Union Against Cancer have agreed on a TNM (tumor, regional lymph nodes, distant metastases) staging system for breast cancer. The use of this uniform TNM staging system will enhance communication between investigators and clinicians. [Table 16-2](#) sets forth the TNM classification.

PATHOLOGIC TYPES

Numerous pathologic subtypes of breast cancer can be identified histologically ([Table 16-3](#)). These types are distinguished by the histologic appearance and growth pattern of the tumor. In general, breast cancer arises either from the epithelial lining of the large or intermediate-sized ducts (ductal) or from the epithelium of the terminal ducts of the lobules (lobular). The cancer may be invasive or in situ. Most breast cancers arise from the intermediate ducts and are invasive (invasive ductal, infiltrating ductal), and most histologic types are merely subtypes of invasive ductal cancer with unusual growth patterns (colloid, medullary, scirrhous, etc). Ductal carcinoma that has not invaded the extraductal tissue is intraductal or in situ ductal. Lobular carcinoma may be either invasive or in situ.

Except for the in situ cancers, the histologic subtypes have only a slight bearing on prognosis when outcomes are compared after accurate staging. Various histologic parameters, such as invasion of blood vessels, tumor differentiation, invasion of breast lymphatics, and tumor necrosis have been examined, but they too seem to have little prognostic value.

The noninvasive cancers by definition are confined by the basement membrane of the ducts and lack the ability to spread. However, in patients whose biopsies show noninvasive intraductal cancer, associated invasive ductal cancers metastasize to lymph nodes in about 1-3% of cases. Lobular carcinoma in situ (LCIS) is a premalignant lesion that is not a true cancer but is a risk factor associated with subsequent development of invasive cancer in at least 20% of cases, and the cancer may be in either breast.

SPECIAL CLINICAL FORMS OF BREAST CANCER

Paget's Carcinoma

The basic lesion is usually an infiltrating ductal carcinoma, usually well differentiated, or a ductal carcinoma in situ (DCIS). The ducts of the nipple epithelium are infiltrated, but gross nipple changes are often minimal, and a tumor mass may not be palpable. The first symptom is often itching or burning of the nipple, with superficial erosion or ulceration. The diagnosis is established by biopsy of the erosion.

Paget's carcinoma is not common (about 1% of all breast cancers), but it is important because the nipple changes appear innocuous. These are frequently diagnosed and treated as dermatitis or bacterial infection, leading to delay in detection. When the lesion consists of nipple changes only, the incidence of axillary metastases is less than 5%, and the prognosis is excellent. When a breast mass is also present, the incidence of axillary metastases rises, with an associated marked decrease in prospects for cure by surgical or other treatment.

Inflammatory Carcinoma

This is the most malignant form of breast cancer and constitutes less than 3% of all cases. The clinical findings consist of a rapidly growing, sometimes painful mass that enlarges the breast. The overlying skin becomes erythematous, edematous, and warm. Often there is no distinct mass, since the tumor infiltrates the involved breast diffusely. The diagnosis should be made when the redness involves more than one-third of the skin over the breast and biopsy shows infiltrating carcinoma with invasion of the subdermal lymphatics. The inflammatory changes, often mistaken for an infection, are caused by carcinomatous invasion of the subdermal lymphatics, with resulting edema and hyperemia. If the physician suspects infection but the lesion does not respond rapidly (1-2 weeks) to antibiotics, biopsy is performed. Metastases tend to occur early and widely, and for this reason inflammatory carcinoma is rarely curable. Mastectomy is seldom indicated unless chemotherapy and radiation have resulted in clinical remission with no evidence of distant metastases. In these cases, residual disease in the breast may be eradicated. Radiation, hormone therapy, and chemotherapy are the measures most likely to be of value rather than operation.

Breast Cancer Occurring During Pregnancy or Lactation

Breast cancer complicates approximately one in 3000 pregnancies. The diagnosis is frequently delayed, because physiologic changes in the breast may obscure the lesion. This results in a tendency of both patients and physicians to misinterpret findings and to delay biopsy. When the cancer is confined to the breast, the 5-year survival rate after mastectomy is about 70%. Axillary metastases are already present in 60-70% of patients, and for them the 5-year survival rate after mastectomy is only 30-40%. Pregnancy (or lactation) is not a contraindication to operation, and treatment should be based on the stage of the disease as in the nonpregnant (or nonlactating) woman. Overall survival rates have improved, since cancers are now diagnosed in pregnant women earlier than in the past. Breast-conserving surgery may be performed—and radiation and chemotherapy given—even during the pregnancy.

Woo JC et al: Breast cancer in pregnancy: a literature review. Arch Surg 2003;138:91. [\[PMID: 12511159\]](#)

Bilateral Breast Cancer

Clinically evident simultaneous bilateral breast cancer occurs in less than 1% of cases, but there is a 5-8% incidence of later occurrence of cancer in the second breast. Bilaterality occurs more often in familial breast cancer, in women under age 50, and when the tumor in the primary breast is lobular. The incidence of second breast cancers increases directly with the length of time the patient is alive after her first cancer—about 1% per year.

In patients with breast cancer, mammography should be performed before primary treatment and at regular intervals thereafter, to search for occult cancer in the opposite breast. Routine biopsy of the opposite breast is usually not warranted even for lobular cancer.

Noninvasive Cancer

Noninvasive cancer can occur within the ducts (ductal carcinoma in situ) or lobules (lobular carcinoma in situ). While ductal carcinoma in situ (DCIS) behaves as an early malignancy, lobular carcinoma in situ (LCIS) would perhaps better be called lobular neoplasia because it is not truly carcinoma. DCIS tends to be unilateral and most often progresses to invasive cancer if untreated. Approximately 40-60% of women who have DCIS treated with biopsy alone develop invasive cancer within the same breast. Lobular carcinoma in situ, however, appears to be a risk factor calling attention to the probability of developing invasive cancer in either breast. One in five women with lobular carcinoma in situ develop invasive cancer. This invasive cancer may occur in either breast regardless of the side of the original biopsy and is usually ductal.

The treatment of intraductal lesions is controversial. Ductal carcinoma can be treated with total mastectomy or by wide excision with or without radiation therapy. Lobular carcinoma in situ is well managed with observation, but patients unwilling to accept the increased risk of breast cancer may be offered bilateral total mastectomy. Another alternative is tamoxifen, which is effective in preventing invasive breast cancer from developing in both lobular cancer in situ and intraductal cancer in situ. Axillary metastases from in situ cancers should not occur unless there is an occult invasive cancer.

HORMONE RECEPTOR SITES

The presence or absence of estrogen and progesterone receptors in the cytoplasm of tumor cells is of paramount importance in managing patients with breast cancer. Patients whose primary tumors are receptor-positive have a more favorable course than those whose tumors are receptor-negative. Receptors are of value in determining adjuvant therapy and for treatment of advanced disease. Up to 60% of patients with metastatic breast cancer will respond to hormonal manipulation if their tumors contain estrogen receptors. Fewer than 5% of patients with metastatic, estrogen receptor-negative tumors can be treated successfully in this fashion.

Receptor status is valuable not only in management of metastatic disease but also helps select patients for adjuvant therapy. Adjuvant hormonal therapy (tamoxifen) with receptor-positive tumors and adjuvant chemotherapy with receptor-negative tumors improve survival rates even in the absence of lymph node metastases (see Adjuvant Therapy, below).

Progesterone receptors may be a more sensitive indicator than estrogen receptors of patients who may respond to hormonal manipulation. Up to 80% of patients with metastatic progesterone receptor-positive tumors improve with hormonal manipulation. Receptors have no relationship to response to chemotherapy.

The estrogen, progesterone, and HER-2/*neu* receptor status and proliferative indices of the tumor should be determined at the time of initial biopsy. This is performed on paraffin-fixed tissue by immunohistochemistry. HER-2/*neu* assessment in breast cancer by immunohistochemistry is appropriate for patients with tumors that score 3+. Fluorescence in situ hybridization (FISH) is recommended for women with 2+ immunohistochemistry scores to more accurately assess HER-2/*neu* amplification and provide better prognostic information. Receptor status may change after hormonal therapy, radiotherapy, or chemotherapy.

CURATIVE TREATMENT

Treatment may be curative or palliative. Curative treatment is advised for clinical stage I and stage II disease ([Table 16-2](#)). Patients with locally advanced (stage III) and even inflammatory tumors may be cured with multimodality therapy, but in most palliation is all that can be expected. Palliative treatment is appropriate for all patients with stage IV disease and for previously treated patients who develop distant metastases or who have unresectable local cancers.

The growth potential of tumors and host resistance factors vary widely from patient to patient and may be altered during the course of the disease. The doubling time of breast cancer cells ranges from several weeks in a rapidly growing lesion to a year in a slowly growing one. Assuming that the rate of doubling is constant and that the neoplasm originates in one cell, a carcinoma with a doubling time of 100 days may not reach clinically detectable size (1 cm) for about 8 years. Rapidly growing cancers have a much shorter preclinical course and a greater tendency to metastasize by the time a breast mass is discovered.

The long preclinical growth phase and the tendency of breast cancers to metastasize have led clinicians to believe that most breast cancer is a systemic disease at the time of diagnosis. Although it may be true that breast cancer cells are released from the tumor prior to diagnosis, variations in the host-tumor relationship prohibit the growth of disseminated disease in many patients. Clearly, not all breast cancer is systemic at the time of diagnosis. For this reason, a pessimistic attitude concerning the management of localized breast cancer is unwarranted, and many patients can be cured.

Controversy surrounds the timing of surgery with respect to the menstrual cycle. Some suggest that operation during the time of unopposed estrogen adversely affects survival, but most studies support no such effect. Several trials are currently examining this question.

Choice of Primary Therapy

The extent of disease and its biologic aggressiveness are the principal determinants of the outcome of primary therapy. Clinical and pathologic staging help in assessing extent of disease ([Table 16-2](#)), but each is to some extent imprecise. Other factors such as DNA flow cytometry, tumor grade, hormone receptor assays, and oncogene amplification may be of prognostic value but are not important in determining the type of local therapy. Since two-thirds of patients eventually manifest distant disease regardless of the form of primary therapy, there is a tendency to think of breast carcinoma as being systemic in most patients at the time of presentation.

Controversy surrounds the choice of primary therapy of stage I, II, and III breast carcinoma. A number of states require physicians to inform patients of alternative treatment methods in the management of breast cancer. Currently, the standard of care for stage I or stage II cancer is surgical resection.

Breast-Conserving Therapy

Many nonrandomized trials, the Milan trial, and a large randomized trial conducted by the National Surgical Adjuvant Breast Project (NSABP) in the United States show that disease-free survival rates are similar for patients treated by partial mastectomy plus axillary dissection followed by radiation therapy and for those treated by modified radical mastectomy (total mastectomy plus axillary dissection). All patients whose axillary nodes contained tumor received adjuvant chemotherapy.

In the NSABP trial, patients were randomized to three treatment types: (1) "lumpectomy" (removal of the tumor with *confirmed* tumor-free margins) plus whole breast irradiation, (2) lumpectomy alone, and (3) total mastectomy. All patients underwent axillary lymph node dissection, and some had tumors as large as 4 cm with (or without) palpable axillary lymph nodes. The lowest local recurrence rate was among patients treated with lumpectomy and postoperative irradiation; the highest—nearly 40% at 8 years of follow-up—was among patients treated with lumpectomy alone. However, no statistically significant differences were observed in overall or disease-free survival among the three treatment groups. This study shows that lumpectomy and axillary dissection with postoperative radiation therapy are as effective as modified radical mastectomy for the management of patients with stage I and stage II breast cancer.

The results of these and other trials have demonstrated that much less aggressive surgical treatment of the primary lesion than has previously been thought necessary gives equivalent therapeutic results and may preserve an acceptable cosmetic appearance.

Tumor size is a major consideration in determining the feasibility of breast conservation. The lumpectomy trial of the NSABP randomized patients with tumors as large as 4 cm. To achieve an acceptable cosmetic result, the patient must have a breast of sufficient size to enable excision of a 4 cm tumor without considerable deformity. Therefore, large size is only a relative contraindication. Subareolar tumors, also difficult to excise without deformity, are not contraindications to breast conservation. Clinically detectable multifocality is a relative contraindication to breast-conserving surgery, as is fixation to the chest wall or skin or involvement of the nipple or overlying skin. The patient—not the surgeon—should be the judge of what is cosmetically acceptable.

Axillary dissection is valuable in preventing axillary recurrences, in staging cancer, and in planning therapy. Intraoperative lymphatic mapping and sentinel node dissection identify lymph nodes most likely to harbor metastases if present in the axillary nodes. Numerous studies have confirmed the validity of this technique. Ongoing trials are examining the replacement of formal axillary dissection with sentinel node dissection. Results to date suggest that sentinel node biopsy may replace axillary dissection for staging and treatment in histopathologically node-negative women. A trial by the American College of Surgeons Oncology Group is examining the role of sentinel node dissection without axillary dissection for node-positive women. Bone marrow biopsy with examination by immunocytochemistry to detect early metastases may be as sensitive a staging procedure as axillary dissection and may identify patients at high risk for disseminating disease.

Recommendations

Earlier consensus held that breast-conserving surgery with radiation was the preferred form of treatment for patients with early-stage breast cancer. Despite the numerous randomized trials showing no survival benefit of mastectomy over breast-conserving partial mastectomy and irradiation, breast-conserving surgery appears underutilized and mastectomy remains the more common treatment. About 25% of patients in the United States with stage I or stage II breast cancer are treated with breast-conserving surgery and radiation therapy, compared with 75% treated with mastectomy. Use of breast-conserving surgery and radiation therapy varies by region of the country, ranging from 15% in the South Central United States to 30% in the Pacific Region.

Modified radical mastectomy (total mastectomy plus axillary lymph node dissection) has been the standard therapy for most patients with breast cancer. This operation removes the entire breast, overlying skin, nipple, and areolar complex as well as the underlying pectoralis fascia with the axillary lymph nodes in continuity. The major advantage of modified radical mastectomy is that radiation therapy may not be necessary. The disadvantage, of course, is the psychologic impact associated with breast loss. Radical mastectomy, which removes the underlying pectoralis muscle, should be performed rarely, if at all. Axillary node dissection is not indicated for noninfiltrating cancers, because nodal metastases are rarely present. Skin-sparing mastectomy is currently gaining favor but is appropriate in only a small subgroup of patients. At an international consensus conference in Philadelphia in April 2001, participants recommended sentinel node biopsy as an alternative to axillary dissection in selected patients with invasive cancer. Radiotherapy after partial mastectomy consists of 5-6 weeks of five daily fractions to a total dose of 5000-6000 cGy. Some radiotherapists use a boost dose. Current studies suggest that radiotherapy after mastectomy may improve survival. The use of radiation in mastectomy patients is being further researched in a large cooperative trial to better identify which subgroups will benefit. Researchers are also examining the utility of axillary irradiation as an alternative to axillary dissection in the clinically node-negative patient.

Preoperatively, full discussion with the patient regarding the rationale for operation and various alternative forms of treatment is essential. Breast-conserving surgery and radiation should be offered whenever possible, since most patients would prefer to save the breast. Breast reconstruction, immediate or delayed, should be discussed with patients who choose or require mastectomy. Patients should have an interview with a reconstructive plastic surgeon to discuss options prior to making a decision regarding reconstruction. Time is well spent preoperatively in educating the patient and family about these matters.

Adjuvant Systemic Therapy

Following surgery and radiation therapy, chemotherapy or hormonal therapy is advocated for most patients with curable breast cancer. The objective of adjuvant systemic therapy is to eliminate the occult metastases responsible for late recurrences while they are microscopic and most vulnerable to anticancer agents. In addition, adjuvant chemotherapy may decrease local recurrence in patients treated with breast conservation, while adjuvant tamoxifen decreases contralateral breast cancer occurrence.

Numerous clinical trials with various adjuvant chemotherapeutic regimens have been completed. The most extensive clinical experience is with the CMF (cyclophosphamide, methotrexate, and fluorouracil) regimen. Cyclophosphamide can be given either orally, in a dose of 100 mg/m² daily for 14 days, or intravenously, in a dose of 600 mg/m² on days 1 and 8. Methotrexate is given intravenously, 40 mg/m² on days 1 and 8, and fluorouracil is given intravenously, 600 mg/m² on days 1 and 8. This cycle is repeated every 4 weeks. Some clinicians prefer to give the drugs on 1 day only every 3 weeks. There appears to be no obvious advantage except that patient compliance is assured when the cyclophosphamide is given intravenously. The regimen is continued for 6 months in patients with axillary metastases. Premenopausal women with positive axillary nodes benefit from adjuvant chemotherapy. The recurrence rate in premenopausal patients who received no adjuvant chemotherapy is more than half again the rate of those who received such therapy. No therapeutic effect with CMF has been shown in postmenopausal women with positive nodes, perhaps because therapy was modified so often in response to side effects that the total amount of drugs administered was less than planned. Other trials with different agents support the value of adjuvant chemotherapy in postmenopausal women. There are many forms of combination chemotherapy that are effective. Most are variations of CMF or AC (Adriamycin [doxorubicin] plus cyclophosphamide). The addition of taxanes (docetaxel, paclitaxel) to AC improved survival in a subgroup of node-positive women.

Selection of patients to receive chemotherapy must take into account common concomitant health problems and the effects of chemotherapy on the patient's overall health. Tamoxifen can be given with fewer side effects even in the elderly. It appears to increase bone density and favorably affect lipid and lipoprotein profiles, which may explain the observed decreased mortality rate from coronary artery disease seen in patients taking tamoxifen.

The addition of hormonal therapy, usually tamoxifen, may improve the results of adjuvant therapy. It also has been shown to enhance the beneficial effects of melphalan and fluorouracil in postmenopausal women whose tumors are estrogen receptor (ER)-positive. Tamoxifen alone in a dosage of 20 mg daily has long been the recommended treatment for postmenopausal women with ER-positive tumors. Finally, an NSABP trial showed that tamoxifen plus chemotherapy (Adriamycin [doxorubicin] plus cyclophosphamide [AC] or prednisone plus Adriamycin plus fluorouracil [PAF]) lowered recurrence rates more than tamoxifen alone in postmenopausal women with ER-positive tumors. Currently, a large clinical trial (ATAC) is evaluating the use of anastrozole, an aromatase inhibitor used as second-line therapy for metastatic breast cancer, as first-line adjuvant treatment alone or in combination with tamoxifen. Preliminary results show promise in the estrogen receptor-positive postmenopausal patient.

The length of time adjuvant therapy must be administered remains uncertain. Shorter treatment periods may be as effective as longer ones. For example, one study compared 6 versus 12 cycles of postoperative CMF and found 5-year disease-free survival rates to be comparable. One of the earliest adjuvant trials used a 6-day perioperative regimen of intravenous cyclophosphamide alone; follow-up at 15 years shows a 15% improvement in disease-free survival rates for treated patients, suggesting that short-term therapy may be effective. NSABP study B-14 showed that 5 years of treatment with tamoxifen is superior to 10 years.

Several studies of adjuvant therapy in node-negative women reveal a beneficial effect of adjuvant chemotherapy or tamoxifen in delaying recurrence and improving survival. A number of protocols, including CMF with leucovorin rescue as well as tamoxifen alone, have increased disease-free survival. The magnitude of this improvement is about one-third, ie, a group of women with an estimated 30% recurrence rate would have a 20% recurrence rate after adjuvant systemic therapy. Quality of life while receiving chemotherapy does not appear to be greatly altered.

An NIH consensus conference has reexamined the standards for adjuvant therapy of breast cancer. Since the last conference on this topic in 1990, the long-term advantage of systemic therapy has been further established. In the last 10 years, no new prognostic factors have been validated to aid in the selection of patients for adjuvant treatment. Its use should be based on the patient's age; on the size, histopathologic grade, and hormone receptor status of the breast tumor; and on the status of the regional lymph nodes. The value of HER-2/*neu*, *TP53*, angiogenesis factors, and vascular invasion are being investigated but as yet are not proven prognostic factors. Studies are being conducted evaluating trastuzumab in the adjuvant setting in a group of patients whose tumors overexpress HER-2/*neu*. The panel concluded that regardless of other factors, adjuvant systemic chemotherapy with drug combinations improves survival and should be used for most women who have potentially curable breast cancer. The use of anthracyclines is superior to combinations without anthracyclines. Tamoxifen should be used as a systemic agent in all women whose tumors are hormone receptor-positive—regardless of age, menopausal status, or other prognostic factors. HER-2/*neu* status should not affect the choice of agents or the use of hormone therapy. Ovarian ablation in premenopausal patients with estrogen receptor-positive tumors may produce a benefit similar to that of adjuvant systemic chemotherapy. Taxanes have demonstrated benefit in patients with metastatic cancer and are being evaluated in node-negative patients. Adjuvant systemic therapy should not be given to women who have small node-negative breast cancers with favorable histologic subtypes, such as mucinous or tubular carcinoma.

In practice, most medical oncologists are currently using systemic adjuvant therapy for patients with node-negative and node-positive breast cancer. Other prognostic factors being used to determine the patient's risks are tumor size, estrogen and progesterone receptor status, nuclear grade, histologic type, proliferative rate, and oncogene expression ([Table 16-4](#)). The assumption is made that all patients with node-negative aggressive tumors should receive adjuvant therapy save those who have serious coexistent medical problems. Most patients tolerate at least tamoxifen. The use of chemotherapy prior to resection of the primary tumor (neoadjuvant) has also been examined. This enables the assessment of in vivo chemosensitivity. A complete tumor response in vivo prior to operation appears to be associated with improvement in survival. Neoadjuvant chemotherapy also permits breast conservation by shrinking the primary tumor in women who would otherwise need mastectomy

for local control.

Important questions remaining to be answered are the timing and duration of adjuvant chemotherapy, which chemotherapeutic agents should be applied for which subgroups of patients, how best to coordinate adjuvant chemotherapy with postoperative radiation therapy, the use of combinations of hormonal therapy and chemotherapy, and the value of prognostic factors other than hormone receptors in predicting response to adjuvant therapy. Adjuvant systemic therapy is not generally used in patients with small tumors and those with negative lymph nodes who have favorable tumor markers. A small disease-free survival benefit even in patients with small favorable tumors has been suggested. It appears that adjuvant systemic therapy benefits all breast cancer patients, but the clinician must decide if the benefits outweigh the risks, complications, and expense.

PALLIATIVE TREATMENT

This section covers palliative therapy of disseminated disease incurable by surgery (stage IV).

Radiotherapy

Palliative radiotherapy may be advised for locally advanced cancers with distant metastases in order to control ulceration, pain, and other manifestations in the breast and regional nodes. Irradiation of the breast and chest wall and the axillary, internal mammary, and supraclavicular nodes should be undertaken in an attempt to cure locally advanced and inoperable lesions when there is no evidence of distant metastases. A small number of patients in this group are cured in spite of extensive breast and regional node involvement.

Palliative irradiation is of value also in the treatment of certain bone or soft tissue metastases to control pain or avoid fracture. Radiotherapy is especially useful in the treatment of isolated bony metastasis, chest wall recurrences, brain metastases, and acute spinal cord compression.

Hormone Therapy

Disseminated disease may shrink—or grow less rapidly—after endocrine therapy such as administration of hormones (eg, estrogens, androgens, progestins; see [Table 16-5](#)); ablation of the ovaries, adrenals, or pituitary; or administration of drugs that block hormone receptor sites (eg, antiestrogens) or drugs that block the synthesis of hormones (eg, aminoglutethimide). Hormonal manipulation is usually more successful in postmenopausal women even if they have received estrogen replacement therapy. If treatment is based on the presence of estrogen receptor protein in the primary tumor or metastases, however, the rate of response is nearly equal in premenopausal and postmenopausal women. A favorable response to hormonal manipulation occurs in about one-third of patients with metastatic breast cancer. Of those whose tumors contain estrogen receptors, the response is about 60% and perhaps as high as 80% for patients whose tumors contain progesterone receptors as well. Because only 5-10% of women whose tumors do not contain estrogen receptors respond, they should not receive hormonal therapy except in unusual circumstances, eg, in an older patient who cannot tolerate chemotherapy. Since the quality of life during a remission induced by endocrine manipulation is usually superior to a remission following cytotoxic chemotherapy, it is usually best to try endocrine manipulation first in cases where the estrogen receptor status is unknown. When receptor status is unknown but the disease is progressing rapidly or involves visceral organs, however, endocrine therapy is rarely successful, and introducing it may waste valuable time.

In general, only one type of therapy should be given at a time unless it is necessary to irradiate a destructive lesion of weight-bearing bone while the patient is on another regimen. The regimen should be changed only if the disease is clearly progressing. This is especially important for patients with destructive bone metastases, since changes in the status of these lesions are difficult to determine radiographically. A plan of therapy that would simultaneously minimize toxicity and maximize benefits is often best achieved by hormonal manipulation.

The choice of endocrine therapy depends on the menopausal status of the patient. Women within 1 year of their last menstrual period are considered to be

premenopausal, while women whose menstruation ceased more than a year ago are postmenopausal. If endocrine therapy is the initial choice, it is referred to as primary hormonal manipulation; subsequent endocrine treatment is called secondary or tertiary hormonal manipulation.

A. The Premenopausal Patient

1. Primary hormonal therapy—The potent antiestrogen tamoxifen is the endocrine treatment of choice in the premenopausal patient. Tamoxifen is usually given orally in a dose of 20 mg daily. There is no significant difference in survival or response between tamoxifen therapy and bilateral oophorectomy. Tamoxifen is by far the most common and preferred method of hormonal manipulation for both pre- and postmenopausal women. The average remission is about 12 months. Tamoxifen can be given with little morbidity and few side effects. Toremifene, a tamoxifen analog, is currently available and has similar side effects but is less likely to cause uterine cancer. Controversy continues about whether a response to tamoxifen is predictive of probable success with other forms of endocrine manipulation.

Bilateral oophorectomy is less desirable than primary hormonal manipulation in premenopausal women because tamoxifen is so well tolerated. Oophorectomy can be achieved rapidly and safely by surgery, however, or, if the patient is a poor operative risk, by irradiation of the ovaries. Ovarian radiation therapy should be avoided in otherwise healthy patients because of the high rate of complications and the longer time necessary to achieve results. Chemical ovarian ablation using a GnRH analog can also be utilized. Oophorectomy presumably works by eliminating estrogens, progestins, and androgens, which stimulate growth of the tumor.

2. Secondary or tertiary hormonal therapy—Although patients who do not respond to tamoxifen or oophorectomy should be treated with cytotoxic drugs, those who respond and then relapse may subsequently respond to another form of endocrine treatment ([Table 16-5](#)). The initial choice for secondary endocrine manipulation has not been clearly defined.

Patients who improve after oophorectomy but subsequently relapse should receive tamoxifen. If tamoxifen fails, aminoglutethimide or megestrol acetate should be considered. Aminoglutethimide is an inhibitor of adrenal hormone synthesis and, when combined with a corticosteroid, provides a therapeutically effective "medical adrenalectomy." Megestrol is a progestational agent. Both drugs cause less morbidity and mortality than surgical adrenalectomy, can be discontinued once the patient improves, and are not associated with the many problems of postsurgical hypoadrenalism, so that patients who require chemo- therapy are more easily managed. Adrenalectomy or hypophysectomy induces regression in 30-50% of patients who have previously responded to oophorectomy. Pharmacologic hormonal manipulation has in large part replaced these invasive procedures. Toremifene has shown no added value in women whose tumors no longer respond to tamoxifen.

B. The Postmenopausal Patient

1. Primary hormonal therapy—Tamoxifen, 20 mg daily, is the initial therapy of choice for postmenopausal women with metastatic breast cancer amenable to endocrine manipulation. It has fewer side effects than diethylstilbestrol, the former therapy of choice, and is equally as effective. The main side effects of tamoxifen are nausea, vomiting, skin rash, and hot flushes. Rarely, it may induce hypercalcemia in patients with bony metastases.

2. Secondary or tertiary hormonal therapy—Postmenopausal patients who do not respond to tamoxifen should be given cytotoxic drugs such as cyclophosphamide, methotrexate, and fluorouracil (CMF) or Adriamycin (doxorubicin) and cyclophosphamide (AC). Postmenopausal women who respond initially to tamoxifen but later manifest progressive disease may be given diethylstilbestrol or megestrol acetate. Aromatase inhibitors (aminoglutethimide) have been available for the treatment of advanced breast cancer in postmenopausal women who fail tamoxifen treatment. Recent trials comparing an aromatase inhibitor, anastrozole, with tamoxifen suggest that the former is just as effective and has fewer side effects. Aromatase inhibitors may achieve the status of primary hormonal therapy in postmenopausal women. Clinical trials have proved the efficacy of anastrozole for such purposes. Anastrozole, easily administered in daily doses of 1 mg, has few side effects. Androgens have many toxicities and should rarely be used. As in premenopausal patients, neither hypophysectomy nor adrenalectomy is still being performed.

Chemotherapy

Cytotoxic drugs should be considered for the treatment of metastatic breast cancer (1) if visceral metastases are present (especially brain or lymphangitic pulmonary), (2) if hormonal treatment is unsuccessful or the disease has progressed after an initial response to hormonal manipulation, or (3) if the tumor is ER-negative. The most useful single chemotherapeutic agent to date is doxorubicin (Adriamycin), with a response rate of 40-50%. Single agents are rarely used but rather given in combination with other cytotoxic drugs.

Combination chemotherapy using multiple agents has proved to be more effective, with objectively observed favorable responses achieved in 60-80% of patients with stage IV disease. Various combinations of drugs have been used, and clinical trials are continuing in an effort to improve results and reduce undesirable side effects. Nausea and vomiting are well controlled with drugs that directly affect the central nervous system, such as ondansetron and granisetron. These drugs are selective antagonists of serotonin receptors in the central nervous system and block nausea caused by cytotoxic chemotherapy. Doxorubicin (40 mg/m² intravenously on day 1) and cyclophosphamide (200 mg/m² orally on days 3-6) produce an objective response in about 85% of patients so treated. Other chemotherapeutic regimens have consisted of various combinations of drugs, including cyclophosphamide, vincristine, methotrexate, fluorouracil, and taxanes with response rates ranging up to 60-70%. Prior adjuvant chemotherapy does not seem to alter response rates in patients who relapse. Growth factors such as erythropoietin (epoetin alfa), which stimulates red blood cell production and mimics the effect of erythropoietin, and filgrastim (granulocyte colony-stimulating factor; G-CSF), which stimulates proliferation and differentiation of hematopoietic cells, prevent life-threatening anemia and neutropenia seen commonly with high doses of chemotherapy. These agents greatly diminish the incidence of infections that may complicate the use of myelosuppressive chemotherapy.

Paclitaxel, given by intravenous infusion in a dose of 135-175 mg/m², has been shown to be very effective for patients with breast cancer. It is usually given after failure of combination chemotherapy for metastatic disease or relapse shortly after completion of adjuvant chemotherapy. Paclitaxel has response rates of 30-40% in patients with metastatic disease and is used both as a first-line agent and as an adjuvant systemic agent, usually in combination with doxorubicin.

Docetaxel, another taxane (like paclitaxel), shows promise for treatment of patients with anthracycline-resistant tumors. Both agents are currently being used after treatment with anthracyclines in patients with advanced disease as well as in adjuvant and neoadjuvant settings. Trastuzumab is a monoclonal antibody that binds to HER-2/*neu* receptors on the cancer cell and has been shown to be highly effective in HER-2/*neu*-expressive cancers. It appears superior to doxorubicin alone or doxorubicin and cyclophosphamide.

High-dose chemotherapy and autologous bone marrow or stem cell transplantation have aroused widespread interest for the treatment of metastatic breast cancer. With this technique, the patient receives high doses of cytotoxic agents, eradicating the marrow, for which the patient subsequently undergoes autologous bone marrow or stem cell transplantation. Complete response rates are as high as 30-35%—considerably better than what can be achieved with conventional chemotherapy. Most randomized trials, however, comparing high-dose chemotherapy with stem cell support show no improvement in survival over conventional chemotherapy. A study purporting to show a survival advantage to high-dose chemotherapy in South Africa was found to be falsified and discredited. Enthusiasm for high-dose chemotherapy with stem cell support has waned, but additional studies continue. The technique is extremely costly, and the treatment itself is associated with a mortality rate of about 3-7%.

PROGNOSIS

Stage of breast cancer is the most reliable indicator of prognosis ([Table 16-6](#)). Patients with disease localized to the breast and no evidence of regional spread after microscopic examination of the lymph nodes have by far the most favorable prognosis. Axillary lymph node status is the best-analyzed prognostic factor and correlates with survival at all tumor sizes. In addition, increased number of axillary nodes involved correlates directly with lower survival rates. Estrogen and progesterone receptors are prognostic variables because patients with hormone receptor-negative tumors and no evidence of metastases to the axillary lymph nodes have a much higher recurrence rate than do patients with hormone receptor-positive tumors and no regional metastases. The histologic subtype of breast cancer (eg, medullary, lobular, colloid) seems to have little significance in prognosis once these tumors are truly invasive. Flow cytometry of tumor cells to analyze DNA index and S-phase frequency aid in prognosis. Tumors with marked aneuploidy have a poor prognosis ([Table 16-4](#)). HER-2/*neu* oncogene amplification, epidermal growth factor receptors, and cathepsin D may have some prognostic value, but no markers are as significant as lymph node metastases in predicting outcome.

The mortality rate of breast cancer patients exceeds that of age-matched normal controls for nearly 20 years. Thereafter, the mortality rates are equal, though deaths that occur among breast cancer patients are often directly the result of tumor. Five-year statistics do not accurately reflect the final outcome of therapy.

When cancer is localized to the breast, with no evidence of regional spread after pathologic examination, the clinical cure rate with most accepted methods of therapy is 75-90%. Exceptions to this generalization may be related to the hormonal receptor content of the tumor, tumor size, host resistance, or associated illness. Patients with small mammographically detected estrogen and progesterone receptor-positive tumors and no evidence of axillary spread have a 5-year survival rate greater than 90%. When the axillary lymph nodes are involved with tumor, the survival rate drops to 40-50% at 5 years and probably around 25% at 10 years. In general, breast cancer appears to be somewhat more malignant in younger than in older women, and this may be related to the fact that fewer younger women have ER-positive tumors.

For those patients whose disease progresses despite treatment, supportive group therapy may improve survival. As they approach the end of life, such patients will require meticulous efforts at palliative care (see [Chapter 5](#)).

Younes M et al: Stratified multivariate analysis of prognostic markers in breast cancer: a preliminary report. Anticancer Res 1997;17:1383. [[PMID: 9137503](#)]

FOLLOW-UP CARE

After primary therapy, patients with breast cancer should be followed for life for at least two reasons: to detect recurrences and to observe the opposite breast for a second primary carcinoma. Local and distant recurrences occur most frequently within the first 3 years. During this period, the patient should be examined every 6 months. Thereafter, examination is done annually. Special attention is paid to the contralateral breast, because 10% of patients will develop a new primary breast malignancy. The patient should examine her own breast monthly, and a mammogram should be obtained annually. In some cases, metastases are dormant for long periods and may appear 10-15 years or longer after removal of the primary tumor. Estrogen and progestational agents are rarely used for a patient free of disease after treatment of primary breast cancer, particularly if the tumor was hormone receptor-positive. Studies nevertheless have failed to show an adverse effect of hormonal agents in patients who are free of disease. Even pregnancy has not been clearly associated with shortened survival of patients rendered disease-free—yet most oncologists are reluctant to advise a young patient with breast cancer that she may become pregnant, and most are less than enthusiastic about prescribing hormone replacement therapy for the postmenopausal breast cancer patient. Estrogen replacement therapy may be prescribed for a woman with a history of breast cancer after discussion of the benefits and risks of such therapy for such conditions as osteoporosis and hot flashes.

Local Recurrence

The incidence of local recurrence correlates with tumor size, the presence and number of involved axillary nodes, the histologic type of tumor, the presence of skin edema or skin and fascia fixation with the primary, and the type of initial local (breast) therapy. About 8% of patients develop local recurrence on the chest wall after total mastectomy and axillary dissection. When the axillary nodes are not involved, the local recurrence rate is 5%, but the rate is as high as 25% when they are heavily involved. A similar difference in local recurrence rate was noted between small and large tumors. Factors affecting the rate of local recurrence in patients who have had partial mastectomies are not yet determined. Early studies show that factors such as multifocal cancer, in situ tumors, positive resection margins, chemotherapy, and radiotherapy are important.

Chest wall recurrences usually appear within the first 2 years but may occur as late as 15 or more years after mastectomy. Suspicious nodules and skin lesions should be biopsied. Local excision or localized radiotherapy may be feasible if an isolated nodule is present. If lesions are multiple or accompanied by evidence of regional involvement in the internal mammary or supraclavicular nodes, the disease is best managed by radiation treatment of the entire chest wall including the parasternal, supraclavicular, and axillary areas.

Local recurrence after mastectomy usually signals the presence of widespread disease and is an indication for bone scans, abdominal CT or liver ultrasound, posteroanterior and lateral chest x-rays, and other examinations as needed to search for evidence of metastases. Most patients with locally recurrent tumor will develop distant metastases within 2 years. When there is no evidence of metastases beyond the chest wall and regional nodes, irradiation for cure or complete local excision should be attempted. Patients with local recurrence may be cured with local resection and radiation. After partial mastectomy, local recurrence may not have as serious a prognostic significance as after mastectomy. However, those patients who do develop a breast recurrence have a worse prognosis than those who do not. It is speculated that the ability of a cancer to recur locally after radiotherapy is a sign of aggressiveness. Completion of the mastectomy should be done for local recurrence after partial mastectomy; some of these patients will survive for prolonged periods, especially if the breast recurrence is DCIS or more than 5 years after initial treatment. Systemic chemotherapy or hormonal treatment should be used for women who develop disseminated disease or those in whom local recurrence occurs.

Edema of the Arm

Significant edema of the arm occurs in about 10-30% of patients after axillary dissection with or without mastectomy. It occurs more commonly if radiotherapy has been given or if there was postoperative infection. Partial mastectomy with radiation to the axillary lymph nodes is followed by chronic edema of the arm in 10-20% of patients. To avoid this complication, many authorities advocate axillary lymph node sampling rather than complete axillary dissection. However, since axillary dissection is a more accurate staging operation than axillary sampling, it is recommended that at least level I and II lymph nodes be removed, in combination with partial mastectomy. Sentinel lymph node dissection offers accurate staging without the risk of lymphedema for node-negative patients. Judicious use of radiotherapy, with treatment fields carefully planned to spare the axilla as much as possible, can greatly diminish the incidence of edema, which will occur in only 5% of patients if no radiotherapy is given to the axilla after a partial mastectomy and lymph node dissection.

Late or secondary edema of the arm may develop years after treatment, as a result of axillary recurrence or of infection in the hand or arm, with obliteration of lymphatic channels. Infection in the arm or hand on the dissected side should be treated with antibiotics, rest, and elevation. When edema develops, careful examination of the axilla for recurrence should be done. If there is no sign of recurrence, the swollen extremity should be treated with rest and elevation. A mild diuretic may be helpful. If there is no improvement, a compressor pump or manual decompression decreases the swelling, and the patient is then fitted with an elastic glove or sleeve. Most patients are not bothered enough by mild edema to wear an uncomfortable glove or sleeve and will treat themselves with elevation alone. Benzopyrones have been reported to decrease lymphedema but are not approved for this use in the United States. Rarely, edema may be severe enough to interfere with use of the limb.

Breast Reconstruction

Breast reconstruction is usually feasible after standard or modified radical mastectomy. Reconstruction should be discussed with patients prior to mastectomy, because it offers an important psychologic focal point for recovery. Reconstruction is not an obstacle to the diagnosis of recurrent cancer. The most common breast reconstruction has been implantation of a silicone gel prosthesis in the subpectoral plane between the pectoralis minor and pectoralis major muscles. Although the FDA has placed a moratorium on the purely cosmetic use of silicone gel implants because of possible leakage of silicone and possible associated autoimmune phenomena, they can be used in the reconstructed patient with appropriate prior consent. Most plastic surgeons currently would place a saline-filled prosthesis rather than a silicone gel implant. Alternatively, autologous tissue can be used for reconstruction.

Autologous tissue flaps are aesthetically superior to implant reconstruction in most patients. They also have the advantage of not feeling like a foreign body to the patient. The most popular autologous technique currently is the trans-rectus abdominis muscle flap (TRAM flap), which is done by rotating the rectus abdominis muscle with attached fat and skin cephalad to make a breast mound. The free TRAM flap is done by completely removing the rectus with overlying fat and skin and using microvascular surgical techniques reconstructing the vascular supply on the chest wall. A latissimus dorsi flap can be swung from the back but offers less fullness than the TRAM flap and is therefore less acceptable cosmetically. Reconstruction may be performed immediately (at the time of initial mastectomy) or may be delayed until later, usually when the patient has completed adjuvant therapy. When considering reconstructive options, concomitant illnesses should be considered, since the ability for an autologous flap to survive depends on medical comorbidities.

Risks of Pregnancy

Data are insufficient to determine whether interruption of pregnancy improves the prognosis of patients who are discovered during pregnancy to have potentially curable breast cancer and who receive definitive treatment. Theoretically, the increasingly high levels of estrogen produced by the placenta as the pregnancy progresses could be detrimental to the patient with occult metastases of hormone-sensitive breast cancer. Moreover, occult metastases are present in most patients with positive axillary nodes, and treatment by adjuvant chemotherapy could be potentially harmful to the fetus, although chemotherapy has been given to pregnant women. Under these circumstances, interruption of early pregnancy seems reasonable, with progressively less rationale for the procedure as term approaches. The decision is affected by many factors, including the patient's desire to have the baby and the generally poor prognosis when axillary nodes are involved.

Equally important is the advice regarding future pregnancy (or abortion in case of pregnancy) to be given to women of child-bearing age who have had definitive treatment for breast cancer. Under these circumstances, one must assume that pregnancy will be harmful if occult metastases are present, though this has not been demonstrated. Patients whose tumors are ER-negative (most younger women) probably would not be affected by pregnancy. To date, no adverse effect of pregnancy on survival of pregnant women who have had breast cancer has been demonstrated, though most oncologists advise against it.

In patients with inoperable or metastatic cancer (stage IV disease), induced abortion is usually advisable because of the possible adverse effects of hormonal treatment, radiotherapy, or chemotherapy upon the fetus.

■ **CARCINOMA OF THE MALE BREAST**

- A painless lump beneath the areola in a man usually over 50 years of age.
- Nipple discharge, retraction, or ulceration may be present.

General Considerations

Breast cancer in men is a rare disease; the incidence is only about 1% of that in women. The average age at occurrence is about 60—somewhat older than the commonest presenting age in women. The prognosis, even in stage I cases, is worse in men than in women. Blood-borne metastases are commonly present when the male patient appears for initial treatment. These metastases may be latent and may not become manifest for many years. As in women, hormonal influences are probably related to the development of male breast cancer. There is a high incidence of both breast cancer and gynecomastia in Bantu men, theoretically owing to failure of estrogen inactivation by a damaged liver by associated liver disease. It is important to note that first-degree relatives of men with breast cancer are considered to be at high risk. This risk should be taken into account when discussing options with the patient and family. In addition, *BRCA2* mutations are common in men with breast cancer. These individuals should receive genetic counseling.

Clinical Findings

A painless lump, occasionally associated with nipple discharge, retraction, erosion, or ulceration, is the chief complaint. Examination usually shows a hard, ill-defined, nontender mass beneath the nipple or areola. Gynecomastia not uncommonly precedes or accompanies breast cancer in men. Nipple discharge is an uncommon presentation for breast cancer in men, but is an ominous finding associated with carcinoma in nearly 75% of cases.

Breast cancer staging is the same in men as in women. Gynecomastia and metastatic cancer from another site (eg, prostate) must be considered in the differential diagnosis. Biopsy settles the issue.

Treatment

Treatment consists of modified radical mastectomy in operable patients, who should be chosen by the same criteria as women with the disease. Irradiation is the first step in treating localized metastases in the skin, lymph nodes, or skeleton that are causing symptoms. Examination of the cancer for hormone receptor proteins may prove to be of value in predicting response to endocrine ablation. Adjuvant chemotherapy is used for the same indications as in breast cancer in women.

Since breast cancer in men is frequently a disseminated disease, endocrine therapy is of considerable importance in its management. Tamoxifen and castration are the main therapeutic resources for management of advanced breast cancer in men. Tamoxifen (20 mg daily) should be the initial treatment, though there is little experience. Castration in advanced breast cancer is a successful palliative measure and more beneficial than the same procedure in women. Objective evidence of regression may be seen in 60-70% of men who are castrated—approximately twice the proportion in women. The average duration of tumor growth remission is about 30 months, and life is prolonged. Bone is the most frequent site of metastases from breast cancer in men (as in women), and castration relieves bone pain in most patients so treated. The longer the interval between mastectomy and recurrence, the longer the tumor growth remission following castration. As in women, there is no correlation between the histologic type of the tumor and the likelihood of remission following castration.

Aminoglutethimide (250 mg orally four times a day) should replace adrenalectomy in men as it has in women. Corticosteroid therapy alone has been considered to be efficacious but probably has no value when compared with major endocrine ablation.

Estrogen therapy—5 mg of diethylstilbestrol three times daily orally—may be effective as secondary hormonal manipulation after medical adrenalectomy (with aminoglutethimide). Androgen therapy may exacerbate bone pain. Chemotherapy should be administered for the same indications and using the same dosage schedules as for women with metastatic disease.

Prognosis

The prognosis of breast cancer is poorer in men than in women. The crude 5- and 10-year survival rates for clinical stage I breast cancer in men are about 58% and 38%, respectively. For clinical stage II disease, the 5- and 10-year survival rates are approximately 38% and 10%. The survival rates for all stages at 5 and 10 years are 36% and 17%. For those patients whose disease progresses despite treatment, meticulous efforts at palliative care are essential (see [Chapter 5](#)).

Primary tumor (T)	
Definitions for classifying the primary tumor (T) are the same for clinical and for pathologic classification. If the measurement is made by physical examination, the examiner will use the major headings (T1, T2, or T3). If other measurements, such as mammographic or pathologic measurements, are used, the subsets of T1 can be used. Tumors should be measured to the nearest 0.1 cm increment.	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma <i>in situ</i>
Tis (DCIS)	Ductal carcinoma in situ
Tis (LCIS)	Lobular carcinoma in situ
Tis (Paget's)	Paget's disease of the nipple with no tumor
 <i>Note:</i> Paget's disease associated with a tumor is classified according to the size of the tumor.	
T1	Tumor 2 cm or less in greatest dimension
T1mic	Microinvasion 0.1 cm or less in greatest dimension
T1a	Tumor more than 0.1 cm but not more than 0.5 cm in greatest dimension
T1b	Tumor more than 0.5 cm but not more than 1 cm in greatest dimension
T1c	Tumor more than 1 cm but not more than 2 cm in greatest dimension
T2	Tumor more than 2 cm but not more than 5 cm in greatest dimension
T3	Tumor more than 5 cm in greatest dimension
T4	Tumor of any size with direct extension to (a) chest wall or (b) skin, only as described below
T4a	Extension to chest wall, not including pectoralis muscle
T4b	Edema (including peau d'orange) or ulceration of the skin of the breast, or satellite skin nodules confined to the same breast
T4c	Both T4a and T4b
T4d	Inflammatory carcinoma
Regional lymph nodes (N)	
<i>Clinical</i>	
NX	Regional lymph nodes cannot be assessed (e.g., previously removed)
N0	No regional lymph node metastasis
N1	Metastasis to movable ipsilateral axillary lymph node(s)
N2	Metastases in ipsilateral axillary lymph nodes fixed or matted, or in clinically apparent ipsilateral internal mammary nodes in the <i>absence</i> of clinically evident axillary lymph node metastasis
N2a	Metastasis in ipsilateral axillary lymph nodes fixed to one another (matted) or to other structures
N2b	Metastasis only in clinically apparent ¹ ipsilateral internal mammary nodes and in the <i>absence</i> of clinically evident axillary lymph node metastasis
N3	Metastasis in ipsilateral infraclavicular lymph node(s) with or without axillary lymph node involvement, or in clinically apparent ¹ ipsilateral internal mammary lymph node(s) and in the <i>presence</i> of clinically evident axillary lymph node metastasis; or metastasis in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
N3a	Metastasis in ipsilateral infraclavicular lymph node(s)
N3b	Metastasis in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
N3c	Metastasis in ipsilateral supraclavicular lymph node(s)
 <i>Pathologic (pN)</i> ²	
pNX	Regional lymph nodes cannot be assessed (eg, previously removed, or not removed for pathologic study)
pN0	No regional lymph node metastasis histologically, no additional examination for isolated tumor cells (ITC)
 <i>Note:</i> Isolated tumor cells (ITC) are defined as single tumor cells or small cell clusters not greater than 0.2 mm, usually detected only by immunohistochemical (IHC) or molecular methods but which may be verified on H&E stains. ITCs do not usually show evidence of malignant activity, eg, proliferation or stromal reaction.	
pN0(i-)	No regional lymph node metastasis histologically, negative IHC
pN0(i+)	No regional lymph node metastasis histologically, positive IHC, no IHC cluster greater than 0.2 mm
pN0(mol-)	No regional lymph node metastasis histologically, negative molecular findings (RT-PCR) ³

pN0(mol+)	No regional lymph node metastasis histologically, positive molecular findings (RT-PCR) ³		
pN1	Metastasis in 1 to 3 axillary lymph nodes, and/or in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent ⁴		
pN1mi	Micrometastasis (greater than 0.2 mm, none greater than 2.0 mm)		
pN1a	Metastasis in 1 to 3 axillary lymph nodes		
pN1b	Metastasis in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent ⁴		
pN1c	Metastasis in 1 to 3 axillary lymph nodes and in internal mammary lymph nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent. ⁴ (If associated with greater than 3 positive axillary lymph nodes, the internal mammary nodes are classified as pN3b to reflect increased tumor burden)		
pN2	Metastasis in 4 to 9 axillary lymph nodes, or in clinically apparent ⁴ internal mammary lymph nodes in the <i>absence</i> of axillary lymph node metastasis		
pN2a	Metastasis in 4 to 9 axillary lymph nodes (as least one tumor deposit greater than 2.0 mm)		
pN2b	Metastasis in clinically apparent ⁴ internal mammary lymph nodes in the <i>absence</i> of axillary lymph node metastasis		
pN3	Metastasis in 10 or more axillary lymph nodes, or in infraclavicular lymph nodes, or in clinically apparent ⁴ ipsilateral internal mammary lymph nodes in the <i>presence</i> of 1 or more positive axillary lymph nodes; or in more than 3 axillary lymph nodes with clinically negative microscopic metastasis in internal mammary lymph nodes; or in ipsilateral supraclavicular lymph nodes		
pN3a	Metastasis in 10 or more axillary lymph nodes (at least one tumor deposit greater than 2.0 mm), or metastasis to the infraclavicular lymph nodes		
pN3b	Metastasis in clinically apparent ⁴ ipsilateral internal mammary lymph nodes in the <i>presence</i> of 1 or more positive axillary lymph nodes; or in more than 3 axillary lymph nodes and in internal mammary lymph nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent ⁴		
pN3c	Metastasis in ipsilateral supraclavicular lymph nodes		
	Distant Metastasis (M)		
MX	Distant metastasis cannot be assessed		
M0	No distant metastasis		
M1	Distant metastasis		
	Stage grouping		
Stage 0	Tis	N0	M0
Stage I	T1 ⁵	N0	M0
Stage IIA	T0	N1	M0
	T1 ⁵	N1	M0
	T2	N0	M0
Stage IIB	T2	N1	M0
	T3	N0	M0
	T0	N2	M0
Stage IIIA	T1 ⁵	N2	M0
	T2	N2	M0
	T3	N1	M0
	T3	N2	M0
	T4	N0	M0
Stage IIIB	T4	N1	M0
	T4	N2	M0
	T4	N2	M0
Stage IIIC	Any T	N3	M0
Stage IV	Any T	Any N	M1

Note: Stage designation may be changed if post-surgical imaging studies reveal the presence of distant metastases, provided that the studies are carried out within 4 months of diagnosis in the absence of disease progression and provided that the patient has not received neoadjuvant therapy.

¹*Clinically apparent* is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination or grossly visible pathologically.

²Classification is based on axillary lymph node dissection with or without sentinel lymph node dissection. Classification based solely on sentinel lymph node dissection without subsequent axillary lymph node dissection is designated (sn) for "sentinel node," eg, pN0(i+) (sn).

³RT-PCR: reverse transcriptase/polymerase chain reaction.

⁴*Clinically apparent* is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination.

Not *clinically apparent* is defined as not detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination.

ABNORMAL PREMENOPAUSAL BLEEDING

Normal menstrual bleeding lasts an average of 4 days (range, 2-7 days), with a mean blood loss of 40 mL. Blood loss of over 80 mL per cycle is abnormal and frequently produces anemia. Excessive bleeding, often with the passage of clots, may occur at regular menstrual intervals (**menorrhagia**) or irregular intervals (**dysfunctional uterine bleeding**). When there are fewer than 21 days between the onset of bleeding episodes, the cycles are likely to be anovular. **Ovulation bleeding**, a single episode of spotting between regular menses, is quite common. Heavier or irregular intermenstrual bleeding warrants investigation.

Dysfunctional uterine bleeding is usually caused by overgrowth of endometrium due to estrogen stimulation without adequate progesterone to stabilize growth; this occurs in anovular cycles. Anovulation associated with high estrogen levels commonly occurs in teenagers, in women aged late 30s to late 40s, and in extremely obese women or those with polycystic ovary syndrome.

Clinical Findings

A. Symptoms and Signs

The diagnosis of the disorders underlying the bleeding usually depends upon the following: (1) A careful description of the duration and amount of flow, related pain, and relationship to the last menstrual period (LMP). The presence of blood clots or the degree of inconvenience caused by the bleeding may be more useful indicators. (2) A history of pertinent illnesses. (3) A history of all medications the patient has taken in the past month. (4) A careful pelvic examination to look for pregnancy, uterine myomas, adnexal masses, or infection.

B. Laboratory Studies

Cervical smears should be obtained as needed for cytologic and culture studies. Blood studies should include a complete blood count, sedimentation rate, and glucose levels to rule out diabetes. Diabetes may occasionally initially present with abnormal bleeding. A test for pregnancy and studies of thyroid function and coagulation disorders should be considered in the clinical evaluation. Tests for ovulation in cyclic menorrhagia include basal body temperature records, serum progesterone measured 1 week before the expected onset of menses, and analysis of an endometrial biopsy specimen for secretory activity shortly before the onset of menstruation.

C. Imaging

Ultrasound may be useful to evaluate endometrial thickness or to diagnose intrauterine or ectopic pregnancy or adnexal masses. Endovaginal ultrasound with saline infusion sonohysterography may be used to diagnose endometrial polyps or subserous myomas. MRI can definitively diagnose submucous myomas and adenomyosis.

D. Cervical Biopsy and Endometrial Curettage

Biopsy, curettage, or aspiration of the endometrium and curettage of the endocervix may be necessary to diagnose the cause of bleeding. These and other invasive gynecologic diagnostic procedures are described in [Table 17-1](#). Polyps, endometrial hyperplasia, and submucous myomas are commonly identified in this way. If cancer of the cervix is suspected, colposcopically directed biopsies and endocervical curettage are indicated as first steps.

E. Hysteroscopy

Hysteroscopy can visualize endometrial polyps, submucous myomas, and exophytic endometrial cancers. It is useful immediately before D&C.

Treatment

Premenopausal patients with abnormal uterine bleeding include those with submucous myomas, infection, early abortion, or pelvic neoplasms. The history, physical examination, and laboratory findings should identify such patients, who require definitive therapy depending upon the cause of the bleeding. A large group of patients remains, most of whom have dysfunctional uterine bleeding on a hormonal basis.

Dysfunctional uterine bleeding can usually be treated hormonally. Women over the age of 35 should have endometrial sampling to rule out endometrial hyperplasia or carcinoma prior to initiation of hormonal therapy. Progestins, which limit and stabilize endometrial growth, are generally effective. Medroxyprogesterone acetate, 10 mg/d, or norethindrone acetate, 5 mg/d, should be given for 10-14 days starting on day 15 of the cycle, following which withdrawal bleeding (so-called medical curettage) will occur. The treatment is repeated for several cycles; it can be reinstituted if amenorrhea or dysfunctional bleeding recurs. In women who are bleeding actively, any of the combination oral contraceptives can be given four times daily for one or 2 days followed by two pills daily through day 5 and then one pill daily through day 20; after withdrawal bleeding occurs, pills are taken in the usual dosage for three cycles. In cases of intractable heavy bleeding, danazol, 200 mg four times daily, is sometimes used to create an atrophic endometrium. Alternatively, a GnRH agonist such as depot leuprolide, 3.75 mg intramuscularly monthly, or nafarelin, 0.2-0.4 mg intranasally twice daily, can be used for up to 6 months to create a temporary cessation of menstruation by ovarian suppression.

In cases of heavy bleeding, intravenous conjugated estrogens, 25 mg every 4 hours for three or four doses, can be used, followed by oral conjugated estrogens, 2.5 mg daily, or ethinyl estradiol, 20 ug daily, for 3 weeks, with the addition of medroxyprogesterone acetate, 10 mg daily for the last 10 days of treatment, or a combination oral contraceptive daily for 3 weeks. This will thicken the endometrium and control the bleeding. If the abnormal bleeding is not controlled by hormonal treatment, a D&C is necessary to check for incomplete abortion, polyps, submucous myomas, or endometrial cancer.

Endometrial ablation through the hysteroscope with laser photocoagulation or electrocautery—or blindly with hyperthermia or cryotherapy—is an option; these techniques are designed to reduce or prevent any future menstrual flow.

Nonsteroidal anti-inflammatory drugs such as naproxen or mefenamic acid in the usual anti-inflammatory doses will often reduce blood loss in menorrhagia—even that associated with a copper IUD. The levonorgestrel-releasing IUD will markedly reduce menstrual blood loss and may be a good alternative to other medical or surgical therapies.

Prolonged use of a progestin, as in a minipill, in injectable contraceptives, or in the therapy of endometriosis, can also lead to intermittent bleeding, sometimes severe. In this instance, the endometrium is atrophic and fragile. If bleeding occurs, it should be treated with estrogen as follows: ethinyl estradiol, 20 ug/d for 7 days, or conjugated estrogens, 1.25 mg/d for 7 days.

It is useful for the patient and the clinician to discuss stressful situations or lifestyles that may contribute to anovulation and dysfunctional bleeding, such as prolonged emotional turmoil or excessive use of drugs or alcohol.

POSTMENOPAUSAL VAGINAL BLEEDING

Vaginal bleeding that occurs 6 months or more following cessation of menstrual function should be investigated. The most common causes are atrophic endometrium, endometrial proliferation or hyperplasia, endometrial or cervical cancer, and administration of estrogens without added progestin. Other causes include atrophic vaginitis, trauma, endometrial polyps, friction ulcers of the cervix associated with prolapse of the uterus, and blood dyscrasias. Uterine bleeding is usually painless, but pain will be present if the cervix is stenotic, if bleeding is severe and rapid, or if infection or torsion or extrusion of a tumor is present. The patient may report a single episode of spotting or profuse bleeding for days or months.

Diagnosis

The vulva and vagina should be inspected for areas of bleeding, ulcers, or neoplasms. A cytologic smear of the cervix and vaginal pool should be taken. If available, transvaginal sonography should be used to measure endometrial thickness. A measurement of 4 mm or less indicates a very low likelihood of hyperplasia or endometrial cancer. In 20 studies of a total of 4759 women with postmenopausal bleeding and an endometrial thickness of 4 mm or less, only 0.25% were found to have endometrial cancer. If the thickness is greater than 4 mm, endocervical curettage and endometrial aspiration should be performed, preferably in conjunction with hysteroscopy.

Treatment

Aspiration curettage (with polypectomy if indicated) will frequently be curative. Simple endometrial hyperplasia calls for cyclic progestin therapy (medroxyprogesterone acetate, 10 mg/d, or norethindrone acetate, 5 mg/d) for 21 days of each month for 3 months. A repeat D&C or endometrial biopsy should be performed, and if tissues are normal and estrogen replacement therapy is reinstituted, a progestin should be prescribed (as above) in a cyclic or continuous regimen. If endometrial hyperplasia with atypical cells or carcinoma of the endometrium is found, hysterectomy is necessary.

Gull B et al: Transvaginal ultrasonography in women with postmenopausal bleeding: is it always necessary to perform an endometrial biopsy? Am J Obstet Gynecol 2000;185:509. [PMID: 10739500]

PREMENSTRUAL SYNDROME (PREMENSTRUAL TENSION)

The premenstrual syndrome is a recurrent, variable cluster of troublesome physical and emotional symptoms that develop during the 7-14 days before the onset of menses and subside when menstruation occurs. The syndrome intermittently affects about one-third of all premenopausal women, primarily those 25-40 years of age. In about 10% of affected women, the syndrome may be severe. Although not every woman experiences all the symptoms or signs at one time, many describe bloating, breast pain, ankle swelling, a sense of increased weight, skin disorders, irritability, aggressiveness, depression, inability to concentrate, libido change, lethargy, and food cravings.

The pathogenesis of premenstrual syndrome is still uncertain. Psychosocial factors may play a role. Suppression of ovarian function with a GnRH agonist has been shown to diminish all symptoms during therapy. "Add-back therapy" to provide the hormones suppressed by the GnRH agonist with low-dose estrogen and progestin may allow extended use of a GnRH agonist. Suppression of ovulation with an oral contraceptive is sometimes helpful, but the patient often complains that she still has premenstrual syndrome.

Current treatment methods are mainly empirical. The clinician should provide the best support possible for the patient's emotional and physical distress. This includes the following:

1. Careful evaluation of the patient, with understanding, explanation, and reassurance, is of first importance.
2. Advise the patient to keep a daily diary of all symptoms for 2-3 months, to help in evaluating the timing and characteristics of the syndrome. If her symptoms occur throughout the month rather than in the 2 weeks before menses, she may be depressed or may have other emotional problems in addition to premenstrual syndrome.
3. A program of regular conditioning exercise, such as jogging, has been found to decrease depression, anxiety, and fluid retention premenstrually in several studies.
4. Serotonin reuptake inhibitors such as fluoxetine, 20 mg/d, are effective in relieving tension, irritability, and dysphoria with few side effects.
5. Luteal phase administration of danazol, 200 mg/d on cycle days 14-28, is effective in reducing symptoms of mastalgia. Other symptoms are not affected by this low-dose therapy.
6. Spironolactone, 100 mg daily during the luteal phase, is effective for reduction of bloating and breast tenderness.
7. NSAIDs—eg, mefenamic acid, 500 mg three times a day—have been shown to reduce a number of symptoms, though not breast pain.

DYSMENORRHEA

1. Primary Dysmenorrhea

Primary dysmenorrhea is menstrual pain associated with ovular cycles in the absence of pathologic findings. The pain usually begins within 1-2 years after the menarche and may become more severe with time. The frequency of cases increases up to age 20 and then decreases with age and markedly with parity. Fifty to 75 percent of women are affected at some time, and 5-6% have incapacitating pain.

Primary dysmenorrhea is low, midline, wave-like, cramping pelvic pain often radiating to the back or inner thighs. Cramps may last for 1 or more days and may be associated with nausea, diarrhea, headache, and flushing. The pain is produced by uterine vasoconstriction, anoxia, and sustained contractions mediated by prostaglandins.

Clinical Findings

The pelvic examination is normal between menses; examination during menses may produce discomfort, but there are no pathologic findings.

Treatment

Nonsteroidal anti-inflammatory drugs (ibuprofen, ketoprofen, mefenamic acid, naproxen) are generally helpful. Drugs should be started at the onset of bleeding to avoid inadvertent drug use during early pregnancy. Medication should be continued on a regular basis for 2-3 days. Ovulation can be suppressed and dysmenorrhea usually prevented by oral contraceptives.

Proctor M et al: Dysmenorrhea. Clin Evid 2002;7:1639. [PMID: 12230777]

2. Secondary Dysmenorrhea

Secondary dysmenorrhea is menstrual pain for which an organic cause exists. It usually begins well after menarche, sometimes even as late as the third or fourth decade of life.

Clinical Findings

The history and physical examination commonly suggest endometriosis or pelvic inflammatory disease. Other causes may be submucous myoma, IUD use, cervical stenosis with obstruction, or blind uterine horn (rare).

Diagnosis

Laparoscopy is often needed to differentiate endometriosis from pelvic inflammatory disease. Submucous myomas can be detected most reliably by MRI but also by hystrogram, by hysteroscopy, or by passing a sound or curette over the uterine cavity during D&C. Cervical stenosis may result from induced abortion, creating crampy pain at the time of expected menses with no blood flow; this is easily cured by passing a sound into the uterine cavity after administering a paracervical block.

Treatment

A. Specific Measures

Periodic use of analgesics, including the nonsteroidal anti-inflammatory drugs given for primary dysmenorrhea, may be beneficial, and oral contraceptives may give relief, particularly in endometriosis. Danazol and GnRH agonists are effective in the treatment of endometriosis (see below).

B. Surgical Measures

If disability is marked or prolonged, laparoscopy or exploratory laparotomy is usually warranted. Definitive surgery depends upon the degree of disability and the findings at operation.

Proctor M et al: Dysmenorrhea. Clin Evid 2002;7:1639. [\[PMID: 12230777\]](#)

VAGINITIS

Inflammation and infection of the vagina are common gynecologic problems, resulting from a variety of pathogens, allergic reactions to vaginal contraceptives or other products, or the friction of coitus. The normal vaginal pH is 4.5 or less, and lactobacillus is the predominant organism. At the time of the midcycle estrogen surge, clear, elastic, mucoid secretions from the cervical os are often profuse. In the luteal phase and during pregnancy, vaginal secretions are thicker, white, and sometimes adherent to the vaginal walls. These normal secretions can be confused with vaginitis by concerned women.

Clinical Findings

When the patient complains of vaginal irritation, pain, or unusual discharge, a careful history should be taken, noting the onset of the last menstrual period; recent sexual activity; use of contraceptives, tampons, or douches; and the presence of vaginal burning, pain, pruritus, or unusually profuse or malodorous discharge. The physical examination should include careful inspection of the vulva and speculum examination of the vagina and cervix. The cervix is cultured for gonococcus or chlamydia if applicable. A specimen of vaginal discharge is examined under the microscope in a drop of 0.9% saline solution to look for trichomonads or clue cells and in a drop of 10% potassium hydroxide to search for candida. The vaginal pH should be tested; it is frequently greater than 4.5 in infections due to trichomonads and bacterial vaginosis. A bimanual examination to look for evidence of pelvic infection should follow.

A. Vulvovaginal Candidiasis

Pregnancy, diabetes, and use of broad-spectrum antibiotics or corticosteroids predispose to candida infections. Heat, moisture, and occlusive clothing also contribute to the risk. Pruritus, vulvovaginal erythema, and a white curd-like discharge that is not malodorous are found. Microscopic examination with 10% potassium hydroxide reveals filaments and spores. Cultures with Nickerson's medium may be used if candida is suspected but not demonstrated.

B. Trichomonas vaginalis Vaginitis

This protozoal flagellate infects the vagina, Skene's ducts, and lower urinary tract in women and the lower genitourinary tract in men. It is transmitted through coitus. Pruritus and a malodorous frothy, yellow-green discharge occur, along with diffuse vaginal erythema and red macular lesions on the cervix in severe cases. Motile organisms with flagella are seen by microscopic examination of a wet mount with saline solution.

C. Bacterial Vaginosis

This condition is considered to be a polymicrobial disease which is not sexually transmitted. An overgrowth of gardnerella and other anaerobes is often associated with increased malodorous discharge without obvious vulvitis or vaginitis. The discharge is grayish and sometimes frothy, with a pH of 5.0-5.5. An amine-like ("fishy") odor is present if a drop of discharge is alkalized with 10% potassium hydroxide. On wet mount in saline, epithelial cells are covered with bacteria to such an extent that cell borders are obscured (clue cells). Vaginal cultures are generally not useful in diagnosis.

D. Condylomata Acuminata (Genital Warts)

Warty growths on the vulva, perianal area, vaginal walls, or cervix are caused by various types of the human papillomavirus. They are sexually transmitted. Pregnancy and immunosuppression favor growth. Vulvar lesions may be obviously wart-like or may be diagnosed only after application of 4% acetic acid (vinegar) and colposcopy, when they appear whitish, with prominent papillae. Fissures may be present at the fourchette. Vaginal lesions may show diffuse hypertrophy or a cobblestone appearance. Cervical lesions may be visible only by colposcopy after pretreatment with 4% acetic acid. These lesions may be related to dysplasia and cervical cancer. Vulvar cancer is also currently considered to be associated with the human papillomavirus.

Treatment

A. Vulvovaginal Candidiasis

A variety of regimens are available to treat vulvovaginal candidiasis. Women with uncomplicated vulvovaginal candidiasis will usually respond to a 1- to 3-day regimen of a topical azole. Women with complicated infection (including four or more episodes in 1 year, severe signs and symptoms, non-albicans species, uncontrolled diabetes, HIV infection, corticosteroid treatment, or pregnancy) should receive 7-14 days of a topical regimen or two doses of fluconazole 3 days apart. (Pregnant women should use only topical azoles.)

1. Three-day regimens—Butoconazole (2% cream, 5 g), clotrimazole (two 100-mg vaginal tablets), terconazole (0.8% cream, 5 g, or 80-mg suppository), or miconazole (200-mg vaginal suppository) once daily.

2. Seven-day regimens—Clotrimazole (1% cream or 100-mg vaginal tablet), miconazole (2% cream, 5 g, or 100-mg vaginal suppository), or terconazole (0.4% cream, 5 g) once daily.

3. Single-dose regimens—Clotrimazole (500-mg tablet) or tioconazole ointment (6.5%, 5 g). Fluconazole, 150 mg orally in a single dose, is also effective.

4. Fourteen-day regimens—Nystatin (100,000-unit vaginal tablet once daily).

5. Recurrent vulvovaginitis (maintenance therapy)—Ketoconazole, 100 mg orally once daily for up to 6 months, clotrimazole, 500-mg vaginal suppository once weekly, fluconazole, 100-150 mg once weekly, or itraconazole, 400 mg once monthly or 100 mg once daily.

B. Trichomonas vaginalis Vaginitis

Treatment of both partners simultaneously is recommended; metronidazole, 2 g as a single dose or 500 mg twice a day for 7 days, is usually employed. In the case of treatment failure in the absence of reexposure, the patient should be re-treated with metronidazole, 500 mg twice a day for 7 days. If treatment failure occurs again, give metronidazole, 2 g once daily for 3-5 days. If this is not effective in eradicating the organisms, metronidazole susceptibility testing can be arranged with the CDC at 770-488-4115.

C. Bacterial Vaginosis

The recommended regimens are metronidazole, 500 mg twice daily for 7 days, clindamycin vaginal cream (2%, 5 g), once daily for 7 days, or metronidazole gel (0.75%, 5 g), twice daily for 5 days. Alternative regimens include metronidazole, 2 g orally as a single dose, clindamycin, 300 mg orally twice daily for 7 days, or clindamycin ovules, 100 g intravaginally at bedtime for 3 days.

D. Condylomata Acuminata

Recommended treatments for vulvar warts include podophyllum resin 10-25% in tincture of benzoin (do not use during pregnancy or on bleeding lesions) or 80-90% trichloroacetic or bichloroacetic acid, carefully applied to avoid the surrounding skin. The pain of bi- or trichloroacetic acid application can be lessened by a sodium bicarbonate paste applied immediately after treatment. Podophyllum resin must be washed off after 2-4 hours. Freezing with liquid nitrogen or a cryoprobe and electrocautery are also effective. Patient-applied regimens include podofilox 0.5% solution or gel and imiquimod 5% cream. Vaginal warts may be treated with cryotherapy with liquid nitrogen, trichloroacetic acid, or podophyllum resin. Extensive warts may require treatment with CO₂ laser under local or general anesthesia. Interferon is not recommended for routine use because it is very expensive, associated with systemic side effects, and no more effective than other therapies. Routine examination of sex partners is not necessary for the management of genital warts since the risk of reinfection is probably minimal and curative therapy to prevent transmission is not available. However, partners may wish to be examined for detection and treatment of genital warts and other STDs.

Sexually transmitted disease treatment guidelines 2002. Centers for Disease Control and Prevention. MMWR Recomm Rep 2002;51(RR-6):1. [\[PMID: 12184549\]](#)

CERVICITIS

Infection of the cervix must be distinguished from physiologic ectopy of columnar epithelium, which is common in young women. Mucopurulent cervicitis is characterized by a red edematous cervix with a purulent yellow discharge. The infection may result from a sexually transmitted pathogen such as *Neisseria gonorrhoeae*, chlamydia, or herpesvirus (which presents with vesicles and ulcers on the cervix during a primary herpetic infection), though in most cases none of these organisms can be isolated.

Mucopurulent cervicitis is an insensitive predictor of either gonorrheal or chlamydial infection and in addition has a low positive predictive value. Treatment should be based on microbiologic testing. Presumptive antibiotic treatment of mucopurulent cervicitis is not indicated unless there is a high prevalence of either *N gonorrhoeae* or chlamydia in the population or if the patient is unlikely to return for treatment. (See [Chapter 33](#) for discussion.)

CERVICAL POLYPS

Cervical polyps commonly occur after menarche and are occasionally noted in postmenopausal women. The cause is not known, but inflammation may play an etiologic role. The principal symptoms are discharge and abnormal vaginal bleeding. However, abnormal bleeding should not be ascribed to a cervical polyp without sampling the endocervix and endometrium. The polyps are visible in the cervical os on speculum examination.

Cervical polyps must be differentiated from polypoid neoplastic disease of the endometrium, small submucous pedunculated myomas, and endometrial polyps. Cervical polyps rarely contain malignant foci.

Treatment

Cervical polyps can generally be removed in the office by avulsion with a uterine packing forceps or ring forceps. If the cervix is soft, patulous, or definitely dilated and the polyp is large, surgical D&C is required (especially if the pedicle is not readily visible). Because of the possibility of endometrial disease, cervical polypectomy should be accompanied by endometrial sampling, and all tissue removed should be submitted for microscopic examination.

Ozsaran AA et al: Endometrial hyperplasia co-existing with cervical polyps. Int J Obstet Gynecol 1999;66:185. [\[PMID: 10468348\]](#)

CYST & ABSCESS OF BARTHOLIN'S DUCT

Trauma or infection may involve Bartholin's duct, causing obstruction of the gland. Drainage of secretions is prevented, leading to pain, swelling, and abscess formation. The infection usually resolves and pain disappears, but stenosis of the duct outlet with distention often persists. Reinfection causes recurrent tenderness and further enlargement of the duct.

The principal symptoms are periodic painful swelling on either side of the introitus and dyspareunia. A fluctuant swelling 1-4 cm in diameter in the inferior portion of either labium minus is a sign of occlusion of Bartholin's duct. Tenderness is evidence of active infection.

Pus or secretions from the gland should be cultured for gonococci, chlamydiae, and other pathogens and treated accordingly (see [Chapter 33](#)); frequent warm soaks may be helpful. If an abscess develops, aspiration or incision and drainage are the simplest forms of therapy, but the problem may recur. Marsupialization, incision and drainage with the insertion of an indwelling Word catheter, or laser treatment will establish a new duct opening. An asymptomatic cyst does not require therapy.

EFFECTS OF EXPOSURE TO DIETHYLSTILBESTROL IN UTERO

Between 1947 and 1971, diethylstilbestrol (DES) was widely used in the United States for diabetic women during pregnancy and to treat threatened abortion. It is estimated that 2-3 million fetuses were exposed. A relationship between fetal DES exposure and clear cell carcinoma of the vagina was later discovered, and a number of other related anomalies have since been noted. In one-third of all exposed women, there are changes in the vagina (adenosis, septa), cervix (deformities and hypoplasia of the vaginal portion of the cervix), or uterus (T-shaped cavity).

At present, all exposed women are advised to have an initial colposcopic examination to outline vaginal and cervical areas of abnormal epithelium, followed by cytologic examination of the vagina (all four quadrants of the upper half of the vagina) and cervix at yearly intervals. Lugol's iodine stain of the vagina and cervix will also outline areas of metaplastic squamous epithelium.

Many women are not aware of having been exposed to DES. Therefore, in the age groups at risk (30-56 years), examiners should pay attention to structural changes of the vagina and cervix that may signal the possibility of DES exposure and indicate the need for follow-up.

The incidence of clear cell carcinoma is approximately one in 1000 exposed women, and the incidence of cervical and vaginal intraepithelial neoplasia (dysplasia and carcinoma in situ) is twice as high as in unexposed women. DES daughters have more difficulty conceiving and have an increased incidence of early abortion, ectopic pregnancy, and premature births. In addition, mothers treated with DES in pregnancy appear to have a small increase in the incidence of breast cancer, beginning 20 years after exposure.

Goldberg JM et al: Effect of diethylstilbestrol on reproductive function. Fertil Steril 1999;72:1. [\[PMID: 10418139\]](#)

CERVICAL INTRAEPITHELIAL NEOPLASIA (CIN; DYSPLASIA OF THE CERVIX)

The squamocolumnar junction of the cervix is an area of active squamous cell proliferation. In childhood, this junction is located on the exposed vaginal portion of the cervix. At puberty, because of hormonal influence and possibly because of changes in the vaginal pH, the squamous margin begins to encroach on the single-layered, mucus-secreting epithelium, creating an area of metaplasia (transformation zone). Factors associated with coitus (see Prevention, below) may lead to cellular abnormalities, which over a period of time can result in the development of squamous cell dysplasia or cancer. There are varying degrees of dysplasia ([Table 17-2](#)), defined by the degree of cellular atypia; all types must be observed and treated if they persist or become more severe. At present, the malignant potential of a specific lesion cannot be predicted. Some lesions remain stable for long periods of time, some regress, and others advance.

Clinical Findings

There are no specific symptoms or signs of cervical intraepithelial neoplasia. The presumptive diagnosis is made by cytologic screening of an asymptomatic population with no grossly visible cervical changes. All visibly abnormal cervical lesions should be biopsied.

Diagnosis

A. Cytologic Examination (Papanicolaou Smear)

Specimens should be taken from a nonmenstruating patient, spread on a single slide, and fixed or rinsed directly into preservative solution if a thin layer slide system (ThinPrep) is to be used. A specimen should be obtained from the squamocolumnar junction with a wooden or plastic spatula and from the endocervix with a cotton swab or nylon brush.

Cytologic reports from the laboratory may describe findings in one of several ways (see [Table 17-2](#)). While use of class I-IV is disappearing, the CIN classification continues to be used along with a description of abnormal cells, including evidence of human papillomavirus (HPV). The Bethesda System uses the terminology "squamous intraepithelial lesions (SIL)," low-grade or high-grade. Cytopathologists consider a Pap smear to be a medical consultation and will recommend further diagnostic procedures, treatment for infection, and comments on factors preventing adequate evaluation of the specimen. HPV testing of cytologic smears may be useful for triage of atypia (atypical squamous cells of unknown significance; ASC-US).

B. Colposcopy

Viewing the cervix with 10-20× magnification allows for assessment of the size and margins of an abnormal transformation zone and determination of extension into the endocervical canal. The application of 3-5% acetic acid (vinegar) dissolves mucus, and the acid's desiccating action sharpens the contrast between normal and actively proliferating squamous epithelium. Abnormal changes include white patches and vascular atypia, which indicate areas of greatest cellular activity. Paint the cervix with Lugol's solution (strong iodine solution [Schiller's test]). Normal squamous epithelium will take the stain; nonstaining squamous epithelium should be biopsied. (The single-layered, mucus-secreting endocervical tissue will not stain either but can readily be distinguished by its darker pink, shinier appearance.)

C. Biopsy

Colposcopically directed punch biopsy and endocervical curettage are office procedures. If colposcopic examination is not available, the normal-appearing cervix shedding atypical cells can be evaluated by endocervical curettage and multiple punch biopsies of nonstaining squamous epithelium or biopsies from each quadrant of the cervix.

Data from both cervical biopsy and endocervical curettage are important in deciding on treatment.

Prevention

Current data suggest that cervical infection with the human papillomavirus (HPV) is associated with a high percentage of all cervical dysplasias and cancers. There are over 70 recognized HPV subtypes, of which types 6 and 11 tend to cause mild dysplasia, while types 16, 18, 31, and others cause higher-grade cellular changes.

Cervical cancer almost never occurs in virginal women; it is epidemiologically related to the number of sexual partners a woman has had and the number of other female partners a male partner has had. Use of the diaphragm or condom has a protective effect. Long-term oral contraceptive users develop more dysplasias and cancers of the cervix than users of other forms of birth control, and smokers are also more at risk. Preventive measures include regular cytologic screening to detect

abnormalities, limiting the number of sexual partners, using a diaphragm or condom for coitus, and stopping smoking.

Women with HIV infection appear to be at increased risk of the disease and of recurrent disease after treatment. Women with HIV infection should receive regular cytologic screening and should be followed closely after treatment for cervical intraepithelial neoplasia.

Because of the very low rate of abnormal Papanicolaou smears in women who have undergone hysterectomy for benign disease, routine screening is not justified in this population.

Treatment

Treatment varies depending on the degree and extent of cervical intraepithelial neoplasia. Biopsies should always precede treatment.

A. Cauterization or Cryosurgery

The use of either hot cauterization or freezing (cryosurgery) is effective for noninvasive small lesions visible on the cervix without endocervical extension.

B. CO₂ Laser

This well-controlled method minimizes tissue destruction. It is colposcopically directed and requires special training. It may be used with large visible lesions. In current practice it involves the vaporization of the transformation zone on the cervix and the distal 5-7 mm of endocervical canal.

C. Loop Resection

When the CIN is clearly visible in its entirety, a wire loop can be used for excisional biopsy. Cutting and hemostasis are effected with a low-voltage electrosurgical machine (Bovie). This office procedure with local anesthesia is quick and uncomplicated.

D. Conization of the Cervix

Conization is surgical removal of the entire transformation zone and endocervical canal. It should be reserved for cases of severe dysplasia or cancer in situ (CIN III), particularly those with endocervical extension. The procedure can be performed with the scalpel, the CO₂ laser, the needle electrode, or by large-loop excision.

E. Follow-Up

Because recurrence is possible—especially in the first 2 years after treatment—and because the false-negative rate of a single cervical cytologic test is 20%, close follow-up is imperative. Vaginal cytologic examination should be repeated at 3-month intervals for at least 1 year.

CARCINOMA OF THE CERVIX

Essentials of Diagnosis

- Abnormal uterine bleeding and vaginal discharge.
- Cervical lesion may be visible on inspection as a tumor or ulceration.
- Vaginal cytology usually positive; must be confirmed by biopsy.

General Considerations

Cancer appears first in the intraepithelial layers (the preinvasive stage, or carcinoma in situ). Preinvasive cancer (CIN III) is a common diagnosis in women 25-40 years of age and is etiologically related to infection with the human papillomavirus. Two to 10 years are required for carcinoma to penetrate the basement membrane and invade the tissues. After invasion, death usually occurs within 3-5 years in untreated or unresponsive patients.

Clinical Findings

A. Symptoms and Signs

The most common signs are metrorrhagia, postcoital spotting, and cervical ulceration. Bloody or purulent, odorous, nonpruritic discharge may appear after invasion. Bladder and rectal dysfunction or fistulas and pain are late symptoms.

B. Cervical Biopsy and Endocervical Curettage, or Conization

These procedures are necessary steps after a positive Papanicolaou smear to determine the extent and depth of invasion of the cancer. Even if the smear is positive, treatment is never justified until definitive diagnosis has been established through biopsy.

C. "Staging," or Estimate of Gross Spread of Cancer of the Cervix

The depth of penetration of the malignant cells beyond the basement membrane is a reliable clinical guide to the extent of primary cancer within the cervix and the likelihood of metastases. It is customary to stage cancers of the cervix under anesthesia as shown in [Table 17-3](#). Further assessment may be carried out by abdominal and pelvic CT scanning or MRI.

Complications

Metastases to regional lymph nodes occur with increasing frequency from stage I to stage IV. Paracervical extension occurs in all directions from the cervix. The ureters are often obstructed lateral to the cervix, causing hydroureter and hydronephrosis and consequently impaired kidney function. Almost two-thirds of patients with untreated carcinoma of the cervix die of uremia when ureteral obstruction is bilateral. Pain in the back, in the distribution of the lumbosacral plexus, is often indicative of neurologic involvement. Gross edema of the legs may be indicative of vascular and lymphatic stasis due to tumor.

Vaginal fistulas to the rectum and urinary tract are severe late complications. Hemorrhage is the cause of death in 10-20% of patients with extensive invasive carcinoma.

Treatment

A. Emergency Measures

Vaginal hemorrhage originates from gross ulceration and cavitation in stage II-IV cervical carcinoma. Ligation and suturing of the cervix are usually not feasible, but ligation of the uterine or hypogastric arteries may be lifesaving when other measures fail. Styptics such as Monsel's solution or acetone are effective, although delayed sloughing may result in further bleeding. Wet vaginal packing is helpful. Emergency irradiation usually controls bleeding.

B. Specific Measures

1. Carcinoma in situ (stage 0)—In women who have completed childbearing, total hysterectomy is the treatment of choice. In women who wish to retain the uterus, acceptable alternatives include cervical conization or ablation of the lesion with cryotherapy or laser. Close follow-up with Papanicolaou smears every 3 months for 1 year and every 6 months for another year is necessary after cryotherapy or laser.

2. Invasive carcinoma—Microinvasive carcinoma (stage IA) is treated with simple, extrafascial hysterectomy. Stage IB and stage IIA cancers may be treated with either radical hysterectomy or radiation therapy. Stage IIB and stage III and IV cancers are treated with radiation therapy plus concurrent cisplatin-based chemotherapy. Because radical surgery results in fewer long-term complications than irradiation and may allow preservation of ovarian function, it may be the preferred mode of therapy in younger women without contraindications to major surgery.

Prognosis

The overall 5-year relative survival rate for carcinoma of the cervix is 68% in white women and 55% in black women in the United States. Survival rates are inversely proportionate to the stage of cancer: stage 0, 99-100%; stage IA, > 95%; stage IB-IIA, 80-90%; stage IIB, 65%; stage III, 40%; and stage IV, < 20%.

LEIOMYOMA OF THE UTERUS (FIBROID TUMOR)

Essentials of Diagnosis

- Irregular enlargement of the uterus (may be asymptomatic).
- Heavy or irregular vaginal bleeding, dysmenorrhea.
- Acute and recurrent pelvic pain if the tumor becomes twisted on its pedicle or infarcted.
- Symptoms due to pressure on neighboring organs (large tumors).

General Considerations

Uterine leiomyoma is the most common benign neoplasm of the female genital tract. It is a discrete, round, firm, often multiple uterine tumor composed of smooth muscle and connective tissue. The most convenient classification is by anatomic location: (1) intramural, (2) submucous, (3) subserous, (4) intraligamentous, (5) parasitic (ie, deriving its blood supply from an organ to which it becomes attached), and (6) cervical. A submucous myoma may become pedunculated and descend through the cervix into the vagina.

Clinical Findings

A. Symptoms and Signs

In nonpregnant women, myomas are frequently asymptomatic. However, they can cause urinary frequency, dysmenorrhea, heavy bleeding (often with anemia), or other complications due to the presence of an abdominal mass. Occasionally, degeneration occurs, causing intense pain. Infertility may be due to a myoma that significantly distorts the uterine cavity.

B. Laboratory Findings

Hemoglobin levels may be decreased as a result of blood loss, but in rare cases polycythemia is present, presumably as a result of the production of erythropoietin by the myomas.

C. Imaging

Ultrasonography will confirm the presence of uterine myomas and can be used sequentially to monitor growth. When multiple subserous or pedunculated myomas are being followed, ultrasonography is important to exclude ovarian masses. MRI can delineate intramural and submucous myomas accurately. HysteroGRAPHY or hysteroscopy can also confirm cervical or submucous myomas.

Differential Diagnosis

Irregular myomatous enlargement of the uterus must be differentiated from the similar but symmetric enlargement that may occur with pregnancy or adenomyosis (the presence of endometrial glands and stroma in the myometrium). Subserous myomas must be distinguished from ovarian tumors. Leiomyosarcoma is an unusual tumor occurring in 0.5% of women operated on for symptomatic myoma. It is very rare under the age of 40 and increases in incidence thereafter.

Treatment

A. Emergency Measures

If the patient is markedly anemic as a result of long, heavy menstrual periods, preoperative treatment with depot medroxyprogesterone acetate, 150 mg intramuscularly every 28 days, or danazol, 400-800 mg orally daily, will slow or stop bleeding, and medical treatment of anemia can be given prior to surgery. Emergency surgery is required for acute torsion of a pedunculated myoma. The only emergency indication for myomectomy during pregnancy is torsion; abortion is not an inevitable result.

B. Specific Measures

Women who have small asymptomatic myomas should be examined at 6-month intervals. If necessary, elective myomectomy can be done to preserve the uterus. Myomas do not require surgery on an urgent basis unless they cause significant pressure on the ureters, bladder, or bowel or severe bleeding leading to anemia or unless they are undergoing rapid growth. Cervical myomas larger than 3-4 cm in diameter or pedunculated myomas that protrude through the cervix must be removed. Submucous myomas can be removed using a hysteroscope and laser or resection instruments.

Because the risk of surgical complications increases with the increasing size of the myoma, preoperative reduction of myoma size is desirable. GnRH analogs such as depot leuprolide, 3.75 mg intramuscularly monthly, or nafarelin, 0.2-0.4 mg intranasally twice a day, are used preoperatively for 3- to 4-month periods to induce reversible hypogonadism, which temporarily reduces the size of myomas, suppresses their further growth, and reduces surrounding vascularity.

C. Surgical Measures

Surgical measures available for the treatment of myoma are laparoscopic or abdominal myomectomy and total or subtotal abdominal, vaginal, or laparoscopy-assisted vaginal hysterectomy. Myomectomy is the treatment of choice during the childbearing years. Recent developments include transcatheter bilateral uterine artery embolization and myolysis with cryotherapy or cauterization. While these approaches are promising and potentially cost-effective alternatives, randomized clinical trials to compare long-term outcomes with these new methods with conventional therapy are needed.

Prognosis

Surgical therapy is curative. Future pregnancies are not endangered by myomectomy, although cesarean delivery may be necessary after wide dissection with entry into the uterine cavity.

Baker CM et al: Estimated costs for uterine artery embolization and abdominal myomectomy for uterine leiomyomata: a comparative study at a single institution. J Vasc Interv Radiol 2002;13:1207. [\[PMID: 12471183\]](#)

Olive DL: New approaches to the management of fibroids. Obstet Gynecol Clin North Am 2000;27:669. [\[PMID: 10958011\]](#)

CARCINOMA OF THE ENDOMETRIUM

Adenocarcinoma of the uterine corpus is the second most common cancer of the female genital tract. It occurs most often in women 50-70 years of age. Some patients will have taken unopposed estrogen in the past; their increased risk appears to persist for 10 or more years after stopping the drug. Obesity, nulliparity, diabetes, and polycystic ovaries with prolonged anovulation and the extended use of tamoxifen for the treatment of breast cancer are also risk factors.

Abnormal bleeding is the presenting sign in 80% of cases. Endometrial carcinoma may cause obstruction of the cervix with collection of pus (pyometra) or blood (hematometra) causing lower abdominal pain. However, pain generally occurs late in the disease, with metastases or infection.

Papanicolaou smears of the cervix occasionally show atypical endometrial cells but are an insensitive diagnostic tool. Endocervical and endometrial sampling is the only reliable means of diagnosis. Adequate specimens of each can usually be obtained during an office procedure performed following local anesthesia (paracervical block). Simultaneous hysteroscopy can be a valuable addition in order to localize polyps or other lesions within the uterine cavity. Vaginal ultrasonography may be used to determine the thickness of the endometrium as an indication of hypertrophy and possible neoplastic change.

Pathologic assessment is important in differentiating hyperplasias, which often can be treated with cyclic oral progestins.

Prevention

Prompt endometrial sampling for patients who report abnormal menstrual bleeding or postmenopausal uterine bleeding will reveal many incipient as well as clinical cases of endometrial cancer. In comparison with the use of unopposed estrogen for menopausal therapy, there is a relative risk of endometrial cancer of 0.3 among women using continuous combined regimens of estrogen and progestin. Younger women with chronic anovulation are at risk for endometrial hyperplasia and subsequent endometrial cancer. They can reduce the risk of hyperplasia almost completely with the use of oral contraceptives or cyclic progestin therapy.

Staging

Examination under anesthesia, endometrial and endocervical sampling, chest x-ray, intravenous urography, cystoscopy, sigmoidoscopy, transvaginal sonography, and MRI will help determine the extent of the disease and its appropriate treatment. The staging is based on the surgical and pathologic evaluation.

Treatment

Treatment consists of total hysterectomy and bilateral salpingo-oophorectomy. Peritoneal material for cytologic examination is routinely taken. Preliminary external irradiation or intracavitary radium therapy is indicated if the cancer is poorly differentiated or if the uterus is definitely enlarged in the absence of myomas. If invasion deep into the myometrium has occurred or if sampled preaortic lymph nodes are positive for tumor, postoperative irradiation is indicated.

Palliation of advanced or metastatic endometrial adenocarcinoma may be accomplished with large doses of progestins, eg, medroxyprogesterone, 400 mg intramuscularly weekly, or megestrol acetate, 80-160 mg daily orally.

Prognosis

With early diagnosis and treatment, the overall 5-year survival is 80-85%. With stage I disease, the depth of myometrial invasion is the strongest predictor of survival, with a 98% 5-year survival with < 66% depth of invasion and 78% survival with = 66% invasion.

CARCINOMA OF THE VULVA

Essentials of Diagnosis

- History of genital warts.
- History of prolonged vulvar irritation, with pruritus, local discomfort, or slight bloody discharge.
- Early lesions may suggest or include nonneoplastic epithelial disorders.
- Late lesions appear as a mass, an exophytic growth, or a firm, ulcerated area in the vulva.
- Biopsy is necessary to make the diagnosis.

General Considerations

The vast majority of cancers of the vulva are squamous lesions that classically have occurred in women over 50 years of age. Several subtypes (particularly 16, 18, and 31) of the human papillomavirus have been identified in some but not all vulvar cancers. As with squamous cell lesions of the cervix, a grading system of vulvar intraepithelial neoplasia (VIN) from mild dysplasia to carcinoma in situ has been established.

Differential Diagnosis

Biopsy is essential for the diagnosis of VIN and vulvar cancer and should be performed with any localized atypical vulvar lesion, including white patches. Multiple skin-punch specimens can be taken in the office under local anesthesia, with care to include tissue from the edges of each lesion sampled.

Benign vulvar disorders that must be excluded in the diagnosis of carcinoma of the vulva include chronic granulomatous lesions (eg, lymphogranuloma venereum, syphilis), condylomas, hidradenoma, or neurofibroma. Lichen sclerosus and other associated leukoplakic changes in the skin should be biopsied. The likelihood that a superimposed vulvar cancer will develop in a woman with a nonneoplastic epithelial disorder (vulvar dystrophy) ranges from 1% to 5%.

Treatment

A. General Measures

Early diagnosis and treatment of irritative or other predisposing or contributing causes to carcinoma of the vulva should be pursued. A 7:3 combination of betamethasone and crotamiton is particularly effective for itching. After an initial response, fluorinated steroids should be replaced with hydrocortisone because of their skin atrophying effect. For lichen sclerosus, recommended treatment is clobetasol propionate cream 0.05% twice daily for 2-3 weeks, then once daily until symptoms resolve. Application one to three times a week can be used for long-term maintenance therapy.

B. Surgical Measures

High-grade VIN may be treated with a variety of approaches including topical chemotherapy, laser ablation, wide local excision, skinning vulvectomy, and simple vulvectomy. Small, invasive basal cell carcinoma of the vulva should be excised with a wide margin. If the VIN is extensive or multicentric, laser therapy or superficial surgical removal of vulvar skin may be required. In this way, the clitoris and uninvolved portions of the vulva may be spared.

Invasive carcinoma confined to the vulva without evidence of spread to adjacent organs or to the regional lymph nodes will necessitate radical vulvectomy and inguinal lymphadenectomy if the patient is able to withstand surgery. Debilitated patients may be candidates for palliative irradiation only.

Prognosis

Basal cell carcinomas very seldom metastasize, and carcinoma in situ by definition has not metastasized. With adequate excision, the prognosis for both lesions is excellent. Patients with invasive vulvar squamous cell carcinoma 3 cm in diameter or less without inguinal lymph node metastases who can sustain radical surgery have about a 90% chance of a 5-year survival. If the lesion is greater than 3 cm and has metastasized, the likelihood of 5-year survival is less than 25%.

Hopkins MP et al: Carcinoma of the vulva. Obstet Gynecol Clin North Am 2001;28:791. [PMID: 11766152]

ENDOMETRIOSIS

Endometriosis is an aberrant growth of endometrium outside the uterus, particularly in the dependent parts of the pelvis and in the ovaries and is a common cause of abnormal bleeding and secondary dysmenorrhea. Its causes, pathogenesis, and natural course are poorly understood. The prevalence in the United States is 2% among fertile women and three- to fourfold greater than that in the infertile. Depending on the location and extent of the endometrial implants, infertility, dyspareunia, or rectal pain with bleeding may result. Aching pain tends to be constant, beginning 2-7 days before the onset of menses, and becomes increasingly severe until flow slackens. Pelvic examination may disclose tender indurated nodules in the cul-de-sac, especially if the examination is done at the onset of menstruation.

Endometriosis must be distinguished from pelvic inflammatory disease, ovarian neoplasms, and uterine myomas. In general, only in salpingitis and endometriosis are the symptoms aggravated by menstruation. Bowel invasion by endometrial tissue may produce clinical findings, including blood in the stool, that must be distinguished from bowel neoplasm. Differentiation in these instances depends upon proctosigmoidoscopy and biopsy.

Ultrasound examination will often reveal complex fluid-filled masses that cannot be distinguished from neoplasms. MRI is more sensitive and specific than ultrasound, particularly in the diagnosis of adnexal masses. However, the clinical diagnosis of endometriosis is presumptive and usually confirmed by laparoscopy or laparotomy.

Treatment

A. Medical Treatment

Medical treatment, using a variety of hormonal therapies, is effective in the amelioration of pain associated with endometriosis. However, there is no evidence that any of these agents increase the likelihood of pregnancy. Their preoperative use is of questionable value in reducing the difficulty of surgery. Most of these regimens are designed to inhibit ovulation over 4-9 months and lower hormone levels, thus preventing cyclic stimulation of endometriotic implants and decreasing their size. The optimum duration of therapy is not clear, and the relative merits in terms of side effects and long-term risks and benefits show insignificant differences when compared with each other and, in mild cases, with placebo.

1. The GnRH analogs such as nafarelin nasal spray, 0.2-0.4 mg twice daily, or long-acting injectable leuprolide acetate, 3.75 mg intramuscularly monthly, used for 6 months, suppress ovulation. Side effects consisting of vasomotor symptoms and bone demineralization may be relieved by "add-back" therapy with norethindrone, 5-10 mg daily.
2. Danazol is used for 6-9 months in the lowest dose necessary to suppress menstruation, usually 200- 400 mg twice daily. Side effects are androgenic and include decreased breast size, weight gain, acne, and hirsutism.
3. Any of the combination oral contraceptives may be given, one daily, without interruption, for 6-12 months. Breakthrough bleeding can be treated with conjugated estrogens, 1.25 mg daily for 1 week, or estradiol, 2 mg daily for 1 week.
4. Medroxyprogesterone acetate, 100 mg intramuscularly every 2 weeks for four doses and then 100 mg every 4 weeks; add oral estrogen or estradiol valerate, 30 mg intramuscularly, for breakthrough bleeding. Use for 6-9 months.
5. Low-dose oral contraceptives can also be given cyclically; prolonged suppression of ovulation will often inhibit further stimulation of residual endometriosis, especially if taken after one of the therapies mentioned above.
6. Analgesics, with or without codeine, may be needed during menses. Nonsteroidal anti-inflammatory drugs may be helpful.

B. Surgical Measures

Surgical treatment of endometriosis—particularly extensive disease—is effective both in reducing pain and in promoting fertility. Laparoscopic ablation of endometrial implants along with uterine nerve ablation significantly reduces pain. Ablation of implants and, if necessary, removal of ovarian endometriomas enhance fertility, though subsequent pregnancy rates are related to the severity of disease. Women with disabling pain who no longer desire childbearing can be treated definitively with total abdominal hysterectomy and bilateral salpingo-oophorectomy (TAH-BSO).

Prognosis

The prognosis for reproductive function in early or moderately advanced endometriosis is good with conservative therapy. TAH-BSO is curative for patients with severe and extensive endometriosis with pain.

GENITAL PROLAPSE (CYSTOCELE, RECTOCELE, ENTEROCELE)

Cystocele, rectocele, and enterocele are vaginal hernias commonly seen in multiparous women. Cystocele is a hernia of the bladder wall into the vagina, causing a soft anterior fullness. Cystocele may be accompanied by urethrocele, which is not a hernia but a sagging of the urethra following its detachment from the pubic symphysis during childbirth. Rectocele is a herniation of the terminal rectum into the posterior vagina, causing a collapsible pouch-like fullness. Enterocele is a vaginal vault hernia containing small intestine, usually in the posterior vagina and resulting from a deepening of the pouch of Douglas. Enterocele may also accompany uterine prolapse or follow hysterectomy, when weakened vault supports or a deep unobliterated cul-de-sac containing intestine protrudes into the vagina. Two or all three types of hernia may occur in combination.

Supportive measures include a high-fiber diet. Weight reduction in obese patients and limitation of straining and lifting are helpful. Pessaries may reduce cystocele, rectocele, or enterocele temporarily and are helpful in women who do not wish surgery or are chronically ill.

The only cure for symptomatic cystocele, rectocele, or enterocele is corrective surgery. The prognosis following an uncomplicated procedure is good.

UTERINE PROLAPSE

Uterine prolapse most commonly occurs as a delayed result of childbirth injury to the pelvic floor (particularly the transverse cervical and uterosacral ligaments). Unrepaired obstetric lacerations of the levator musculature and perineal body augment the weakness. Attenuation of the pelvic structures with aging and congenital weakness can accelerate the development of prolapse.

In slight prolapse, the uterus descends only part way down the vagina; in moderate prolapse, the corpus descends to the introitus and the cervix protrudes slightly beyond; and in marked prolapse (procidentia), the entire cervix and uterus protrude beyond the introitus and the vagina is inverted. Inability to walk comfortably because of protrusion or discomfort from the presence of a vaginal mass is an indication that surgical treatment should be considered.

Treatment

The type of surgery depends upon the extent of prolapse and the patient's age and her desire for menstruation, pregnancy, and coitus. The simplest, most effective procedure is vaginal hysterectomy with appropriate repair of the cystocele and rectocele. If the patient desires pregnancy, a partial resection of the cervix with plication of the cardinal ligaments can be attempted. For elderly women who do not desire coitus, partial obliteration of the vagina is surgically simple and effective. Abdominal uterine suspension or ventrofixation will fail in the treatment of prolapse.

A well-fitted vaginal pessary (eg, inflatable doughnut type, Gellhorn pessary) may give relief if surgery is refused or contraindicated.

PELVIC INFLAMMATORY DISEASE (PID; SALPINGITIS, ENDOMETRITIS)

Pelvic inflammatory disease is a polymicrobial infection of the upper genital tract associated with the sexually transmitted organisms *N gonorrhoeae* and *C trachomatis* as well as endogenous organisms, including anaerobes, *H influenzae*, enteric gram-negative rods, and streptococci. It is most common in young, nulliparous, sexually active women with multiple partners. Other risk markers include nonwhite race, douching, and smoking. The use of oral contraceptives or barrier methods of contraception may provide significant protection.

Tuberculous salpingitis is rare in the United States but more common in developing countries; it is characterized by pelvic pain and irregular pelvic masses not responsive to antibiotic therapy. It is not sexually transmitted.

Clinical Findings

A. Symptoms and Signs

Patients with pelvic inflammatory disease may have lower abdominal pain, chills and fever, menstrual disturbances, purulent cervical discharge, and cervical and adnexal tenderness. Right upper quadrant pain (Fitz-Hugh and Curtis syndrome) may indicate an associated perihepatitis. However, diagnosis of PID is complicated by the fact that many women may have subtle or mild symptoms, not readily recognized as PID.

B. Minimum Diagnostic Criteria

Women with uterine adnexal or cervical motion tenderness should be considered to have PID and be treated with antibiotics unless there is a competing diagnosis such as ectopic pregnancy or appendicitis.

C. Additional Criteria

The following criteria may be used to enhance the specificity of the diagnosis: (1) oral temperature > 38.3°C, (2) abnormal cervical or vaginal discharge with white cells

on saline microscopy, (3) elevated erythrocyte sedimentation rate, (4) elevated C-reactive protein, and (5) laboratory documentation of cervical infection with *N gonorrhoeae* or *C trachomatis*. Endocervical culture should be performed routinely, but treatment should not be delayed while awaiting results.

D. Definitive Criteria

In selected cases where the diagnosis based on clinical or laboratory evidence is uncertain, the following criteria may be used: (1) histopathologic evidence of endometritis on endometrial biopsy, (2) transvaginal sonography or MRI showing thickened fluid-filled tubes with or without free pelvic fluid or tubo-ovarian complex, and (3) laparoscopic abnormalities consistent with PID.

Differential Diagnosis

Appendicitis, ectopic pregnancy, septic abortion, hemorrhagic or ruptured ovarian cysts or tumors, twisted ovarian cyst, degeneration of a myoma, and acute enteritis must be considered. Pelvic inflammatory disease is more likely to occur when there is a history of pelvic inflammatory disease, recent sexual contact, recent onset of menses, or an IUD in place or if the partner has a sexually transmitted disease. Acute pelvic inflammatory disease is highly unlikely when recent intercourse has not taken place or an IUD is not being used. A sensitive serum pregnancy test should be obtained to rule out ectopic pregnancy. Culdocentesis will differentiate hemoperitoneum (ruptured ectopic pregnancy or hemorrhagic cyst) from pelvic sepsis (salpingitis, ruptured pelvic abscess, or ruptured appendix). Pelvic and vaginal ultrasound are helpful in the differential diagnosis of ectopic pregnancy of over 6 weeks. Laparoscopy is often utilized to diagnose pelvic inflammatory disease, and it is imperative if the diagnosis is not certain or if the patient has not responded to antibiotic therapy after 48 hours. The appendix should be visualized at laparoscopy to rule out appendicitis. Cultures obtained at the time of laparoscopy are often specific and helpful.

Treatment

A. Hospitalization

Patients with acute pelvic inflammatory disease should be admitted for intravenous antibiotic therapy if (1) surgical emergencies such as appendicitis cannot be ruled out, (2) the patient has a tubo-ovarian abscess, (3) the patient is pregnant, (4) the patient is unable to follow or tolerate an outpatient regimen, (5) the patient has failed to respond clinically to outpatient therapy, or (6) the patient has severe illness, nausea and vomiting, or high fever. In the past, many experts recommended that all patients with PID be hospitalized for bed rest and supervised treatment with parenteral antibiotics. However, a recent large, randomized clinical trial suggests that in women with mild to moderate pelvic inflammatory disease there is no difference between inpatient and outpatient therapy in short-term clinical outcomes or in long-term reproductive outcomes. Patients with tubo-ovarian abscesses should have direct inpatient observation for at least 24 hours prior to switching to outpatient parenteral therapy.

B. Antibiotics

Early treatment with appropriate antibiotics effective against *N gonorrhoeae*, *C trachomatis*, and the endogenous organisms listed above is essential to prevent long-term sequelae. The sexual partner should be examined and treated appropriately.

Two inpatient regimens have been shown to be effective in the treatment of acute pelvic inflammatory disease: (1) Cefoxitin, 2 g intravenously every 6 hours, or cefotetan, 2 g every 12 hours, plus doxycycline, 100 mg intravenously or orally every 12 hours. This regimen is continued for at least 24 hours after the patient shows significant clinical improvement. Doxycycline, 100 mg twice daily, should be continued to complete a total of 14 days therapy. If a tubo-ovarian abscess is present, it is advisable to add oral clindamycin or metronidazole to the doxycycline to provide more effective anaerobic coverage. (2) Clindamycin, 900 mg intravenously every 8 hours, plus gentamicin intravenously in a loading dose of 2 mg/kg followed by 1.5 mg/kg every 8 hours. This regimen is continued for at least 24 hours after the patient shows significant clinical improvement and is followed by either clindamycin, 450 mg four times daily, or doxycycline, 100 mg twice daily, to complete a total of 14 days of therapy.

Limited data exist on other parenteral regimens. Two regimens providing broad-spectrum coverage have been investigated in at least one clinical trial: (1) ofloxacin, 400 mg intravenously every 12 hours, or levofloxacin, 500 mg intravenously once daily, plus metronidazole, 500 mg intravenously every 8 hours; and (2) ampicillin-sulbactam, 3 g intravenously every 6 hours, plus doxycycline, 100 mg intravenously or orally every 12 hours.

Two outpatient regimens are recommended: (1) ofloxacin, 400 mg orally twice daily for 14 days, or levofloxacin, 500 mg orally once daily for 14 days, plus metronidazole, 500 mg orally twice daily, for 14 days; and (2) either a single dose of cefoxitin, 2 g intramuscularly, with probenecid, 1 g orally, or ceftriaxone, 250 mg intramuscularly, plus doxycycline, 100 mg orally twice daily, for 14 days, with or without metronidazole, 500 mg orally twice daily for 14 days.

C. Surgical Measures

Tubo-ovarian abscesses may require surgical excision or transcutaneous or transvaginal aspiration. Unless rupture is suspected, institute high-dose antibiotic therapy in the hospital, and monitor therapy with ultrasound. In 70% of cases, antibiotics are effective; in 30%, there is inadequate response in 48-72 hours, and intervention is required. Unilateral adnexectomy is acceptable for unilateral abscess. Hysterectomy and bilateral salpingo-oophorectomy may be necessary for overwhelming infection or in cases of chronic disease with intractable pelvic pain.

Prognosis

In spite of treatment, one-fourth of women with acute disease develop long-term sequelae, including repeated episodes of infection, chronic pelvic pain, dyspareunia, ectopic pregnancy, or infertility. The risk of infertility increases with repeated episodes of salpingitis: it is estimated at 10% after the first episode, 25% after a second episode, and 50% after a third episode.

OVARIAN TUMORS

Essentials of Diagnosis

- Vague gastrointestinal discomfort.
- Pelvic pressure and pain.
- Many cases of early-stage cancer are asymptomatic.
- Pelvic examination, CA 125, and ultrasound are mainstays of diagnosis.

General Considerations

Ovarian tumors are common. Most are benign, but malignant ovarian tumors are the leading cause of death from reproductive tract cancer. The wide range of types and patterns of ovarian tumors is due to the complexity of ovarian embryology and differences in tissues of origin ([Table 17-4](#)).

In women with no family history of ovarian cancer, the lifetime risk is 1.6%, whereas a woman with one affected first-degree relative has a 5% lifetime risk. With two or more affected first-degree relatives, the risk is 7%. Approximately 3% of women with two or more affected first-degree relatives will have a hereditary ovarian cancer syndrome with a lifetime risk of 40%. Women with a *BRCA1* gene mutation have a 45% lifetime risk of ovarian cancer and those with a *BRCA2* mutation a 25% risk. These women should be screened annually with transvaginal sonography (TVS) and CA 125 testing, and prophylactic oophorectomy is recommended by age 35 or whenever childbearing is completed because of the high risk of disease. The benefits of such screening for women with one or no affected first-degree relatives are unproved, and the risks associated with unnecessary surgical procedures may outweigh the benefits in low-risk women.

Clinical Findings

A. Symptoms and Signs

Unfortunately, most women with both benign and malignant ovarian neoplasms are either asymptomatic or experience only mild nonspecific gastrointestinal symptoms or pelvic pressure. Women with early disease are typically detected on routine pelvic examination. Women with advanced malignant disease may experience abdominal pain and bloating, and a palpable abdominal mass with ascites is often present.

B. Laboratory Findings

An elevated serum CA 125 (> 35 units) indicates a greater likelihood that an ovarian tumor is malignant. CA 125 is elevated in 80% of women with epithelial ovarian cancer overall but in only 50% of women with early disease. Furthermore, serum CA 125 may be elevated in premenopausal women with benign disease such as

endometriosis.

C. Imaging Studies

TVS is useful for screening high-risk women but has inadequate sensitivity for screening low-risk women. Ultrasound is helpful in differentiating ovarian masses that are benign and likely to resolve spontaneously from those with malignant potential. Color Doppler imaging may further enhance the specificity of ultrasound diagnosis.

Differential Diagnosis

Once an ovarian mass has been detected, it must be categorized as functional, benign neoplastic, or potentially malignant. Predictive factors include age, size of the mass, ultrasound configuration, CA 125 levels, the presence of symptoms, and whether the mass is unilateral or bilateral. In a premenopausal woman, an asymptomatic, mobile, unilateral, simple cystic mass less than 8-10 cm may be observed for 4-6 weeks. Most will resolve spontaneously. If the mass is larger or unchanged on repeat pelvic examination and TVS, surgical evaluation is required.

Most ovarian masses in postmenopausal women require surgical evaluation. However, a postmenopausal woman with an asymptomatic unilateral simple cyst less than 5 cm in diameter and a normal CA 125 level may be followed closely with TVS. All others require surgical evaluation.

Exploratory laparotomy has been the standard approach. Laparoscopy may be considered for a premenopausal woman with an ovarian mass small enough to be removed using a laparoscopic approach. If malignancy is suspected, preoperative workup should include chest x-ray, evaluation of liver and kidney function, and hematologic indices.

Treatment

If a malignant ovarian mass is suspected, surgical evaluation should be performed by a gynecologic oncologist. For benign neoplasms, tumor removal or unilateral oophorectomy is usually performed. For ovarian cancer in an early stage, the standard therapy is complete surgical staging followed by abdominal hysterectomy and bilateral salpingo-oophorectomy with omentectomy and selective lymphadenectomy. With more advanced disease, aggressive removal of all visible tumor improves survival. Except for women with low-grade ovarian cancer in an early stage, postoperative chemotherapy is indicated. Several chemotherapy regimens are effective, such as the combination of cisplatin or carboplatin with paclitaxel, with clinical response rates of up to 60-70%.

Prognosis

Unfortunately, approximately 75% of women with ovarian cancer are diagnosed with advanced disease after regional or distant metastases have become established. The overall 5-year survival is approximately 17% with distant metastases, 36% with local spread, and 89% with early disease.

Kauff ND et al: Risk-reducing salpingo-oophorectomy in women with a BRCA1 or BRCA2 mutation. *N Engl J Med* 2002; 346:1609. [PMID: [12023992](#)]

PERSISTENT ANOVULATION (POLYCYSTIC OVARY SYNDROME)

Essentials of Diagnosis

- Chronic anovulation.
- Infertility.
- Elevated plasma testosterone.
- Insulin resistance.
- Hirsutism (in 50% of patients).

General Considerations

Polycystic ovary syndrome (PCOS) is a common endocrine disorder affecting 4-6% of women of reproductive age. The primary lesion is unknown. These patients have a steady state of relatively high estrogen, androgen, and LH levels rather than the fluctuating condition seen in ovulating women. Increased levels of estrone come from obesity (conversion of ovarian and adrenal androgens to estrone in body fat) or from excessive levels of androgens seen in some women of normal weight. The high estrone levels are believed to cause suppression of pituitary FSH and a relative increase in LH. Constant LH stimulation of the ovary results in anovulation, multiple cysts, and theca cell hyperplasia with excess androgen output.

Women with Cushing's syndrome, congenital adrenal hyperplasia, and androgen-secreting adrenal tumors also tend to have high circulating androgen levels and anovulation with polycystic ovaries.

Clinical Findings

PCOS is manifested by hirsutism (50% of cases), obesity (40%), and virilization (20%). Fifty percent of patients have amenorrhea, 30% have abnormal uterine bleeding, and 20% have normal menstruation. Additionally, they show insulin resistance and hyperinsulinemia when infused with glucose, and these women are at increased risk of early-onset type 2 diabetes mellitus. The patients are generally infertile, although they may ovulate occasionally. They have an increased long-term risk of cancer of the breast and endometrium because of unopposed estrogen secretion.

Differential Diagnosis

Anovulation in the reproductive years may also be due to (1) premature menopause (high FSH and LH levels); (2) rapid weight loss, extreme physical exertion (normal FSH and LH levels for age), or obesity; (3) discontinuation of oral contraceptives (anovulation for 6 months or more occasionally occurs); (4) pituitary adenoma with elevated prolactin (galactorrhea may or may not be present); and (5) hyper- or hypothyroidism. When amenorrhea has persisted for 6 months or more without a diagnosis, FSH, LH, prolactin, TSH, testosterone, and dehydroepiandrosterone sulfate (DHEAS) should be checked. A 10-day course of progestin (eg, medroxyprogesterone acetate, 10 mg/d) will cause withdrawal bleeding if estrogen levels are high. This will aid in the diagnosis and prevent endometrial hyperplasia. Because of the high risk of insulin resistance and dyslipidemia, all women with PCOS should have a 2-hour glucose determination after a 75-g glucose load and a lipoprotein profile.

Treatment

In obese patients with PCOS, weight reduction is often effective; a decrease in body fat will lower the conversion of androgens to estrone and thereby help to restore ovulation.

If the patient wishes to become pregnant, clo-miphene or other drugs can be employed for ovulatory stimulation. (See Infertility, this chapter.) The addition of dexamethasone, 0.5 mg at bedtime, to a clomiphene regimen may increase the likelihood of ovulation by suppression of ACTH and circulating adrenal androgens. For women who are unresponsive to clomiphene, 3- to 6-month courses of the oral hypoglycemic agent metformin, 500 mg three times daily, may bring resumption of regular cycles and ovulation. This agent reduces the hyperinsulinemia and hyperandrogenemia seen with polycystic ovary syndrome.

If the patient does not desire pregnancy, medroxyprogesterone acetate, 10 mg/d for the first 10 days of each month, should be given. This will ensure regular shedding of the endometrium so that hyperplasia will not occur. If contraception is desired, a low-dose combination oral contraceptive can be used; this is also useful in controlling hirsutism, for which treatment must be continued for 6-12 months before results are seen.

Hirsutism may be managed with epilation and electrolysis. Dexamethasone, 0.5 mg each night, is helpful in women with excess adrenal androgen secretion. If hirsutism is severe, some patients will elect to have a hysterectomy and bilateral oophorectomy followed by estrogen replacement therapy. Spironolactone, an aldosterone antagonist, is also useful for hirsutism in doses of 25 mg three or four times daily. Flutamide, 250 mg daily, and finasteride, 5 mg daily, are also effective for treating hirsutism. Because these three agents are potentially teratogenic, they should be used only in conjunction with secure contraception.

PAINFUL INTERCOURSE (DYSPAREUNIA)

Questions related to sexual functioning should be asked as part of the reproductive history. Two helpful questions are, "Are you sexually active?" and "Are you having any sexual difficulties at this time?"

During the pelvic examination, the patient should be placed in a half-sitting position and given a hand-held mirror and then asked to point out the site of pain and describe the type of pain.

Etiology

A. Vulvovaginitis

Vulvovaginitis is inflammation or infection of the vagina. Areas of marked tenderness in the vulvar vestibule without visible inflammation occasionally show lesions resembling small condylomas on colposcopy (see Vaginitis, this chapter).

B. Vaginismus

Vaginismus is voluntary or involuntary contraction of muscles around the introitus. It results from fear, pain, sexual trauma, or having learned negative attitudes toward sex during childhood.

C. Remnants of the Hymen

The hymen is usually adequately stretched during initial intercourse, so that pain does not occur subsequently. In some women, the pain of initial intercourse may produce vaginismus. In others, a thin or thickened rim or partial rim of hymen remains after several episodes of intercourse, causing pain.

D. Insufficient Lubrication of the Vagina

See vaginal atrophy in the section on menopausal syndrome, this chapter.

E. Infection, Endometriosis, Tumors, or Other Pathologic Conditions

Pain occurring with deep thrusting during coitus is usually due to acute or chronic infection of the cervix, uterus, or adnexa; endometriosis; adnexal tumors; or adhesions resulting from prior pelvic disease or operation. Careful history taking and a pelvic examination will generally help in the differential diagnosis.

F. Vulvodynia

This is the most frequent cause of dyspareunia in premenopausal women. It is characterized by a sensation of burning along with other symptoms including pain, itching, stinging, irritation, and rawness. The discomfort may be constant or intermittent, focal or diffuse, and experienced as either deep or superficial. There are generally no physical findings except minimal erythema that may be associated with a subset of vulvodynia, vulvar vestibulitis.

Treatment

A. Vulvovaginitis

Lesions resembling warts on colposcopy or biopsy should be treated in the appropriate way (see Vaginitis). Irritation from spermicides may be a factor. The couple may be helped by a discussion of noncoital techniques to achieve orgasm until the infection subsides.

B. Vaginismus

Sexual counseling and education on anatomy and sexual functioning may be appropriate. The patient can be instructed in self-dilation, using a lubricated finger or test tubes of graduated sizes. Before coitus (with adequate lubrication) is attempted, the patient—and then her partner—should be able to easily and painlessly introduce two fingers into the vagina. Penetration should never be forced, and the woman should always be the one to control the depth of insertion during dilation or intercourse.

C. Remnants of the Hymen

In rare situations, manual dilation of a remaining hymen under general anesthesia is necessary. Surgery should be avoided.

D. Insufficient Lubrication of the Vagina

If inadequate sexual arousal is the cause, sexual counseling is helpful. Lubricants may be used during sexual foreplay. For women with low plasma estrogen levels, use of a lubricant during coitus is sometimes sufficient. If not, systemic hormone replacement therapy (see Menopausal Syndrome, this chapter) or estrogen vaginal cream may be used. An alternative is the estradiol vaginal ring. The ring may be worn continuously and replaced every 3 months. Concomitant progestin therapy is not needed with the ring.

E. Infection, Endometriosis, Tumors, or Other Pathologic Conditions

Medical treatment of acute cervicitis, endometritis, or salpingitis and temporary abstention from coitus usually relieve pain. Hormonal or surgical treatment of endometriosis may be helpful. Dyspareunia resulting from chronic pelvic inflammatory disease or any condition causing extensive adhesions or fixation of pelvic organs is difficult to treat without extirpative surgery. Couples can be advised to try coital positions that limit deep thrusting and to use manual and oral sexual techniques.

F. Vulvodynia

Since the cause of vulvodynia is unknown, management is difficult. Few treatment approaches have been subjected to methodologically rigorous trials. Surgery, usually consisting of vestibulectomy, has reportedly been the most consistently successful approach. A variety of specific (antiviral or antifungal) and nonspecific (corticosteroid or anesthetic) agents have been tried with varying degrees of success. Pain control through behavioral therapy, biofeedback, or acupuncture has also been tried. No single approach has been consistently shown to be effective. Patients with continuous genital burning or pain may benefit from treatment with a tricyclic antidepressant such as amitriptyline in gradually increasing doses from 10 mg/d to 75-100 mg/d.

INFERTILITY

A couple is said to be infertile if pregnancy does not result after 1 year of normal sexual activity without contraceptives. About 25% of couples experience infertility at some point in their reproductive lives; the incidence of infertility increases with age. The male partner contributes to about 40% of cases of infertility, and a combination of factors is common.

Diagnostic Survey

During the initial interview, the clinician can present an overview of infertility and discuss a plan of study. Separate private consultations are then conducted, allowing appraisal of psychosexual adjustment without embarrassment or criticism. Pertinent details (eg, sexually transmitted disease or prior pregnancies) must be obtained. The ill effects of cigarettes, alcohol, and other recreational drugs on male fertility should be discussed. Prescription drugs that impair male potency should be discussed as well. The gynecologic history should include queries regarding the menstrual pattern. The present history includes use and types of contraceptives, douches, libido, sex techniques, frequency and success of coitus, and correlation of intercourse with time of ovulation. Family history includes repeated abortions and maternal DES use.

General physical and genital examinations are performed on both partners. Basic laboratory studies include complete blood count, urinalysis, cervical culture for chlamydia, serologic test for syphilis, rubella antibody determination, and thyroid function tests. Tay-Sachs screening should be offered if both parents are Jews and sickle cell screening if both parents are black.

The patient is instructed to chart her basal body temperature orally daily on arising and to record on a graph episodes of coitus and days of menstruation.

Self-performed urine tests for the midcycle LH surge can be used to enhance temperature observations relating to ovulation. Couples should be advised that coitus resulting in conception occurs during the 6-day period ending with the day of ovulation.

The male partner is instructed to bring a complete ejaculate for analysis. Sexual abstinence for at least 3 days before the semen is obtained is emphasized. A clean, dry, wide-mouthed bottle for collection is preferred. Condoms should not be employed, as the protective powder or lubricant may be spermicidal. Semen should be examined within 1-2 hours after collection. Semen is considered normal with the following minimum values: volume, 1.5-5 mL; concentration, 20 million sperm per milliliter; motility, 60%; and normal forms, 35%. If the sperm count is abnormal, further evaluation includes a search for exposure to environmental and workplace toxins, alcohol or drug abuse, and hypogonadism.

A. First Testing Cycle

While the contribution of cervical factors to infertility is controversial, most gynecologists include a postcoital test in their workup. The test is scheduled for just before ovulation (eg, day 12 or 13 in an expected 28-day cycle). Preovulation timing can be enhanced by serial urinary LH tests. The patient is examined within 6 hours after coitus. The cervical mucus should be clear, elastic, and copious owing to the influence of the preovular estrogen surge. (The mucus is scantier and more viscid before and after ovulation.) A good spinnbarkeit (stretching to a fine thread 4 cm or more in length) is desirable. A small drop of cervical mucus should be obtained from within the cervical os and examined under the microscope. The presence of five or more active sperm per high-power field constitutes a satisfactory postcoital test. If no spermatozoa are found, the test should be repeated (assuming that active spermatozoa were present in the semen analysis). Sperm agglutination and sperm immobilization tests should be considered if the sperm are immotile or show ineffective tail motility.

The presence of more than three white blood cells per high-power field in the postcoital test suggests cervicitis in the woman or prostatitis in the man. When estrogen levels are normal, the cervical mucus dried on the slide will form a fern-like pattern when viewed with a low-power microscope. This type of mucus is necessary for normal sperm transport.

The serum progesterone level should be measured at the midpoint of the secretory phase (21st day); a level of > 3 ng/mL confirms ovulation.

B. Second Testing Cycle

Hysterosalpingography using an oil dye is performed within 3 days following the menstrual period. This x-ray study will demonstrate uterine abnormalities (septa, polyps, submucous myomas) and tubal obstruction. A repeat x-ray film 24 hours later will confirm tubal patency if there is wide pelvic dispersion of the dye. This test has been associated with an increased pregnancy rate by some observers. If the woman has had prior pelvic inflammation, one should give doxycycline, 100 mg twice daily, beginning immediately before and for 7 days after the x-ray study.

C. Further Testing

1. Gross deficiencies of sperm (number, motility, or appearance) require repeat analysis. Zona-free hamster egg penetration tests are available to evaluate the ability of human sperm to fertilize an egg.

2. Obvious obstruction of the uterine tubes requires assessment for microsurgery or in vitro fertilization.

3. Absent or infrequent ovulation requires additional laboratory evaluation. Elevated FSH and LH levels indicate ovarian failure causing premature menopause. Elevated LH levels in the presence of normal FSH levels confirm the presence of polycystic ovaries. Elevation of blood prolactin (PRL) levels suggests pituitary microadenoma.

4. Ultrasound monitoring of folliculogenesis may reveal the occurrence of unruptured luteinized follicles.

5. Endometrial biopsy in the luteal phase associated with simultaneous serum progesterone levels will rule out luteal phase deficiency.

D. Laparoscopy

Approximately 25% of women whose basic evaluation is normal will have findings on laparoscopy explaining their infertility (eg, peritubal adhesions, endometriotic implants).

Treatment

A. Medical Measures

Fertility may be restored by appropriate treatment in many patients with endocrine imbalance, particularly those with hypo- or hyperthyroidism. Antibiotic treatment of cervicitis is of value. In women with abnormal postcoital tests and demonstrated antisperm antibodies causing sperm agglutination or immobilization, condom use for up to 6 months may result in lower antibody levels and improved pregnancy rates.

Women who engage in vigorous athletic training often have low sex hormone levels; fertility improves with reduced exercise and some weight gain.

B. Surgical Measures

Excision of ovarian tumors or ovarian foci of endometriosis can improve fertility. Microsurgical relief of tubal obstruction due to salpingitis or tubal ligation will reestablish fertility in a significant number of cases. In special instances of cornual or fimbrial block, the prognosis with newer surgical techniques has become much better. Peritubal adhesions or endometriotic implants often can be treated via laparoscopy or via laparotomy immediately following laparoscopic examination if prior consent has been obtained.

With varicocele in the male, sperm characteristics are often improved following surgical treatment.

C. Induction of Ovulation

1. Clomiphene citrate—Clomiphene citrate stimulates gonadotropin release, especially LH. Consequently, plasma estrone (E_1) and estradiol (E_2) also rise, reflecting ovarian follicle maturation. If E_2 rises sufficiently, an LH surge occurs to trigger ovulation.

After a normal menstrual period or induction of withdrawal bleeding with progestin, one should give 50 mg of clomiphene orally daily for 5 days. If ovulation does not occur, the dosage is increased to 100 mg orally daily for 5 days. If ovulation still does not occur, the course is repeated with 150 mg daily and then 200 mg daily for 5 days, with the addition of chorionic gonadotropin, 10,000 units intramuscularly, 7 days after clomiphene.

The rate of ovulation following this treatment is 90% in the absence of other infertility factors. The pregnancy rate is high. Twinning occurs in 5% of these patients, and three or more fetuses are found in rare instances (< 0.5% of cases). An increased incidence of congenital anomalies has not been reported. Painful ovarian cyst formation occurs in 8% of patients and may warrant discontinuation of therapy. Several studies have suggested a two- to threefold increased risk of ovarian cancer with the use of clomiphene for more than 1 year.

In the presence of increased androgen production (DHEA-S > 200 ug/dL), the addition of dexamethasone, 0.5 mg, or prednisone, 5 mg, at bedtime, improves the response to clomiphene. Dexamethasone should be discontinued after pregnancy is confirmed.

2. Bromocriptine—Bromocriptine is used only if PRL levels are elevated and there is no withdrawal bleeding following progesterone administration (otherwise, clomiphene is used). To minimize side effects (nausea, diarrhea, dizziness, headache, fatigue), bromocriptine should be taken with meals. The initial dosage is 2.5 mg once daily, increased to two or three times daily in increments of 1.25 mg. The drug is discontinued once pregnancy has occurred.

3. Human menopausal gonadotropins (hMG)—hMG or recombinant FSH is indicated in cases of hypogonadotropism and most other types of anovulation (exclusive of ovarian failure). Because of the complexities, laboratory tests, and expense associated with this treatment, these patients should be referred to a specialist.

4. Gonadotropin-releasing hormone (GnRH)—Hypothalamic amenorrhea unresponsive to clomiphene will be reliably and successfully treated with subcutaneous pulsatile gonadotropin-releasing hormone (GnRH). Use of this substance will avoid the dangerous ovarian complications and the 25% incidence of multiple pregnancy associated with hMG, though the overall rate of ovulation and pregnancy is lower than when hMG is used.

D. Treatment of Endometriosis

See above.

E. Treatment of Inadequate Transport of Sperm

Intrauterine insemination of concentrated washed sperm has been used to bypass a poor cervical environment associated with scant or hostile cervical mucus. The sperm must be handled by sterile methods, washed in sterile saline or tissue culture solutions, and centrifuged. A small amount of fluid (0.5 mL) containing the sperm is then instilled into the uterus.

F. Artificial Insemination in Azoospermia

If azoospermia is present, artificial insemination by a donor usually results in pregnancy, assuming female function is normal. The use of frozen sperm is currently preferable to fresh sperm because the frozen specimen can be held pending cultures and blood test results for sexually transmitted diseases, including HIV infection.

G. Assisted Reproductive Technologies

Couples who have failed to respond to traditional infertility treatments, including those with tubal disease, severe endometriosis, oligospermia, and immunologic or unexplained infertility, may benefit from in vitro fertilization (IVF), gamete intrafallopian transfer (GIFT), and zygote intrafallopian transfer (ZIFT). These techniques are

complex and require a highly organized team of specialists. All of the procedures involve ovarian stimulation to produce multiple oocytes, oocyte retrieval by TVS-guided needle aspiration, and handling of the oocytes outside the body. With IVF, the eggs are fertilized in vitro and the embryos transferred to the uterine fundus. Extra embryos may be cryopreserved for subsequent cycles. The rate of live births per retrieval for 360 programs in the United States and Canada in 1999 was 29%. Age is an important determinant of success—for couples under the age of 35, the average rate of live birth was 32% per retrieval, while the rate for women over 40 was 8%. In 1998, 38% of pregnancies were multiple.

GIFT involves the placement of sperm and eggs in the uterine tube by laparoscopy or minilaparotomy and is more invasive than IVF. In 1990, for all age groups, the success rate for GIFT was 28%. GIFT is not appropriate for women with severe tubal diseases and is less successful than IVF with male factor infertility since fertilization cannot be documented. With ZIFT, fertilization occurs in vitro, and the early development of the embryo occurs in the uterine tube after transfer by laparoscopy or minilaparotomy. The average rate of live births per retrieval in 1999 was 30%.

A recent development is intracytoplasmic sperm injection (ICSI), which allows fertilization with a single sperm. This provides the opportunity for men with severe oligospermia or obstructive azoospermia to father children.

Prognosis

The prognosis for conception and normal pregnancy is good if minor (even multiple) disorders can be identified and treated; it is poor if the causes of infertility are severe, untreatable, or of prolonged duration (over 3 years).

It is important to remember that in the absence of identifiable causes of infertility, 60% of couples will achieve a pregnancy within 3 years. Couples with unexplained infertility who do not achieve pregnancy within 3 years should be offered ovulation induction or assisted reproductive technology. Also, offering appropriately timed information about adoption is considered part of a complete infertility regimen.

CONTRACEPTION

Voluntary control of childbearing benefits women, men, and the children born to them. Contraception should be available to all women and men of reproductive ages. Education about contraception and access to contraceptive pills or devices are especially important for sexually active teenagers and for women following childbirth or abortion.

1. Oral Contraceptives

Combined Oral Contraceptives

A. Efficacy and Methods of Use

Oral contraceptives have a theoretical failure rate of less than 0.5% if taken absolutely on schedule and a typical failure rate of 3%. Their primary mode of action is suppression of ovulation. The pills are initially started on the first or fifth day of the ovarian cycle and taken daily for 21 days, followed by 7 days of placebos or no medication, and this schedule is then continued for each cycle. If a pill is missed at any time, two pills should be taken the next day. A backup method should be used during the first cycle if the pills are started later than the fifth day. Low-dose oral contraceptives are no longer contraindicated in women aged 35-50 who are nonsmokers and have no risk factors for cardiovascular disease.

B. Benefits of Oral Contraceptives

There are many noncontraceptive advantages to oral contraceptives. Menstrual flow is lighter, resultant anemia is less common, and dysmenorrhea is relieved for most women. Functional ovarian cysts generally disappear with oral contraceptive use, and new cysts do not occur. Pain with ovulation and postovulatory aching are relieved. The risk of ovarian and endometrial cancer is decreased. The risks of salpingitis and ectopic pregnancy may be diminished. Acne is usually improved. The frequency of developing myomas is lower in long-term users (> 4 years). There is a beneficial effect on bone mass.

C. Selection of an Oral Contraceptive

Any of the combination oral contraceptives containing 35 ug or less of estrogen are suitable for most women. There is some variation in potency of the various progestins in the pills, but there are essentially no clinically significant differences for most women among the progestins in the low-dose pills. Women who have acne or hirsutism may benefit from use of one of the pills containing the third-generation progestins, desogestrel, drospirenone, or norgestimate, as they are the least androgenic. The low-dose oral contraceptives commonly used in the United States are listed in [Table 17-5](#).

D. Drug Interactions

Several drugs interact with oral contraceptives to decrease their efficacy by causing induction of microsomal enzymes in the liver, by increasing sex hormone-binding globulin, and by other mechanisms. Some commonly prescribed drugs in this category are phenytoin, phenobarbital (and other barbiturates), primidone, carbamazepine, and rifampin. Women taking these drugs should use another means of contraception for maximum safety.

E. Contraindications and Adverse Effects

Oral contraceptives have been associated with many adverse effects; they are contraindicated in some situations and should be used with caution in others ([Table 17-6](#)).

1. Myocardial infarction—The risk of heart attack is higher with use of oral contraceptives, particularly with pills containing 50 ug of estrogen or more. Cigarette smoking, obesity, hypertension, diabetes, or hypercholesterolemia increases the risk. Young nonsmoking women have minimal increased risk. Smokers over age 40 and women with other cardiovascular risk factors should use other methods of birth control.

2. Thromboembolic disease—An increased rate of venous thromboembolism is found in oral contraceptive users, especially if the dose of estrogen is 50 ug or more. While the overall risk is very low (15 per 100,000 woman-years), several studies have reported a twofold increased risk in women using oral contraceptives containing the progestins gestodene (not available in the United States) or desogestrel compared with women using oral contraceptives with levonorgestrel and norethindrone. Women who develop thrombophlebitis should stop using this method, as should those at risk of thrombophlebitis because of surgery, fracture, serious injury, or immobilization.

3. Cerebrovascular disease—Overall, a small increased risk of hemorrhagic stroke and subarachnoid hemorrhage and a somewhat greater increased risk of thrombotic stroke has been found; smoking, hypertension, and age over 35 years are associated with increased risk. Women who develop warning symptoms such as severe headache, blurred or lost vision, or other transient neurologic disorders should stop using oral contraceptives.

4. Carcinoma—A relationship between long-term (3-4 years) oral contraceptive use and occurrence of cervical dysplasia and cancer has been found in various studies. A recent study has shown no increased risk of breast cancer in women aged 35-64 who were current or former users of oral contraceptives. Women with a family history of breast cancer or women who started oral contraceptive use at a young age were not at increased risk. Combination oral contraceptives reduce the risk of endometrial carcinoma by 40% after 2 years of use and 60% after 4 or more years of use. The risk of ovarian cancer is reduced by 30% with pill use for less than 4 years, by 60% with use for 5-11 years, and by 80% after 12 or more years. Rarely, oral contraceptives have been associated with the development of benign or malignant hepatic tumors; this may lead to rupture of the liver, hemorrhage, and death. The risk increases with higher dosage, longer duration of use, and older age.

5. Metabolic disorders—A decrease in glucose tolerance and an increase in triglyceride levels is seen in pill takers, and women with diabetes using this method should be carefully monitored.

6. Hypertension—Oral contraceptives may cause hypertension in some women; the risk is increased with longer duration of use and older age. Women who develop hypertension while using oral contraceptives should use other contraceptive methods. However, with regular blood pressure monitoring, nonsmoking women under the age of 40 with well-controlled mild hypertension may use oral contraceptives.

7. Headache—Migraine or other vascular headaches may occur or worsen with pill use. If severe or frequent headaches develop while using this method, it should be discontinued.

8. Amenorrhea—Postpill amenorrhea lasting a year or longer occurs occasionally, sometimes with galactorrhea. Prolactin levels should be checked; if elevated, a pituitary prolactinoma may be present.

9. Disorders of lactation—Combined oral contraceptives can impair the quantity and quality of breast milk. While it is preferable to avoid the use of combination oral contraceptives during lactation, the effects on milk quality are small and are not associated with developmental abnormalities in infants. Combination oral contraceptives should be started no earlier than 6 weeks postpartum to allow for establishment of lactation. Progestin-only pills, levonorgestrel implants, and depot medroxyprogesterone acetate are alternatives with no adverse effects on milk quality.

10. Other disorders—Depression may occur or be worsened with oral contraceptive use. Fluid retention may occur. Patients who had cholestatic jaundice during pregnancy may develop it while taking birth control pills.

F. Minor Side Effects

Nausea and dizziness may occur in the first few months of pill use. A weight gain of 2-5 lb commonly occurs. Spotting or breakthrough bleeding between menstrual periods may occur, especially if a pill is skipped or taken late; this may be helped by switching to a pill of slightly greater potency (see section C, above). Missed menstrual periods may occur, especially with low-dose pills. A pregnancy test should be performed if pills have been skipped or if two or more menstrual periods are missed. Depression, fatigue, and decreased libido can occur. Chloasma may occur, as in pregnancy, and is increased by exposure to sunlight.

Progestin Minipill

A. Efficacy and Methods of Use

Formulations containing 0.35 mg of norethindrone or 0.075 mg of norgestrel are available in the United States. Their efficacy is slightly lower than that of combined oral contraceptives, with failure rates of 1-4% being reported. The minipill is believed to prevent conception by causing thickening of the cervical mucus to make it hostile to sperm, alteration of ovum transport (which may account for the higher rate of ectopic pregnancy with these pills), and inhibition of implantation. Ovulation is inhibited inconsistently with this method. The minipill is begun on the first day of a menstrual cycle and then taken continuously for as long as contraception is desired.

B. Advantages

The low dose and absence of estrogen make the minipill safe during lactation; it may increase the flow of milk. It is often tried by women who want minimal doses of hormones and by patients who are over age 35. The minipill can be used by women with uterine myomas or sickle cell disease (S/S or S/C). Like the combined pill, the minipill decreases the likelihood of pelvic inflammatory disease by its effect on cervical mucus.

C. Complications and Contraindications

Minipill users often have bleeding irregularities (eg, prolonged flow, spotting, or amenorrhea); such patients may need monthly pregnancy tests. Ectopic pregnancies are more frequent, and complaints of abdominal pain should be investigated with this in mind. The absolute contraindications and many of the relative contraindications listed in [Table 17-6](#) apply to the minipill. Exceptions are mentioned in section E, above. Minor side effects of combination oral contraceptives such as weight gain and mild headache may also occur with the minipill.

2. Contraceptive Injections & Implants (Long-Acting Progestins)

The injectable progestin medroxyprogesterone acetate is approved for contraceptive use in the United States. There is extensive worldwide experience with this method over the past 3 decades. The medication is given as a deep intramuscular injection of 150 mg every 3 months and has a contraceptive efficacy of 99.7%. Common side effects include irregular bleeding, amenorrhea, weight gain, and headache. Bone mineral loss may occur. Users commonly have irregular bleeding initially and subsequently develop amenorrhea. Ovulation may be delayed after the last injection. Contraindications are similar to those for the minipill.

A monthly injectable containing both depot medroxyprogesterone acetate and an estrogen, estradiol cypionate (Lunelle), is available in the United States. It is highly effective, with a first-year pregnancy rate of 0.2% and a side-effect profile similar to that of oral contraceptives.

The other long-acting progestin contraceptive is the Norplant system, a contraceptive implant containing levonorgestrel. The system consists of six small Silastic capsules that are inserted subcutaneously in the inner aspect of the upper arm. They release daily and provide highly effective contraception for 5 years. In the first year of use, Norplant is 99.8% effective. Contraceptive effectiveness drops slightly in succeeding years, but even in the fifth year it is more effective than the combination pill. The most common side effects include irregular bleeding and spotting, amenorrhea, headache, acne, and weight gain. Irregular bleeding is the most common reason for discontinuation. Hormone levels drop rapidly after removal of the implants, and there is no delay in the return of fertility. Contraindications are similar to those for the minipill. Insertion of the implants requires a minor surgical procedure under local anesthesia. Removal is also done under local anesthesia and may be more difficult than insertion. Removal may be facilitated by the "U" technique, involving use of a modified vasectomy clamp through a 4-mm incision parallel to the implants between implants three and four.

Kovalevsky G et al: Norplant and other implantable contraceptives. Clin Obstet Gynecol 2001;44:92. [\[PMID: 11219249\]](#)

3. Other Hormonal Methods

A transdermal contraceptive patch containing 150 ug norelgestromin and 20 ug ethinyl estradiol and measuring 20 cm² is available. The patch is applied to the lower abdomen, upper torso, or buttock once a week for 3 consecutive weeks, followed by 1 week without the patch. The mechanism of action, side effects, and efficacy are similar to those associated with oral contraceptives, though compliance may be better.

A contraceptive vaginal ring that measures 54 mm in diameter and releases 120 ug of etonogestrel and 15 ug of ethinyl estradiol daily is available. The ring is soft and flexible and is placed in the upper vagina for 3 weeks, removed, and replaced 1 week later. The efficacy, mechanism of action, and systemic side effects are similar to those associated with oral contraceptives. In addition, users may experience an increased incidence of vaginal discharge.

4. Intrauterine Devices (IUDs)

IUDs available in the United States include the Mirena (which releases levonorgestrel) and the copper-bearing TCu380A. The mechanism of action of IUDs is thought to involve either spermicidal or inhibitory effects on sperm capacitation and transport. IUDs are not abortifacients.

The Mirena is effective for 5 years and the TCu380A for 10 years. The hormone-containing IUDs have the advantage of reducing cramping and menstrual flow.

The IUD is an excellent contraceptive method for most women. The devices are highly effective, with failure rates similar to those achieved with surgical sterilization. Nulliparity is not a contraindication to IUD use. Women who are not in mutually monogamous relationships should use condoms for protection from STDs. The Mirena may have a protective effect against upper tract infection similar to that of the oral contraceptives.

Insertion

Insertion can be performed during or after the menses, at midcycle to prevent implantation, or later in the cycle if the patient has not become pregnant. Most clinicians wait for 6-8 weeks postpartum before inserting an IUD. When insertion is performed during lactation, there is greater risk of uterine perforation or embedding of the IUD. Insertion immediately following abortion is acceptable if there is no sepsis and if follow-up insertion a month later will not be possible; otherwise, it is wise to wait until 4 weeks postabortion.

Contraindications & Complications

Contraindications to use of IUDs are outlined in [Table 17-7](#).

A. Pregnancy

A copper-containing IUD can be inserted within 5 days following a single episode of unprotected mid-cycle coitus as a postcoital contraceptive. An IUD should not be

inserted into a pregnant uterus. If pregnancy occurs as an IUD failure, there is a greater chance of spontaneous abortion if the IUD is left in situ (50%) than if it is removed (25%). Spontaneous abortion with an IUD in place is associated with a high risk of severe sepsis, and death can occur rapidly. Women using an IUD who become pregnant should have the IUD removed if the string is visible. It can be removed at the time of abortion if this is desired. If the string is not visible and the patient wants to continue the pregnancy, she should be informed of the serious risk of sepsis and, occasionally, death with such pregnancies. She should be informed that any flu-like symptoms such as fever, myalgia, headache, or nausea warrant immediate medical attention for possible septic abortion.

Since the ratio of ectopic to intrauterine pregnancies is increased among IUD wearers, clinicians should search for adnexal masses in early pregnancy and should always check the products of conception for placental tissue following abortion.

B. Pelvic Infection

There is an increased risk of pelvic infection during the first month following insertion. The subsequent risk of pelvic infection appears to be primarily related to the risk of acquiring sexually transmitted infections. Infertility rates do not appear to be increased among women who have previously used the currently available IUDs. At the time of insertion, women with an increased risk of STDs should be screened for gonorrhea and chlamydia. Women with a history of recent or recurrent pelvic infection are not good candidates for IUD use.

C. Menorrhagia or Severe Dysmenorrhea

The copper IUD can cause heavier menstrual periods, bleeding between periods, and more cramping, so it is generally not suitable for women who already suffer from these problems. However, hormone-releasing IUDs can be tried in these cases, as they often cause decreased bleeding and cramping with menses. Nonsteroidal anti-inflammatory drugs are also helpful in decreasing bleeding and pain in IUD users.

D. Complete or Partial Expulsion

Spontaneous expulsion of the IUD occurs in 10-20% of cases during the first year of use. Any IUD should be removed if the body of the device can be seen or felt in the cervical os.

E. Missing IUD Strings

If the transcervical tail cannot be seen, this may signify unnoticed expulsion, perforation of the uterus with abdominal migration of the IUD, or simply retraction of the string into the cervical canal or uterus owing to movement of the IUD or uterine growth with pregnancy. Once pregnancy is ruled out, one should probe for the IUD with a sterile sound or forceps designed for IUD removal, after administering a paracervical block. If the IUD cannot be detected, pelvic ultrasound will demonstrate the IUD if it is in the uterus. Alternatively, obtain anteroposterior and lateral x-rays of the pelvis with another IUD or a sound in the uterus as a marker, to confirm an extrauterine IUD. If the IUD is in the abdominal cavity, it should generally be removed by laparoscopy or laparotomy. Open-looped all-plastic IUDs such as the Lippes Loop can be left in the pelvis without danger, but ring-shaped IUDs may strangulate a loop of bowel and copper-bearing IUDs may cause tissue reaction and adhesions.

Perforations of the uterus are less likely if insertion is performed slowly, with meticulous care taken to follow directions applicable to each type of IUD.

Grimes DA: Intrauterine device and upper-genital-tract infection. Lancet 2000;356:1013. [\[PMID: 11041414\]](#)

5. Diaphragm & Cervical Cap

The diaphragm (with contraceptive jelly) is a safe and effective contraceptive method with features that make it acceptable to some women and not others. Failure rates range from 2% to 20%, depending on the motivation of the woman and the care with which the diaphragm is used. The advantages of this method are that it has no systemic side effects and gives significant protection against pelvic infection and cervical dysplasia as well as pregnancy. The disadvantages are that it must be inserted near the time of coitus and that pressure from the rim predisposes some women to cystitis after intercourse.

The cervical cap (with contraceptive jelly) is similar to the diaphragm but fits snugly over the cervix only (the diaphragm stretches from behind the cervix to behind the pubic symphysis). The cervical cap is more difficult to insert and remove than the diaphragm. The main advantages are that it can be used by women who cannot be fitted for a diaphragm because of a relaxed anterior vaginal wall or by women who have discomfort or develop repeated bladder infections with the diaphragm.

Because of the small risk of toxic shock syndrome, a cervical cap or diaphragm should not be left in the vagina for over 12-18 hours, nor should these devices be used during the menstrual period (see above).

6. Contraceptive Foam, Cream, Film, Sponge, Jelly, & Suppository

These products are available without prescription, are easy to use, and are fairly effective, with reported failure rates of 2-30%. All contain the spermicide nonoxynol-9, which also has some virucidal and bactericidal activity. Nonoxynol-9 does not appear to adversely affect the vaginal colonization of hydrogen peroxide-producing lactobacilli. Recent data suggest that nonoxynol-9 may not be protective against HIV infection, particularly in women who have frequent intercourse. The products have the advantages of being simple to use and easily available. Their disadvantage is a slightly higher failure rate than the diaphragm or condom.

Van Damme L et al: Effectiveness of COL-1492, a nonoxynol-9 vaginal gel, on HIV-1 transmission in female sex workers: a randomised controlled trial. Lancet 2002;360:971. [\[PMID: 12383665\]](#)

7. Condom

The male sheath of latex or animal membrane affords good protection against pregnancy—equivalent to that of a diaphragm and spermicidal jelly; latex (but not animal membrane) condoms also offer protection against sexually transmitted disease and cervical dysplasia. Men and women seeking protection against HIV transmission are advised to use a latex condom along with spermicide during vaginal or rectal intercourse. When a spermicide such as vaginal foam is used with the condom, the failure rate approaches that of oral contraceptives. Condoms coated with spermicide are available in the United States. The disadvantages of condoms are dulling of sensation and spillage of semen due to tearing, slipping, or leakage with detumescence of the penis.

A female condom made of polyurethane is available in the United States. The reported failure rates range from 5% to 21%; the efficacy is comparable to that of the diaphragm. This is the only female-controlled method that offers significant protection from both pregnancy and sexually transmitted diseases.

Rosen AD et al: Study of condom integrity after brief exposure to over-the-counter vaginal preparations. South Med J 1999;92:305. [\[PMID: 10094272\]](#)

8. Contraception Based on Awareness of Fertile Periods

There is renewed interest in methods to identify times of ovulation and avoidance of unprotected intercourse at that time as a means of family planning. These methods are most effective when the couple restricts intercourse to the postovular phase of the cycle or uses a barrier method at other times. Women benefit from learning to identify their fertile periods. Well-instructed, motivated couples may achieve low pregnancy rates with fertility awareness, but in many field trials, the pregnancy rates were as high as 20%.

"Symptothermal" Natural Family Planning

The basis for this approach is patient-observed increase in clear elastic cervical mucus, brief abdominal midcycle discomfort ("mittelschmerz"), and a sustained rise of the basal body temperature about 2 weeks after onset of menstruation. Unprotected intercourse is avoided from shortly after the menstrual period, when fertile mucus is first identified, until 48 hours after ovulation, as identified by a sustained rise in temperature and the disappearance of clear elastic mucus.

Calendar Method

After the length of the menstrual cycle has been observed for at least 8 months, the following calculations are made: (1) The first fertile day is determined by subtracting 18 days from the shortest cycle, and (2) the last fertile day is determined by subtracting 11 days from the longest cycle. For example, if the observed cycles run from 24 to 28 days, the fertile period would extend from the sixth day of the cycle (24 minus 18) through the 17th day (28 minus 11). Day 1 of the cycle is the first day of menses.

Basal Body Temperature Method

This method indicates the safe time for intercourse after ovulation has passed. The temperature must be taken immediately upon awakening, before any activity. A slight drop in temperature often occurs 12-24 hours before ovulation, and a rise of about 0.4°C occurs 1-2 days after ovulation. The elevated temperature continues throughout the remainder of the cycle. Data suggest that the risk of pregnancy increases starting 5 days prior to the day of ovulation, peaks on the day of ovulation, and then rapidly decreases to zero by the day after ovulation.

This fertility awareness method requires the use of a set of beads that reminds the couple to avoid intercourse (or use a barrier method of contraception) during days 8 through 19 of the menstrual cycle. The beads are in a circle and color-coded to show the days when a woman is likely to become pregnant and the days that are "safe" during the cycle. A movable ring is repositioned to a new bead each day starting on the first day of menses. In a small multicenter trial, the perfect use failure rate was 5% and the typical use failure rate was 12%. The method is applicable to women with a history of menstrual cycles between 29 and 32 days.

Arevalo M et al: Efficacy of a new method of family planning: the Standard Days Method. *Contraception* 2002;65:333. [\[PMID: 12057784\]](#)

Wilcox AJ et al: The timing of the "fertile window" in the menstrual cycle: day specific estimates from a prospective study. *BMJ* 2000;321:1259. [\[PMID: 11082086\]](#)

9. Emergency Contraception

If unprotected intercourse occurs in midcycle and the woman is certain she has not inadvertently become pregnant earlier in the cycle, the following regimens are effective in preventing implantation. These methods should be started within 72 hours after unprotected coitus. (1) Levonorgestrel, 0.75 mg given in two doses 12 hours apart (available in the United States prepackaged as Plan B), has a 1% failure rate and is associated with less nausea and vomiting than the following combination regimen. A recent study has demonstrated that levonorgestrel, 1.5 mg as a single dose, given within 72 hours after intercourse, is slightly more effective than the two-dose regimen. It remains efficacious up to 120 hours after intercourse, though less so compared with earlier use. (2) Ethinyl estradiol, 50 ug, with 0.5 mg norgestrel (available in the United States prepackaged as Preven), given in a regimen of two tablets initially followed by two tablets 12 hours later. A comparable regimen includes four pills 12 hours apart of Lo/Ovral, Nordette, or Levlen, or the same regimen with the yellow pills of Triphasil or Tri-Levlen. The failure rate is approximately 3%, and anti-nausea medication should be provided. (3) Ethinyl estradiol, 2.5 mg twice daily for 5 days. This regimen is as efficacious as the others but is associated with a higher likelihood of nausea, vomiting, and breast tenderness. Mifepristone, 10 mg as a single dose, has been shown to have the same failure rate as the levonorgestrel regimen. It is not currently available at this dose in the United States.

IUD insertion within 5 days after one episode of unprotected midcycle coitus will also prevent pregnancy; copper-bearing IUDs have been tested for this purpose. The disadvantage of this method is possible infection, especially in rape cases; the advantage is ongoing contraceptive protection if this is desired in a patient for whom the IUD is a suitable choice.

Information on clinics or individual clinicians providing emergency contraception in the United States may be obtained by calling 1-888-668-2528.

von Hertzen H et al: Low dose mifepristone and two regimens of levonorgestrel for emergency contraception: a WHO multicentre randomized trial. *Lancet* 2002;360:1803. [\[PMID: 12480356\]](#)

10. Abortion

Since the legalization of abortion in the United States in 1973, the related maternal mortality rate has fallen markedly, because illegal and self-induced abortions have been replaced by safer medical procedures. Abortions in the first trimester of pregnancy are performed by vacuum aspiration under local anesthesia. A similar technique, dilation and evacuation, is often used in the second trimester, with general or local anesthesia. Techniques utilizing intra-amniotic instillation of hypertonic saline solution or prostaglandins are also occasionally used after 18 weeks from the LMP but are more difficult for the patient. Abortions are rarely performed after 20 weeks from the LMP. It is currently believed that fetal viability is established at about 24 weeks. Legal abortion has a mortality rate of 1:100,000. Rates of morbidity and mortality rise with length of gestation. Currently in the United States, 90% of abortions are performed before 12 weeks' gestation and only 3-4% after 17 weeks. If abortion is chosen, every effort should be made to encourage the patient to seek an early procedure.

Complications resulting from abortion include retained products of conception (often associated with infection and heavy bleeding) and unrecognized ectopic pregnancy. Immediate analysis of the removed tissue for placenta can exclude or corroborate the diagnosis of ectopic pregnancy. Women presenting with fever, bleeding, or abdominal pain after abortion should be examined; use of broad-spectrum antibiotics and reaspiration of the uterus are frequently necessary. Hospitalization is advisable if acute salpingitis requires intravenous administration of antibiotics. Complications following illegal abortion often need emergency care for hemorrhage, septic shock, or uterine perforation.

Rh immune globulin should be given to all Rh-negative women following abortion. Contraception should be thoroughly discussed and contraceptive supplies or pills provided at the time of abortion. In women with a past history of pelvic inflammatory disease, prophylactic antibiotics are indicated: A one-dose regimen is doxycycline, 200 mg orally 1 hour before the procedure, or aqueous penicillin G, 1 million units intravenously 30 minutes before. In the second trimester, use cefazolin, 1 g intravenously 30 minutes before the procedure. Many clinics prescribe tetracycline, 500 mg four times daily for 5 days after the procedure, for all patients.

Long-term sequelae of repeated induced abortions have been studied, but as yet there is no consensus on whether there are increased rates of fetal loss or premature labor. It is felt that such adverse sequelae can be minimized by performing early abortion with minimal cervical dilation or by the use of osmotic dilators to induce gradual cervical dilation. One population-based study showed no evidence of an increased risk of breast cancer in women who had undergone an induced abortion.

An FDA-approved oral abortifacient, mifepristone (RU 486), 200 mg as a single dose followed in 36-48 hours by a prostaglandin vaginally or orally, is 95% successful in terminating pregnancies of up to 9 weeks' duration with minimum complications. The drug acts as an antihormone to progesterone and glucocorticoids without producing adrenal insufficiency. Although not approved by the FDA for this indication, a combination of intramuscular methotrexate, 50 mg/m² of body surface area, followed 7 days later by vaginal misoprostol, 800 ug, was 98% successful in terminating pregnancy at 8 weeks or less. Minor side effects such as nausea, vomiting, and diarrhea are common with these regimens. There is a 5-10% incidence of hemorrhage or incomplete abortion requiring curettage, but there are no known long-term complications.

Newhall EP et al: Abortion with mifepristone and misoprostol: regimens, efficacy, acceptability and future directions. *Am J Obstet Gynecol* 2000;183:S44. [\[PMID: 10944369\]](#)

11. Sterilization

In the United States, sterilization is the most popular method of birth control for couples who want no more children. Although sterilization is reversible in some instances, reversal surgery in both men and women is costly, complicated, and not always successful. Therefore, patients should be counseled carefully before sterilization and should view the procedure as final.

Vasectomy is a safe, simple procedure in which the vas deferens is severed and sealed through a scrotal incision under local anesthesia. Long-term follow-up studies on vasectomized men show no excess risk of cardiovascular disease. Several studies have shown a possible association with prostate cancer, but the evidence is weak and inconsistent.

Female sterilization is currently performed via laparoscopic bipolar electrocoagulation or plastic ring application on the uterine tubes or via minilaparotomy with Pomeroy tubal resection. The advantages of laparoscopy are minimal postoperative pain, small incisions, and rapid recovery. The advantages of minilaparotomy are that it can be performed with standard surgical instruments under local or general anesthesia. However, there is more postoperative pain and a longer recovery period. The cumulative 10-year failure rate for all methods combined is 1.85%, varying from 0.75% for postpartum partial salpingectomy and laparoscopic unipolar coagulation to 3.65% for spring clips; this fact should be discussed with women preoperatively. Some studies have found an increased risk of menstrual irregularities as a long-term complication of tubal ligation, but findings in different studies have been inconsistent. A new method of transcervical sterilization, Essure, has recently been approved by the FDA. The method involves the placement of an expanding microcoil of titanium into the proximal uterine tube under hysteroscopic guidance. The efficacy rate at 1 year is 99.8%.

Kerin JF et al: The safety and effectiveness of a new hysteroscopic method for permanent birth control: results of the first Essure pbc clinical study. *Aust N Z J Obstet Gynaecol* 2001;41:364. [\[PMID: 11787907\]](#)

RAPE

Rape, or sexual assault, is legally defined in different ways in various jurisdictions. Clinicians and emergency room personnel who deal with rape victims should be familiar with the laws pertaining to sexual assault in their own state. From a medical and psychologic viewpoint, it is essential that persons treating rape victims recognize the nonconsensual and violent nature of the crime. About 95% of reported rape victims are women. Penetration may be vaginal, anal, or oral and may be by the penis, hand, or a foreign object. The absence of genital injury does not imply consent by the victim. The assailant may be unknown to the victim or, more frequently, may be an acquaintance or even the spouse.

"Unlawful sexual intercourse," or statutory rape, is intercourse with a female before the age of majority even with her consent.

Rape represents an expression of anger, power, and sexuality on the part of the rapist. The rapist is usually a hostile man who uses sexual intercourse to terrorize and humiliate a woman. Women neither secretly want to be raped nor do they expect, encourage, or enjoy rape.

Rape involves severe physical injury in 5-10% of cases and is always a terrifying experience in which most victims fear for their lives. Consequently, all victims suffer some psychologic aftermath. Moreover, some rape victims may acquire sexually transmissible disease or become pregnant.

Because rape is a personal crisis, each patient will react differently. The rape trauma syndrome comprises two principal phases. (1) Immediate or acute: Shaking, sobbing, and restless activity may last from a few days to a few weeks. The patient may experience anger, guilt, or shame or may repress these emotions. Reactions vary depending on the victim's personality and the circumstances of the attack. (2) Late or chronic: Problems related to the attack may develop weeks or months later. The lifestyle and work patterns of the individual may change. Sleep disorders or phobias often develop. Loss of self-esteem can rarely lead to suicide.

Clinicians and emergency room personnel who deal with rape victims should work with community rape crisis centers whenever possible to provide ongoing support and counseling.

General Office Procedures

The clinician who first sees the alleged rape victim should be empathetic. Begin with a statement such as, "This is a terrible thing that has happened to you. I want to help."

1. Secure written consent from the patient, guardian, or next of kin for gynecologic examination, and for photographs if they are likely to be useful as evidence. If police are to be notified, do so, and obtain advice on the preservation and transfer of evidence.
2. Obtain and record the history in the patient's own words. The sequence of events, ie, the time, place, and circumstances, must be included. Note the date of the LMP, whether or not the woman is pregnant, and the time of the most recent coitus prior to the sexual assault. Note the details of the assault such as body cavities penetrated, use of foreign objects, and number of assailants. Note whether the victim is calm, agitated, or confused (drugs or alcohol may be involved). Record whether the patient came directly to the hospital or whether she bathed or changed her clothing. Record findings but do not issue even a tentative diagnosis lest it be erroneous or incomplete.
3. Have the patient disrobe while standing on a white sheet. Hair, dirt, and leaves; underclothing; and any torn or stained clothing should be kept as evidence. Scrape material from beneath fingernails and comb pubic hair for evidence. Place all evidence in separate clean paper bags or envelopes and label carefully.
4. Examine the patient, noting any traumatized areas that should be photographed. Examine the body and genitals with a Wood light to identify semen, which fluoresces; positive areas should be swabbed with a premoistened swab and air-dried in order to identify acid phosphatase. Colposcopy can be used to identify small areas of trauma from forced entry especially at the posterior fourchette.
5. Perform a pelvic examination, explaining all procedures and obtaining the patient's consent before proceeding gently with the examination. Use a narrow speculum lubricated with water only. Collect material with sterile cotton swabs from the vaginal walls and cervix and make two air-dried smears on clean glass slides. Wet and dry swabs of vaginal secretions should be collected and refrigerated for subsequent acid phosphatase and DNA evaluation. Swab the mouth (around molars and cheeks) and anus in the same way, if appropriate. Label all slides carefully. Collect secretions from the vagina, anus, or mouth with a premoistened cotton swab, place at once on a slide with a drop of saline, and cover with a coverslip. Look for motile or nonmotile sperm under high, dry magnification, and record the percentage of motile forms.
6. Perform appropriate laboratory tests as follows. Culture the vagina, anus, or mouth (as appropriate) for *N gonorrhoeae* and chlamydia. Perform a Papanicolaou smear of the cervix, a wet mount for *T vaginalis*, a baseline pregnancy test, and VDRL test. A confidential test for HIV antibody can be obtained if desired by the patient and repeated in 2-4 months if initially negative. Repeat the pregnancy test if the next menses is missed, and repeat the VDRL test in 6 weeks. Obtain blood (10 mL without anticoagulant) and urine (100 mL) specimens if there is a history of forced ingestion or injection of drugs or alcohol.
7. Transfer clearly labeled evidence, eg, laboratory specimens, directly to the clinical pathologist in charge or to the responsible laboratory technician, in the presence of witnesses (never via messenger), so that the rules of evidence will not be breached.

Treatment

Give analgesics or sedatives if indicated. Administer tetanus toxoid if deep lacerations contain soil or dirt particles.

Give ceftriaxone, 125 mg intramuscularly, to prevent gonorrhea. In addition, give metronidazole, 2 g as a single dose, and doxycycline, 100 mg twice daily for 7 days to treat chlamydial infection. Incubating syphilis will probably be prevented by these medications, but the VDRL test should be repeated 6 weeks after the assault.

Prevent pregnancy by using one of the methods discussed under Postcoital Contraception, if necessary (this chapter).

Vaccinate against hepatitis B. Consider HIV prophylaxis (see [Chapter 31](#)).

Make sure the patient and her family and friends have a source of ongoing psychologic support.

MENOPAUSAL SYNDROME

Essentials of Diagnosis

- Cessation of menses due to aging or to bilateral oophorectomy.
- Elevation of FSH and LH levels.
- Hot flushes and night sweats (in 80% of women).
- Decreased vaginal lubrication; thinned vaginal mucosa with or without dyspareunia.

General Considerations

The term "menopause" denotes the final cessation of menstruation, either as a normal part of aging or as the result of surgical removal of both ovaries. In a broader sense, as the term is commonly used, it denotes a 1- to 3-year period during which a woman adjusts to a diminishing and then absent menstrual flow and the physiologic changes that may be associated—hot flushes, night sweats, and vaginal dryness.

The average age at menopause in Western societies today is 51 years. Premature menopause is defined as ovarian failure and menstrual cessation before age 40; this often has a genetic or autoimmune basis. Surgical menopause due to bilateral oophorectomy is common and can cause more severe symptoms owing to the sudden rapid drop in sex hormone levels.

There is no objective evidence that cessation of ovarian function is associated with severe emotional disturbance or personality changes. However, mood changes toward depression and anxiety can occur at this time. Furthermore, the time of menopause often coincides with other major life changes, such as departure of children from the home, a midlife identity crisis, or divorce. These events, coupled with a sense of the loss of youth, may exacerbate the symptoms of menopause and cause psychologic distress.

Clinical Findings

A. Symptoms and Signs

1. Cessation of menstruation—Menstrual cycles generally become irregular as menopause approaches. Anovular cycles occur more often, with irregular cycle length and occasional menorrhagia. Menstrual flow usually diminishes in amount owing to decreased estrogen secretion, resulting in less abundant endometrial growth. Finally, cycles become longer, with missed periods or episodes of spotting only. When no bleeding has occurred for 1 year, the menopausal transition can be said to have occurred. Any bleeding after this time warrants investigation by endometrial curettage or aspiration to rule out endometrial cancer.

- 2. Hot flushes**—Hot flushes (feelings of intense heat over the trunk and face, with flushing of the skin and sweating) occur in 80% of women as a result of the decrease in ovarian hormones. Hot flushes can begin before the cessation of menses. An increase in pulsatile release of gonadotropin-releasing hormone from the hypothalamus is believed to trigger the hot flushes by affecting the adjacent temperature-regulating area of the brain. Hot flushes are more severe in women who undergo surgical menopause. Flushing is more pronounced late in the day, during hot weather, after ingestion of hot foods or drinks, or during periods of tension. Occurring at night, they often cause sweating and insomnia and result in fatigue on the following day.
- 3. Vaginal atrophy**—With decreased estrogen secretion, thinning of the vaginal mucosa and decreased vaginal lubrication occur and may lead to dyspareunia. The introitus decreases in diameter. Pelvic examination reveals pale, smooth vaginal mucosa and a small cervix and uterus. The ovaries are not normally palpable after the menopause. Continued sexual activity will help prevent tissue shrinkage.
- 4. Osteoporosis**—Osteoporosis may occur as a late sequela of menopause.

B. Laboratory Findings

Serum FSH and LH levels are elevated. Vaginal cytologic examination will show a low estrogen effect with predominantly parabasal cells, indicating lack of epithelial maturation due to hypoestrinism.

Treatment

A. Natural Menopause

Education and support from health providers, midlife discussion groups, and reading material will help most women having difficulty adjusting to the menopause. Physiologic symptoms can be treated as follows.

- 1. Vasomotor symptoms**—Oral conjugated estrogens, 0.3 mg or 0.625 mg, estradiol, 0.5 or 1 mg; or estrone sulfate, 0.625 mg, or estradiol can be given transdermally as skin patches that are changed once or twice weekly and secrete 0.05-0.1 mg of hormone daily. When either form of estrogen is used, add a progestin (medroxyprogesterone acetate) to prevent endometrial hyperplasia or cancer. The hormones can be given in several differing regimens. Give estrogen on days 1-25 of each calendar month, with 5-10 mg of medroxyprogesterone acetate added on days 14-25. Withhold hormones from day 26 until the end of the month, when the endometrium will be shed, producing a light, generally painless monthly period. Alternatively, give the estrogen along with 2.5 mg of medroxyprogesterone acetate daily, without stopping. This regimen causes some initial bleeding or spotting, but within a few months it produces an atrophic endometrium that will not bleed. If the patient has had a hysterectomy, a progestin need not be used. Explain to the patient that hot flushes will probably return if the hormone is discontinued.

Recent data from the Women's Health Initiative study suggest that women should not use combination progestin-estrogen therapy for more than 3 or 4 years. In this study, the increased risk of cardiovascular disease, cerebrovascular disease, and breast cancer with this regimen outweighed the benefits. Women who cannot find relief with alternative approaches may wish to consider continuing use of combination therapy after a thorough discussion of the risks and benefits. Alternatives to hormone therapy for vasomotor symptoms include selective serotonin reuptake inhibitors such as paroxetine or fluoxetine, 20 mg daily.

Clonidine given orally or transdermally, 100-150 ug daily, may also reduce the frequency of hot flushes, but its use is limited by side effects, including dry mouth, drowsiness, and hypotension.

- 2. Vaginal atrophy**—This problem can be treated with hormone therapy as outlined above. Alternatively, an estradiol vaginal ring that can be left in place for 3 months and is suitable for long-term use provides effective relief of vaginal atrophy. There is minimal systemic absorption of estradiol with the ring, and progestin therapy to protect the endometrium is unnecessary. Short-term use of estrogen vaginal cream will relieve symptoms of atrophy, but because of variable absorption, therapy with either systemic hormone replacement or the vaginal ring is preferable. Testosterone propionate 1-2%, 0.5-1 g, in a vanishing cream base used in the same manner is also effective if estrogen is contraindicated. A bland lubricant such as unscented cold cream or water-soluble gel can be helpful at the time of coitus.
- 3. Osteoporosis**—(See also discussion in [Chapter 26](#).) Women should ingest at least 800 mg of calcium daily throughout life. Nonfat or low-fat milk products, calcium-fortified orange juice, green leafy vegetables, corn tortillas, and canned sardines or salmon consumed with the bones are good dietary sources. In addition, 1 g of elemental calcium should be taken as a daily supplement at the time of the menopause and thereafter; calcium supplements should be taken with meals to increase their absorption. Vitamin D, 400 units/d from food, sunlight, or supplements, is necessary to enhance calcium absorption. A daily program of energetic walking and exercise to strengthen the arms and upper body helps maintain bone mass.

Women most at risk for osteoporotic fractures should consider bisphosphonates, raloxifene, or hormone replacement therapy. This includes Caucasian and Asian women, especially if they have a family history of osteoporosis; are thin, short, cigarette smokers, and physically inactive; or have had a low calcium intake in adult life.

B. Advantages and Risks of Hormone Therapy

A number of observational studies have demonstrated a 35-50% decrease in the primary risk of cardiovascular disease with estrogen therapy and menopause. However, double-blinded randomized, controlled trials have shown no overall cardiovascular benefit with estrogen-progestin replacement therapy in a group of postmenopausal women with or without established coronary disease. Both in the Women's Health Initiative trial and the Heart and Estrogen/Progestin Replacement Study (HERS), the overall health risks (increased risk of coronary heart events, strokes, thromboembolic disease, breast cancers, gallstones) exceeded the benefits from the use of combination estrogen and progesterone. The trial of unopposed estrogen use in the Women's Health Initiative study is ongoing. Progestins counteract some but not all favorable effects of estrogen. Whether women who have been on long-term estrogen-progestin hormone replacement therapy (HRT) without complications should stop is unclear, but it seems prudent to do so, especially if they do not have menopausal symptoms. Definitive evidence of beneficial effects of HRT on cognitive function is lacking. Several studies have shown an increased risk of breast cancer in women taking estrogen-progestin therapy, while estrogen alone did not increase the risk. Endometrial cancer can occur if adequate progestin is not used. Estrogen may cause the growth of uterine myomas, which otherwise shrink after the menopause. (See also discussions of estrogen and progestin replacement therapy in [Chapter 26](#).)

C. Surgical Menopause

The abrupt hormonal decrease resulting from oophorectomy generally results in severe vasomotor symptoms and rapid onset of dyspareunia and osteoporosis unless treated. Estrogen replacement is generally started immediately after surgery. Conjugated estrogens 1.25 mg, estrone sulfate 1.25 mg, or estradiol 2 mg is given for 25 days of each month. After age 45-50 years, this dose can be tapered to 0.625 mg of conjugated estrogens or equivalent.

Table 17-1. Common gynecologic diagnostic procedures.

Colposcopy

Visualization of cervical, vaginal, or vulvar epithelium under 5-50× magnification to identify abnormal areas requiring biopsy. Used to identify genital warts on males as well as females. An office procedure.

D&C

Dilation of the cervix and curettage of the entire endometrial cavity, using a metal curette or suction cannula and often using forceps for the removal of endometrial polyps. Performed to diagnose endometrial disease and to stop heavy bleeding. Can usually be done in the office under local anesthesia.

Endometrial biopsy

Removal of one or more areas of the endometrium by means of a curette or small aspiration device without cervical dilation. Less accurate diagnostically than D&C. An office procedure performed under local anesthesia.

Endocervical curettage

Removal of endocervical epithelium with a small curette for diagnosis of cervical dysplasia and cancer. An office procedure performed under local anesthesia.

Hysteroscopy

Visual examination of the uterine cavity with a small fiberoptic endoscope passed through the cervix. Biopsies, excision of myomas, and other procedures can be performed. Can be done in the office under local anesthesia or in the operating room under general anesthesia.

Hysterosalpingography

Injection of radiopaque dye through the cervix to visualize the uterine cavity and oviducts. Mainly used in investigation of infertility.

Laparoscopy

Visualization of the abdominal and pelvic cavity through a small fiberoptic endoscope passed through a subumbilical incision. Permits diagnosis, tubal sterilization, and treatment of many conditions previously requiring laparotomy. General anesthesia is usually used.

Table 17-3. International classification of cancer of the cervix.¹

Preinvasive carcinoma

Stage 0 Carcinoma in situ, intraepithelial carcinoma.

Invasive carcinoma

Stage I	Carcinoma strictly confined to the cervix (extension to the corpus should be disregarded).
IA	Invasive cancer diagnosed only by microscopy. All gross lesions, even with superficial invasion, are stage IB. Invasion is limited to maximum depth of 5 mm from the base of epithelium from which it originates and no wider than 7 mm. Vascular space involvement should not alter staging. IA1 Measured invasion of stroma no greater than 3 mm in depth and no wider than 7 mm. IA2 Measured invasion of stroma greater than 3 mm in depth and no greater than 5 mm in depth and no wider than 7 mm.
IB	Clinical lesions confined to the cervix or preclinical lesions greater than 1A. IB1 Clinical lesions no greater than 4 cm in size. IB2 Clinical lesions greater than 4 cm in size.
Stage II	Carcinoma extends beyond the cervix but has not extended to the pelvic wall. The carcinoma involves the vagina but not as far as the lower third.
IIA	No obvious parametrial involvement.
IIB	Obvious parametrial involvement.
Stage III	Carcinoma has extended either to the lower third of the vagina or to the pelvic sidewall. All cases of hydronephrosis or nonfunctioning kidney, unless known to be due to other causes.
IIIA	Involvement of lower third of vagina. No extension to pelvic sidewall.
IIIB	Extension onto the pelvic wall and/or hydronephrosis or nonfunctioning kidney.
Stage IV	Carcinoma extended beyond the true pelvis or clinically involving the mucosa of the bladder or rectum. Does not include edema of bladder mucosa.
IVA	Spread of growth to adjacent organs (ie, rectum or bladder with positive biopsy from those organs).
IVB	Spread of growth to distant organs.

Table 17-4. Ovarian functional and neoplastic tumors.

Tumor	Incidence	Size	Consistency	Menstrual Irregularities	Endocrine Effects
Follicle cysts	Rare in childhood; frequent in menstrual years; never in post-menopausal years.	< 6 cm, often bilateral.	Occasional	Occasional anovulation with persistently proliferative endometrium	None
Corpus luteum cysts	Occasional, in menstrual years.	4-6 cm, unilateral.	Moderate	Occasional delayed period	Prolonged secretory phase
Theca lutein cysts therapy.	Occurs with hydatidiform mole, choriocarcinoma; also with gonadotropin or clomiphene	To 4-5 cm, multiple, bilateral. (Ovaries may be = 20 cm in diameter.)	Tense	Amenorrhea	hCG elevated as a result of trophoblastic proliferation
Inflammatory (tuboovarian abscess)	Concomitant with acute salpingitis.	To 15-20 cm, often bilateral.	Variable, painful	Menometrorrhagia	Anovulation usual
Endometriotic cysts	Never in preadolescent or postmenopausal years. Most common in women aged 20-40 years.	To 10-12 cm, occasionally bilateral.	Moderate to softened	Rare	None
Teratoid tumors:					
Benign teratomas (dermoid cysts)	Childhood to post-menopause.	< 15 cm; 15% are bilateral.	Moderate to softened	None	None
Malignant teratomas	< 1% of ovarian tumors. Usually in infants and young adults.	> 20 cm, unilateral.	Irregularly firm	None	Occasionally, hCG elevated
Cystadenoma, cystadenocarcinoma	Common in reproductive years.	Serous: < 25 cm, 33% bilateral; mucinous: up to 1 cm, 10% bilateral.	Moderate to softened	None	None
Endometrioid carcinoma	15% of ovarian carcinomas.	Moderate, 13% bilateral.	Firm	None	None
Fibroma	< 5% of ovarian tumors.	Usually < 15 cm.	Very firm	None	None
Arrhenoblastoma	Rare. Average age 30 years or more.	Often small (< 10 cm), unilateral.	Firm to softened	Amenorrhea	Androgens elevated
Theca cell tumor (thecoma)	Uncommon.	< 10 cm, unilateral.	Firm	Occasional irregularity	Estrogens or androgens elevated
Granulosa cell tumor	Uncommon. Usually in prepubertal girls or women older than 50 years.	May be very small.	Firm to softened	Menometrorrhagia	Estrogens elevated
Dysgerminoma	About 1-2% of ovarian tumors.	< 30 cm, bilateral in 33%.	Moderate to softened	None	. . .
Brenner tumor	About 1% of ovarian tumors.	< 30 cm, unilateral.	Firm	None	. . .
Secondary ovarian tumors	10% of fatal malignant disease in women.	Varies; often bilateral.	Firm to softened	Occasional	Very rare (thyroid, adrenocortical origin)

Table 17-5. Commonly used low-dose oral contraceptives.
-

Table 17-6. Contraindications to use of oral contraceptives.

Absolute contraindications

- Pregnancy
- Thrombophlebitis or thromboembolic disorders (past or present)
- Stroke or coronary artery disease (past or present)
- Cancer of the breast (known or suspected)
- Undiagnosed abnormal vaginal bleeding
- Estrogen-dependent cancer (known or suspected)
- Benign or malignant tumor of the liver (past or present)

Relative contraindications

- Age over 35 years and heavy cigarette smoking (> 15 cigarettes daily)
- Migraine or recurrent persistent severe headache
- Hypertension
- Cardiac or renal disease
- Diabetes
- Gallbladder disease
- Cholestasis during pregnancy
- Active hepatitis or infectious mononucleosis
- Sickle cell disease (S/S or S/C type)
- Surgery, fracture, or severe injury
- Lactation
- Significant psychologic depression

DIAGNOSIS & DIFFERENTIAL DIAGNOSIS OF PREGNANCY

It is advantageous to diagnose pregnancy as promptly as possible when a sexually active woman misses a menstrual period or has symptoms suggestive of pregnancy. In the event of a desired pregnancy, prenatal care can begin early, and potentially harmful medications and activities such as drug and alcohol use, smoking, and occupational chemical exposure can be halted. In the event of an unwanted pregnancy, counseling about adoption or termination of the pregnancy can be provided at an early stage.

Pregnancy Tests

All urine or blood pregnancy tests rely on the detection of hCG produced by the placenta. hCG levels increase shortly after implantation, double approximately every 48 hours, reach a peak at 50-75 days, and fall to lower levels in the second and third trimesters. Laboratory and home pregnancy tests now use monoclonal antibodies specific for hCG. These tests are performed on serum or urine and are accurate at the time of the missed period or shortly after it.

Compared with intrauterine pregnancies, ectopic pregnancies may show lower levels of hCG that level off or fall in serial determinations. Quantitative assays of hCG repeated at 48- to 72-hour intervals are used in the diagnosis of ectopic pregnancy as well as in cases of molar pregnancy, threatened abortion, and missed abortion. Comparison of hCG levels between laboratories may be misleading in a given patient because different international standards may produce results that vary by as much as twofold.

Manifestations of Pregnancy

The following symptoms and signs are usually due to pregnancy, but none are diagnostic. A record of the time and frequency of coitus is helpful for diagnosing and dating a pregnancy.

A. Symptoms

Amenorrhea, nausea and vomiting, breast tenderness and tingling, urinary frequency and urgency, "quickening" (perception of first movement noted at about the 18th week), weight gain.

B. Signs (in Weeks From LMP)

Breast changes (enlargement, vascular engorgement, colostrum), abdominal enlargement, cyanosis of vagina and cervical portio (about the seventh week), softening of the cervix (seventh week), softening of the cervicouterine junction (eighth week), generalized enlargement and diffuse softening of the corpus (after eighth week).

The uterine fundus is palpable above the pubic symphysis by 12-15 weeks from the LMP and reaches the umbilicus by 20-22 weeks. Fetal heart tones can be heard by Doppler at 10-12 weeks of gestation and at 20 weeks with an ordinary fetoscope.

Differential Diagnosis

The nonpregnant uterus enlarged by myomas can be confused with the gravid uterus, but it is usually very firm and irregular. An ovarian tumor may be found midline, displacing the nonpregnant uterus to the side or posteriorly. Ultrasonography and a pregnancy test will provide accurate diagnosis in these circumstances.

ESSENTIALS OF PRENATAL CARE

The first prenatal visit should occur as early as possible after the diagnosis of pregnancy and should include the following.

History

Age, ethnic background, occupation. Onset of LMP and its normality, possible conception dates, bleeding after LMP, medical history, all prior pregnancies (duration, outcome, and complications), symptoms of present pregnancy. Use of drugs, alcohol, tobacco, caffeine, nutritional habits ([Table 18-1](#)). Family history of congenital anomalies and heritable diseases. History of childhood varicella. Prior STDs or risk factors for HIV infection.

Physical Examination

Height, weight, blood pressure, general physical examination. Abdominal and pelvic examination: (1) estimate uterine size or measure fundal height; (2) evaluate bony pelvis for symmetry and adequacy; (3) evaluate cervix for structural anatomy, infection, effacement, dilation; (4) detect fetal heart sounds by Doppler device after 10 weeks or fetoscope after 18 weeks.

Laboratory Tests

Urinalysis, culture of a clean-voided midstream urine sample, complete blood count with red cell indices, serologic test for syphilis, rubella antibody titer, blood group, Rh type, atypical antibody screening, and HBsAg evaluation. Human immunodeficiency virus (HIV) screening should be offered to all pregnant women. Cervical cultures are usually obtained for *Neisseria gonorrhoeae* and chlamydia, along with a Papanicolaou smear of the cervix. All black women should have sickle cell screening. Women of African, Asian, or Mediterranean ancestry with anemia or low MCV values should have hemoglobin electrophoresis performed to identify abnormal hemoglobins (Hb S, C, F, α -thalassemia, β -thalassemia). Tuberculosis skin testing is increasingly indicated for immigrant and inner city populations. Genetic counseling with the option of chorionic villus sampling or genetic amniocentesis should be offered to all women who will be 35 years of age or older at delivery and those who have had prior offspring with chromosomal abnormalities. Tay-Sachs blood screening is offered to Jewish women with Jewish partners. Screening for cystic fibrosis is offered to all pregnant women. Hepatitis C antibody screening should be offered only to those pregnant women who are at high risk of infection.

Pregnant women who work in medical-dental health care or the police and fire departments and those who are household contacts of a hepatitis B virus carrier or a hemodialysis patient and are HBsAg-negative at prenatal screening are at high risk of acquiring hepatitis B. They should be vaccinated during pregnancy.

Advice to Patients

A. Prenatal Visits

Prenatal care should begin early and maintain a schedule of regular prenatal visits: 0-28 weeks, every 4 weeks; 28-36 weeks, every 2 weeks; 36 weeks on, weekly.

B. Diet

1. Eat a balanced diet containing the major food groups.
2. Take prenatal vitamins with iron and folic acid.
3. Expect to gain 20-40 lb. Do not diet to lose weight during pregnancy.
4. Decrease caffeine intake to 0-1 cup of coffee, tea, or caffeinated cola daily.
5. Avoid eating raw or rare meat, and wash hands after handling raw meat.
6. Eat fresh fruits and vegetables and wash them before eating.

C. Medications

Do not take medications unless prescribed or authorized by your provider.

D. Alcohol and Other Drugs

Abstain from alcohol, tobacco, and all recreational ("street") drugs. No safe level of alcohol intake has been established for pregnancy. Fetal effects are manifest in the **fetal alcohol syndrome**, which includes growth restriction, facial abnormalities, and serious central nervous system dysfunction. These effects are thought to result from direct toxicity of ethanol itself as well as of its metabolites such as acetaldehyde. Characteristic findings include shortened palpebral fissures, low-set ears,

midfacial hypoplasia, a smooth philtrum, a thin upper lip, microcephaly, mental retardation, and attention deficit disorder. Skeletal and cardiac abnormalities may also be seen.

Cigarette smoking results in fetal exposure to carbon monoxide and nicotine, and this is thought to eventuate in a number of adverse pregnancy outcomes. An increased risk of abruptio placentae, placenta previa, and premature rupture of the membranes is documented among women who smoke. Premature delivery occurs 20% more frequently among smoking pregnant women, and the birth weights of their infants are on average 200 g lower than infants of nonsmokers. Women who smoke should quit smoking or at least reduce the number of cigarettes smoked per day to as few as possible. Pregnant women should also avoid exposure to environmental smoke ("passive smoking").

Sometimes compounding the above effects on pregnancy outcome are the independent adverse effects of illicit drugs. Cocaine use in pregnancy is associated with an increased risk of premature rupture of membranes, preterm delivery, placental abruption, intrauterine growth restriction, neurobehavioral deficits, and sudden infant death syndrome. Similar adverse pregnancy effects are associated with amphetamine use, perhaps reflecting the vasoconstrictive potential of both amphetamines and cocaine. Adverse effects associated with opioid use include intrauterine growth restriction, prematurity, stillbirth, and fetal death.

E. X-Rays and Noxious Exposures

Avoid x-rays unless essential and approved by a physician. Inform your dentist and your providers that you are pregnant. Avoid chemical or radiation hazards. Avoid excessive heat in hot tubs or saunas. Avoid handling cat feces or cat litter. Wear gloves when gardening.

F. Rest and Activity

Obtain adequate rest each day. Abstain from strenuous physical work or activities, particularly when heavy lifting or weight bearing is required. Exercise regularly at a mild to moderate level. Avoid exhausting or hazardous exercises or new athletic training programs during pregnancy. Heart rate should be kept below 140 beats/min during exercise.

G. Birth Classes

Enroll with your partner in a childbirth preparation class well before your due date.

Tests & Procedures

A. Each Visit

Weight, blood pressure, fundal height, fetal heart rate, urine specimen for protein and glucose. Review patient's concerns about pregnancy, health, and nutrition.

B. 6-12 Weeks

Confirm uterine size and growth by pelvic examination. Document fetal heart tones (audible at 10-12 weeks of gestation by Doppler). Transvaginal chorionic villus sampling (CVS) between 10 and 12 weeks when indicated or screening for trisomy 18, 21, and cardiac defects using nuchal translucency measurement on sonography, hCG, and pregnancy-associated plasma protein-A (PAPP-A).

C. 12-18 Weeks

Genetic counseling for women age 35 years or older at EDC and those with a family history of congenital anomalies or a previous child with a chromosomal abnormality, metabolic disease, or neural tube defect. Amniocentesis is performed as indicated and requested by the patient.

D. 12-24 Weeks

Fetal ultrasound examination to determine pregnancy dating and evaluate fetal anatomy. An earlier examination provides the most accurate dating, and a later examination demonstrates fetal anatomy in greater detail. The best compromise is at 18-20 weeks of gestation.

E. 16-20 Weeks

Maternal serum alpha-fetoprotein testing is offered to all women to screen for neural tube defects. In some states, such testing is mandatory. Serum a-fetoprotein is usually combined with measurement of estriol and hCG (triple screen) for the detection of fetal Down's syndrome.

F. 20-24 Weeks

Instruct patient in symptoms and signs of preterm labor and rupture of membranes.

G. 24 Weeks to Delivery

Ultrasound examination is performed as indicated. Typically, fetal size and growth are evaluated when fundal height is 3 cm less than or more than expected for gestational age. In multiple pregnancies, ultrasound should be performed every 4 weeks to evaluate for discordant growth.

H. 26-28 Weeks

Screening for gestational diabetes by a 50-g glucose load (Glucola) and a 1-hour post-Glucola blood glucose determination. Abnormal values should be followed up with a 3-hour glucose tolerance test ([Table 18-3](#)).

I. 28 Weeks

If initial antibody screen is negative, repeat antibody testing for Rh-negative patients, but result is not required before Rh₀(D) immune globulin is administered.

J. 28-32 Weeks

Repeat the complete blood count to evaluate for anemia of pregnancy.

K. 28 Weeks to Delivery

Determination of fetal position and presentation. Question the patient at each visit for symptoms or signs of preterm labor or rupture of membranes. Assess maternal perception of fetal movement at each visit. Antepartum fetal testing is performed as medically indicated.

L. 36 Weeks to Delivery

Repeat syphilis and HIV testing, cervical cultures for *N gonorrhoeae*, and *Chlamydia trachomatis* in at-risk patients. Discuss with the patient the indicators of onset of labor, admission to hospital, management of labor and delivery, and options for analgesia and anesthesia. Weekly cervical examinations are not necessary unless indicated to assess a specific clinical situation. Elective delivery (whether by induction or cesarean section) prior to 39 weeks of gestation requires confirmation of fetal lung maturity.

The CDC has recommended universal prenatal culture-based screening for group B streptococcal colonization in pregnancy. A single standard culture of the distal vagina and anorectum is collected at 35-37 weeks. No prophylaxis is needed if the screening culture is negative. Patients whose cultures are positive receive intrapartum penicillin prophylaxis with labor. Patients with risk factors such as a previous infant with invasive group B streptococcal disease, or group B streptococcal bacteriuria during the pregnancy, or delivery at less than 37 weeks of gestation also receive intrapartum prophylaxis. Patients whose cultures at 35-37 weeks were not done or whose results are not known receive prophylaxis only with the risk factors of intrapartum temperature greater than 38°C or membrane rupture greater than 18 hours.

The routine recommended regimen for prophylaxis is penicillin G, 5 million units intravenously as a loading dose and then 2.5 million units intravenously every 4 hours until delivery. In penicillin-allergic patients not at high risk for anaphylaxis, one should give cefazolin 2 g intravenously as an initial dose and then 1 g intravenously every 8 hours until delivery. In patients at high risk for anaphylaxis, use vancomycin 1 g intravenously every 12 hours until delivery or, after confirmed susceptibility testing of group B streptococcal isolate, clindamycin 900 mg intravenously every 8 hours or erythromycin 500 mg intravenously every 6 hours until delivery.

M. 41 Weeks and Beyond

Cervical examination to determine the probability of successful induction of labor. Based on this, induction of labor is undertaken if the cervix is favorable; if unfavorable, antepartum fetal testing is begun.

NUTRITION IN PREGNANCY

Nutrition in pregnancy significantly affects maternal health and infant size and well-being. Pregnant women should have nutrition counseling early in prenatal care and access to supplementary food programs if necessary. Counseling should stress abstinence from alcohol, smoking, and recreational drugs. Caffeine and artificial sweeteners should be used only in small amounts. "Empty calories" should be avoided, and the diet should contain the following foods: protein foods of animal and vegetable origin, milk and milk products, whole-grain cereals and breads, and fruits and vegetables—especially green leafy vegetables.

Weight gain in pregnancy should be 20-40 lb, which includes the added weight of the fetus, placenta, and amniotic fluid and of maternal reproductive tissues, fluid, blood, increased fat stores, and increased lean body mass. Maternal fat stores are a caloric reserve for pregnancy and lactation; weight restriction in pregnancy to avoid developing such fat stores may affect the development of other fetal and maternal tissues and is not advisable. Obese women can have normal infants with less weight gain (15-20 lb) but should be encouraged to eat high-quality foods. Normally, a pregnant woman gains 2-5 lb in the first trimester and slightly less than 1 lb/wk thereafter. She needs approximately an extra 200-300 kcal/d (depending on energy output) and 30 g/d of additional protein for a total protein intake of about 75 g/d. Appropriate caloric intake in pregnancy helps prevent the problems associated with low birth weight.

Rigid salt restriction is not necessary. While consumption of highly salted snack foods and prepared foods is not desirable, 2-3 g/d of sodium is permissible. The increased calcium needs of pregnancy (1200 mg/d) can be met with milk, milk products, green vegetables, soybean products, corn tortillas, and calcium carbonate supplements.

The increased need for iron and folic acid should be met from foods as well as vitamin and mineral supplements. (See section on anemia in pregnancy.) Megavitamins should not be taken in pregnancy, as they may result in fetal malformation or disturbed metabolism. However, a balanced prenatal supplement containing 30-60 mg of elemental iron, 0.5-0.8 mg of folate, and the recommended daily allowances of various vitamins and minerals is widely used in the United States and is probably beneficial to many women with marginal diets. There is evidence that periconceptional folic acid supplements can decrease the risk of neural tube defects in the fetus. For this reason, the United States Public Health Service recommends the consumption of 0.4 mg of folic acid per day for all pregnant women (and thus all women capable of becoming pregnant). Women with a prior pregnancy complicated by neural tube defect may require higher supplemental doses as determined by their providers. Lactovegetarians and ovolactovegetarians do well in pregnancy; vegetarian women who eat neither eggs nor milk products should have their diets assessed for adequate calories and protein and should take oral vitamin B₁₂ supplements during pregnancy and lactation.

Institute of Medicine, National Academy of Sciences: *Nutrition During Pregnancy*. Part I, *Weight Gain*; Part II, *Nutrient Supplements*. National Academy Press, 1990.

TRAVEL & IMMUNIZATIONS DURING PREGNANCY

During an otherwise normal low-risk pregnancy, travel can be planned most safely between the 18th and 32nd weeks. Commercial flying in pressurized cabins does not pose a threat to the fetus. An aisle seat will allow frequent walks. Adequate fluids should be taken during the flight.

It is not advisable to travel to endemic areas of yellow fever in Africa or Latin America; similarly, it is inadvisable to travel to areas of Africa or Asia where chloroquine-resistant falciparum malaria is a hazard, since complications of malaria are more common in pregnancy.

Ideally, all immunizations should precede pregnancy. Live virus products are contraindicated (measles, rubella, yellow fever), including smallpox. Inactivated poliovaccine (Salk) can be used instead of the oral vaccine. Vaccines against pneumococcal pneumonia, meningococcal meningitis, and hepatitis A can be used as indicated. Influenza vaccine is indicated in all pregnant women who will be in their second or third trimester during "flu season."

Pooled immune globulin to prevent hepatitis A is safe and does not carry a risk of HIV transmission. Hepatitis A vaccine contains formalin-inactivated virus but can be given in pregnancy when needed. Chloroquine can be used for malaria prophylaxis in pregnancy, and proguanil is also safe.

Water should be purified by boiling, since iodine purification may provide more iodine than is safe during pregnancy.

Do not use prophylactic antibiotics or bismuth subsalicylate during pregnancy to prevent diarrhea. Use oral rehydration fluids, and treat bacterial diarrhea with erythromycin or ampicillin if necessary.

VOMITING OF PREGNANCY (MORNING SICKNESS) & HYPEREMESIS GRAVIDARUM (PERNICIOUS VOMITING OF PREGNANCY)

Essentials of Diagnosis

- Morning or evening nausea and vomiting.
- Persistent vomiting severe enough to result in weight loss, dehydration, starvation ketosis, hypochloremic alkalosis, hypokalemia.
- May have transient elevation of liver enzymes.
- Appears related to high or rising serum hCG.
- More common with multiple gestation or hydatidiform mole.

General Considerations

Nausea and vomiting begin soon after the first missed period and cease by the fifth month of gestation. Up to three-fourths of women complain of nausea and vomiting during early pregnancy, with the vast majority noting nausea throughout the day. This problem exerts no adverse effects on the pregnancy and does not presage other complications.

Persistent, severe vomiting during pregnancy—hyperemesis gravidarum—can be disabling and require hospitalization. Thyroid dysfunction can be associated with hyperemesis gravidarum, so it is advisable to determine TSH and free T₄ values in these patients.

Treatment

A. Mild Nausea and Vomiting of Pregnancy

Reassurance and dietary advice are all that is required in most instances. Because of possible teratogenicity, drugs used during the first half of pregnancy should be restricted to those of major importance to life and health. Antiemetics, antihistamines, and antispasmodics are generally unnecessary to treat nausea of pregnancy. Vitamin B₆ (pyridoxine), 50-100 mg/d orally, is nontoxic and may be helpful in some patients.

B. Hyperemesis Gravidarum

Hospitalize the patient in a private room at bed rest. Give nothing by mouth for 48 hours, and maintain hydration and electrolyte balance by giving appropriate parenteral fluids and vitamin supplements as indicated. Rarely, total parenteral nutrition may become necessary. As soon as possible, place the patient on a dry diet consisting of six small feedings daily plus clear liquids 1 hour after eating. Prochlorperazine rectal suppositories may be useful. After in-patient stabilization, the patient can be maintained at home even if she requires intravenous fluids in addition to her oral intake.

Lacroix R et al: Nausea and vomiting during pregnancy: a prospective study of its frequency, intensity, and patterns of change. Am J Obstet Gynecol 2000;182:931. [\[PMID: 10764476\]](#)

SPONTANEOUS ABORTION

Essentials of Diagnosis

- Intrauterine pregnancy at less than 20 weeks.
- Low or falling levels of hCG.
- Bleeding, midline cramping pain.
- Open cervical os.
- Complete or partial expulsion of products of conception.

General Considerations

About three-fourths of spontaneous abortions occur before the 16th week; of these, three-fourths occur before the eighth week. Almost 20% of all clinically recognized pregnancies terminate in spontaneous abortion.

More than 60% of spontaneous abortions result from chromosomal defects due to maternal or paternal factors; about 15% appear to be associated with maternal trauma, infections, dietary deficiencies, diabetes mellitus, hypothyroidism, or anatomic malformations. There is no reliable evidence that abortion may be induced by psychic stimuli such as severe fright, grief, anger, or anxiety. In about one-fourth of cases, the cause of abortion cannot be determined. There is no evidence that video display terminals or associated electromagnetic fields are related to an increased risk of spontaneous abortion.

It is important to distinguish women with a history of incompetent cervix from those with more typical early abortion and those with premature labor or rupture of the membranes. Characteristically, incompetent cervix presents as "silent" cervical dilation (ie, with minimal uterine contractions) between 16 and 28 weeks of gestation. Women with incompetent cervix often present with significant cervical dilation (2 cm or more) and minimal symptoms. When the cervix reaches 4 cm or more, active uterine contractions or rupture of the membranes may occur secondary to the degree of cervical dilation. This does not change the primary diagnosis. Factors that predispose to incompetent cervix are a history of incompetent cervix with a previous pregnancy, cervical conization or surgery, cervical injury, DES exposure, and anatomic abnormalities of the cervix. Prior to pregnancy or during the first trimester, there are no methods for determining whether the cervix will eventually be incompetent. After 14-16 weeks, ultrasound may be used to evaluate the internal anatomy of the lower uterine segment and cervix for the funneling and shortening abnormalities consistent with cervical incompetence.

Clinical Findings

A. Symptoms and Signs

1. Threatened abortion—Bleeding or cramping occurs, but the pregnancy continues. The cervix is not dilated.

2. Inevitable abortion—The cervix is dilated and the membranes may be ruptured, but passage of the products of conception has not occurred. Bleeding and cramping persist, and passage of the products of conception is considered inevitable.

3. Complete abortion—The fetus and placenta are completely expelled. Pain ceases, but spotting may persist.

4. Incomplete abortion—Some portion of the products of conception (usually placental) remain in the uterus. Only mild cramps are reported, but bleeding is persistent and often excessive.

5. Missed abortion—The pregnancy has ceased to develop, but the conceptus has not been expelled. Symptoms of pregnancy disappear. There is a brownish vaginal discharge but no free bleeding. Pain does not develop. The cervix is semifirm and slightly patulous, the uterus becomes smaller and irregularly softened, and the adnexa are normal.

B. Laboratory Findings

Pregnancy tests show low or falling levels of hCG. A complete blood count should be obtained if bleeding is heavy. Determine Rh type, and give Rh₀(D) immune globulin if the type is Rh-negative. All tissue recovered should be assessed by a pathologist and may be sent for genetic analysis in selected cases.

C. Ultrasonographic Findings

The gestational sac can be identified at 5-6 weeks from the LMP, a fetal pole at 6 weeks, and fetal cardiac activity at 6-7 weeks. Serial observations are often required to evaluate changes in size of the embryo. A small, irregular sac without a fetal pole with accurate dating is diagnostic of an abnormal pregnancy.

Differential Diagnosis

The bleeding that occurs in abortion of a uterine pregnancy must be differentiated from the abnormal bleeding of an ectopic pregnancy and anovular bleeding in a nonpregnant woman. The passage of hydropic villi in the bloody discharge is diagnostic of hydatidiform mole.

Treatment

A. General Measures

1. Threatened abortion—Place the patient at bed rest for 24-48 hours followed by gradual resumption of usual activities, with abstinence from coitus and douching. Hormonal treatment is contraindicated. Antibiotics should be used only if there are signs of infection.

2. Missed or inevitable abortion—This calls for counseling regarding the fate of the pregnancy and planning for its elective termination at a time chosen by the patient and physician. Insertion of a laminaria to dilate the cervix followed by aspiration is the method of choice for a missed abortion. Prostaglandin vaginal suppositories are an effective alternative.

B. Surgical Measures

1. Incomplete abortion—Prompt removal of any products of conception remaining within the uterus is required to stop bleeding and prevent infection. Analgesia and a paracervical block are useful, followed by uterine exploration with ovum forceps or uterine aspiration.

2. Cerclage and restriction of activities—These are the treatment of choice for incompetent cervix. A variety of suture materials including a 5-mm Mersilene band can be used to create a purse-string type of stitch around the cervix, using either the McDonald or Shirodkar method. Cerclage should be undertaken with caution when there is advanced cervical dilation or when the membranes are prolapsed into the vagina. Rupture of the membranes and infection are specific contraindications to cerclage. Cervical cultures for *N gonorrhoeae*, chlamydia, and group B streptococci should be obtained before or at the time of cerclage.

George L et al: Plasma folate levels and risk of spontaneous abortion. JAMA 2002;288:1867. [PMID: 12377085]

RECURRENT (HABITUAL) ABORTION

Recurrent abortion has been defined for years as the loss of three or more previable (< 500 g) pregnancies in succession. Recurrent abortion occurs in about 0.4-0.8% of all pregnancies. Abnormalities related to recurrent abortion can be identified in approximately half of the couples. If a woman has lost three previous pregnancies without identifiable cause, she still has a 70-80% chance of carrying a fetus to viability. If she has aborted four or five times, the likelihood of a successful pregnancy is 65-70%.

Recurrent abortion is a clinical rather than pathologic diagnosis. The clinical findings are similar to those observed in other types of abortion (see above).

Treatment

A. Preconception Therapy

Preconception therapy is aimed at detection of maternal or paternal defects that may contribute to abortion. A thorough general and gynecologic examination is essential. Polycystic ovaries should be ruled out. A random blood glucose test and thyroid function studies (including thyroid antibodies) should be done. Detection of lupus anticoagulant and other hemostatic abnormalities (proteins S and C and antithrombin III deficiency, hyperhomocysteinemia, anticardiolipin antibody, factor V Leiden mutation) and an antinuclear antibody test may be indicated. Endometrial tissue should be examined in the postovulation stage of the cycle to determine the adequacy of the response of the endometrium to hormones. The competency of the cervix must be determined and hysteroscopy or hystero-graphy used to exclude submucous myomas and congenital anomalies. Chromosomal (karyotype) analysis of both partners rules out balanced translocations (found in 5% of infertile couples).

Studies have focused on the major histocompatibility complex (MHC) of chromosome 6, which carries HLA loci and other genes that may influence reproductive success. Some women demonstrate a lack of maternal antibody response to paternal lymphocytes, which is customarily found in normal women after successful childbearing. However, several randomized controlled trials have found no benefit of IGIV therapy for recurrent spontaneous abortion.

B. Postconception Therapy

Provide early prenatal care and schedule frequent office visits. Complete bed rest is justified only for bleeding or pain. Empiric sex steroid hormone therapy is contraindicated.

Prognosis

The prognosis is excellent if the cause of abortion can be corrected.

Management of recurrent pregnancy loss. ACOG Practice Bulletin No. 24, 2001. Int J Gynaecol Obstet 2002;78:179. [PMID: 12360906]

ECTOPIC PREGNANCY

Essentials of Diagnosis

- Amenorrhea or irregular bleeding and spotting.
- Pelvic pain, usually adnexal.
- Adnexal mass by clinical examination or ultrasound.
- Failure of serum level of hCG to double every 48 hours.
- No intrauterine pregnancy on transvaginal ultrasound with serum β -hCG of > 2000 mU/mL.

General Considerations

Ectopic implantation occurs in about one out of 150 live births. About 98% of ectopic pregnancies are tubal. Other sites of ectopic implantation are the peritoneum or abdominal viscera, the ovary, and the cervix. Any condition that prevents or retards migration of the fertilized ovum to the uterus can predispose to an ectopic pregnancy, including a history of infertility, pelvic inflammatory disease, ruptured appendix, and prior tubal surgery. Combined intra- and extrauterine pregnancy (heterotopic) may occur rarely. In the United States, undiagnosed or undetected ectopic pregnancy is currently the most common cause of maternal death during the first trimester.

Clinical Findings

A. Symptoms and Signs

They may be acute or chronic.

1. Acute (40%)—Severe lower quadrant pain occurs in almost every case. It is sudden in onset, lancinating, intermittent, and does not radiate. Backache is present during attacks. Shock occurs in about 10%, often after pelvic examination. At least two-thirds of patients give a history of abnormal menstruation; many have been infertile.

2. Chronic (60%)—Blood leaks from the tubal ampulla over a period of days, and considerable blood may accumulate in the peritoneum. Slight but persistent vaginal spotting is reported, and a pelvic mass can be palpated. Abdominal distention and mild paralytic ileus are often present.

B. Laboratory Findings

Blood studies may show anemia and slight leukocytosis. Quantitative serum pregnancy tests will show levels generally lower than expected for normal pregnancies of the same duration. If pregnancy tests are followed over a few days, there may be a slow rise or a plateau rather than the near doubling every 2 days associated with normal early intrauterine pregnancy or the falling levels that occur with spontaneous abortion.

C. Imaging

Ultrasonography can reliably demonstrate a gestational sac 6 weeks from the LMP and a fetal pole at 7 weeks if located in the uterus. An empty uterine cavity raises a strong suspicion of extrauterine pregnancy, which can occasionally be revealed by endovaginal ultrasound. Specified levels of serum hCG have been reliably correlated with ultrasound findings of an intrauterine pregnancy. For example, an hCG level of 6500 mU/mL with an empty uterine cavity by transabdominal ultrasound is virtually diagnostic of an ectopic pregnancy. Similarly, an hCG value of 2000 mU/mL or more can be indicative of an ectopic pregnancy if no products of conception are detected within the uterine cavity by transvaginal ultrasound.

D. Special Examinations

With the advent of high-resolution transvaginal ultrasound, culdocentesis is rarely used in evaluation of possible ectopic pregnancy. Laparoscopy is the surgical procedure of choice both to confirm an ectopic pregnancy and in most cases to permit pelviscopic removal of the ectopic pregnancy without the need for exploratory laparotomy.

Differential Diagnosis

Clinical and laboratory findings suggestive or diagnostic of pregnancy will distinguish ectopic pregnancy from many acute abdominal illnesses such as acute appendicitis, acute pelvic inflammatory disease, ruptured corpus luteum cyst or ovarian follicle, and urinary calculi. Uterine enlargement with clinical findings similar to those found in ectopic pregnancy is also characteristic of an aborting uterine pregnancy or hydatidiform mole. Ectopic pregnancy should be suspected when postabortal tissue examination fails to reveal placenta. Steps must be taken for immediate diagnosis, including prompt microscopic tissue examination, ultrasonography, and serial hCG titers every 48 hours. Patients must be warned of possible ectopic pregnancy problems and followed very closely.

Treatment

When a patient is unstable or when surgical therapy is planned, the patient is hospitalized with a diagnosis of ectopic pregnancy. Blood is typed and cross-matched. Ideally, diagnosis and operative treatment should precede frank rupture of the tube and intra-abdominal hemorrhage.

Surgical treatment is definitive. In a stable patient, diagnostic laparoscopy is the initial surgical procedure performed. Depending on the size of the ectopic pregnancy and whether or not it has ruptured, salpingostomy with removal of the ectopic or a partial or complete salpingectomy can usually be performed pelviscopically through the laparoscope. Clinical conditions permitting, patency of the contralateral tube can be established by injection of indigo carmine into the uterine cavity and flow through the contralateral tube confirmed visually by the surgeon.

In a stable patient, methotrexate (50 mg/m^2)—given systemically as single or multiple doses—is acceptable medical therapy for early ectopic pregnancy. Favorable criteria are that the pregnancy should be less than 3.5 cm and unruptured, with no active bleeding.

Iron therapy for anemia may be necessary during convalescence. Give Rh₀(D) immune globulin (300 ug) to Rh-negative patients.

Prognosis

Repeat tubal pregnancy occurs in about 12% of cases. This should not be regarded as a contraindication to future pregnancy, but the patient requires careful observation and early ultrasound confirmation of an intrauterine pregnancy.

Lipscomb GH et al: Oral methotrexate for treatment of ectopic pregnancy. Am J Obstet Gynecol 2002;186:1192. [PMID: 12066097]

PREECLAMPSIA-ECLAMPSIA

Essentials of Diagnosis

Preeclampsia

- Blood pressure of ≥ 140 mm Hg systolic or ≥ 90 mm Hg diastolic after 20 weeks of gestation.
- Proteinuria of ≥ 0.3 g in 24 hours.

Eclampsia

- Blood pressure of = 160 mm Hg systolic or = 110 mm Hg diastolic.
- Proteinuria = 5 g in 24 hours or 4+ on dipstick.
- Oliguria of < 500 mL in 24 hours.
- Thrombocytopenia.
- Hemolysis, elevated liver enzymes, low platelets (HELLP).
- Pulmonary edema.
- Fetal growth restriction.

General Considerations

Preeclampsia is defined as the presence of elevated blood pressure and proteinuria during pregnancy. Eclampsia occurs with the addition of seizures. Classically, the presence of three elements was required for the diagnosis of preeclampsia-eclampsia: hypertension, proteinuria, and edema. Edema was difficult to objectively quantify and is no longer a required element.

Preeclampsia-eclampsia can occur any time after 20 weeks of gestation and up to 6 weeks postpartum. It is a disease unique to pregnancy, with the only cure being delivery of the fetus and placenta. Approximately 7% of pregnant women in the United States develop preeclampsia-eclampsia. Primiparas are most frequently affected; however, the incidence of preeclampsia-eclampsia is increased with multiple pregnancies, chronic hypertension, diabetes, renal disease, collagen-vascular and autoimmune disorders, and gestational trophoblastic disease. Five percent of women with preeclampsia progress to eclampsia. Uncontrolled eclampsia is a significant cause of maternal death.

The basic cause of preeclampsia-eclampsia is not known. Epidemiologic studies suggest an immunologic cause for preeclampsia, since it occurs predominantly in women who have had minimal exposure to sperm (having used barrier methods of contraception) or have new consorts, in primigravidas, and in women both of whose parents have similar HLA antigens. Preeclampsia is an endothelial disorder resulting from poor placental perfusion, which releases a factor that injures the endothelium, causing activation of coagulation and an increased sensitivity to pressors. Before the syndrome becomes clinically manifest in the second half of pregnancy, there has been vasospasm in various small vessel beds, accounting for the pathologic changes in maternal organs and the placenta with consequent adverse effects on the fetus.

The use of diuretics, dietary restriction or enhancement, sodium restriction, aspirin, and vitamin-mineral supplements such as calcium has not been shown to be useful in clinical studies. The only cure is termination of the pregnancy at a time as favorable as possible for fetal survival.

Clinical Findings

Clinically, the severity of preeclampsia-eclampsia can be measured with reference to the six major sites in which it exerts its effects: the central nervous system, the kidneys, the liver, the hematologic and vascular systems, and the fetal-placental unit. By evaluating each of these areas for the presence of mild to moderate versus severe preeclampsia-eclampsia, the degree of involvement can be assessed, and an appropriate management plan can be formulated that is integrated with gestational age assessment ([Table 18-2](#)).

A. Preeclampsia

1. Mild to moderate—Precise differentiation between mild and moderate preeclampsia is difficult because the abnormalities that define the disease are quite variable and fail to accurately predict progression to more severe disease. Symptoms are generally minimal or mild. With mild preeclampsia, patients usually have few complaints, and the diastolic blood pressure is less than 90-100 mm Hg. Edema is usually more pronounced with moderate disease, and diastolic blood pressures are in the range of 90-110 mm Hg. The platelet count is over 100,000/uL, antepartum fetal testing is reassuring, central nervous system irritability is minimal, epigastric pain is not present, and liver enzymes are not elevated.

2. Severe—Symptoms are more dramatic and persistent. The blood pressure is often quite high, with readings over 160/110 mm Hg. Thrombocytopenia (platelet counts < 100,000/uL) may be present and progress to disseminated intravascular coagulation. Severe epigastric pain may be present from hepatic subcapsular hemorrhage with significant stretch or rupture of the liver capsule. The HELLP syndrome (hemolysis, elevated liver enzymes, low platelets) is a form of severe preeclampsia.

B. Eclampsia

The occurrence of seizures defines eclampsia. It is a manifestation of severe central nervous system involvement. The other abnormal findings of severe pre-eclampsia are also observed with eclampsia.

Differential Diagnosis

Preeclampsia-eclampsia can mimic and be confused with many other diseases, including chronic hypertension, chronic renal disease, primary seizure disorders, gallbladder and pancreatic disease, immune or thrombotic thrombocytopenic purpura, and hemolytic uremic syndrome. It must always be considered a possibility in any pregnant woman beyond 20 weeks of gestation. It is particularly difficult to diagnose when preexisting disease such as hypertension is present. Uric acid values can be quite helpful in such situations, since hyperuricemia is uncommon in pregnancy except with gout, renal failure, or preeclampsia-eclampsia.

Treatment

A. Preeclampsia

Early recognition is the key to treatment. This requires careful attention to the details of prenatal care—especially subtle changes in blood pressure and weight. The objectives are to prolong pregnancy if possible, to allow fetal lung maturity while preventing progression to severe disease and eclampsia. The critical factors are the gestational age of the fetus, fetal pulmonary maturity status, and the severity of maternal disease. Preeclampsia-eclampsia at 36 weeks or more of gestation is managed by delivery regardless of how mild the disease is judged to be. Prior to 36 weeks, severe preeclampsia-eclampsia requires delivery except in unusual circumstances associated with extreme fetal prematurity, in which case prolongation of pregnancy may be attempted. Epigastric pain, thrombocytopenia, and visual disturbances are strong indications for delivery of the fetus. For mild to moderate preeclampsia-eclampsia, bed rest is the cornerstone of therapy. This increases central blood flow to the kidneys, heart, brain, liver, and placenta and may stabilize or even improve the degree of preeclampsia-eclampsia for a period of time.

Bed rest may be attempted at home or in the hospital. Prior to making this decision, the provider should evaluate the six sites of involvement listed in [Table 18-2](#) and make an assessment about the severity of disease.

1. Home management—Home management with bed rest may be attempted for patients with mild preeclampsia and a stable home situation. This requires homemaking assistance, rapid access to the hospital, a reliable patient, and the ability to obtain frequent blood pressure readings. A home health nurse can often provide frequent home visits and assessment.

2. Hospital care—Hospitalization is required for women with moderate or severe preeclampsia or those with unreliable home situations. Regular assessment of blood pressure, reflexes, urine protein, and fetal heart tones and activity are required. A complete blood count, platelet count, and electrolyte panel including liver enzymes should be checked every 1 or 2 days. A 24-hour urine collection for creatinine clearance and total protein should be obtained on admission and repeated as indicated. Sedatives and opioids should be avoided because the fetal central nervous system depressant effects interfere with fetal testing. Magnesium sulfate is not used until the diagnosis of severe preeclampsia-eclampsia is made or until labor occurs.

Fetal evaluation should be obtained as part of the workup. If the patient is being admitted to the hospital, fetal testing must be performed on the same day to make certain that the fetus is safe. This may be done by fetal heart rate testing with nonstress or stress testing or by biophysical profile. A regular schedule of fetal surveillance must then be followed. Daily fetal kick counts can be recorded by the patient herself. Consideration should be given to amniocentesis to evaluate fetal lung maturity status if hospitalization occurs at 30-37 weeks of gestation. If immaturity is present, steroids (betamethasone 12 mg or dexamethasone 16 mg, two doses intramuscularly 12-24 hours apart) can be administered to the mother. Fetuses between 26 and 30 weeks of gestation can be presumed to be immature, and steroids should be given.

The method of delivery is determined by the maternal and fetal status. Cesarean section is reserved for the usual fetal indications.

B. Eclampsia

1. Emergency care—If the patient is convulsing, she is turned on her side to prevent aspiration and to improve blood flow to the placenta. Fluid or food is aspirated from the glottis or trachea. The seizure may be stopped by giving an intravenous bolus of either magnesium sulfate, 4 g, or diazepam, 5-10 mg, over 4 minutes or until the seizure stops. A continuous intravenous infusion of magnesium sulfate is then started at a rate of 2-3 g/h unless the patient is known to have significantly reduced renal function. Magnesium blood levels are then checked every 4-6 hours and the infusion rate adjusted to maintain a therapeutic blood level (4-6 meq/L). Urine output

is checked hourly and the patient assessed for signs of possible magnesium toxicity such as loss of deep tendon reflexes or decrease in respiratory rate and depth, which can be reversed with calcium gluconate.

2. General care—The occurrence of eclampsia necessitates delivery once the patient is stabilized. It is important, however, that assessment of the status of the patient and fetus take place first. Continuous fetal monitoring must be performed and blood typed and cross-matched quickly. A urinary catheter is inserted to monitor urine output, and blood is sent for complete blood count, platelets, liver enzymes, uric acid, creatinine or urea nitrogen, and electrolytes. If hypertension is present with diastolic values over 110 mm Hg, antihypertensive medications should be administered to reduce the diastolic blood pressure to 90-100 mm Hg. Lower blood pressures than this may induce placental insufficiency through reduced perfusion. Hydralazine given in 5- to 10-mg increments intravenously every 20 minutes is frequently used to lower blood pressure. Nifedipine, 10 mg sublingually or orally, or labetalol, 10-20 mg intravenously, both every 20 minutes, can also be used.

3. Delivery—Except in unusual circumstances, delivery is mandated once eclampsia has occurred. Vaginal delivery may be attempted if the patient has already been in active labor or the cervix is quite favorable *and* the patient is clinically stable. The rapidity with which delivery must be achieved depends on the fetal and maternal status following the seizure and the availability of laboratory data on the patient. Oxytocin may be used to induce or augment labor. Regional analgesia or anesthesia is acceptable. Cesarean section is used for the usual obstetric indications or when rapid delivery is necessary for maternal or fetal indications.

4. Postpartum—Magnesium sulfate infusion (2-3 g/h) should be continued until preeclampsia-eclampsia has begun to resolve postpartum, but in any case for at least 24 hours. This may take 1-7 days. The most reliable indicator of this is the onset of diuresis with urine output of over 100-200 mL/h. When this occurs, magnesium sulfate can be discontinued. Late-onset preeclampsia-eclampsia can occur during the postpartum period. It is usually manifested by either hypertension or seizures. Treatment is the same as prior to delivery—ie, with magnesium sulfate—though other antiseizure medications can be used since the fetus is no longer present.

GESTATIONAL TROPHOBLASTIC DISEASE (HYDATIDIFORM MOLE & CHORIOCARCINOMA)

Essentials of Diagnosis

Hydatidiform Mole

- Amenorrhea.
- Irregular uterine bleeding.
- Serum hCG β -subunit > 40,000 mU/mL.
- Passage of grape-like clusters of enlarged edematous villi per vagina.
- Ultrasound of uterus with characteristic "snowstorm" image and no fetus or placenta.
- Cytogenetic composition is 46,XX (85%), completely of paternal origin.

General Considerations

Gestational trophoblastic disease is a spectrum of disorders that includes hydatidiform mole, invasive mole, and choriocarcinoma. Partial moles generally show evidence of an embryo or gestational sac; are polypoid, slower-growing, and less symptomatic; and often present clinically as a missed abortion. Partial moles tend to follow a benign course, while complete moles have a greater tendency to become choriocarcinomas.

The highest rates of gestational trophoblastic disease occur in some developing countries, with rates of 1:125 pregnancies in certain areas of Asia. In the United States, the frequency is 1:1500 pregnancies. Risk factors include low socioeconomic status, a history of mole, and age below 18 or above 40. Approximately 10% of women require further treatment after evacuation of the mole; 5% develop choriocarcinoma.

Clinical Findings

A. Symptoms and Signs

Excessive nausea and vomiting occur in over one-third of patients with hydatidiform mole. Uterine bleeding, beginning at 6-8 weeks, is observed in virtually all instances. In about one-fifth of cases, the uterus is larger than would be expected in a normal pregnancy of the same duration. Bilaterally enlarged cystic ovaries are sometimes palpable. They are the result of ovarian hyperstimulation due to excess of hCG.

Preeclampsia-eclampsia, frequently of the fulminating type, may develop during the second trimester of pregnancy, but this is unusual.

Choriocarcinoma may be manifested by continued or recurrent uterine bleeding after evacuation of a mole or following delivery, abortion, or ectopic pregnancy. The presence of an ulcerative vaginal tumor, pelvic mass, or evidence of distant metastatic tumor may be the presenting observation. The diagnosis is established by pathologic examination of curettings or by biopsy.

B. Laboratory Findings

A serum hCG β -subunit value above 40,000 mU/mL or a urinary hCG value in excess of 100,000 units/24 h increases the likelihood of hydatidiform mole.

C. Imaging

Ultrasound has virtually replaced all other means of preoperative diagnosis of hydatidiform mole. A preoperative chest film is indicated to rule out pulmonary metastases of trophoblast.

Treatment

A. Specific (Surgical) Measures

The uterus should be emptied as soon as the diagnosis of hydatidiform mole is established, preferably by suction. Ovarian cysts should not be resected nor ovaries removed; spontaneous regression of theca lutein cysts will occur with elimination of the mole.

If malignant tissue is discovered at surgery or during the follow-up examination, chemotherapy is indicated.

Thyrototoxicosis indistinguishable clinically from that of thyroid origin may occur. While hCG usually has minimal TSH-like activity, the very high hCG levels associated with moles result in the release of T_3 and T_4 and cause hyperthyroidism. Patients thyrotoxic on this basis should be stabilized with beta-blockers prior to induction of anesthesia for their surgical evacuation. Surgical removal of the mole promptly corrects the thyroid overactivity.

B. Follow-Up Measures

Effective contraception (preferably birth control pills) should be prescribed. Weekly quantitative hCG level measurements are initially required. Following successful surgical evacuation, moles show a progressive decline in hCG. After two negative weekly tests (< 5 mU/mL), the interval may be increased to monthly for 6 months and then to every 2 months for a total of 1 year. If levels plateau or begin to rise, the patient should be evaluated by repeat chest film and D&C before the initiation of chemotherapy.

C. Antitumor Chemotherapy

For low-risk patients with a good prognosis, methotrexate, 0.4 mg/kg intramuscularly over a 5-day period, or dactinomycin, 10-12 ug/kg/d intravenously over a 5-day period, is used (see [Table 40-3](#)). Patients with a poor prognosis should be referred to a cancer center, where multiple-agent chemotherapy probably will be given. The side effects—*anorexia, nausea and vomiting, stomatitis, rash, diarrhea, and bone marrow depression*—usually are reversible in about 3 weeks and can be ameliorated by the administration of leucovorin (0.1 mg/kg). Repeated courses of methotrexate 2 weeks apart generally are required to destroy the trophoblast and maintain a zero chorionic gonadotropin titer, as indicated by β -hCG determination.

D. Supportive Measures

Oral contraceptives (if acceptable) or another reliable birth control method should be prescribed to avoid the hazard and confusion of elevated hCG from a new pregnancy. The hCG levels should be negative for a year before pregnancy is again attempted. In the pregnancy following a mole, the hCG level should be checked 6 weeks postpartum.

Prognosis

Five years' survival after courses of chemotherapy, even when metastases have been demonstrated, can be expected in at least 85% of cases of choriocarcinoma.

Seckl MJ et al: Choriocarcinoma and partial hydatidiform moles. Lancet 2000;356:36. [PMID: 10892763]

THIRD-TRIMESTER BLEEDING

Five to 10 percent of women have vaginal bleeding in late pregnancy. The clinician must distinguish between placental causes (placenta previa, placental abruption, vasa previa) and nonplacental causes (infection, disorders of the lower genital tract, systemic disease). The approach to bleeding in late pregnancy should be conservative and expectant unless fetal distress or risk of maternal hemorrhage occurs.

The patient should be hospitalized and placed at bed rest with continuous fetal monitoring. A complete blood count (including platelets) should be obtained and two to four units of blood typed and cross-matched. Coagulation studies should be ordered as clinically indicated. Ultrasound examination should be performed to determine placental location. Speculum and digital pelvic examinations are done only after ultrasound study has ruled out placenta previa. Continuous electronic fetal monitoring is required to exclude fetal distress. While uterine contractions, pain, or tenderness often indicate associated abruptio placentae, an ultrasound negative for retroplacental clot does not exclude it.

If the patient is at less than 36 weeks of gestation, continued hospitalization and bed rest may be necessary, especially with placenta previa during the initial 7-10 days following vaginal bleeding. If the patient has close proximity to the hospital and immediate access, can be on strict bed rest, and has complete resolution of bleeding and uterine contractions, home management may be considered. She must be well instructed and counseled regarding the risks. Patients with vaginal bleeding at less than 36 weeks of gestation should also be considered for amniocentesis to test for fetal lung maturity. Steroid therapy (betamethasone 12 mg intramuscularly, two doses 12-24 hours apart) is indicated if fetal lung immaturity is present.

MEDICAL CONDITIONS COMPLICATING PREGNANCY

Anemia

Plasma volume increases 50% during pregnancy, while red cell volume increases 25%, causing lower hemoglobin and hematocrit values, which are maximally changed around the 24th to 28th weeks. Anemia in pregnancy is often defined as a hemoglobin measurement below 10 g/dL or hematocrit below 30%. Anemia is very common in pregnancy, causing fatigue, anorexia, dyspnea, and edema. Prevention through optimal nutrition and iron and folic acid supplementation is desirable.

A. Iron Deficiency Anemia

Many women enter pregnancy with low iron stores resulting from heavy menstrual periods, previous pregnancies, breast feeding, or poor nutrition. It is difficult to meet the increased requirement for iron through diet, and anemia often develops unless iron supplements are given. Red cells may not become hypo-chromic and microcytic until the hematocrit has fallen significantly. When this occurs, a serum iron level below 40 ug/dL and a transferrin saturation less than 10% suggest iron deficiency anemia (see [Chapter 13](#)). Treatment consists of a diet containing iron-rich foods and 60 mg of elemental iron (eg, 300 mg of ferrous sulfate) three times a day with meals. Iron is best absorbed if taken with a source of vitamin C (raw fruits and vegetables, lightly cooked greens). All pregnant women should take daily iron supplements.

B. Folic Acid Deficiency Anemia

Folic acid deficiency anemia is the main cause of macrocytic anemia in pregnancy, since vitamin B₁₂ deficiency anemia is rare in the childbearing years. The daily requirement of folic acid doubles from 0.4 mg to 0.8 mg in pregnancy. Twin pregnancies, infections, malabsorption, and use of anticonvulsant drugs such as phenytoin can precipitate folic acid deficiency. The anemia may first be seen in the puerperium owing to the increased need for folate during lactation.

The diagnosis is made by finding macrocytic red cells and hypersegmented neutrophils in a blood smear (see [Chapter 13](#)). However, blood smears in pregnancy may be difficult to interpret, since they frequently show iron deficiency changes as well. Because the deficiency is hard to diagnose and folate intake is inadequate in some socioeconomic groups, 0.8-1 mg of folic acid is given as a supplement in pregnancy; the dose in established deficiency is 1-5 mg/d.

Good sources of folate in food are leafy green vegetables, orange juice, peanuts, and beans. Cooking and storage of food destroy folic acid. Strict vegetarians who eat no eggs or milk products should take vitamin B₁₂ supplements during pregnancy and lactation.

C. Sickle Cell Anemia

Women with sickle cell anemia are subject to serious complications in pregnancy. The anemia becomes more severe, and crises may occur more frequently. Complications include infections, bone pain, pulmonary infarction, congestive heart failure, and preeclampsia. There is an increased rate of spontaneous abortion and higher maternal and perinatal mortality rates. Intensive medical treatment may improve the outcome for mother and fetus. Frequent indicated transfusions of packed cells or leukocyte-poor washed red cells lower the level of hemoglobin S and elevate the level of hemoglobin A; this minimizes the severity of anemia and the risk of sickle cell crises.

Genetic counseling should be offered to patients with sickle cell disease or sickle trait. They may wish to undergo first-trimester chorionic villus biopsy or second-trimester amniocentesis to determine whether the abnormality has been passed on to the fetus. IUDs and oral contraceptives are relatively contraindicated, but progestin-only contraceptives may be used. Women with sickle cell trait alone usually have an uncomplicated gestation except for an increased risk of urinary tract infection. Sickle cell-hemoglobin C disease in pregnancy is similar to sickle cell anemia and is treated similarly.

Allen LH: Anemia and iron deficiency: effects on pregnancy outcome. Am J Clin Nutr 2000;71(5 Suppl):1280S. [PMID: 10799402]

Lupus Anticoagulant-Anticardiolipin-Antiphospholipid Antibody Syndrome

The presence of antibodies to phospholipids and a variety of clinical symptoms, including vascular thromboses, thrombocytopenia, and recurrent pregnancy loss, characterize the lupus anticoagulant-antiscardiolipin-antiphospholipid antibody syndrome. Many of these patients have SLE-like symptoms but do not meet specific diagnostic criteria for that disease. The lupus anticoagulant and anticardiolipin antibody may occur in these patients, and both may cause arterial and venous thromboses. Detection of these antiphospholipid antibodies may require a combination of laboratory tests. The lupus anticoagulant will prolong both the partial thromboplastin time (PTT) and the Russell viper venom time. The latter is a more sensitive predictor of disease. Such patients should also be screened for the presence of the factor V Leiden mutation. Anticardiolipin antibody may be detected with ELISA testing. Either antibody may cause false-positive serologic tests for syphilis.

This syndrome may require treatment with anticoagulant medications. In a small number of patients with recurrent pregnancy loss and a diagnosis of lupus anticoagulant syndrome, improved outcomes have been reported following treatment with heparin anticoagulation (8000-20,000 units in two or three doses daily) or low-molecular-weight heparin (1 mg/kg twice daily) and low-dose aspirin begun before or early in pregnancy and continued until the postpartum period. The addition of monthly infusions of IGIV to this regimen did not improve outcomes in such patients.

Levine JS et al: The antiphospholipid syndrome. N Engl J Med 2002;346:752. [PMID: 11882732]

Asthma

The effect of pregnancy on asthma is unpredictable. About 50% of patients have no change, 25% improve, and 25% get worse. Management of acute and chronic asthma during pregnancy does not differ significantly from that of nonpregnant women. The goal is to maintain maternal PO₂ > 80 mm Hg to sustain normal fetal oxygenation (see [Chapter 9](#)).

The use of newer asthma and allergy medications during pregnancy. ACOG and ACAAI. Ann Allergy Asthma Immunol 2000;84:475. [PMID: 10830999]

AIDS During Pregnancy

Heterosexual acquisition (51%) and injecting drug use (45%) are the principal modes of HIV infection in women. In 15%, no risk factor is reported or identified. Asymptomatic infection is associated with a normal pregnancy rate and no increased risk of adverse pregnancy outcomes. There is no evidence that pregnancy causes AIDS progression.

Although some fetuses appear to acquire HIV infection antenatally by transplacental transmission, approximately two-thirds are infected close to or during the time of delivery. Zidovudine given to the mother antenatally (500 mg/d orally) and during labor (1 mg/kg/h intravenously) and then to the infant (2 mg/kg orally four times daily) for the first 6 weeks of life reduces the transmission rate from 25% to 8%. Pregnancy does not preclude the use of combinations of highly active antiretroviral therapy (HAART). HIV-positive pregnant women should be assessed by CD4 count, plasma RNA levels, and prior or current antiretroviral use. In general, pregnant HIV-positive women should receive at least zidovudine but also HAART as appropriate for their HIV disease status after counseling regarding the potential impact of therapy on the fetus and infant after delivery. The use of prophylactic elective cesarean section before the onset of labor or rupture of the membranes to prevent vertical transmission of HIV infection from mother to fetus has been shown to reduce the transmission rate to 2% in infants of mothers taking zidovudine. There is limited information on the impact of elective cesarean section on transmission rates in infants of mothers on HAART or with viral loads less than 1000 copies/mL. HIV-infected women should be advised not to breast-feed their infants.

Diabetes Mellitus

Pregnancy is associated with increased tissue resistance to insulin, resulting in increased levels of blood insulin as well as glucose and triglycerides. These changes are due to placental lactogen and elevated circulating estrogens and progesterone. Although pregnancy does not appear to alter the long-term consequences of diabetes, retinopathy and nephropathy may first appear or become worse during pregnancy. The White classification of diabetes has been largely abandoned. The emphasis in classifying diabetes mellitus has shifted more to etiology. Type 1 diabetics often express particular HLA haplotypes and have anti-islet cell antibodies contributing to their insulin dependence and risk of ketoacidosis. Type 2 diabetics have minimal to no risk of ketoacidosis even though they may require insulin to control their blood glucose levels. Debate continues over whether gestational diabetics are women whose glucose intolerance is solely a function of their pregnant compared with their nonpregnant state. Alternatively, pregnancy may merely serve to unmask an underlying propensity for glucose intolerance, which will be evident even in the nonpregnant state at some time in the future if not in the immediate postpartum period. However, goals for glycemic control during pregnancy are the same whether the diagnosis is made before or during the pregnancy.

Prepregnancy counseling and evaluation of diabetic women should include a complete chemistry panel, HbA_{1c} determination, 24-hour urine collection for total protein and creatinine clearance, funduscopy examination, and an ECG. Any medical problems should be addressed, and HbA_{1c} levels of less than 8% should be achieved before pregnancy. Euglycemia should be established before conception and maintained during pregnancy with daily home glucose monitoring by the patient. A well-planned dietary program is a key component, with an intake of 1800-2200 kcal/d divided into three meals and three snacks. Insulin is given subcutaneously in a split-dose regimen with frequent dosage adjustments. Patients taking oral agents prior to pregnancy should be switched to insulin. However, limited information suggests that agents such as glyburide may be safe and effective in pregnancy. The use of continuous insulin pump therapy has been found to be very useful during pregnancy in women with type 1 diabetes mellitus.

Congenital anomalies result from hyperglycemia during the first 4-8 weeks of pregnancy. They occur in 4-10% of diabetic pregnancies (two to three times the rate in nondiabetic pregnancies). Euglycemia in the early weeks of pregnancy, when organogenesis is occurring, reduces the rate of anomalies to near-normal levels. Even so, because few women with diabetes begin a rigorous program to achieve euglycemia until well after they have become pregnant, congenital anomalies are the principal cause of perinatal fetal deaths in diabetic pregnancies. All women with diabetes should receive counseling about pregnancy and, when the decision has been made to start a family, should receive prepregnancy management by physicians experienced in diabetic pregnancies.

Fasting and preprandial glucose values are lower during pregnancy in both diabetic and nondiabetic women. Euglycemia is considered to be 60-80 mg/dL while fasting and 30-45 minutes before meals and < 120 mg/dL 2 hours after meals. This is the target for good diabetic control during pregnancy. Glycated hemoglobin levels help determine the quality of glucose control both before and during pregnancy.

While perinatal problems for mother and baby are decreased by fastidious diabetic control, the incidence of hydramnios, preeclampsia-eclampsia, infections, and prematurity is increased even in carefully managed diabetic pregnancies. Diabetes is an inherently unstable disease characterized by fluctuations of blood glucose levels, particularly late in pregnancy. The risk of fetal demise in the third trimester (stillbirth) and neonatal death increases with the level of hyperglycemia. Consequently, pregnant women with diabetes must receive regular antepartum fetal testing (nonstress testing, contraction stress testing, biophysical profile) during the third trimester. The timing of delivery is dictated by the quality of diabetic control, the presence or absence of medical complications, and fetal status. The goal is to reach 39 weeks (38 completed weeks) and then proceed with delivery. Confirmation of lung maturity is necessary only for delivery prior to 39 weeks. Cesarean sections are performed for obstetric indications.

Because 15% of patients with gestational diabetes require insulin during pregnancy and because the infants of gestational diabetics have some risks similar to those of infants of diabetic mothers (particularly macrosomia), screening of women for glucose intolerance has been recommended between the 24th and 28th weeks of pregnancy ([Table 18-3](#)). Patients with gestational diabetes should be evaluated 6-8 weeks postpartum by a 2-hour oral glucose tolerance test (75-g glucose load).

Heart Disease

Overall, 5% of maternal deaths are due to heart disease. Most heart disease complicating pregnancy in the USA is congenital heart disease. Normal pregnancy causes a faster pulse, an increase of cardiac output of more than 30%, and a rise in plasma volume greater than red cell mass with relative hemodilution. Vital capacity and oxygen consumption rise only slightly.

For practical purposes, the functional capacity of the heart is the best single measurement of cardiopulmonary status.

FUNCTIONAL CARDIAC ASSESSMENT

- Class I Ordinary physical activity causes no discomfort (perinatal mortality rate about 5%).
- Class II Ordinary activity causes discomfort and slight disability (perinatal mortality rate 10-15%).
- Class III Less than ordinary activity causes discomfort or disability; patient is barely compensated (perinatal mortality rate about 35%).
- Class IV Patient decompensated; any physical activity causes acute distress

(perinatal mortality rate over 50%).

In general, patients with class I or class II functional disability (80% of pregnant women with heart disease) do well obstetrically, with four-fifths of maternal deaths due to heart disease occurring in women with class III or class IV disability. Congestive failure is the usual cause of death. Most deaths occur in the early puerperium. Pregnancy is contraindicated in Eisenmenger's complex, in primary pulmonary hypertension, in severe mitral stenosis with secondary pulmonary hypertension, and in Marfan's syndrome, in which the aorta is prone to dissection and rupture. In addition, pregnancy is poorly tolerated in patients with aortic stenosis, aortic coarctation, tetralogy of Fallot, and active rheumatic carditis.

Therapeutic abortion and elective sterilization should be offered to patients with significant cardiac disease. Cesarean section should be performed only for obstetric indications. Women with valvular heart disease, mitral valve prolapse associated with mitral insufficiency, or idiopathic hypertrophic cardiomyopathy should receive appropriate antibiotic prophylaxis against infective endocarditis during labor and delivery or termination of pregnancy.

Peripartum Cardiomyopathy

Cardiac failure that develops during pregnancy or during the first 6 months postpartum in a woman without a history of heart disease and with no cause for heart failure other than pregnancy is termed peripartum cardiomyopathy. The incidence varies from 1:4000 to 1:1000. It is higher in Africa. It occurs more often in older women, those with twins, and in patients with pregnancy-induced hypertension. The cause of peripartum cardiomyopathy is unknown. In patients who continue to have symptoms and signs of disease for more than 6 months postpartum, the mortality rate is high, and subsequent pregnancy is especially dangerous.

Symptoms of peripartum cardiomyopathy are those of congestive heart failure. An ECG may reveal tachycardia and atrial or ventricular arrhythmias. Death may occur as a result of arrhythmia or embolism. Autopsy usually reveals an enlarged, dilated heart, and mural thrombi (the source of pulmonary and systemic emboli) are often found.

The treatment of peripartum cardiomyopathy is that of congestive cardiomyopathy (see [Chapter 10](#)). Patients with persistent cardiomegaly or mural thrombi shown by echocardiography require anticoagulant therapy. The long-term prognosis in these patients depends on whether cardiomegaly resolves within 6 months after the onset of symptoms. If it does not resolve, the 5-year mortality rate is 6%. If cardiomegaly does not resolve and another pregnancy intervenes, cardiomyopathy recurs in 50% of cases, with a 19% mortality rate.

Pearson GD et al: Peripartum cardiomyopathy: National Heart Lung and Blood Institute and Office of Rare Disease (National Institutes of Health) workshop recommendations and review. *JAMA* 2000;283:1183. [\[PMID: 10703781\]](#)

Herpes Genitalis (See also [Chapter 6](#).)

Infection of the lower genital tract by herpes simplex virus type 2 (HSV-2) is a common sexually transmitted disease of potential seriousness to pregnant women and their newborn infants. Although up to 20% of women in an obstetric practice may have antibodies to HSV-2, a history of the infection is unreliable and the incidence of neonatal infection is low (1:20,000-1:3000 live births). Most infected neonates are born to women with no symptoms, signs, or history of infection.

Women who have had *primary* herpes infection late in pregnancy are at high risk of shedding virus at delivery. Some authors suggest use of prophylactic acyclovir, 400 mg orally twice daily, to decrease the likelihood of active lesions at the time of labor and delivery.

Women with a history of *recurrent* genital herpes have a neonatal attack rate of 5% and should be followed by clinical observation and culture of any suspicious lesions. Since asymptomatic viral shedding is not predictable by antepartum cultures, current recommendations do not include routine cultures in individuals with a history of herpes without active disease. However, when labor begins, vulvar and cervical inspection and cultures should be performed, with prompt treatment of a newborn after a positive culture.

For treatment, see [Chapter 32](#). The use of acyclovir in pregnancy is acceptable when there is significant fetal or neonatal risk.

Cesarean section is indicated at the time of labor if there are prodromal symptoms, active genital lesions, or a positive cervical culture obtained within the preceding week.

Hypertensive Disease

Hypertensive disease in women of childbearing age is usually essential hypertension, but secondary causes should be considered: coarctation of the aorta, pheochromocytoma, hyperaldosteronism, and renovascular and renal hypertension.

Preeclampsia is superimposed on 20% of pregnancies in hypertensive women and appears earlier, is more severe, and is more often associated with intrauterine growth retardation. It may be difficult to determine whether or not hypertension in a pregnant woman precedes or derives from the pregnancy if she is not examined until after the 20th week. Serum uric acid can help differentiate, since it is elevated with preeclampsia and normal in chronic hypertension unless the patient is receiving diuretics. If hypertension persists for 6-8 weeks postpartum, essential hypertension is likely.

Pregnant women with chronic hypertension require medication only if the diastolic pressure is sustained at or above 100 mm Hg. For initiation of treatment, methyldopa has the longest record of safety in a dosage of 250 mg orally twice daily, increasing in divided doses as needed to as much as 3 g daily. The goal is to keep the diastolic pressure between 80 mm Hg and 100 mm Hg.

If a hypertensive woman is being managed successfully by medical treatment when she registers for antenatal care, one may generally continue the antihypertensive medication. Diuretics may be continued in pregnancy. ACE inhibitors should be replaced with a drug of another class because of reports of fetal and neonatal renal failure with these compounds.

Use of antihypertensive medications in preeclampsia remains controversial. This should be attempted only with significant fetal prematurity, absence of fetal compromise, and close supervision of the patient.

Therapeutic abortion may be indicated in cases of severe hypertension during pregnancy. If pregnancy is allowed to continue, the risk to the fetus must be assessed periodically in anticipation of early delivery. An early second-trimester ultrasound examination will confirm the duration of pregnancy, and follow-up examinations after 28 weeks will evaluate intrauterine growth retardation.

Maternal Hepatitis B & C Carrier State

There are an estimated 200 million chronic carriers of hepatitis B virus worldwide. Among these people there is an increased incidence of chronic active hepatitis, cirrhosis, and hepatocellular carcinoma. The frequency of the hepatitis B carrier state varies from 1% in the United States and Western Europe to 35% in parts of Africa and Asia. All pregnant women should be screened for hepatitis B surface antigen (HBsAg). Transmission of the virus to the baby after delivery is likely if both surface antigen and e antigen are positive. Vertical transmission can be blocked by the immediate postdelivery administration to the newborn of 0.5 mL of hepatitis B immunoglobulin and hepatitis B vaccine intramuscularly. The vaccine dose is repeated at 1 and 6 months of age.

Hepatitis C virus infection is the most common chronic blood-borne infection in the United States. Risk factors for transmission include blood transfusion, injecting drug use, employment in patient care or clinical laboratory work, exposure to a sex partner or household member who has had a history of hepatitis, exposure to multiple sex partners, and low socioeconomic level. The average rate of HCV infection among infants born to HCV-positive, HIV-negative women is 5-6%. However, the average infection rate increases to 14% when mothers are coinfectd with HCV and HIV. The principal factor associated with transmission is the presence of HCV RNA

in the mother at the time of birth.

Roberts EA: Maternal-infant transmission of hepatitis C virus infection. Hepatology 2002;36(5 Suppl 1):S106. [\[PMID: 12407583\]](#)

Acute Fatty Liver of Pregnancy

Acute fatty liver of pregnancy is a disorder limited to the gravid state. It occurs in the third trimester of pregnancy and involves acute hepatic failure. With improved recognition and immediate delivery, the mortality range is now 20-30%. The disorder is usually seen after the 35th week of gestation and is more common in primigravidas and those with twins. The incidence is about 1:14,000 deliveries.

The cause of acute fatty liver of pregnancy is not known. Pathologic findings are unique to the disorder, with fatty engorgement of hepatocytes. Clinical onset is gradual, with flu-like symptoms that progress to the development of abdominal pain, jaundice, encephalopathy, disseminated intravascular coagulation, and death. On examination, the patient shows signs of hepatic failure.

Laboratory findings show marked elevation of alkaline phosphatase but only moderate elevations of ALT and AST. Prothrombin time and bilirubin are also elevated. The white blood cell count is elevated, and the platelet count is depressed. Hypoglycemia may be extreme.

The differential diagnosis is that of fulminant hepatitis. However, liver aminotransferases for fulminant hepatitis are higher (> 1000 units/mL) than those for acute fatty liver of pregnancy (usually < 500 units/mL). It is also important to review the appropriate history and perform the appropriate tests for toxins that cause liver failure. Preeclampsia may involve the liver but typically does not cause jaundice. The elevations in liver function tests in patients with pre-eclampsia usually do not reach the levels seen in patients with acute fatty liver of pregnancy.

Diagnosis of acute fatty liver of pregnancy mandates immediate delivery. Supportive care during labor includes administration of glucose, platelets, and fresh frozen plasma as needed. Vaginal delivery is preferred. Resolution of encephalopathy occurs over days, and supportive care with a low-protein diet is needed.

Recurrence rates for this liver disorder are unclear. Most authorities advise against subsequent pregnancy, but there have been reported cases of successful outcomes in later pregnancies.

Castro MA et al: Reversible peripartum liver failure: a new perspective on the diagnosis, treatment, and cause of acute fatty liver of pregnancy, based on 28 consecutive cases. Am J Obstet Gynecol 1999;181:389. [\[PMID: 10454689\]](#)

Seizure Disorders

Epileptic women contemplating pregnancy who have not had a seizure for 5 years should consider a prepregnancy trial of withdrawal from treatment. Those with recurrent epilepsy should use a single drug with blood level monitoring. Trimethadione and valproate are contraindicated during pregnancy; phenytoin and carbamazepine may be teratogenic in the first trimester and should not be used unless absolutely necessary. Newer antiepilepsy drugs (eg, lamotrigine) have recently been introduced, but there is limited information available on their safety in pregnancy and they should generally be avoided.

Phenobarbital is considered the drug of choice. Serum levels should be measured in each trimester and dosage adjustments made to keep serum levels in the low normal therapeutic range. Pregnant women taking phenobarbital and phenytoin should receive vitamin supplements, including folic acid and vitamin D, throughout pregnancy. Vitamin K, 10-20 mg/d, is administered during the last month to help prevent bleeding problems in the newborn, who is at risk of bleeding tendencies due to decreased levels of clotting factors. Such infants should receive an injection of vitamin K₁, 1 mg subcutaneously immediately after delivery, and should have clotting studies 2-4 hours later. Breast feeding is not contraindicated for infants of mothers taking antiseizure medications.

Syphilis, Gonorrhea, & *Chlamydia trachomatis* Infection (See also [Chapters 33 and 34.](#))

These sexually transmitted diseases have significant consequences for mother and child. Untreated syphilis in pregnancy will cause late abortion, stillbirth, transplacental infection, and congenital syphilis. Gonorrhea will produce large-joint arthritis by hematogenous spread as well as ophthalmia neonatorum. Maternal chlamydial infections are largely asymptomatic but are manifested in the newborn by inclusion conjunctivitis and, at age 2-4 months, by pneumonia. The diagnosis of each can be reliably made by appropriate laboratory tests, which should be included in all prenatal care. The sexual partners of women with sexually transmitted diseases should be identified and treated also if that can be done.

Gene M et al: Syphilis in pregnancy. Sex Transm Infect 2000; 76:73. [\[PMID: 10858706\]](#)

Group B Streptococcal Infection

Group B streptococci frequently colonize the lower female genital tract, with an asymptomatic carriage rate in pregnancy of 5-30%. This rate depends on maternal age, gravidity, and geographic variation. Vaginal carriage is asymptomatic and intermittent, with spontaneous clearing in approximately 30% and recolonization in about 10% of women. Adverse perinatal outcomes associated with group B streptococcal colonization include urinary tract infection, intrauterine infection, premature rupture of membranes, preterm delivery, and postpartum endometritis.

Women with postpartum endometritis due to infection with group B streptococci, especially after cesarean section, develop fever, tachycardia, and abdominal distention, usually within 24 hours after delivery. Approximately 35% of these women are bacteremic.

Group B streptococcal infection is a common cause of neonatal sepsis. Transmission rates are high, yet the rate of neonatal sepsis is surprisingly low at less than 4:1000 live births. Unfortunately, the mortality rate associated with early-onset disease can be as high as 50% in premature infants and approaches 25% even in those at term. Moreover, these infections can contribute markedly to chronic morbidity, including mental retardation and neurologic disabilities. Late-onset disease develops through contact with hospital nursery personnel. Up to 45% of these health care workers can carry the bacteria on their skin and transmit the infection to newborns.

CDC recommendations for screening for and prophylaxis of group B streptococcal colonization are set forth in this chapter in the section on tests and procedures.

Shrag SJ et al: A population-based comparison of strategies to prevent early-onset group B streptococcal disease in neonates. N Engl J Med 2002;347:233. [\[PMID: 12140298\]](#)

Varicella

Commonly known as chickenpox, varicella-zoster virus (VZV) infection has a fairly benign course when incurred during childhood but may result in serious illness in adults, particularly during pregnancy. Infection results in lifelong immunity. Approximately 95% of women born in the United States have VZV antibodies by the time they reach reproductive age. The incidence of VZV infection during pregnancy has been reported as up to 7:10,000.

The incubation period for this infection is 10-20 days. A primary infection follows and is characterized by a flu-like syndrome with malaise, fever, and development of a pruritic maculopapular rash on the trunk which becomes vesicular and then crusts. Pregnant women are prone to the development of VZV pneumonia, often a fulminant infection sometimes requiring respiratory support. After primary infection, the virus becomes latent, ascending to dorsal root ganglia. Subsequent reactivation can occur as zoster, often under circumstances of immunocompromise, though this is rare during pregnancy.

Two types of fetal infection have been documented. The first is congenital VZV syndrome, which typically occurs in 0.4-2% of fetuses exposed to primary VZV infection during the first trimester. Anomalies include limb and digit abnormalities, microphthalmos, and microcephaly.

Infection during the second and third trimesters is less threatening. Maternal IgG crosses the placenta, protecting the fetus. The only infants at risk for severe infection are those born after maternal viremia but before development of maternal protective antibody. Maternal infection manifesting 5 days before or after delivery is the time period arbitrarily determined to be most hazardous for transmission to the fetus.

Diagnosis is commonly made on clinical grounds. Laboratory verification of recent infection is made most often by antibody detection techniques, including ELISA, fluorescent antibody, and hemagglutination inhibition. Serum obtained by cordocentesis may be tested for VZV IgM to document fetal infection.

Varicella-zoster immune globulin (VZIG) has been shown to prevent or modify the symptoms of infection in some women. Treatment success depends on identification of susceptible women at or just following exposure. Women with a questionable or negative history of chickenpox should be checked for antibody, since the

overwhelming majority will have been exposed previously. If the antibody is negative, VZIG (625 units intramuscularly) should be given within 96 hours after exposure. There are no known adverse effects of VZIG administration during pregnancy. Infants born within 5 days after onset of maternal infection should also receive VZIG (125 units).

Infected pregnant women should be closely observed and hospitalized at the earliest signs of pulmonary involvement. Intravenous acyclovir (10-15 mg/kg every 8 hours for 7-10 days) is recommended in the treatment of VZV pneumonia.

Harger JH et al: Frequency of congenital varicella syndrome in a prospective cohort of 347 pregnant women. *Obstet Gynecol* 2002;100:260. [\[PMID: 12151147\]](#)

Thyroid Disease

Thyrotoxicosis during pregnancy may result in fetal anomalies, late abortion, or preterm labor and fetal hyperthyroidism with goiter. Thyroid storm in late pregnancy or labor is a life-threatening emergency.

Radioactive isotope therapy must never be given during pregnancy. The thyroid inhibitor of choice is propylthiouracil, which acts to prevent further thyroxine formation by blocking iodination of tyrosine. There is a 2- to 3-week delay before the pretreatment hormone level begins to fall. The initial dose of propylthiouracil is 100-150 mg three times a day; the dose is lowered as the euthyroid state is approached. It is desirable to keep free T₄ in the high normal range during pregnancy. A maintenance dose of 100 mg/d minimizes the chance of fetal hypothyroidism and goiter.

Recurrent postpartum thyroiditis occurs 3-6 months after delivery. A hyperthyroid state of 1-3 months' duration is followed by hypothyroidism, sometimes misdiagnosed as depression. Thyroperoxidase antibodies and thyroglobulin antibodies are present. Recovery is spontaneous in over 90% of cases after 3-6 months.

Maternal hypothyroidism—even subclinical hypothyroidism manifested only by elevated levels of thyroid-stimulating hormone (TSH)—may adversely affect subsequent neuropsychologic development of the child. Mothers with known or suspected hypothyroidism should have the TSH level measured at the first prenatal visit. Replacement therapy with levothyroxine should be adjusted to maintain levels of TSH in the normal range.

Lazarus JH et al: Thyroid disease in relation to pregnancy: a decade of change. *Clin Endocrinol* 2000;53:265. [\[PMID: 10971442\]](#)

Tuberculosis

The diagnosis of tuberculosis in pregnancy is made by history taking, physical examination, and skin testing, with special attention to women from ethnic groups with a high prevalence of the disease (such as women from southeast Asia). Chest films should not be obtained as a routine screening measure in pregnancy but should be used only in patients with a skin test conversion or with suggestive findings in the history and physical examination. Abdominal shielding must be used if a chest film is obtained.

If adequately treated, tuberculosis in pregnancy has an excellent prognosis. There is no increase in spontaneous abortion, fetal problems, or congenital anomalies.

Treatment is with isoniazid and ethambutol or isoniazid and rifampin (see [Chapters 9](#) and [33](#)). Because isoniazid therapy may result in vitamin B₆ deficiency, a supplement of 50 mg/d of vitamin B₆ should be given simultaneously. Streptomycin, ethionamide, and most other antituberculous drugs should be avoided in pregnancy.

Urinary Tract Infection

The urinary tract is especially vulnerable to infections during pregnancy because the altered secretions of steroid sex hormones and the pressure exerted by the gravid uterus upon the ureters and bladder cause hypotonia and congestion and predispose to urinary stasis. Labor and delivery and urinary retention postpartum also may initiate or aggravate infection. *Escherichia coli* is the offending organism in over two-thirds of cases.

From 2% to 8% of pregnant women have asymptomatic bacteriuria, which some believe to be associated with an increased risk of prematurity. It is estimated that 20-40% of these women will develop pyelonephritis during pregnancy if untreated.

A first-trimester urine culture is indicated in women with a history of recurrent or recent episodes of urinary tract infection. If the culture is positive, treatment should be initiated as a prophylactic measure. Nitrofurantoin (100 mg twice daily), ampicillin (500 mg four times daily), and cephalexin (500 mg four times daily) are acceptable medications for 3-7 days. Sulfonamides should not be given in the third trimester because they interfere with bilirubin binding and thus impose a risk of neonatal hyperbilirubinemia and kernicterus. Fluoroquinolones are also contraindicated because of their potential teratogenic effects on fetal cartilage and bone. If bacteriuria returns, suppressive medication (one daily dose of an appropriate antibiotic) for the remainder of the pregnancy is indicated. Acute pyelonephritis requires hospitalization for intravenous administration of antibiotics until the patient is afebrile; this is followed by a full course of oral antibiotics.

Delzell JE Jr et al: Urinary tract infections during pregnancy. *Am Fam Physician* 2000;61:713. [\[PMID: 10695584\]](#)

SURGICAL COMPLICATIONS DURING PREGNANCY

Elective major surgery should be avoided during pregnancy. Normal uncomplicated pregnancy does not alter operative risk except as it may interfere with the diagnosis of abdominal disorders and increase the technical problems of intra-abdominal surgery. Abortion is not a serious hazard after operation unless peritoneal sepsis or other significant complications occur. During the first trimester, congenital anomalies may be induced in the developing fetus by hypoxia. Thus, the second trimester is usually the optimal time for operative procedures.

Appendicitis

Appendicitis occurs in about one of 1500 pregnancies. Diagnosis may be difficult, since the appendix is carried high and to the right, away from McBurney's point, as the uterus enlarges, and localization of pain does not always occur. Nausea, vomiting, fever, and leukocytosis occur regularly. Any right-sided abdominal pain associated with these symptoms should arouse suspicion. In at least 20% of obstetric patients, the diagnosis of appendicitis is not made until rupture occurs and peritonitis has become established. Such a delay may lead to premature labor or abortion. With early diagnosis and appendectomy, the prognosis is good for mother and baby.

Sharp HT: The acute abdomen during pregnancy. *Clin Obstet Gynecol* 2002;45:405. [\[PMID: 12048399\]](#)

Carcinoma of the Breast

Cancer of the breast (see also [Chapter 16](#)) is diagnosed approximately once in 3500 pregnancies. Pregnancy may accelerate the growth of cancer of the breast, and delay in diagnosis affects the outcome of treatment. Inflammatory carcinoma is an extremely virulent type of breast cancer that occurs most commonly during lactation. Prepregnancy mammography should be encouraged for women over age 35 who are anticipating a pregnancy.

Breast enlargement during pregnancy obscures parenchymal masses, and breast tissue hyperplasia decreases the accuracy of mammography. Any discrete mass should be evaluated by aspiration to verify its cystic structure, with fine-needle biopsy if it is solid. A definitive diagnosis may require excisional biopsy under local anesthesia. If breast biopsy confirms the diagnosis of cancer, surgery should be done regardless of the stage of the pregnancy. If spread to the regional glands has occurred, irradiation or chemotherapy should be considered. Under these circumstances, the alternatives are termination of an early pregnancy or delay of therapy for fetal maturation.

Choledocholithiasis, Cholecystitis, & Idiopathic Cholestasis of Pregnancy

Severe choledocholithiasis and cholecystitis are not uncommon during pregnancy. When they do occur, it is usually in late pregnancy or in the puerperium. About 90% of patients with cholecystitis have gallstones; 90% of stones will be visualized by ultrasonography. Symptomatic relief may be all that is required.

Conventional gallbladder surgery in pregnant women should be attempted only in complicated cases (eg, obstruction), because it may increase the perinatal mortality rate to about 15%. Cholecystostomy and lithotomy may be all that is feasible during advanced pregnancy, cholecystectomy being deferred until after delivery. On the other hand, withholding surgery may result in necrosis and perforation of the gallbladder and peritonitis. Cholangitis due to impacted common duct stone requires surgical removal of gallstones and establishment of biliary drainage. Endoscopic retrograde cholangiopancreatography and endoscopic retrograde sphincterotomy can

be performed safely in pregnant women if precautions are taken to minimize exposure to radiation. In the early to mid second trimester, laparoscopic cholecystectomy can be performed with minimal maternal morbidity and no fetal mortality.

Idiopathic cholestasis of pregnancy is due to a hereditary metabolic (hepatic) deficiency aggravated by the high estrogen levels of pregnancy. It causes intrahepatic biliary obstruction of varying degrees. The rise in bile acids is sufficient in the third trimester to cause severe, intractable, generalized itching and sometimes clinical jaundice. There may be mild elevations in blood bilirubin and alkaline phosphatase levels. The fetus is also threatened by this condition. An increased incidence of preterm delivery has been reported as well as unexplained intrauterine fetal demise. For this reason, antenatal surveillance of the fetus is mandatory in patients with this diagnosis. Resins such as cholestyramine (4 g three times a day) absorb bile acids in the large bowel and relieve pruritus but are difficult to take and may cause constipation. Their use requires vitamin K supplementation. Limited but very encouraging experience has been reported with ursodeoxycholic acid, 16 mg/kg/d orally for 3 weeks, or dexamethasone, 12 mg/d orally for 7 days. The disorder is relieved once the infant has been delivered, but it recurs in subsequent pregnancies and sometimes with the use of oral contraceptives.

Ovarian Tumors

The most common adnexal mass in early pregnancy is the corpus luteum, which may become cystic and enlarge to 6 cm in diameter. Any persistent mass over 6 cm should be evaluated by ultrasound examination; unilocular cysts are likely to be corpus luteum cysts, whereas septated or semisolid tumors are likely to be neoplasms. The incidence of malignancy in ovarian masses over 6 cm in diameter is 2.5%. Ovarian tumors may undergo torsion and cause abdominal pain and nausea and vomiting and must be differentiated from appendicitis, other bowel disease, and ectopic pregnancy. Patients with suspected ovarian cancer should be referred to a tertiary perinatal center to determine whether the pregnancy can progress to fetal viability or whether treatment should be instituted without delay.

PREVENTION OF HEMOLYTIC DISEASE OF THE NEWBORN (ERYTHROBLASTOSIS FETALIS)

The antibody anti-Rh₀(D) is responsible for most severe instances of hemolytic disease of the newborn (erythroblastosis fetalis). About 15% of whites and much lower proportions of blacks and Asians are Rh₀(D)-negative. If an Rh₀(D)-negative woman carries an Rh₀(D)-positive fetus, she may develop antibodies against Rh₀(D) when fetal red cells enter her circulation during small fetomaternal bleeding episodes in the early third trimester or during delivery, abortion, ectopic pregnancy, abruptio placentae, or other antepartum bleeding problems. This antibody, once produced, remains in the woman's circulation and poses the threat of hemolytic disease for subsequent Rh-positive fetuses.

Passive immunization against hemolytic disease of the newborn is achieved with Rh₀(D) immune globulin, a purified concentrate of antibodies against Rh₀(D) antigen. The Rh₀(D) immune globulin (one vial of 300 ug intramuscularly) is given to the mother within 72 hours after delivery (or spontaneous or induced abortion or ectopic pregnancy). The antibodies in the immune globulin destroy fetal Rh-positive cells so that the mother will not produce anti-Rh₀(D). During her next Rh-positive gestation, erythroblastosis will be prevented. An additional safety measure is the administration of the immune globulin at the 28th week of pregnancy. The passive antibody titer that results is too low to significantly affect an Rh-positive fetus. The maternal clearance of the globulin is slow enough that protection will continue for 12 weeks.

Hemolytic disease of varying degrees, from mild to serious, continues to occur in association with Rh subgroups (C, c, or E) or Kell, Kidd, and other factors. Therefore, the presence of atypical antibodies should be checked in the third trimester of all pregnancies.

Prevention of Rh D alloimmunization. Clinical management guidelines for obstetrician-gynecologists. ACOG Practice Bulletin No. 4, 1999. Int J Gynaecol Obstet 1999;66:63. [PMID: 10458556]

PREVENTION OF PRETERM (PREMATURE) LABOR

Preterm (premature) labor is labor that begins before the 37th week of pregnancy; it is responsible for 85% of neonatal illnesses and deaths. The onset of labor is a result of a complex sequence of biologic events involving regulatory factors that are still poorly understood. Significant risk factors for the onset of preterm labor are a past history of preterm delivery, premature rupture of the membranes, urinary tract infection, exposure to diethylstilbestrol, multiple gestation, and abdominal or cervical surgery. In high-risk women (prior preterm birth), ultrasound measurement of cervical length (< 25 mm) in the second trimester may also identify a significant risk.

Low rates of preterm delivery are associated with success in educating patients to identify regular, frequent uterine contractions and in alerting medical and nursing staff to evaluate these patients early and initiate treatment if cervical changes can be identified. Distinguishing true from false labor in patients with a history of previous preterm births can be facilitated by the use of fetal fibronectin measurement in cervicovaginal specimens. This ubiquitous protein can be released by several different stimuli. Its absence (< 50 ng/mL) in the face of uterine contractions in a patient with a previous preterm birth has a negative predictive value of 93-97% for delivery within 7-14 days. On the other hand, despite initial promising findings, several prospective randomized controlled trials have failed to demonstrate a benefit of home uterine activity monitoring in preventing preterm birth.

In more acute situations, intravenous magnesium sulfate is effective, as are intravenous beta-adrenergic drugs. Magnesium sulfate is given as a 4- or 6-g bolus followed by a continuous infusion of 2-3 g/h. The rate may be increased by 1 g/h every 11/2-2 hours until contractions cease or a blood magnesium concentration of 6-8 mg/dL is reached. Magnesium levels are determined every 4-6 hours to monitor the therapeutic blood level. After contractions have ceased for 12-24 hours, magnesium can be stopped and the situation reassessed.

Uterine smooth muscle is largely under sympathetic nervous system control, and stimulation of β_2 -adrenergic receptors relaxes the myometrium. Consequently, inhibition of uterine contractility often can be accomplished by the administration of beta-adrenergic drugs such as ritodrine or terbutaline. Alternatively, use of an oxytocin receptor antagonist might also be expected to inhibit uterine contractility. However, trials of one such antagonist, atosiban, have shown only minimal efficacy.

Ritodrine is no longer manufactured. Terbutaline can be given as an intravenous infusion starting at 2.5 ug/min and increased by 2.5 ug/min every 20 minutes until contractions cease or to a maximum dose of 20 ug/min. Terbutaline can also be administered as subcutaneous injections of 250 ug every 3 hours. Oral terbutaline therapy following parenteral treatment is often elected and consists of giving 2.5-5 mg every 2-4 hours. With terbutaline, a dose-related elevation of heart rate of 20-40 beats/min may occur. An increase of systolic blood pressure up to 10 mm Hg is likely, and the diastolic pressure may fall 10-15 mm Hg during the infusion. Nifedipine has also been used in doses of 10-20 mg orally every 4-6 hours. Blood pressure may fall with nifedipine, but cardiac output increases considerably. Transient elevation of blood glucose, insulin, and fatty acids together with slight reduction of serum potassium have been reported with beta-adrenergic drugs. Fetal tachycardia may be slight or absent. No drug-related perinatal deaths have been reported with beta-agonists. Maternal side effects requiring dose limitation are tachycardia (= 120 beats/min), palpitations, and nervousness. Fluids should be limited to 2500 mL/24 h. Serious side effects (pulmonary edema, chest pain with or without electrocardiographic changes) are often idiosyncratic, not dose-related, and warrant termination of therapy.

One must identify cases in which untimely delivery is the sole threat to the life or health of the infant. An effort should be made to eliminate (1) maternal conditions that compromise the intrauterine environment and make premature birth the lesser risk, eg, preeclampsia-eclampsia; (2) fetal conditions that either are helped by early delivery or render attempts to stop premature labor meaningless, eg, severe erythroblastosis fetalis; and (3) clinical situations in which it is likely that an attempt to stop labor will be futile, eg, ruptured membranes with chorioamnionitis, cervix fully effaced and dilated more than 3 cm, or strong labor in progress.

In pregnancies of less than 34 weeks' duration, betamethasone, 12 mg intramuscularly, or dexamethasone, 16 mg intramuscularly, repeated in 12-24 hours, is administered to hasten fetal lung maturation and permit delivery 48 hours after initial treatment when further prolongation of pregnancy is contraindicated.

LACTATION

Breast feeding should be encouraged by education throughout pregnancy and the puerperium. Mothers should be told the benefits of breast feeding—it is emotionally satisfying, promotes mother-infant bonding, is economical, and gives significant immunity to the infant. The period of amenorrhea associated with frequent and consistent breast feeding provides some (though not completely reliable) birth control until menstruation begins at 6-12 months postpartum or the intensity of breast feeding diminishes. If the mother must return to work, even a brief period of nursing is beneficial. Transfer of immunoglobulins in colostrum and breast milk protects the infant against many systemic and enteric infections. Macrophages and lymphocytes transferred to the infant from breast milk play an immunoprotective role. The intestinal flora of breast-fed infants inhibits the growth of pathogens. Breast-fed infants have fewer bacterial and viral infections, less severe diarrhea, and fewer allergy problems than bottle-fed infants and are less apt to be obese as children and in adult life.

Frequent breast feeding on an infant-demand schedule enhances milk flow and successful breast feeding. Mothers breast feeding for the first time need help and

encouragement from providers, nurses, and other nursing mothers. Milk supply can be increased by increased suckling and increased rest.

Nursing mothers should have a fluid intake of over 2 L/d. The United States RDA calls for 21 g of extra protein (over the 44 g/d baseline for an adult woman) and 550 extra kcal/d in the first 6 months of nursing. Calcium intake should be 1200 mg/d. Continuation of a prenatal vitamin and mineral supplement is wise. Strict vegetarians who eschew both milk and eggs should always take vitamin B₁₂ supplements during pregnancy and lactation.

Effects of Drugs in a Nursing Mother

Drugs taken by a nursing mother may accumulate in milk and be transmitted to the infant (Table 18-4). The amount of drug entering the milk depends on the drug's lipid solubility, mechanism of transport, and degree of ionization.

Suppression of Lactation

A. Mechanical Suppression

The simplest and safest method of suppressing lac-tation after it has started is to gradually transfer the baby to a bottle or a cup over a 3-week period. Milk supply will decrease with decreased demand, and minimal discomfort ensues. If nursing must be stopped abruptly, the mother should avoid nipple stimulation, refrain from expressing milk, and use a snug brassiere. Ice packs and analgesics can be helpful. If suppression is desired before nursing has begun, use this same technique. Engorgement will gradually recede over a 2- to 3-day period.

B. Hormonal Suppression

Oral and long-acting injections of hormonal preparations were used at one time to suppress lactation. Because of their questionable efficacy and particularly because of associated side effects such as thromboembolic episodes and hair growth, their use for this purpose has largely been abandoned in recent years. Similarly, lactation suppression with bromocriptine is to be avoided because of reports of severe hypertension, seizures, strokes, and myocardial infarctions associated with its use.

Zembo CT: Breastfeeding. Obstet Gynecol Clin North Am 2002;29:51. [PMID: 11892874]

PUERPERAL MASTITIS (SEE ALSO CHAPTER 16.)

Postpartum mastitis occurs sporadically in nursing mothers shortly after they return home, or it may occur in epidemic form in the hospital. *Staphylococcus aureus* is usually the causative agent. Inflammation is generally unilateral, and women nursing for the first time are more often affected. Rarely, inflammatory carcinoma of the breast can be mistaken for puerperal mastitis.

Mastitis frequently begins within 3 months after delivery and may start with a sore or fissured nipple. There is obvious cellulitis in an area of breast tissue, with redness, tenderness, local warmth, and fever. Treatment consists of antibiotics effective against penicillin-resistant staphylococci (dicloxacillin or a cephalosporin, 500 mg orally every 6 hours for 5-7 days) and regular emptying of the breast by nursing followed by expression of any remaining milk by hand or with a mechanical suction device.

If the mother begins antibiotic therapy before suppuration begins, infection can usually be controlled in 24 hours. If delay is permitted, breast abscess can result. Incision and drainage are required for abscess formation. Despite puerperal mastitis, the baby usually thrives without prophylactic antimicrobial therapy

Table 18-3. Screening and diagnostic criteria for gestational diabetes mellitus.

Screening for gestational diabetes

1. 50 g oral glucose load, administered between the 24th and 28th weeks, without regard to time of day or time of last meal. Recent recommendations suggest that universal blood glucose screening is appropriate for patients who are of Hispanic, African, Native American, South or East Asian, Pacific Island, or Indigenous Australian ancestry. Other patients who have no known diabetes in first-degree relatives, are under 25 years of age, have normal weight before pregnancy, and have no history of abnormal glucose metabolism or poor obstetric outcome do not require routine screening.
2. Venous plasma glucose measure 1 hour later.
3. Value of 130 mg/dL (7.2 mmol/L) or above in venous plasma indicates the need for a full diagnostic glucose tolerance test.

Diagnosis of gestational diabetes mellitus

1. 100 g oral glucose load, administered in the morning after overnight fast lasting at least 8 hours but not more than 14 hours, and following at least 3 days of unrestricted diet (> 150 g carbohydrate) and physical activity.
2. Venous plasma glucose is measured fasting and at 1, 2, and 3 hours. Subject should remain seated and should not smoke throughout the test.
3. Two or more of the following venous plasma concentrations must be equaled or exceeded for a diagnosis of gestational diabetes: fasting, 95 mg/dL (5.3 mmol/L); 1 hour, 180 mg/dL (10 mmol/L); 2 hours, 155 mg/dL (8.6 mmol/L); 3 hours, 140 mg/dL (7.8 mmol/L).

Table 18-4. Drugs and substances that require a careful assessment of risk before they are prescribed for breast-feeding women.¹

Category	Specific Drugs or Compounds	Management Plan and Rationale
Analgesic drugs	Meperidine, oxycodone	Use alternatives to meperidine and oxycodone. Breast-fed infants whose mothers were receiving meperidine had a higher risk of neurobehavioral depression than breast-fed infants whose mothers were receiving morphine. In breast-fed infants, the level of exposure to oxycodone may reach 10% of the therapeutic dose. For potent analgesia, morphine may be given cautiously. Acetaminophen and nonsteroidal anti-inflammatory drugs are safe.
Antiarthritis drugs	Gold salts, methotrexate, high-dose aspirin	Consider alternatives to gold therapy. Although the bioavailability of elemental gold is unknown, a small amount is excreted in breast milk for a prolonged period. Therefore, the total amount of elemental gold that an infant could ingest may be substantial. No toxicity has been reported. Consider alternatives to methotrexate therapy, although low-dose methotrexate therapy for breast-feeding women with rheumatic diseases had lower risks of adverse effects in their infants than did anticancer chemotherapy. High-dose aspirin should be used with caution, since there is a case report of metabolic acidosis in a breast-fed infant whose mother was receiving high-dose therapy. Although the risk seems small, the infant's condition should be monitored clinically if the mother is receiving long-term therapy with high-dose aspirin.
Anticoagulant drugs	Phenindione ²	Use alternatives to phenindione. Currently available vitamin K antagonists such as warfarin and acenocoumarol are considered safe, as is heparin.
Antidepressant drugs and lithium	Fluoxetine, doxepin, lithium ²	Use fluoxetine, doxepin, and lithium with caution. Although the concentrations of these drugs in breast milk are low, colic (with fluoxetine) and sedation (with doxepin) have been reported in exposed infants. Near-therapeutic plasma concentrations of lithium were reported in an infant exposed to the drug in utero and through breast-feeding. The incidence of these adverse events is unknown.
Antiepileptic drugs	Phenobarbital, ethosuximide, primidone	In breast-fed infants, the level of exposure to phenobarbital, ethosuximide, and primidone may exceed 10% of the weight-adjusted therapeutic dose. Consider alternatives such as carbamazepine, phenytoin, and valproic acid.
Antimicrobial drugs	Chloramphenicol, tetracycline	Use alternatives to chloramphenicol and tetracycline. Idiosyncratic aplastic anemia is a possibility among breast-fed infants whose mothers are receiving chloramphenicol. Although tetracycline-induced discoloration of the teeth of breast-fed infants has not been reported, the potential risk of this event needs to be clearly communicated to lactating women.
Anticancer drugs	All (eg, cyclophosphamide, ² methotrexate, ² doxorubicin ²)	Because of their potent pharmacologic effects, cytotoxic drugs should not be given to breast-feeding women.
Anxiolytic drugs	Diazepam, alprazolam	Avoid long-term use of diazepam and alprazolam in breast-feeding women. Intermittent use poses little risk to their infants, but regular use may result in the accumulation of the drug and its metabolites in the infants. Lethargy and poor weight gain have been reported in an infant exposed to diazepam in breast milk, and the withdrawal syndrome was reported in a breast-fed infant after the mother discontinued alprazolam.
Cardiovascular and antihypertensive drugs	Acebutolol, amiodarone, atenolol, nadolol, sotalol	The use of acebutolol, amiodarone, atenolol, nadolol, and sotalol by breast-feeding women may cause relatively high levels of exposure among their infants, and these agents should therefore be used with caution. The two β -adrenergic antagonists propranolol and labetalol are considered safe.
Endocrine drugs and hormones	Estrogens, bromocriptine ²	Estrogens and bromocriptine may suppress milk production. Oral contraceptives containing little or no estrogen have smaller risk than formulations with higher concentrations of estrogen. Nevertheless, caution should be exercised in their use.
Immunosuppressive drugs	Cyclosporine, ² azathioprine	Maternal plasma concentrations of cyclosporine and azathioprine should be monitored. In nine reported cases in breast-fed infants who were exposed to azathioprine in breast milk, no obvious adverse effects were noted.
Respiratory drugs	Theophylline	Theophylline should be used with caution. When the mother's doses are high, the levels of exposure in the infant may be substantial (ie, 20% of the therapeutic dose).
Radioactive compounds	All	Breast-feeding should be stopped for the length of the half-life of the radiolabeled compound used.
Drugs of abuse	All ¹	The use of drugs of abuse precludes breast-feeding; cocaine-induced toxicity has been reported among breast-fed infants whose mothers abused cocaine. Methadone, used for the treatment of addiction, is safe for infants of breast-feeding women, at doses of up to 80 mg per day. Buprenorphine may be a safer alternative to methadone.
Nonmedicinal substances	Ethanol, caffeine, nicotine	In order to avoid exposure of the infant to ethanol, the mother should not consume alcohol or should consume no more than one drink 2 to 3 hours before breast-feeding. The ingestion of moderate amounts of caffeine should be safe. Because of the effects of second-hand smoke and the fact that nicotine is excreted in breast milk, smoking is contraindicated in breast-feeding women.
Miscellaneous compounds	Iodides and iodine, ergotamine, ² ergonovine	Use alternatives to iodine-containing antiseptic agents. Ergotamine and ergonovine may suppress prolactin secretion in breast-feeding women. However, the use of methylergonovine to stimulate uterine involution is considered safe in breast-feeding women.

¹Data modified from Ito S: Drug therapy for breast-feeding women. N Engl J Med 2000;343:120. Drugs for which there is no information are not included, though a careful risk assessment is necessary before such drugs are prescribed.

²The use of this drug or these drugs by breast-feeding women is contraindicated according to the American Academy of Pediatrics.

19. Allergic & Immunologic Disorders - *Jeffrey L. Kishiyama, MD, & Daniel C. Adelman, MD*

■ I. ALLERGIC DISEASES

Allergy is an immunologically mediated reaction to a foreign antigen manifested by tissue inflammation and organ dysfunction. These responses have a genetic basis, but the clinical expression of disease depends on both immunologic responsiveness and antigen exposure. Allergic disorders may be local or systemic. Because the allergen is foreign (ie, environmental), the skin and respiratory tract are the organs most frequently involved in allergic disease. Allergic reactions may also localize to the vasculature, gastrointestinal tract, or other visceral organs. Anaphylaxis is the most extreme form of systemic allergy.

Immunologic Classification

Hypersensitivity diseases can be classified according to (1) the immunologic mechanism involved in pathogenesis, (2) the organ system affected, and (3) the nature and source of the allergen. An immunologic classification is preferred because it serves as a rational basis for diagnosis and treatment. The classification follows.

A. Type I—IgE-Mediated (Immediate) Hypersensitivity

IgE antibodies occupy receptor sites on mast cells. Within minutes after exposure to the allergen, a multivalent antigen links adjacent IgE molecules, activating and degranulating mast cells. Clinical manifestations depend on the effects of released mediators on target end organs. Both preformed and newly generated mediators cause vasodilation, visceral smooth muscle contraction, mucus secretory gland stimulation, vascular permeability, and tissue inflammation. Arachidonic acid metabolites, cytokines, and other mediators induce a late-phase inflammatory response that appears several hours later. There are two clinical subgroups of IgE-mediated allergy: atopy and anaphylaxis.

1. Atopy—The term atopy is applied to a group of diseases (allergic rhinitis, allergic asthma, atopic dermatitis, and allergic gastroenteropathy) occurring in persons with an inherited tendency to develop antigen-specific IgE to environmental allergens or food antigens. Aeroallergens such as pollens, mold spores, animal danders, and house dust mite antigen are common triggers for allergic conjunctivitis, allergic rhinitis, and allergic asthma. The allergic origin of atopic dermatitis is less well understood, but some patients' symptoms can be triggered by exposure to dust mite antigen and ingestion of certain foods.

The allergic reaction is localized to a susceptible target organ, but more than one of these diseases may occur in an allergic individual. There is a strong familial tendency toward the development of atopy.

2. Anaphylaxis—Certain allergens—especially drugs, insect venoms, latex, and foods—may induce an IgE antibody response, causing a generalized release of mediators from mast cells and resulting in systemic anaphylaxis. This is characterized by (1) hypotension or shock from widespread vasodilation, (2) bronchospasm, (3) gastrointestinal and uterine muscle contraction, and (4) urticaria or angioedema (see [Chapter 6](#)). The condition is potentially fatal and can affect both nonatopic and atopic persons. Isolated urticaria and angioedema are cutaneous forms of anaphylaxis, are much more common, and have a better prognosis.

B. Type II—Antibody-Mediated (Cytotoxic) Hypersensitivity

Cytotoxic reactions involve the specific reaction of either IgG or IgM antibody to cell-bound antigens. This results in activation of the complement cascade and the destruction of the cell to which the antigen is bound. Examples include immune hemolytic anemia and Rh hemolytic disease in the newborn.

C. Type III—Immune Complex-Mediated Hypersensitivity

Immune complex-mediated reactions occur when similar concentrations of antigen and IgG or IgM antibodies form circulating immune complexes. Complexes are usually cleared from the circulation by the phagocytic system. However, deposition of these complexes in tissues or in vascular endothelium can produce immune complex-mediated tissue injury through activation of the complement cascade, anaphylatoxin generation, chemotaxis of polymorphonuclear leukocytes, phagocytosis, and tissue injury. The Arthus reaction is an example of a localized cutaneous and subcutaneous inflammatory response to injected allergen. Serum sickness is characterized by fever, arthralgias, nephritis, and dermatitis. It can be a response to a drug, a foreign serum, or certain infections such as infective endocarditis and hepatitis B.

D. Type IV—T Cell-Mediated Hypersensitivity (Delayed Hypersensitivity, Cell-Mediated Hypersensitivity)

Type IV delayed hypersensitivity is mediated by activated T cells, which accumulate in areas of antigen deposition. The most common expression of delayed hypersensitivity is allergic contact dermatitis, which develops when a low-molecular-weight sensitizing substance haptens with dermal proteins, becoming a complete antigen. Sensitized T cells release cytokines, activating macrophages and promoting the subsequent dermal inflammation; this occurs 1-2 days after the time of contact. Common topical agents associated with allergic contact dermatitis include nickel, formaldehyde, potassium dichromate, thiurams, mercaptos, parabens, quaternium-15, and ethylenediamine. Rhus (poison oak and ivy) contact dermatitis is caused by cutaneous exposure to oils from the toxicodendron plants. Acutely, contact dermatitis is characterized by erythema and induration with vesicle formation, often with pruritus, with exudation and crusting in more severe cases. Chronic allergic contact dermatitis may be associated with fissuring, lichenification, or dyspigmentation and may be mistaken for other forms of dermatitis. To diagnose allergic contact dermatitis, patch testing can be performed. Panels of common sensitizing agents are applied to the skin, and cutaneous responses are observed 48 and 96 hours later for evidence of induration and vesiculation. Hypersensitivity pneumonitis (extrinsic allergic alveolitis) is a pulmonary hypersensitivity disease that appears to be due in part to T cell-mediated inflammation. Although identification of serum precipitins indicates the presence of antigen-specific IgG antibodies in the circulation, specific T cell populations may be found during bronchoalveolar lavage or during histopathologic examination of involved tissue, supporting a role of type IV reactions in the pathophysiology of this disease.

Immunopathophysiology

Atopic disorders are associated with tissue inflammation, characterized immunohistologically by infiltration with certain subsets of CD4 lymphocytes. This has generated interest in the T helper 1 (TH1)/T helper 2 (TH2) paradigm of allergic immunopathology. In this model, antigen-specific CD4 (T helper) cells develop into one of two lymphocyte subsets—TH1 or TH2—which comprise the functional phenotype of the T helper cell. TH1 cells produce gamma interferon (IFN- γ). TH2 cells synthesize interleukin-4 (IL-4), interleukin-5 (IL-5), and interleukin-13 (IL-13). Since both IL-4 and IL-13 stimulate isotype switching with IgE synthesis and since IL-5 promotes eosinophil survival and function, these cytokines have been implicated in the generation of allergic inflammation. TH1 and TH2 phenotypes appear to be mutually exclusive. The development of a dominant TH2 response to an environmental allergen may be the cause of IgE-mediated hypersensitivity disease. The association between early childhood exposure to viral infections and a reduced risk of development of atopy disease may be explained by this paradigm.

Upper & Lower Airway Connections

Up to 80% of asthmatics suffer from rhinitis, and, conversely, 15% of patients with allergic rhinitis have asthma. Furthermore, the immunopathophysiology of inflammation is similar in the upper and lower airways. Both airways are lined by pseudostratified columnar epithelium. In atopic states, these airways are characterized by edematous mucosa, hyperplasia of mucus-secreting goblet cells, numerous mast cells, infiltration with mononuclear cells, including TH2-type lymphocytes and eosinophils, and airway hyperresponsiveness. Only the lower airways contain bronchial smooth muscle, but the similarities in immunohistology otherwise suggest an overlap in the causes of and possible treatments for disease. There is a measurable reduction in bronchial hyperreactivity after treatment of upper airway inflammation with topical nasal corticosteroids alone. Concomitant sinusitis can lead to a worsening of asthma in some patients, and sinobronchial reflexes have been identified. These observations suggest a coordinated approach to airways disease to optimize patient care of atopic individuals.

The Late-Phase Allergic Response

The immediate allergic response occurs after reexposure to allergen in previously sensitized individuals. Six to 12 hours following allergen exposure, a late-phase allergic response can cause a recrudescence of symptoms in anaphylaxis or allergic airways disease. Histologically, the late-phase allergic responses are characterized by infiltration with inflammatory cells, including mononuclear cells, basophils, and eosinophils. These cells release mediators that cause symptoms but also set the stage for chronic inflammation, persistence of disease, and the phenomenon of "priming" or heightened sensitivity to antigen. Increased nonspecific hyperresponsiveness to respiratory irritants can also be secondary to mediators released during the late phase. A rationale for topical corticosteroids or allergen immunotherapy in the treatment of allergic rhinitis or allergic asthma is based on the observation that suppression of the late-phase reaction will decrease eosinophil activity, and inhibit allergen-induced cytokine production and mediator release, inhibiting proinflammatory responses and chronic symptoms.

■ ATOPIC DISEASE

Clinical manifestations resembling allergic hypersensitivity can also occur in the absence of an immunologic mechanism. Specific examples include nonallergic (intrinsic) asthma, which is triggered by the effect of inhaled dusts and fumes, weather changes, viral respiratory infections, and stress rather than by aeroallergen-induced IgE-mediated mast cell degranulation; irritant dermatitis, the result of physical or chemical damage to skin rather than development of sensitized lymphocytes; and "anaphylactoid reactions" from nonimmunologic release of mast cell mediators. Therefore, the diagnosis of allergy requires answers to the following questions: (1) What is the nature of the disease? (2) Is the disease caused by an IgE-mediated mechanism? (3) What specific allergens are responsible?

The relevant history includes a survey of allergen exposure associated with home, work, hobbies, and habits as well as medications. Physical examination is most useful if performed during exposure. Demonstration of allergic hypersensitivity by in vivo or in vitro testing confirms clinical suspicions of allergic disease.

Specific IgE Antibody Tests

To maximize the positive predictive value of allergy testing, a positive test result must be correlated with the history. Patients selected for testing include those with moderate to severe disease, those who are potential candidates for allergen immunotherapy, and those with strong predisposing factors for atopic diatheses, eg, a strong family history of atopy or ongoing exposure to potential sources of allergen. Since the development of rhinitis precedes the presentation of asthma in over half of cases, early intervention may decrease the risk of more severe clinical allergic disease. The type of immune response must be consistent with the nature of the disease. IgE antibody causes allergic rhinitis but not allergic contact dermatitis. IgE antibodies are detected by in vivo (skin tests) or in vitro methods.

A. Skin Tests

Epicutaneous or cutaneous allergen testing produces a localized pruritic wheal (induration) and flare (erythema) that is maximal at 15-20 minutes. It is used most commonly in the diagnosis of allergic respiratory disease (rhinitis and asthma) but also in suspected cases of food or drug allergy and hymenoptera (bee, wasp, hornet or yellow jacket) venom hypersensitivity. Allergen extracts are available for pollens, fungi, animal danders, and dust mites and are selected appropriately for the patient's geographic area.

Skin testing is preferred to in vitro methods (discussed below) because it detects the presence of IgE antibody in tissue and shows biologic activity. In vivo skin testing is generally more sensitive, more specific, more rapid, and less expensive than in vitro radioallergosorbent (RAST) testing. Any drug with antihistamine effects (H₁ antagonists, tricyclic antidepressants, phenothiazines) must be withdrawn prior to testing. Appropriate controls with a negative diluent and a positive histamine response are mandatory for valid results and accurate interpretation. There is a remote risk of inducing a systemic reaction. To avoid this, most allergists perform epicutaneous (prick) testing first, followed by selected intradermal tests to allergens negative by prick testing. Intradermal skin testing techniques are often employed for diagnostic confirmation of hymenoptera (insect venom) or penicillin hypersensitivity, as this method increases sensitivity of the assay for detection of IgE-mediated anaphylaxis. Skin testing with hymenoptera venom or a drug is performed by serial titration, starting with diluted solutions. Special allergenic extracts can be prepared for other allergens (food or latex).

Skin testing for allergy to drugs is reliable for high-molecular-weight proteins (eg, heterologous serum) but not for low-molecular-weight compounds (most drugs), which must bind to larger proteins (haptens) to become immunogenic. With the exception of penicillin, in vivo skin testing for low-molecular-weight drugs is limited in sensitivity and availability. Penicillin testing is available because the immunochemistry has been delineated, identifying all haptenated molecules including the native drug and all immunogenic metabolites. The combination of skin testing with the major and minor metabolic determinants of penicillin is highly predictive of anaphylaxis. (The minor determinants are not available commercially, though they may be synthesized and are often available at specialized centers.) The negative predictive value of skin tests for IgE-mediated reactions to subsequently administered penicillin is good.

B. In Vitro Tests of IgE Antibody

IgE antibodies can be detected in serum by radioallergosorbent test (RAST) or enzyme-linked immunosorbent assay (ELISA). Many of the usual atopic allergens are available commercially for RAST or ELISA testing. In vitro tests detect allergen-specific antibody in serum. Since IgE-mediated allergy is caused by IgE antibodies bound to mast cells (not by circulating IgE), in vitro tests generally are less sensitive than skin tests for diagnostic use. They are not affected by antihistamine therapy but can give false-positive results in patients with high total serum IgE levels and false-negative results in patients treated with immunotherapy who have significant allergen-specific IgG antibodies. The test is significantly more expensive than skin testing, and results are not immediately available. The RAST or ELISA method is particularly useful for detecting IgE antibodies to certain occupational chemicals or potentially toxic allergens. The total IgE level in serum is higher in atopic patients, but because of overlap, it is not a satisfactory diagnostic test for atopy.

ALLERGIC RHINITIS

Essentials of Diagnosis

- Presence of specific-IgE antibody to tested aeroallergens.
- Nasal pruritus, congestion, rhinorrhea, or paroxysms of sneezing, associated with lower respiratory symptoms (chronic cough, wheezing, chest tightness, or dyspnea); eye irritation and pruritus; or eczematous dermatitis.
- Environmental allergen exposure.

Clinical Findings

In addition to the symptoms listed above, the physical examination may reveal edematous or inflamed nasal mucosa. In severe cases, the affected mucosa may be pale, boggy, or blue-tinged from vascular engorgement and venous congestion. Nasal symptoms can be nonspecific, however, and the differential diagnosis can include sinusitis, vasomotor rhinitis, nasal polyposis, drug-induced rhinitis, hormonal rhinitis, rhinitis medicamentosa, atrophic rhinitis, gastroesophageal reflux, and systemic disorders such as thyroid disease.

Treatment

The three basic principles of allergy management are avoidance of the allergen, symptomatic pharmacologic therapy, and specific allergen immunotherapy. Patients with suboptimal responses to reasonable therapeutic interventions benefit from diagnostic allergy skin testing. Patients with comorbidities or associated complications such as allergic asthma, allergic conjunctivitis, chronic cough, sinusitis, polyposis, eczema, or otitis media may also profit from evaluation by a subspecialist.

A. Avoidance Therapy

Avoidance is the most effective treatment for any allergic condition but may be limited in its applicability. It cures the clinical manifestations but does not reduce the sensitivity to the allergen.

1. Pollens—Airborne allergens can travel significant distances, but concentrations are highest near their source. Pollen release occurs in the early morning, and airborne levels depend on temperature and wind velocity. Closing windows and remaining in air-conditioned environments can decrease exposure when pollen counts are high.

2. Animal danders—If the allergy is slight, the patient may benefit from merely keeping the animal out of the bedroom; usually, however, it is necessary to remove the animal from the home altogether. Hypersensitivity to animal dander can be exquisite, and passively transferred dander can accumulate to significant levels in "off-limits" areas. Washing or otherwise treating the fur of a live animal has not been proved to reduce allergenicity.

3. House dust and dust mites—The mattress and pillows should be encased in dust mite-proof material, and all other bedding should be washed weekly and dried at high temperature. The bedroom floor should be uncarpeted. The room should be dusted frequently. Electronic air purifiers are of unproved effectiveness for dust mite reduction since the primary source of exposure is the bed. Acaricides are currently not recommended. Successful dust mite reduction interventions can significantly reduce symptoms and reduce bronchial hyperreactivity and medication requirements in sensitized patients.

4. Mold spores—Out of doors, mold spores are unavoidable during certain seasons. Nevertheless, activities such as gardening and farming can be associated with acute high levels of exposure and should be avoided. Indoor mold contamination can be controlled by repairing leaks, by preventing mold buildup in bathrooms and around windows, and by replacement of mold-contaminated carpeting.

B. Drug Therapy

Three classes of pharmacotherapy are useful for IgE-mediated diseases, based on (1) inhibition of release of mediators from mast cells, (2) inhibition of the action of mediators on their target cells, and (3) reversal of the vascular and inflammatory responses in the target tissues ([Table 19-1](#)).

1. Antihistamines—Antihistamine drugs competitively inhibit the binding of histamine to H₁ receptors and are useful for the treatment of IgE-mediated allergy. There are a number of such drugs, but the use of first-generation antihistamines (chlorpheniramine, brompheniramine, diphenhydramine, clemastine, hydroxyzine) are limited by sedation and dry mucous membranes. Tolerance to soporific effects may develop with continued use, but the causes of effects on neurocognitive processes have not been explained. Rare complications include seizures and tachyarrhythmias. Second-generation nonsedating histamine H₁ receptor-blocking drugs, loratadine, fexofenadine, and desloratadine appear not to be associated with arrhythmias and, along with cetirizine, are now the drugs of choice. Cetirizine is mildly sedating, but the incidence of side effects is markedly lower than that of its parent compound, hydroxyzine. Azelastine is a topical antihistamine preparation that is applied intranasally to decrease its systemic side effects. Although some patients with allergic rhinitis may respond better to one compound over another, an incomplete

response to antihistamine therapy often indicates the need for combined treatment with a corticosteroid nasal spray.

Antihistamine therapy is helpful in allergic rhinitis and in urticaria but not in all patients. It rarely alleviates symptoms of asthma, though it is not contraindicated when used to treat concomitant rhinitis or pruritus. The antipruritic effect of antihistamines may be a useful adjunct in treatment of eczematous diseases. Intramuscular or intravenous antihistamines are used in systemic anaphylaxis as adjunctive treatment only. They relieve cutaneous and gastrointestinal symptoms but have no effect on vascular collapse or airway obstruction.

2. Sympathomimetic drugs—Adrenergic agonists are used for both α -adrenergic (vasoconstricting) and β -adrenergic (bronchodilating) properties. Alpha-adrenergic agonists can be used orally (pseudoephedrine) or topically (phenylephrine, naphazoline, oxymetazoline) as nasal decongestants and topically as conjunctival vasoconstrictors. Daily use of topical preparations can lead to rapid development of rebound vasodilation (rhinitis medicamentosa). The main side effects of oral decongestants are insomnia, tremor, and tachycardia.

3. Glucocorticoids—These drugs have a therapeutic role in virtually all types of allergic diseases because of their anti-inflammatory action rather than by their immunosuppressive effects. Corticosteroids reduce accumulation of immune cells at sites of inflammation by suppressing cytokine synthesis, inducing apoptosis of eosinophils, reducing adhesion molecule expression, and reducing vascular and airway permeability. Systemic use for the treatment of allergic disease, however, requires close attention to toxicity. Steroids are available in oral, intramuscular, intravenous, intranasal, and bronchial inhalation forms; as eye drops; and in topical formulations for dermatologic use. Short-term systemic burst therapy can be used for treatment of severe asthma, allergic contact dermatitis, marked allergic rhinitis, acute exacerbations of hypersensitivity pneumonitis, and allergic bronchopulmonary aspergillosis. Because of complications, including cataracts, corneal ulceration, keratitis, and glaucoma, steroid eye drops are most commonly prescribed by ophthalmologists.

Topical corticosteroid nasal sprays are effective and appear safe for long-term use, but epistaxis can occur and nasal septum perforation is a rare complication. Although the dosages and formulations available for the treatment of asthma vary greatly in terms of dosage and clinical potency, intranasal preparations of flunisolide, fluticasone, beclomethasone, mometasone, budesonide, and triamcinolone are similarly efficacious for the treatment of allergic rhinitis. Long-term topical corticosteroid therapy for allergic rhinitis is an essential aspect of management of the inflammatory phase of the disease. It may take several days of consistent use before optimal responses are seen, but these compounds have consistently proved superior to antihistamine monotherapy for control of nasal pruritus, sneezing, and nasal congestion. Surprisingly, they may also provide some relief from concomitant eye pruritus and have shown positive effects on sleep which can be adversely affected in patients with allergic rhinitis. Topical corticosteroids may also be effective for treatment of vasomotor rhinitis and may be employed as adjunctive treatment for sinusitis in combination with antibiotic therapy.

4. Cromolyn sodium and sodium nedocromil—Pretreatment with these drugs prevents the response to allergen by stabilizing the mast cell, though the specific molecular mechanisms of action are unknown. Although unrelated, they have similar effects and, because of poor bioavailability, are effective only when applied directly to the involved organ. Their action is short-lived, so that they must be given three or four times a day. Cromolyn is available as a bronchial inhaler, nasal spray, and ophthalmologic preparation; nedocromil is available in metered-dose inhalers. In comparison with topical corticosteroids they appear to be much less potent, but the drugs have very few side effects and wide margins of safety. A high-dose oral form of cromolyn has been released for use in treating systemic mastocytosis, but poor oral absorption limits its effectiveness.

5. Anticholinergic agents—Ipratropium bromide is effective as a nasal topical agent for use in rhinitis. Mucous membrane glandular secretion is under cholinergic control and can be inhibited by anticholinergic agents. First-generation antihistamines have systemic anticholinergic activity, but ipratropium is preferred as adjunctive treatment of allergic rhinitis or as primary treatment for many types of nonallergic rhinitis. Ipratropium does not alleviate sneezing, pruritus, or nasal congestion but can be useful for treatment of postnasal drip and rhinorrhea.

6. Leukotriene antagonists—Montelukast has been a useful modality for the treatment of asthma. To a much more limited degree, leukotriene antagonists can be efficacious for the treatment of allergic rhinitis, either as monotherapy or combined with an antihistamine. By inhibiting leukotriene-mediated vasodilation vascular permeability and by potentially reducing eosinophilic inflammation, orally administered montelukast can provide symptomatic relief, especially for nasal congestion. It is less effective than intranasal corticosteroids, however.

C. Immunotherapy

Treatment of atopy—especially allergic rhinitis—by the repeated long-term injection of allergen has been shown in many controlled clinical trials to be an effective method for reducing or eliminating symptoms and signs of the allergic disorder.

1. Indications—This treatment is recommended for patients with severe allergic rhinitis who respond poorly to drug therapy and whose allergens are not avoidable. Immunotherapy is unequivocally effective in patients with allergic rhinitis and allergic conjunctivitis who react to pollens, mold, and house dust mites. It reduces immunologic hypersensitivity, symptoms, and medication requirements. In children with documented allergic rhinitis, immunotherapy may reduce the risk of subsequent development of asthma. Efficacy in allergic asthma is debated. The lower clinical response rates observed in asthma have been attributed to the multifactorial nature of the disease. Immunotherapy is of no value in atopic dermatitis. Food or drug hypersensitivity is treated by avoidance only, since immunotherapy is not available.

2. Immunologic effects—"Allergen immunotherapy" is preferable to "desensitization" because the immunologic basis for this treatment has not been clearly elucidated. Nevertheless, certain immunologic changes can be induced by these injections. Circulating levels of IgE antibodies specific to the injected allergens increase slightly during the first few months, then decrease, eventually to substantially lower levels than before treatment. Seasonal rises in IgE antibodies to pollens are blunted or eliminated. IgG blocking antibody is produced. Changes in regulatory T cells favoring suppression of IgE antibody production and apoptosis of antigen-specific T cell clones have been noted. TH2 cytokine responses may be shifted toward TH1 responses in peripheral blood mononuclear cells. Higher thresholds for release of inflammatory mediators and decreases in late-phase allergic reactions might also be related to the reduction in biologic sensitivity of end-organ systems (eyes, nose, bronchi, skin).

3. Clinical effects—Most patients with allergic rhinitis caused by aeroallergens become more tolerant to natural pollen exposure during successive seasons while on immunotherapy. A small minority become completely asymptomatic, but most patients enjoy a significant decrease in symptoms and medication usage. Only high-dose injected immunotherapy has been demonstrated to be effective. A beneficial response may persist after treatment is stopped. The clinical effects and immunologic responses are antigen-specific.

4. Procedure—A sterile aqueous solution of the allergen or allergens responsible for the patient's disease is administered by subcutaneous injection in increasing doses once or twice a week until a maintenance dose is reached, at which time the interval is advanced to every 4 weeks. The maintenance dose is typically one to ten thousand times the starting dose. Ascending doses are used to minimize the risk of systemic allergic reactions during initial stages of immunotherapy. Three to 5 years is a typical course of therapy. As of 2002, oral immunotherapy is experimental in the United States, and sublingual or low-dose immunotherapy is unconventional and of unproved efficacy.

5. Adverse effects—Reactions to treatment may be local or systemic. Localized immediate and late-phase skin reactions occur at injection sites. These are not harmful, but the dose must be adjusted to avoid excessively large or prolonged local reactions. Immediate systemic reactions or anaphylaxis are a potential problem with each injection and must be prevented by monitoring of dosage. The patient remains at the treatment facility for at least 20 minutes after each injection so that drugs and equipment for treating anaphylaxis will be available if needed. No long-term adverse consequences of aqueous allergen extract immunotherapy are known to have occurred in immunocompetent individuals.

ANAPHYLAXIS, URTICARIA, & ANGIOEDEMA

Essentials of Diagnosis

- Anaphylaxis is a systemic reaction with cutaneous symptoms, associated with dyspnea, visceral edema, and hypotension.
- Urticaria is characterized by large, irregularly shaped, pruritic, erythematous wheals.
- Angioedema is painless, deep, subcutaneous swelling, often involving periorbital, circumoral, and facial regions.
- These disorders may be diagnosed clinically, especially in the context of allergen exposure; detection of specific IgE or elevated serum tryptase can confirm the

diagnosis.

General Considerations

Certain allergens—especially drugs, insect venoms, and foods—may induce an IgE antibody response, causing a generalized release of mediators from mast cells and resulting in systemic anaphylaxis. This potentially fatal condition affects both nonatopic and atopic persons. Isolated urticaria and angioedema are more common cutaneous forms of anaphylaxis with a better prognosis.

Food allergies cause an estimated 150 fatalities per year in the USA, most cases being due to ingestion of peanuts, tree nuts, shellfish, and fish. Common childhood food allergies such as milk, soy, wheat, and egg are often outgrown over time if strict avoidance is practiced. Beta-lactam antibiotics may be involved in 400-800 fatalities per year, and stinging insect venom causes about 50 fatalities per year. Chronic relapsing urticaria, angioedema, and, less commonly, anaphylaxis, however, are not always due to IgE-mediated hypersensitivity. In a minority of cases—perhaps 10% or less—underlying systemic disorders such as systemic mastocytosis or subclinical infection or inflammatory disorders may be manifested by episodic urticaria or angioedema. Idiopathic causes may also be responsible for chronic or relapsing symptoms, suggesting that some cases may be associated with autoimmune processes including the production of histamine-liberating autoantibodies directed against Fcε mast cell membrane receptors. Twenty percent of the population will experience urticaria or angioedema during their lifetime, and the estimated prevalence of idiopathic anaphylaxis is 34,000 patients in the United States.

Clinical Findings

A. Symptoms and Signs

The manifestations are (1) hypotension or shock from widespread vasodilation, (2) respiratory distress from bronchospasm or laryngeal edema, (3) gastrointestinal and uterine muscle contraction, and (4) urticaria and angioedema.

B. Laboratory Findings

In vivo allergy skin testing and in vitro RAST testing can detect allergen-specific IgE for a variety of foods, hymenoptera (bee, wasp, hornet, fire ant) venom, latex, and some medicines. Skin testing for food allergy is appropriate only if the patient has symptoms consistent with IgE-mediated allergy (eg, urticaria, angioedema, or anaphylaxis) within 2 hours after eating the suspect food.

Determination of serum tryptase can be used to identify recent anaphylactic reactions or other reactions due to systemic mast cell activation. Tryptase is a mast cell-derived neutral protease with a half-life of 60-90 minutes. Elevated tryptase levels have been associated with anaphylaxis, systemic mastocytosis, and non-IgE-mediated diseases characterized by mast cell degranulation ("anaphylactoid reactions"). Histamine is released during these disorders but has a very short serum half-life, making detection difficult even during symptomatic periods.

If IgE-mediated hypersensitivity is not found and symptoms become relapsing or chronic (over 6 weeks in duration), a screening battery of laboratory tests may be done after a thorough history and physical examination. Appropriate diagnostic testing should follow any positive findings on examination or review of systems.

Treatment

A. Treatment of Anaphylaxis

At the first suspicion of anaphylaxis, airway, breathing, and circulation are assessed. If systemic anaphylaxis is suspected, aqueous epinephrine 1:1000 in a dose of 0.2-0.5 mL (0.2-0.5 mg) is injected intramuscularly. Repeated injections can be given every 5-15 minutes as necessary. Injection in the anterolateral thigh may lead to more predictable and rapid absorption compared with sites in the arm. Epinephrine can stabilize hemodynamics, cause bronchodilation, and prevent further mast cell degranulation. Rapid intravenous infusion of large volumes of fluids (saline, lactated Ringer's injection, plasma, colloid solutions, or plasma expanders) is essential to replace loss of intravascular plasma into tissues in patients with hypotension caused by marked vasodilation. Other vasopressor drugs (high-dose dopamine, norepinephrine, phenylephrine) may be necessary if the patient remains hypotensive.

Airway obstruction is caused by edema of the larynx and hypopharynx or by bronchospasm. The former is treated by maintenance of an airway with endotracheal intubation or tracheostomy. Bronchospasm responds to subcutaneous epinephrine or terbutaline. Inhalation of selective β₂-adrenergic agonists such as albuterol or terbutaline and intravenous administration of aminophylline are effective for bronchospasm.

Antihistamines (H₁ and H₂ receptor antagonists such as diphenhydramine and ranitidine) may be given orally or intravenously and are useful adjuvant therapies for alleviating the cutaneous manifestations of urticaria or angioedema and pruritus and for the gastrointestinal and uterine smooth muscle spasms. Corticosteroids will not reverse respiratory obstruction or shock but may reduce prolonged reactions or relapses. Long-term combined oral antihistamine and prednisone therapy reduces the number and severity of attacks in patients with frequent life-threatening episodes of idiopathic anaphylaxis. Medical therapy does not reliably prevent true IgE-mediated hypersensitivity reactions.

There may be a clinical late-phase response in anaphylaxis, causing a recrudescence of symptoms hours (most commonly 6-12 hours) after exposure to the allergen. Since this may occur after subsidence of the immediate-phase response, all patients with anaphylaxis should be monitored for up to 24 hours.

Anaphylaxis in a patient being treated with β-adrenergic blocker drugs is a special problem because of refractoriness to epinephrine and selective β-adrenergic agonists. Higher doses of adrenergic drugs are required for the desired effect; glucagon in patients taking beta-blockers may be beneficial. Patients being treated with angiotensin-converting enzyme (ACE) inhibitors may suffer from more severe hypotension due to blockade of renin-angiotensin-dependent compensatory mechanisms.

B. Treatment of Urticaria and Angioedema

These disorders are discussed fully in [Chapter 6](#). If urticaria or angioedema is found to be secondary to underlying inflammatory or infectious processes, treatment of the primary disorder can lead to remission of cutaneous symptoms.

C. Venom Immunotherapy

Patients with immediate hypersensitivity reactions to stinging insects and documented venom-specific IgE on allergy testing should receive venom immunotherapy for prevention of anaphylaxis. Untreated individuals have a 50-60% risk of anaphylactic response to subsequent stings. Venom immunotherapy is highly protective, affording 98% protection from life-threatening reactions on rechallenge.

DRUG ALLERGY

Clinical Findings

A. Symptoms and Signs

The development of symptoms and the nature of the reaction can suggest whether an immunologic process is responsible for symptoms. The classification of immunologic reactions presented above provides a framework for evaluating drug reactions. In previously sensitized individuals, immediate hypersensitivity is manifested by rapid development of urticaria, angioedema, or anaphylaxis. Delayed onset of urticaria accompanied by fever, arthralgias, and nephritis may indicate the development of an immune complex-mediated disorder. Drug fever and Stephens-Johnson syndrome are reactions that do not easily fit within the classification but probably act by immune hypersensitivity mechanisms. Some drugs are clearly more immunogenic than others, and this can be reflected in the incidence of drug hypersensitivity. A partial list of drugs frequently implicated in drug reactions includes beta-lactam antibiotics, sulfonamides, phenytoin, carbamazepine, allopurinol, muscle relaxants used for general anesthesia, nonsteroidal anti-inflammatory drugs, antisera, and antiarrhythmic agents.

Many drugs can be associated with recognizable known toxicities, drug interactions, or idiosyncratic reactions that are not immune-mediated. These must be distinguished from true hypersensitivity reactions because the prognosis and management differ. Some estimate that only 10% or less of adverse reactions to drugs are true hypersensitivity reactions. Patients with multidrug hypersensitivity are quite rare, and those reporting "allergies" to more than three distinct classes of drugs should be carefully evaluated since intolerance to many of these drug classes may not be immunologic.

B. Laboratory Findings

1. Allergy testing—Allergy skin testing is available for a limited number of drugs, since patients may react to the native drug as well as any metabolite that covalently binds to native protein and becomes immunoreactive. Skin testing is available for patients with suspected immediate hypersensitivity to penicillin or beta-lactam antibiotics. The degree of cross-reactivity between the cephalosporin antibiotics and penicillins is uncertain. The incidence of IgE-mediated hypersensitivity appears to be less than 5%. There appears to be no allergic cross-reactivity between the monobactam antibiotics (aztreonam) and penicillin or other beta-lactam antibiotics. A high degree of cross-reactivity exists between penicillin and the carbapenem, imipenem, so this drug should be given to the penicillin-allergic patient with the same degree of caution as if the patient were to receive penicillin.

If the likelihood of immunologic reaction is low—based on the history and the assessment of likely offending agents—and if no allergy testing is available, judicious test dose challenges may be considered in a monitored setting. If the likelihood of IgE-mediated reaction is significant, these challenges are risky and rapid drug desensitization is indicated.

2. Provocation tests—Occasionally, direct allergen challenge of the target organ or tissue under controlled conditions is required for definitive diagnosis. Such challenges may be bronchial, nasal, conjunctival, oral, or cutaneous. A positive test confirms that the test substance can cause the reaction, but it does not prove that an immunologic mechanism is responsible.

a. Bronchoprovocation testing—Natural provocation field testing can be done by having the patient make serial determinations of peak expiratory flow rate (PEFR) using a portable peak flowmeter during periods of natural exposure to a suspected airborne allergen. Bronchoprovocation is not necessary in the routine diagnosis of allergic asthma, but it may be helpful in some cases of occupational asthma. Bronchial provocation with exercise or with inhalation of methacholine, histamine, or cold air can document the presence of nonspecific bronchial hyperreactivity during the diagnostic workup for respiratory symptoms but does not detect allergic sensitivities.

b. Oral provocation—In most cases of suspected allergy to a food or drug, placebo-controlled oral challenge is the definitive test. To be considered a positive result, the reported clinical findings must be reproduced during provocation testing. A blinded provocation test may be preceded by an open challenge (no placebo control), which, if negative, negates the necessity for logistically difficult blinded challenge. Freeze-dried foods in large opaque capsules provide a sufficient dose of allergen for testing. This should not be done in patients with suspected food-induced anaphylaxis.

Treatment

Acute rapid desensitization for IgE allergy to certain drugs—especially penicillin and insulin—has been successful in many cases. This is accomplished by a course of oral or parenteral doses starting with extremely low doses (dilutions of 1×10^{-6} or 1×10^{-5} units) and increasing to the full dose over a period of hours. IgE-mediated reactivity diminishes during the course of this desensitization, creating a temporary drug-specific refractory state. During the refractory period, skin histamine responsiveness is maintained, and mast cells may be activated by other stimuli but the patient may receive the desired drug with a very low risk of anaphylaxis. Acute rapid desensitization may work through cellular mechanisms different from those involved in standard injection immunotherapy, and the refractory period is maintained only throughout the course of uninterrupted therapy.

IMMUNE COMPLEX DISEASE (SERUM SICKNESS)

Essentials of Diagnosis

- Fever, pruritus, and arthropathy.
- Reaction is delayed in onset, usually 7-10 days, when specific IgG antibodies are generated against the allergen.
- Immune complexes found circulating in serum or deposited in affected tissues.

General Considerations

Serum sickness reactions occur when immune complexes are formed by the binding of antigens (eg, drugs, heterologous serum) to antibodies. Deposition of these complexes in tissues or in vascular endothelium can produce immune complex-mediated tissue injury by activation of complement, generation of anaphylatoxins, chemoattraction of polymorphonuclear leukocytes, and tissue injury. The commonly affected organs include skin (urticaria, vasculitis), joints (arthritis), and kidney (nephritis).

Clinical Findings

A. Symptoms and Signs

Constitutional symptoms, such as drug fever, are common.

B. Laboratory Findings

The specific IgG antibody may be present in sufficient quantity in serum to be detected by the precipitin-in-gel method. Detection of these precipitating antibodies by gel diffusion can be useful in the diagnosis of allergic bronchopulmonary aspergillosis or hypersensitivity pneumonitis. ELISA will detect antibodies present in lesser amounts.

Circulating antigen-nonspecific immune complexes can be detected in a variety of malignancies and in autoimmune, hypersensitivity, and infectious diseases. Immunohistochemical techniques can identify immune complexes or complement fragments deposited in tissue biopsy specimens. Depressed serum levels of C3, C4, or CH50 may be sought as nonspecific evidence of immune complex disease with consumption of soluble factors.

The erythrocyte sedimentation rate is increased, and other nonspecific laboratory findings may include elevated hepatic aminotransferases or reduced complement levels. Circulating immune complexes may be found, but current assays are limited in sensitivity. Evidence of nephritis may be found by observing red cell casts at urinalysis.

Treatment

This disease is self-limited, so treatment is usually conservative. Aspirin will relieve the arthralgias. Antihistamines and topical steroids will control the dermatitis. Corticosteroid therapy may be necessary for serious reactions—especially glomerulonephritis, neuropathy, and other manifestations of vasculitis.

PSEUDOALLERGIC REACTIONS

These reactions resemble immediate hypersensitivity reactions but are not mediated by allergen-IgE interaction. Instead, direct mast cell activation occurs. Examples of pseudoallergic or "anaphylactoid" reactions include the now rare "red man syndrome" from rapid infusion of vancomycin, direct mast cell activation by opioids, and radiocontrast reactions. In contrast to IgE-mediated reactions, these can often be prevented by prophylactic medical regimens.

Radiocontrast Media Reactions

Reactions to radiocontrast media do not appear to be mediated by IgE antibodies, yet clinically they are similar to anaphylaxis. If a patient has had an anaphylactoid reaction to conventional radiocontrast media, the risk for a second reaction upon reexposure may be as high as 30%. Patients with asthma or those being treated with β -adrenergic blocking medications may be at increased risk. The management of patients at risk for radiocontrast medium reactions includes use of the low-osmolality contrast preparations and prophylactic administration of prednisone (50 mg orally every 6 hours beginning 18 hours before the procedure) and diphenhydramine (25-50 mg intramuscularly 60 minutes before the procedure). The use of the lower-osmolality radiocontrast media in combination with the pretreatment regimen decreases the incidence of reactions to less than 1%.

■ II. CLINICAL IMMUNOLOGY

CELLS INVOLVED IN IMMUNITY

Development of T & B Lymphocytes

Thymus-derived cells (T lymphocytes) mediate cellular immune responses; bone marrow-derived cells (B lymphocytes) are involved in humoral immunity. Both T and B lymphocytes are derived from precursor or stem cells in the marrow. Precursors of T cells migrate to the thymus, where they develop some of the functional and cell surface characteristics of mature T cells. Through positive and negative selection, clones of autoreactive T cells are eliminated, and mature T cells migrate to the peripheral lymphoid tissues. There they enter the pool of long-lived lymphocytes that recirculate from the blood to the lymph.

B cell maturation proceeds in antigen-independent and antigen-dependent stages. Antigen-independent maturation includes development from precursor cells in the marrow through the naive B cell (a cell that has not been exposed to antigen previously) found in the peripheral lymphoid tissues. Antigen-dependent maturation occurs following the interaction of antigen with naive B cells. The final products of B cell development are circulating long-lived memory B cells and plasma cells found predominantly in primary follicles and germinal centers of the lymph nodes and spleen. Plasma cells are terminally differentiated B cells responsible for synthesis and secretion of immunoglobulin.

Subpopulations of T Cells

T lymphocytes are heterogeneous with respect to their cell surface features ([Table 19-2](#)) and functional characteristics. At least three subpopulations of T cells are now recognized.

A. Helper-Inducer T Cells

These cells help to amplify the production of antibody-forming cells from B lymphocytes after interaction with antigen. Helper (CD4) T cells also amplify the production of effector T cells that mediate cytotoxicity. Activated CD4 T cells regulate immune responses by two mechanisms: through cell-to-cell contact and through elaboration of soluble factors or cytokines. Two subsets of helper T cells can be identified on the basis of their pattern of cytokine production. The subsets are called type 1 T helper (TH1) cells, which produce interleukin (IL)-2 and gamma interferon; and type 2 T helper (TH2) cells, which produce interleukins-4, -5, and -6, among others. Both subsets produce IL-3 and GM-CSF. The TH1 subset of CD4 T cells provides cellular immune responses to intracellular pathogens and underlies the pathogenesis of delayed-type hypersensitivity.

TH2 helper T cells play a central role in immediate hypersensitivity and humoral immune responses, since IL-4 promotes IgE production and IL-5 is an eosinophil proliferation and differentiation factor ([Table 19-3](#)).

B. Cytotoxic or Killer T Cells

These cells are generated after mature T cells interact with certain foreign antigens. They are responsible for defense against intracellular pathogens (eg, viruses), tumor immunity, and organ graft rejection. Most killer T cells express the CD8 phenotype, though in certain circumstances CD4 T cells can be cytotoxic. Cytotoxic T cells may kill their target through osmotic lysis, by secretion of tumor necrosis factor (TNF), or by induction of apoptosis, ie, programmed cell death.

C. Suppressor T Cells

Suppressor T cells are CD8 regulatory cells that modulate antibody formation and cellular immunity in an antigen-specific manner. It is unclear, however, whether suppressor T cells are a distinct T cell phenotype or if their inhibitory functions merely reflect the profile of the factors they secrete.

B Lymphocytes

The majority of B cells express both IgM and IgD on the surface and are derived from pre-B cells found mainly in the bone marrow. Pre-B cells contain intracytoplasmic IgM but do not express surface immunoglobulin.

B cells have been commonly identified by other surface markers in addition to immunoglobulins. These include the receptor for the Fc portion of immunoglobulins, B cell-specific antigens CD19 and CD20, and surface antigens coded for by the HLA-D genetic region in humans. All mature B cells bear surface immunoglobulin that is the antigen-specific receptor. The major role of B cells is differentiation to antibody-secreting plasma cells. However, B cells may also release cytokines and function as antigen-presenting cells.

Other Cells Involved in Immune Responses

A. Macrophages

Macrophages are involved in the ingestion, processing, and presentation of antigens for interaction with lymphocytes. These CD14 cells play an important role in T and B lymphocyte cooperation in the induction of antibody responses. In addition, they are effector cells for certain types of tumor immunity.

B. NK (Natural Killer) Cells

These lymphocytic cells, which are indirectly related to the T cell lineage, can kill a wide spectrum of target cells. They are recognized by the presence of specific surface antigens (CD16 or CD56) and Fc receptors. Many appear as large granular lymphocytes. Their role in host defense is probably the killing of virally infected cells and tumor cells in the absence of prior sensitization and without MHC restriction.

Cytokines

Many T cell functions are mediated by cytokines, humoral factors secreted by immunologically active cells. Cytokines are secreted when cells are activated by antigens or other cytokines. [Table 19-3](#) lists some examples of cytokines and their functions. The cytokines can be functionally organized into groups according to their major activities: (1) those that promote and mediate natural immunity, such as IL-1, IL-6, interferon (IFN)- γ , and IL-8; (2) those that support allergic inflammation, such as IL-4, IL-5, and IL-13; (3) those controlling lymphocyte regulatory activity, such as IL-10, produced by the TH2 helper T cell, and IFN- γ and IL-12, which are produced by the TH1 T helper cell; and (4) those that act as hematopoietic growth factors (IL-3, IL-7, and GM-CSF). This complicated network of interacting cytokines functions to modulate and regulate cellular function in such a way that the host is able to survive in a hostile environment.

TESTS FOR CELLULAR IMMUNITY

Leukocyte Immunophenotyping by Flow Cytometry

Utilizing fluorescent-labeled monoclonal antibodies directed against specific cell surface antigens, or clusters of differentiation (CD), leukocytes can be immunophenotyped and enumerated by flow cytometry. During lymphocyte development, different patterns of CD markers are expressed at various stages of maturation ([Table 19-2](#)). Flow cytometry segregates populations of leukocytes for analysis by cellular size and complexity. By these parameters, polymorphonuclear cells and monocytes can be enumerated and analyzed separately from peripheral blood lymphocyte populations.

In normal individuals, roughly 75% of circulating lymphocytes are T cells (CD3), two-thirds of which are CD4 T helper-inducer cells and one-third CD8 suppressor or cytotoxic T cells. CD19 B cells make up 7-24% of circulating lymphocytes, and the remainder are CD16/CD56 NK cells. Lymphocyte immunophenotyping can be utilized in suspected cases of immunodeficiency or lymphoproliferative syndromes or following organ transplantation.

Thymic hypoplasia (DiGeorge syndrome) is associated with a marked decrease in the number of T cells in the peripheral blood; the absence of B cells in the blood is a feature of X-linked agammaglobulinemia. Marked reductions of both T and B cells occur in severe combined immunodeficiency disease (SCID). Patients with AIDS have reduced numbers of T cells and reduced CD4:CD8 ratios.

Many hematologic neoplasms can express aberrant CD markers or lose characteristic phenotypic patterns. B cell lymphomas can express inappropriate maturational markers or even T cell- or granulocyte-associated clusters of differentiation. In lymphoproliferative diseases, the suspicious lymphocyte population may demonstrate a monoclonal pattern by bearing surface immunoglobulin of a single isotype (IgM, IgG, or IgA) or a single immunoglobulin light chain (? or ?). Immunophenotyping may

be used in conjunction with histopathologic analysis of bone marrow biopsies and fine-needle aspirates from suspicious lymph nodes or peripheral blood. In poorly differentiated leukemias and lymphomas, it can also provide prognostic information and help optimize treatment regimens.

T Cell Antigen Receptors

The structure of T cell antigen receptors and the genes that encode these glycoproteins have been defined. The receptor structure is a complex of two molecules, one containing variable α/β or γ/δ chains and the other the monomorphic CD3 molecule. Genes encoding the β chain are homologous with immunoglobulin genes. Rearrangement of T cell receptor genes proceeds during T cell development to generate diversity for antigen recognition in a fashion similar to that of immunoglobulin genes in B cells. Lymphoid malignancies often feature chromosomal translocations that occur disproportionately in or near the T cell receptor genes. Identification of T cell receptor gene rearrangements has been used to distinguish clonal T cell leukemias and lymphomas from reactive processes.

Functional Testing of Cell-Mediated Immunity

A. Delayed-Type Hypersensitivity Skin Testing

Cell-mediated immune function can be assessed qualitatively by evaluating skin reactivity following intradermal injection of a battery of recall antigens to which humans are frequently sensitized (ie, streptokinase, streptodornase, purified protein derivative, trichophyton, dermatophyton, mumps, tetanus, or candida). Intradermal injections of 0.1 mL of recommended test strengths are observed for maximal induration and erythema at 24 and 48 hours. A positive reaction varies in size with particular antigens but is generally 5-10 mm in diameter. Anergy or lack of skin reactivity to all of these substances indicates a depression of cell-mediated immunity. Delayed hypersensitivity skin tests depend on complex interactions of T cells, macrophages, and other immunoreactants; thus, failure to respond cannot identify the exact cellular defect.

Patch testing can be clinically indicated for the diagnosis of suspected allergic contact dermatitis. The patch test is performed by topical application of the suspected contactant allergen. A positive test at 48-72 hours consists of erythema, swelling, and papules. Concentrations of allergens for patch testing must be screened in nonallergic subjects to avoid false-positive irritant responses.

B. In Vitro Lymphocyte Proliferation After Stimulation with Mitogens or Antigens

T lymphocytes are transformed to blast cells upon short-term incubation with mitogens or recall antigens in vitro. Mitogens stimulate lymphocytes nonspecifically. Phytohemagglutinin (PHA), pokeweed mitogen (PWM), and concanavalin A (ConA) can all be used in clinical laboratory assays. T cell activation is determined quantitatively by following the cellular uptake and incorporation of [^{3} H]thymidine introduced into the culture medium. The uptake indicates T cell function and correlates well with other manifestations of cell-mediated immunity as measured by skin tests. These tests can detect abnormalities in T cells despite normal or slightly reduced cell counts, particularly following bone marrow transplantation or in congenital immunodeficiency diseases. Stimulation of recipients' lymphocytes or donor lymphocytes (the mixed lymphocyte reaction) is a critical test for determining histocompatibility, especially after renal and bone marrow transplantation.

IMMUNOGLOBULIN STRUCTURE & FUNCTION

Disorders of immune function are the cause of many human illnesses. The basic unit of all immunoglobulins consists of four polypeptide chains linked by disulfide bonds. There are two identical heavy chains and two identical light chains. Both heavy and light chains have a carboxyl terminal constant (C) region and an amino terminal variable (V) region. A hypervariable portion of the V regions of heavy and light chains folded together in a three-dimensional conformation forms the combining site, which is responsible for the specific interaction with antigen.

Antibodies contain one of five classes of heavy chains (γ , α , μ , δ , and ϵ) and one of two types of light chains (κ and λ). About 10 million different antibody specificities are thought to exist in a given individual.

Immunoglobulin Classes

A. Immunoglobulin M (IgM)

The IgM molecule is found predominantly in the intravascular compartment and on the surface of B lymphocytes and does not normally cross the placenta. IgM antibody predominates in early, primary immune responses; carbohydrate antigens such as blood group antigens stimulate IgM.

B. Immunoglobulin A (IgA)

IgA is present in blood and in relatively high concentrations in saliva, colostrum, tears, and secretions of the bronchi and gastrointestinal tract. Secretory IgA plays an important role in host defense against viral and bacterial infections by blocking transport of microbes across mucosa.

C. Immunoglobulin G (IgG)

IgG comprises about 70% of total serum immunoglobulins and is distributed in the extracellular fluid; it is the only immunoglobulin that normally crosses the placenta. Antigen-bound IgG fixes complement via the Fc region of the constant chain. Immune effector cells express Fc receptors and complement receptors that facilitate phagocytosis and cytolysis. Immune complex activation of the classic complement pathway also generates soluble factors that chemoattract neutrophils, increase vascular permeability, and amplify the inflammatory response.

D. Immunoglobulin E (IgE)

IgE is present in serum in very low concentrations as a single immunoglobulin unit with ϵ heavy chains. Fifty percent of patients with allergic diseases have increased serum IgE levels. The specific interaction between antigen and mast cell-bound IgE results in the release of histamine, leukotrienes, proteases, chemotactic factors, and cytokines. These mediators can produce bronchospasm, vasodilation, increased vascular permeability, smooth muscle contraction, and chemoattraction of other inflammatory and immune cells.

E. Immunoglobulin D (IgD)

IgD is present in the serum in very low concentrations and is found on the surface of most B lymphocytes in association with IgM, where it probably serves as a receptor for antigen.

Tests for Immunoglobulins

In some diseases, increased serum immunoglobulins, especially monoclonal types, are critical for diagnosis. Chronic liver diseases, chronic infection, or idiopathic inflammatory states can cause polyclonal or oligoclonal increases in immunoglobulins which are incidental or of unknown significance. If immunodeficiency is suspected in the presence of recurrent bacterial infections, measurement of serum immunoglobulin levels provides an essential test of B cell and plasma cell function. In acquired immune deficiencies such as AIDS, paradoxical increases in immunoglobulins can occur.

Antibodies and immunoglobulins can be measured in three ways: (1) by quantitative and qualitative determinations of serum immunoglobulins; (2) by determination of isohemagglutinin and febrile agglutinin titers; and (3) by determination of antibody titers following immunization with tetanus toxoid, diphtheria toxoid, or pneumococcal polysaccharide vaccines. The first method tests for the presence of serum immunoglobulins but not for the functional adequacy of the immunoglobulins. The second tests for functional antibodies present in the serum of almost all individuals as a consequence of exposure to blood group antigens (ABO blood groups) or infection. The third method examines functional humoral immunity in the serum after intentional immunization.

Protein Electrophoresis & Immuno-electrophoresis

Serum protein electrophoresis is a test to measure semiquantitatively various proteins in serum or urine. Proteins are electrically separated on a strip of cellulose acetate, on the basis of charge, into albumin, α_1 , α_2 , β , and γ globulins. This test is useful to screen for diseases with excess or deficiency of immunoglobulins.

Immuno-electrophoresis is used to identify the specific immunoglobulin class in a body fluid. Serum, for example, is separated electrophoretically and then reacted with appropriate antisera directed against IgG, IgA, or IgM. The resulting patterns allow identification of abnormal immunoglobulins such as myeloma (M) proteins. This method is also useful in differentiation of monoclonal from polyclonal increases in immunoglobulins. It is only semiquantitative and thus cannot be used to determine immunoglobulin levels precisely, eg, in Waldenström's macroglobulinemia.

A similar technique called immunofixation electrophoresis has to a large extent replaced immuno-electrophoresis. Serum proteins are separated electrophoretically in a gel and then immunoprecipitated in situ with monospecific antisera. This method has the advantages of more rapid results and slightly higher resolution of low levels of monoclonal immunoglobulin chains. If protein electrophoresis is normal despite suspicion of an M protein, immuno-electrophoresis or immunofixation electrophoresis of

both serum and concentrated urine should be performed because of the greater sensitivity of these tests combined.

Quantitative Immunoglobulin Determinations

Quantitative determinations of total serum IgG, IgA, IgE, and IgM levels can be made rapidly and accurately by nephelometry. Nephelometry detects scattered light when specific antiserum immunoprecipitates soluble antigen. Antiserum is available for a variety of antigens, including all immunoglobulin isotypes. Measurement of serum IgD levels has no recognized clinical use, and antigen-specific IgE levels should be measured with more sensitive techniques such as in vitro radioallergosorbent testing (RAST) or in vivo allergy skin testing.

Functional Testing of Humoral Immunity

Laboratory evaluation of humoral function should include assessment of specific antibody responses. Isohemagglutinins are naturally occurring IgM antibodies against ABO blood groups and can be detected in most patients depending on blood type. Humoral responses can also be assessed by immunization with protein and carbohydrate antigens. This is most easily accomplished by measuring anti-tetanus, anti-diphtheria, and anti-pneumococcal antibody titers, before and 3-4 weeks after vaccination with diphtheria-tetanus (dT) and polyvalent pneumococcal vaccine. In this context, a fourfold increase in antibody titer is considered normal. In patients suspected to be suffering from humoral immunodeficiency, quantification of IgG subclasses may be appropriate, particularly when total IgG immunoglobulins are at the low end of the normal range.

■ IMMUNODEFICIENCY DISORDERS

The primary immunologic deficiency diseases include congenital and acquired disorders of humoral immunity (B cell function) or cell-mediated immunity (T cell function). Most of these diseases are rare, and since they are genetically determined, are seen primarily in children. Several immunodeficiency disorders affect adults, and are discussed below. The WHO classification of immunodeficiency disorders more often affecting adults is set forth in the accompanying box.

WHO CLASSIFICATION

- Primary Immunodeficiency Disorders:
 - Selective IgA deficiency.
 - Common variable immunodeficiency.
 - X-linked agammaglobulinemia.
 - Immunodeficiency with normal serum globulins or hyperimmunoglobulinemia.
 - Immunodeficiency with thymoma.
- Secondary Immunodeficiency Disorders (for example, AIDS)

Buckley RH: Advances in immunology: primary immunodeficiency diseases due to defects in lymphocytes. N Engl J Med 2000;343:1313. [\[PMID: 11058677\]](#)

Sicherer SH et al: Primary immunodeficiency diseases in adults. JAMA 1998;279:58. [\[PMID: 98084662\]](#)

SELECTIVE IMMUNOGLOBULIN A DEFICIENCY

Selective IgA deficiency is the most common primary immunodeficiency disorder and is characterized by the absence of serum IgA with normal levels of IgG and IgM; its prevalence is about 1:500 individuals. Most patients are asymptomatic because of compensatory increases in secreted IgG and IgM. Some affected patients have frequent and recurrent infections such as sinusitis, otitis, and bronchitis. Some cases of IgA deficiency may spontaneously remit. When IgG₂ subclass deficiency occurs in combination with IgA deficiency, affected patients are more susceptible to encapsulated bacteria and the degree of immune impairment can be more severe. Patients with a combined IgA and IgG subclass deficiency should be assessed for functional antibody responses to glycoprotein antigen immunization.

Atopic disease and autoimmune disorders can be associated with IgA deficiency. Occasionally, a sprue-like syndrome with steatorrhea has been associated with an isolated IgA deficit. Treatment with commercial immune globulin is ineffective, since IgA and IgM are present only in trace quantities in these preparations. Frequent infusions of plasma (containing IgA) or unwashed blood transfusions are hazardous, since anti-IgA antibodies may develop, resulting in systemic anaphylaxis or serum sickness.

Cunningham-Rundles C: Physiology of IgA and IgA deficiency. J Clin Immunol 2001; 21:303. [\[PMID: 11720003\]](#)

COMMON VARIABLE IMMUNODEFICIENCY

Essentials of Diagnosis

- Defect in terminal differentiation of B cells, with absent plasma cells and deficient synthesis of secreted antibody.
- Frequent sinopulmonary infections secondary to humoral immune deficiency.
- Confirmation by evaluation of serum immunoglobulin levels and deficient functional antibody responses.

General Considerations

The most common cause of panhypogammaglobulinemia in adults is common variable immunodeficiency, a heterogeneous immunodeficiency disorder clinically characterized by an increased incidence of recurrent infections, autoimmune phenomena, and neoplastic diseases. The onset generally is during adolescence or early adulthood but can occur at any age. The prevalence of common variable immunodeficiency is about 1:80,000 in the United States.

Clinical Findings

A. Symptoms and Signs

The pattern of immunoglobulin isotype deficiency is variable. Most patients present with significantly depressed IgG levels, but over time all antibody classes (IgG, IgA, and IgM) may be affected. Increased susceptibility to pyogenic infections is the hallmark of the disease. Virtually all patients suffer from recurrent sinusitis, with bronchitis, otitis, pharyngitis, and pneumonia also being common infections. Infections may be of prolonged duration or associated with unusual complications such as meningitis or sepsis.

Gastrointestinal disorders are commonly associated, and patients may develop a sprue-like syndrome, with diarrhea, steatorrhea, malabsorption, protein-losing enteropathy, and hepatosplenomegaly. Paradoxically, there is an increased incidence of autoimmune disease (20%), though patients may not display the usual serologic markers. Autoimmune cytopenias are most common, but also commonly seen are autoimmune endocrinopathies, seronegative rheumatic disease, and gastrointestinal disorders. Lymph nodes may be enlarged in these patients, yet biopsies show marked reduction in plasma cells. Noncaseating granulomas are frequently found in the spleen, liver, lungs, or skin. There is an increased propensity for the development of B cell neoplasms (50- to 400-fold increase risk of lymphoma), gastric carcinomas, and skin cancers.

B. Laboratory Findings

Diagnosis is confirmed in patients with recurrent infections by demonstration of functional or quantitative defects in antibody production. Serum IgG levels are usually less than 250 mg/dL; serum IgA and IgM levels are also subnormal. Decreased to absent functional antibody responses to protein antigen immunizations establish the diagnosis.

The cause of the panhypogammaglobulinemia in the majority of common variable immunodeficiency patients is an intrinsic B cell defect preventing terminal maturation into antibody-secreting plasma cells. In a small number, excessive suppressor T cell activity that inhibits B cells—or helper T cell activity inadequate to assist B cells to make antibody—has been identified. The absolute B cell count in the peripheral blood in most patients, despite the underlying cellular defect, is normal. A subset of these patients have concomitant T cell immunodeficiency with increased numbers of activated CD8 cells, splenomegaly, and decreased delayed-type hypersensitivity.

Treatment

Patients may be treated aggressively with antibiotics at the first sign of infection. Since antibody deficiency predisposes patients to high-risk pyogenic infections, antibiotic coverage should be sure to cover encapsulated bacteria. Only after the development of bronchiectasis or after sinus surgery do patients become significantly affected by more virulent organ-isms such as *Staphylococcus aureus* or *Pseudomonas aeruginosa*. Maintenance intravenous immune globulin (IGIV) therapy is indicated, with infusions of 300-500 mg/kg of IGIV given at about monthly intervals. Adjustment of dosage or of the infusion interval is made on the basis of clinical responses and steady-state trough serum IgG levels. Such therapy is effective in decreasing the incidence of potentially life-threatening infections and increasing quality of life. The yearly cost of monthly infusions can be in excess of \$20,000-\$30,000.

Sneller MC: Common variable immunodeficiency. Am J Med Sci 2001;321:42. [\[PMID: 11202479\]](#)

DISEASES OF IMMUNOGLOBULIN OVERPRODUCTION (GAMMOPATHIES)

The monoclonal gammopathies include those diseases in which there is a proliferation of a single clone of immunoglobulin-forming cells that produce a homogeneous heavy chain, light chain, or complete molecule. The amino acid sequence of the variable (V) regions is fixed, and only one type (? or ?) of light chain is produced. Polyclonal gammopathies result from proliferation of many B cell clones, resulting in a diffuse increase of immunoglobulins.

Monoclonal Gammopathy of Uncertain Significance (MGUS)

This diagnosis is made upon finding a monoclonal spike on serum protein electrophoresis, confirmed by immunoelectrophoresis to be a homogeneous immunoglobulin (with either ? or ? chains). The incidence of MGUS increases with age and may approach 3% in persons 70 years of age or older. As many as one-third of individuals with apparently benign monoclonal gammopathies will develop lymphoid malignancies, amyloidosis, or multiple myeloma. No specific therapy is necessary, but close observation is required. MGUS patients should be periodically monitored for changes in serum M components, urinary Bence Jones proteins, evidence of renal failure, anemia, hypercalcemia, lytic bone lesions, or bone marrow plasmacytoses. Risk for the development of a malignant disorder is 33% at 20 years. Parameters that suggest a favorable prognosis include (1) concentration of homogeneous immunoglobulin less than 2 g/dL, (2) no increase in concentration of the immunoglobulin from the time of diagnosis, (3) no decrease in the concentration of normal immunoglobulins, (4) absence of a homogeneous light chain in the urine, and (5) normal hematocrit and serum albumin.

Multiple Myeloma (See also [Chapter 13.](#))

This disease is characterized by the overproduction and spread of neoplastic plasma cells throughout the bone marrow. Myeloma cells sometimes express molecules of early B cell or myelomonocytic lineages. Rarely, extraosseous plasmacytomas may be found. Anemia, hypercalcemia, increased susceptibility to infection, and bone pain are frequent. Renal failure is seen in up to 25% of patients with myeloma. Hypercalcemia, hyperuricemia, recurrent urinary tract infections, infiltration of myeloma cells, and deposits of amyloid in the glomerulus are all contributing factors to renal dysfunction. Diagnosis depends upon the presence of the following: (1) radiographic findings of osteolytic lesions or diffuse osteoporosis, (2) the presence of a homogeneous serum immunoglobulin (myeloma protein) or a single type of light chain in the urine (Bence Jones proteinuria), and (3) finding of an abnormal plasma cell infiltrate in the bone marrow biopsy (see [Chapter 13](#)). The presence of over 20% bone marrow plasma cells reliably differentiates early myeloma from MGUS. There is an approximate correlation between the incidence of immunoglobulin type in myeloma and the normal serum concentration of the immunoglobulin involved.

Waldenstrom's Macroglobulinemia

In Waldenstrom's macroglobulinemia, there is proliferation of abnormal lymphoid cells that have morphologic features of both B cells and plasma cells. These cells secrete a homogeneous macroglobulin (IgM) detectable by immunoelectrophoresis. Monoclonal light chains are present in 10% of cases. Clinical manifestations depend upon the physicochemical characteristics of the macroglobulin. Raynaud's phenomenon and peripheral vascular occlusions are associated with cold-insoluble proteins (cryoglobulins). Retinal hemorrhages, visual impairment, and transient neurologic deficits are common with high-viscosity serum. Bleeding diatheses or hemolytic anemia can occur when the macroglobulin complexes with coagulation factors or binds to the surface of red blood cells.

Amyloidosis

Amyloidosis is a group of disorders manifested by impaired organ function caused by infiltration of tissues with insoluble protein fibrils. Different fibril composition can be correlated with the clinical syndromes.

In primary amyloidosis (AL), the protein fibrils are monoclonal immunoglobulin light chains, whereas secondary amyloid (AA) proteins are derived from acute-phase reactant apolipoprotein precursors. Other types of amyloidosis may also be hereditary. Over 20 types of fibrils have been identified in amyloid deposits.

Symptoms and signs of amyloid infiltration are related to malfunction of the organ involved (eg, nephrotic syndrome and renal failure, cardiomyopathy and cardiac conduction defects, intestinal malabsorption and pseudo-obstruction, carpal tunnel syndrome, macroglossia, peripheral neuropathy, end-organ insufficiency of endocrine glands, respiratory failure, and capillary damage with ecchymosis). Such widespread deposition is typical of primary amyloidosis; secondary amyloidosis more often is confined to liver, spleen, and adrenals. Familial syndromes commonly cause infiltrative neuropathies. Amyloidosis due to deposition of β_2 -microglobulin in carpal ligaments occurs in chronic hemodialysis patients.

The diagnosis of primary amyloidosis is based on clinical suspicion, protein electrophoresis, and microscopic examination of biopsy specimens. In patients with systemic disease, rectal or gingival biopsies show a sensitivity of about 80%, bone-marrow biopsy about 50%, and abdominal fat aspiration between 70% and 80%. The latter is a simple and reliable method for diagnosing systemic amyloidosis.

Treatment of localized amyloid tumors is by surgical excision. There is no effective treatment of systemic amyloidosis, and death usually occurs within 1-3 years. Care is generally supportive, though hemodialysis and immunosuppressive therapy may be useful. When concomitant multiple myeloma is found, it is treated in the standard fashion ([Chapter 13](#)). Secondary disease is usually approached by aggressively treating the predisposing disease, but remission of fibril deposition does not occur. Bone marrow transplant after chemotherapy has been employed in selected patients.

Heavy Chain Disease (a, ?, u)

These are rare disorders in which the abnormal serum and urine protein is a part of a homogeneous a, ?, or u heavy chain. The clinical presentation is more typical of lymphoma than multiple myeloma, and there are no destructive bone lesions. Gamma chain disease presents as a lymphoproliferative disorder with autoimmune features. Alpha chain disease is frequently associated with severe diarrhea and infiltration of the lamina propria of the small intestine with abnormal plasma cells. Mu chain disease is associated with chronic lymphocytic leukemia.

■ AUTOIMMUNITY

Autoimmune diseases cannot be explained by a solitary cause or mechanism. Small amounts of autoantibodies are normally produced and may have physiologic roles in cellular interactions. The major theories regarding the development of autoimmune disease are (1) release of normally sequestered antigens; (2) escape from anergy or defective apoptosis (programmed cell death) leading to abnormal autoreactive cellular clones; (3) shared antigens between the host and microorganisms, ie, "molecular mimicry"; and (4) defects in helper or suppressor T cell function. A genetic susceptibility is also a likely determinant of autoimmune disease. In nearly all autoimmune diseases, multiple mechanisms of autoimmunity are operative.

Cell-Mediated Autoimmunity

Certain autoimmune diseases are mediated by T cells that have become specifically immunized to autologous tissues. Cytotoxic or killer T cells generated by this aberrant immune response injure specific organs in the absence of serum autoantibodies. Diminished suppressor T cell activity or loss of clonal anergy results in disordered regulation of immune function and consequent autoreactivity. The immune damage in systemic (non-organ-specific) diseases such as systemic lupus erythematosus may be due to such a mechanism.

Antibody-Mediated Autoimmunity

Several autoimmune diseases have been shown to be caused by autoantibodies in the absence of cell-mediated autoimmunity. The autoimmune hemolytic anemias, idiopathic thrombocytopenia, and Goodpasture's syndrome appear to be mediated solely by autoantibodies directed against autologous cell membrane constituents. In these diseases, antibody attaches to cell membranes and fixes complement; the ensuing inflammatory reaction injures the cells.

Anti-receptor antibodies that compete with or mimic physiologic agonists for cellular receptors cause several diseases. In Graves' disease, antibodies are present that bind to thyroid cells' TSH receptors and thereby stimulate thyroid hormone production. In rare instances of type 1 diabetes mellitus, anti-insulin receptor antibodies cause insulin resistance in peripheral target tissues. Antibodies to acetylcholine receptors of the myoneural junction in myasthenia gravis block neuromuscular transmission and produce muscle weakness.

Immune Complex Disease

In this group of diseases (systemic lupus erythematosus, lupus nephritis, rheumatoid arthritis, some drug-induced hemolytic anemias, and thrombocytopenias), autologous tissues are injured as "innocent bystanders." Autoantibodies are not directed against cellular components of the target organ but rather against autologous or heterologous antigens in the serum. The resultant antigen-antibody complexes bind nonspecifically to autologous membranes (eg, glomerular basement membrane) and fix complement. Fixation and subsequent activation of complement components produce a local inflammatory response resulting in tissue injury.

AUTOIMMUNE DISEASES (SEE ALSO CHAPTER 20.)

The diagnosis and treatment of specific autoimmune diseases are described elsewhere in this book. Autoantibodies associated with certain autoimmune diseases may not be pathogenetic but are thought to be markers or by-products of the injury (eg, autoimmune thyroiditis and antithyroglobulin antibody). See [Table 19-4](#) for autoantibody patterns in connective tissue diseases.

TESTS FOR AUTOANTIBODIES ASSOCIATED WITH AUTOIMMUNE DISEASE

Agglutination Assays

Red cells are incubated with purified specific antigen (eg, thyroglobulin), which is adsorbed to the cell surface. The antigen-coated cells are suspended in the patient's serum, and antibody is detected by red cell agglutination. Antigen-coated latex particles are substituted for red cells in latex fixation tests.

Enzyme-Linked Immunosorbent Assays (ELISA)

Antibodies to various tissue antigens can be readily detected by these tests. Extracted and purified antigens are fixed to a plastic microtiter well or beads. The patient's serum is added, and excess proteins are removed by washing and centrifugation. Adherent immunoglobulin is then detected when a second antibody coupled to an enzyme (eg, alkaline phosphatase) is added. Finally, the enzyme's substrate is added; color forms and is measured in a spectrophotometer. This test can also be adapted for antigen detection by placing the antibody on the plastic surface. ELISA assays are very sensitive and less cumbersome than radioimmunoassay techniques.

Immunofluorescence Microscopy

This technique is most frequently used for detection of antinuclear antibody (ANA). Frozen sections of mouse liver or other substrates are cut and placed on glass slides or, alternatively, monolayers of cultured cell lines may be used. A patient's serum is placed over the sections and incubated. Fluorescein-conjugated rabbit anti-human immunoglobulin is then applied and washed. Antinuclear antibody specifically binds to the nucleus, and the fluorescein conjugate binds to the human antibody. Fluorescence of the cell nucleus on microscopy indicates a positive test.

Complement Fixation

Specific antigen, unknown serum, and complement are combined. Sheep red blood cells coated with anti-sheep cell antibody are added for 30 minutes at 37 °C. If antigen-specific antibody is present in the patient's serum, complement is bound and consumed, preventing lysis of sheep red cells.

■ IMMUNOGENETICS & TRANSPLANTATION

GENETIC CONTROL OF THE IMMUNE RESPONSE

The ability to mount a specific immune response is under the direct control of genes for the major transplantation antigens (major histocompatibility complex; MHC). These MHC molecules play a critical role in the positive and negative selection of thymocytes during T cell development, the process of antigen presentation between immunocompetent cells, and transplantation rejection reactions to foreign tissue. In a rare immunodeficiency disorder, "bare lymphocyte syndrome," the surface expression of HLA molecules is deficient, leading to impaired immune defenses and recurrent infection.

In humans, this genetic region has been designated the **human leukocyte antigen (HLA)** complex because these antigens were first detected on peripheral blood lymphocytes. The complex includes antigens HLA-A, -B, -C, -DR, and others, each with many alleles. The HLA region has been localized to chromosome 6 and codes for over 200 genes. In nearly all instances, the HLA complex is inherited intact as two haplotypes (one from each parent), and within any particular family, therefore, the number of different combinations found is 25% (ie, siblings have a 1:4 chance of being HLA-identical). In contrast, the number of antigen combinations among unrelated individuals is enormous, resulting in probabilities of less than one in several thousand, depending upon the phenotype involved, of finding HLA-compatible individuals in a random donor pool. This is particularly important when compatible donors are needed for allosensitized patients requiring platelet transfusions or organ transplantation. Family members have the highest likelihood of being compatible donors, whereas compatibility between unrelated individuals has a low probability. HLA-A and -B typing or cross-matching is utilized for selection of compatible donors for platelet transfusions to allosensitized, thrombocytopenic recipients. Typing for these class I antigens as well as for HLA-D (class II) antigens is important in determining compatibility for organ transplantation. Typing for HLA markers is of value in studying associations between the HLA system and genetic control of disease susceptibility.

VanBuskirk AM et al: Transplantation immunology. JAMA 1997;278:1993. [\[PMID: 9396662\]](#)

ASSOCIATIONS BETWEEN HLA ANTIGENS & SPECIFIC DISEASES

In humans, very striking associations are observed between particular HLA antigens and specific diseases. Some of these are listed in [Table 19-5](#). In some diseases, the HLA molecule may be implicated in the pathogenesis. In others, the specific HLA allele may be linked to a gene determining immune responsiveness to a particular antigen.

The standard method for detecting HLA-A, -B, and -C antigens is that of lymphocyte microcytotoxicity. Lymphocytes isolated from peripheral blood or lymph nodes are added to each well of a typing tray filled with sera containing the appropriate cytotoxic alloantibody. When complement is added, cells to which antibody has been

specifically bound will have complement activated at the cell surface, resulting in cell death or lysis. It is thus possible to type for all of the known HLA-A, -B, and -C specificities. An appreciable majority of typing serum samples are obtained from multiparous women since they form antibodies to fetal alloantigens.

Typing for the class II antigens HLA-DR and -DQ by serologic methods is technically more difficult. Antigens of the HLA-D, -DR, -DQ, and -DP series may also be detected by in vitro mixed lymphocyte culture (MLC). Lymphocytes of one individual (responder cells) will undergo proliferation upon encountering lymphocytes from another individual possessing foreign HLA-DR and -DQ antigens (stimulator cells). Lymphocyte proliferation can be readily measured by DNA incorporation of tritiated thymidine. Responders possessing matching -DR and -DQ antigens will remain nonreactive.

Increasingly, HLA class II typing is being performed by molecular technology. The DNA sequences for the HLA genes and their flanking sequences are known. Selected primers that amplify the gene of interest using the polymerase chain reaction (PCR) technique are known as sequence-specific primers. HLA typing by PCR provides better resolution than serologic identification because typing is done at the genetic level.

CLINICAL TRANSPLANTATION

Organ transplants are in widespread use. Limitations include the scarcity of donor organs and expense. Failure to achieve successful grafts is primarily due to histoincompatibility and lack of safe and effective immunosuppressive regimens to halt rejection. Avoiding transmission of infectious agents (eg, HIV, HBV, HCV, CMV) from donor to recipient requires extensive pretransplant serologic testing.

Kidney Transplantation

End-stage renal disease is the indication for kidney transplantation. Factors that determine outcome include antigenic disparity (ABO blood groups and major histocompatibility or HLA) between donor and recipient, the type of immunologic response mounted by the host, and the immunosuppressive regimen used to prevent graft rejection. Nonimmunologic factors that affect the risk of chronic rejection include age and race of recipient, donor age, length of time on dialysis, and coexisting hyperlipidemia, hypertension, or cytomegalovirus infection.

Kidneys from living related donors who are HLA-identical and also red cell ABO-matched grafts have 90% survival at 1 year; grafts from less well matched relatives and from living unrelated donors have lower rates. Antigens are matched for HLA-A, -B and -DR loci, with -DR compatibility most important for long-term graft survival. Grafts from cadaver donors with zero HLA mismatches have a half-life of 11.3 years. Those with six mismatches have a half-life of 6.8 years, compared with those from HLA-identical siblings, which have a half-life of 23.6 years.

Some donors are highly sensitized to HLA antigens from previous transfusions, ie, possess high panel reactive antibody levels. It may be difficult to find a suitable donor, since a positive cross-match by cytotoxicity testing is likely and would be a contraindication to transplant. Donor screening is performed in all cases to assess suitability, rule out hypertension or anatomic anomalies, and avoid transmission of hepatitis viruses, HIV, and other infectious agents. Owing to the scarcity of related donors, living unrelated donors may be used in certain circumstances. Pretreatment of recipients with blood transfusions from the donor appears to extend graft survival even longer.

Delayed allograft function can be due to hyperacute graft rejection, post ischemic acute tubular necrosis, cyclosporine toxicity, or obstructive nephropathy. If conservative measures do not improve function or patients are at high risk of allograft rejection, renal biopsy should be performed for definitive diagnostic purposes. Renal allograft rejection may be due to hyperacute rejection from binding of cytotoxic antibodies and complement activation, acute rejection from cellular immune responses, or chronic rejection. A form of interstitial nephritis secondary to polyomavirus infection is associated with aggressive immunosuppression.

Chronic allograft nephropathy is characterized by vasculopathy and immune-mediated graft obliteration. Previous acute rejection is strongly linked with later chronic rejection, and severity of those episodes has prognostic implications. Cyclosporine-induced nephrotoxicity and recurrent or de novo renal disease are also significant factors affecting long-term survival.

High-Dose Chemotherapy With Hematopoietic Progenitor Cell Transplantation

Transient myelosuppression after cancer chemotherapy is a well-established adverse effect of such treatments. For most regimens, it is rapidly reversible and requires no intervention. Some malignancies (eg, many leukemias, lymphomas, and chemotherapy-sensitive breast and small-cell lung carcinomas) may demonstrate a higher cure rate with higher-dose therapy; however, associated with this approach is an increase in hematologic toxicity. Administering the maximal tolerated chemotherapy dose and restoring all hematopoietic functions as rapidly as possible has led to evolution of the concept of hematopoietic progenitor cell (HPC) or "stem cell" transplant. HPC transplants have also expanded somewhat into the therapy of certain nonmalignant disorders of hematopoiesis and hematologic function; examples are aplastic anemia, sickle cell anemia, thalassemia, myelodysplasia, amyloidosis, and paroxysmal nocturnal hemoglobinuria.

The sources of HPC are the bone marrow, peripheral blood, and cord blood. They comprise less than 0.5-1% of all nucleated bone marrow cells. It has become common practice to harvest HPCs from the peripheral blood by apheresis. As the peripheral blood has approximately one-fortieth the number of circulating HPCs as the bone marrow, these cells must be "mobilized" by the administration of cytotoxic chemotherapy (with the harvest being performed during the recovery phase) or enriched by the administration of hematopoietic growth factors. The cells are frozen and administered at a later date.

Because syngeneic transplants between identical (monozygotic) twins are rare, the two predominant transplants are autologous, where the HPCs are harvested from and returned to the patient; or allogeneic, where the source is an HLA-matched donor, ideally a sibling. The goals of the two procedures—and their associated adverse effects—are frequently different. Allogeneic transplants are most commonly offered to patients with malignant and nonmalignant disorders involving the bone marrow. Chemotherapy is given to ablate the marrow, resulting in maximal suppression or eradication of the recipient's native immune system. The bone marrow is repopulated by infusion of donor cells containing not only HPCs but also functional donor T lymphocytes. These T cells can cause graft-versus-host disease, in which the recipient's tissues are recognized as nonself. While this is occasionally desirable, as in the "graft-versus-leukemia" effect, it is the cause of considerable morbidity and can be fatal. There are two separate phases of graft-versus-host disease: acute, secondary to cytokine-mediated cytotoxicity against the cells of the liver, the mucosa of the gastrointestinal tract, and skin; and chronic, characterized by fibrosis and collagen deposition and resembling autoimmune disease such as scleroderma. The incidence of graft-versus-host disease can be decreased by depleting the donor marrow of T cells, but this is associated with a higher incidence of graft failure and, in the case of leukemia, a higher relapse rate. Allogeneic peripheral HPC transplants have been attempted, and graft-versus-host disease in such cases does not appear to be as severe.

Autologous HPC transplants are performed solely for the treatment of malignancies. In these cases the chemotherapy is intensively myelosuppressive though not necessarily myeloablative. One prominent exception is patients with chronic myelogenous leukemia in blast crisis, who receive their autologous HPC in an effort to return their disease to the chronic phase. Since patients usually have some residual immune function and are receiving their own HPC—and thus do not require post transplant immunosuppression—the risk of opportunistic infections and immunosuppression-related neoplasia is markedly reduced.

The success rates of HPC transplantation depend mostly upon the underlying disease and the associated risk of relapse (in cases of leukemia), the level of matching between donor and recipient (and thus the likelihood of graft-versus-host disease), the age of the recipient, and the complications associated with conditioning (veno-occlusive liver disease and infection). Overall, the survival rates at 1 year are about 60-70% in aplastic anemia and 40-75% in various forms of leukemia and other neoplasms such as non-Hodgkin's lymphomas; results in breast carcinoma are less well defined.

MECHANISM OF ACTION OF IMMUNOSUPPRESSIVE DRUGS

The most frequently used immunosuppressive drugs and their modes of action are briefly summarized below.

Corticosteroids

This group of drugs has potent and direct anti-inflammatory effects on immunocompetent cells. Corticosteroids inhibit lymphocyte proliferation and cell-mediated immune responses more severely than they inhibit antibody responses. T helper cells, eosinophils, and monocytes are reduced in peripheral blood. Corticosteroids down-regulate cytokine gene expression through interference with transcription regulation. By inhibition of phospholipase A₂, synthesis of inflammatory arachidonic acid metabolites (prostaglandins and leukotrienes) is suppressed. Corticosteroids have been shown to block the activation of T cells by interleukin-1 (IL-1) derived from macrophages. They also inhibit the expression of class II histocompatibility antigens on the macrophage surface, thereby interfering with presentation of antigen to T cells. Cumulatively, these cellular changes result in reduced inflammatory responses.

Cytotoxic Drugs

The most frequently used cytotoxic drugs are the anti-metabolites (see below) and cyclophosphamide. Cyclophosphamide is an alkylating agent that damages cells by cross-linking DNA. Although this cycle-specific drug is most effective in killing cells going through the mitotic cycle, it can also cause intermitotic cell injury and death. Cyclophosphamide can inhibit both T and B cell immunity as well as inflammation. Azathioprine and cyclophosphamide are effective inhibitors of the production of serum antibodies.

Antimetabolites

The most commonly used antimetabolites are methotrexate, an inhibitor of folic acid synthesis, and azathioprine, a structural analog of mercaptopurine and an antagonist of purine synthesis. Azathioprine is a phase-specific drug that kills rapidly replicating cells. It inhibits proliferation of both T and B cells as well as macrophages. Methotrexate inhibits rapidly proliferating cells in S phase and suppresses both cell-mediated and humoral immunity as well as inflammation. Without immunosuppression, the incidence of graft-versus-host disease after allogeneic HPC transplant is almost 100%; this can be reduced to 20-30% with immunosuppressive therapy, especially the combination of methotrexate and cyclosporine, in addition to corticosteroids. Cyclosporine prevents T cell activation, while methotrexate inhibits the function of T cells that are already activated.

Cyclosporine

This cyclic polypeptide derived from a fungus is used as an immunosuppressive drug in organ transplant recipients. Cyclosporine binds to cyclophilin, a cytoplasmic protein, thereby interfering with calcium-dependent events including secretion of interleukin-2 (IL-2) by T lymphocytes. Since IL-2 is necessary for T cell replication, this drug is a potent inhibitor of T cell proliferation and thereby inhibits T cell-mediated immune responses. Little effect has been shown on direct B cell immune responses or on inflammation. Its toxic effects are primarily on renal and, to a lesser extent, hepatic function. In addition to methotrexate, methylprednisolone has also been utilized with cyclosporine to treat graft-versus-host disease, though T cell-directed immunotoxins have not proved to be of any benefit. A recently developed microemulsion formulation offers improved oral bioavailability, safety, and efficacy.

Tacrolimus

This drug was developed for use in transplantation and is a macrolide with potent anti-T cell properties and a mode of action similar to that of cyclosporine. Like cyclosporine, tacrolimus inhibits IL-2 and interferon- γ production and T cell activation. It has been approved for use in kidney and liver transplantation as a primary immunosuppressive agent or as rescue therapy. Both cyclosporine and tacrolimus block the intracellular pathway of calcineurin dephosphorylation of nuclear transcription factors.

Tacrolimus is approximately 100 times more potent than cyclosporine. Rates of graft-versus-host disease are lower for tacrolimus-based regimens. Tacrolimus appears to be at least as effective as cyclosporine, possibly better as prophylaxis of acute rejection. The major toxicities include hyperglycemia, nephrotoxicity, and neurotoxicity.

Mycophenolate Mofetil

Mycophenolate mofetil is used primarily as an adjunctive agent in kidney transplantation. By blocking lymphocyte production of guanine nucleotides, it inhibits T and B lymphocyte proliferation. Its use in combination with cyclosporine or tacrolimus has led to a lower incidence of acute graft rejection, reducing the need for high-dose corticosteroids or OKT3 (muromonab-CD3).

Humanized Anti-Interleukin-2 Receptor Antibody

A humanized monoclonal antibody directed to the low-affinity IL-2 receptor is approved for use in kidney transplantation. This antibody, administered for 8 weeks following the transplant, when added to standard immunosuppressive therapy, results in a reduction of the incidence of acute graft rejection to about 25%. Although the incidence of acute rejection is not substantially lower than that of other combinations of immunosuppressive agents, there appears to be a lower incidence and severity of side effects compared with antilymphocyte alternatives.

Muromonab-CD3

A murine monoclonal antibody, muromonab-CD3, is directed against human CD3, the T cell receptor. Indicated for acute graft rejection refractory to corticosteroids, large doses of the drug purge T cells from the systemic circulation. The drug has numerous side effects related to the release of cytokines, including fever, myalgias, dyspnea, and aseptic meningitis, and has also been associated with increased susceptibility to cytomegalovirus infection. Most patients are limited to a single course of therapy since recurrent courses may be associated with posttransplant lymphoproliferative disease.

Tumor Necrosis Factor (TNF) Antagonists

Several approaches have been developed to mitigate the biologic effects of TNF, a cytokine produced by macrophages and other antigen-presenting cells. TNF activates gene expression of proinflammatory mediators, up-regulates adhesion molecule expression, stimulates neutrophil function, possesses antitumor and antiviral activity, and is an endogenous pyrogen. In addition to its proinflammatory properties, TNF has been associated with bone resorption and cartilage degradation and appears to play a central role in rheumatic joint disease. Two molecules have been designed to inhibit binding of TNF to its cellular receptor and thereby reduce its cellular and biologic effects. Etanercept is a dimeric construct—containing the soluble TNF receptor—joined to the Fc domain of a human IgG molecule. Infliximab is a chimeric antibody molecule containing a human Fc domain and a murine variable region. Both are disease-modifying drugs that have been shown to slow joint destruction and markedly decrease symptomatology in rheumatoid arthritis; etanercept may also be effective in ankylosing spondylitis. It must be administered by subcutaneous injection twice weekly; infliximab is given intravenously every 2 months.

IMMUNOMODULATING THERAPIES

Cytokine Therapy

The experimental and clinical applications of cytokines, as biologic response modifiers and therapeutic agents, have been greatly expanded in recent years. Some cytokines, such as tumor necrosis factor and interferon alfa, have direct antitumor activity. Other cytokines affect tumor immune responses by lymphokine-activated killer cells, tumor-infiltrating lymphocytes, and activated natural killer cells. Cytokines have been used to activate immune cells ex vivo prior to adoptive transfer or have been given concurrently with activated effector cells. Phase I and phase II trials of cellular adoptive therapy, with IL-2 activated killer cells, for the treatment of renal cell carcinoma and melanoma have demonstrated feasibility and regression of metastasis in some patients. Modest results, significant morbidity, and high cost have hampered widespread adoption of these techniques.

Interferon alfa is used in hairy cell leukemia, chronic myelogenous leukemia, Kaposi's sarcoma, and chronic active hepatitis B and C. Interferon beta is used for multiple sclerosis and interferon gamma for the treatment of chronic granulomatous disease. Constitutional symptoms are common with cytokine therapy, and in some instances toxicity is considerable.

Intravenous Gamma Globulin

Immune globulin IV (IGIV) has numerous immunomodulatory and anti-inflammatory activities and is the standard of care for immunologically mediated disorders such as Kawasaki's syndrome and for antibody replacement in humoral immunodeficiency. When used in humoral immunodeficiency, serum IgG levels can become normal but the IGIV contains virtually no IgM and only traces of IgA.

Each lot of IGIV produced from donated serum contains millions of antibody specificities, reflecting the humoral immune repertoire from thousands of normal blood

donors. Most current products undergo numerous purification and viral inactivation steps, including solvent-detergent treatment or pasteurization. The antibody reactivities can be directed against a wide range of foreign and self antigens. In addition to the above disorders, IGIV is effective in Guillain-Barre syndrome, immune-mediated neuropathies, idiopathic thrombocytopenic purpura, pediatric HIV infection, and after bone marrow transplantation. Many other potential indications have been supported only by anecdotal reports or uncontrolled trials.

Cluster of Differentiation	Primary Cellular Distribution	Function
CD2	T cells, NK cells	Adhesion molecule
CD3	Pan-T cell marker	T cell receptor
CD4	T helper-inducer cells, macrophage	Binds to MHC class II
CD5	T cells, B cell subset	
CD7	T cells	
CD8	T cytotoxic-suppressor cells	Binds MHC class I
CD10	Immature B cells	CALLA; also found in ALL
CD11a	Leukocytes	Adhesion molecule
CD11b		
CD11c		
CD13/33	Granulocytes	Granulocyte marker
CD14	Monocytes	Monocyte marker
CD16/56	NK cells	NK cell markers; CD16 is low-affinity Fc? receptor
CD19	Pan-B cell marker	Appears early in B cell maturation
CD20/21/22	B cell markers	Appear after CD19; CD21 is complement receptor (CR2)
CD23	Activated B cells, macrophages	Low-affinity Fce receptor
CD25	Activated T, B cells and macrophages	IL-2 receptor; activation marker
CD28	T cells	Costimulatory receptor
CD34	Hematopoietic progenitor cells	"Stem cell" marker
CD38	Plasma cells	
CD45	Leukocytes	Panleukocyte marker
CD45RA/RO	T cells	CD45RA on "naive" T cells; CD45RO on "memory" T cells

Table 19-3. Major activities of selected cytokines.

Cytokine	Primary Biologic Activity
IL-1	Major source is activated macrophages. Enhances T and B cell activation. Endogenous pyrogen and major inflammatory mediator.
IL-2	Autocrine and paracrine T cell activation and growth factor.
IL-3	Multilineage hematopoietic growth factor.
IL-4	T and B cell growth factor. Induces IgE isotype switching; TH2 CD4 cell and mast cell growth factor.
IL-5	Promotes eosinophil growth and differentiation and IgA synthesis.
IL-6	B cell differentiation factor; acute phase reactant.
IL-7	Growth factor for very early B and T lymphocytes.
IL-8	Chemotactic factor for neutrophils, lymphocytes. Up-regulates adhesion molecule expression.
IL-10	Down-regulates cellular activation. Inhibits production of proinflammatory cytokines by monocytes and macrophages.
IL-12	Augments IFN- γ production, enhances TH1 CD4 response.
IL-13	Functions overlap with those of IL-4.
TNF	Overlaps with activity with IL-1 but has more antitumor activity. Mediates host response to gram-negative bacteria and systemic toxicity of LPS.
IFN- α , - β , - γ	Antiviral and antitumor activities. Activates macrophages. Enhances cytotoxic lymphocyte and NK activity.
GM-CSF	Growth factor for granulocytes, macrophages, and eosinophils. Activates neutrophil phagocytosis. Enhances eosinophil-mediated cytotoxicity. Promotes basophil histamine release.
TGF- β	Major regulatory factor, inhibiting leukocyte growth, proliferation and proinflammatory cytokines.

Table 19-4. Autoantibodies: Associations with connective tissue diseases.¹

Suspected Disease State	Test	Primary Disease Association (Sensitivity, Specificity)	Other Disease Associations	Comments
CREST ² syndrome	Anticentromere antibody	CREST (70-90%, high)	Scleroderma (10-15%), Raynaud's disease (10-30%).	Predictive value of a positive test is > 95% for scleroderma or related disease (CREST, Raynaud's). Diagnosis of CREST is made clinically.
Systemic lupus - erythematosus (SLE)	Antinuclear antibody (ANA)	SLE (> 95%, low)	Rheumatoid arthritis (30-50%), discoid lupus, scleroderma (60%), drug-induced lupus (100%), Sjogren's syndrome (80%), miscellaneous inflammatory disorders.	Often used as a screening test; a negative test virtually excludes SLE; a positive test, while nonspecific, increases posttest probability of SLE. Titer does not correlate with disease activity.
	Anti-double-stranded-DNA (anti-ds-DNA)	SLE (60-70%, high)	Lupus nephritis, rarely rheumatoid arthritis, other connective tissue disease, usually in low titer.	Predictive value of a positive test is > 90% for SLE if present in high titer; a decreasing titer may correlate with worsening renal disease. Titer generally correlates with disease activity.
	Anti-Smith antibody (anti-Sm)	SLE (30-40%, high)		SLE-specific. A positive test substantially increases posttest probability of SLE. Test rarely indicated.
Mixed connective tissue disease (MCTD)	Anti-ribonucleo-protein antibody (RNP)	Scleroderma (20-30%, low), MCTD (95-100%, low)	SLE (30%), Sjogren's syndrome, rheumatoid arthritis (10%), discoid lupus (20-30%)	A negative test essentially excludes MCTD; a positive test in high titer, while nonspecific, increases posttest probability of MCTD.
Rheumatoid arthritis	Rheumatoid factor (RF)	Rheumatoid arthritis (50-90%)	Other rheumatic diseases, chronic infections, some malignancies, some healthy individuals, elderly patients.	Titer does not correlate with disease activity.
Scleroderma	Anti-Scl-70 antibody	Scleroderma (15-20%, low)		Predictive value of a positive test is > 95% for scleroderma.
Sjogren's syndrome	Anti-SS-A/Ro antibody	Sjogren's (60-70%, low)	SLE (30-40%), rheumatoid arthritis (10%), subacute cutaneous lupus, vasculitis.	Useful in counseling women of child-bearing age with known connective tissue disease, since a positive test is associated with a small but real risk of neonatal SLE and congenital heart block.
Wegener's granulomatosis	Anti-neutrophil cytoplasmic antibody (ANCA)	Wegener's granulomatosis (systemic necrotizing vasculitis) (56-96%, high)	Crescentic glomerulonephritis or other systemic vasculitis (eg, polyarteritis nodosa).	Ability of this assay to reflect disease activity remains unclear.

¹Reproduced, with permission, from Klein J et al: The HLA system. First of two parts. N Engl J Med 2000;343:782.

²Symbols with asterisks indicate alleles, and symbols without asterisks indicate serologically defined antigens. For each disease, the marker or markers with the strongest associations are given. In many cases in which it is difficult to decide whether HLA-DR or DQ markers are responsible for association, both markers are given.

³The relative risk indicates the frequency of a disease in persons with the HLA marker as compared with persons without the marker. A positive association (ie, when the HLA marker is more frequent in persons with the disease than in those without it) is indicated by a relative risk of more than 1.0, a negative association by a relative risk of less than 1.0, and no association by a relative risk of 1.0.

⁴The risk has not been assessed separately for this allele.

■ DIAGNOSIS & EVALUATION

Examination of the Patient

In the patient with arthritis, the two clinical clues most helpful for diagnosis are the joint pattern and the presence or absence of extra-articular manifestations. The joint pattern is defined by answering three questions: (1) Is inflammation present? (2) How many joints are involved? and (3) What joints are affected? Joint inflammation is manifested by redness, warmth, swelling, and morning stiffness of at least 30 minutes' duration. Both the number of affected joints and the specific sites of involvement help determine the differential diagnosis ([Table 20-1](#)). Some diseases—gout, for example—are characteristically monarticular, whereas other diseases, such as rheumatoid arthritis, are chiefly polyarticular. The location of joint involvement can also be distinctive. Only two diseases frequently cause prominent involvement of the distal interphalangeal joint (DIP): osteoarthritis and psoriatic arthritis. Extra-articular manifestations such as fever, rash, nodules, or neuropathy help narrow the differential diagnosis (see [Table 20-1](#)).

Arthrocentesis & Examination of Joint Fluid

Synovial fluid examination ([Table 20-2](#)) may provide specific diagnostic information in joint disease. Contraindications to arthrocentesis include infection of the overlying skin, bleeding disorder, or inability of the patient to cooperate. For patients who are chronically anticoagulated with warfarin, joints can be aspirated if the INR is less than 3.0. In such patients, use of a small-gauge needle (eg, 22F or 25F) and application of firm pressure to the aspiration site are prudent measures. Most large joints are easily aspirated ([Figure 20-1](#)).

A. Types of Studies

1. Gross examination—If fluid is green or purulent, a Gram's stain is indicated. If bloody, a bleeding disorder, trauma, or traumatic tap is most likely.

2. Microscopic examination—Compensated polarized light microscopy identifies and distinguishes monosodium urate (gout) and calcium pyrophosphate (pseudogout) crystals.

3. Culture—Bacterial cultures as well as special studies for gonococci, tubercle bacilli, or fungi are ordered as appropriate.

B. Interpretation

(See [Table 20-2](#).) Although synovial fluid analysis is diagnostic in infectious or microcrystalline arthritis, there is considerable overlap in the cytologic and biochemical values obtained in these and other diseases ([Table 20-3](#)). These studies do make possible, however, a differentiation according to severity of inflammation. Inflammatory joint fluids have more than 3000 white blood cells per microliter, of which 50% or more are polymorphonuclear neutrophils ([Table 20-2](#)). Noninflammatory fluids have less than 3000/uL white cells and less than 25% polymorphonuclear neutrophils. Synovial fluid glucose and protein levels ([Table 20-2](#)) add little information.

■ DEGENERATIVE & CRYSTAL-INDUCED ARTHRITIS

DEGENERATIVE JOINT DISEASE (OSTEOARTHRITIS)

Essentials of Diagnosis

- Commonly secondary to other articular disease.
- A degenerative disorder without systemic manifestations.
- Pain relieved by rest; morning stiffness brief; articular inflammation minimal.
- X-ray findings: narrowed joint space, osteophytes, increased density of subchondral bone, bony cysts.

General Considerations

Osteoarthritis is the most common form of joint disease, sparing no age, race, or geographic area. At least 20 million adults in the United States suffer from the effects of this condition at any one time, and 90% of all people will have radiographic features of osteoarthritis in weight-bearing joints by age 40. Symptomatic disease also increases with age.

This arthropathy is characterized by degeneration of cartilage and by hypertrophy of bone at the articular margins. Inflammation is usually minimal. Hereditary and mechanical factors may be involved in the pathogenesis.

Degenerative joint disease is divided into two types: (1) primary, which most commonly affects some or all of the following: the terminal interphalangeal joints (Heberden's nodes) and less commonly the proximal interphalangeal joints (Bouchard's nodes), the metacarpophalangeal and carpometacarpal joints of the thumb, the hip, the knee, the metatarsophalangeal joint of the big toe, and the cervical and lumbar spine; and (2) secondary, which may occur in any joint as a sequela to articular injury resulting from either intra-articular (including rheumatoid arthritis) or extra-articular causes. The injury may be acute, as in a fracture; or chronic, as that due to occupational overuse of a joint, metabolic disease (eg, hyperparathyroidism, hemochromatosis, ochronosis), or neurologic disorders (tabes dorsalis; see below). Obesity is a risk factor for knee osteoarthritis and probably for the hip. Recreational running does not increase the incidence of osteoarthritis, but participation in competitive contact sports does. Jobs requiring frequent bending and carrying increase the risk of knee osteoarthritis.

Pathologically, the articular cartilage is first roughened and finally worn away, and spur formation and lipping occur at the edge of the joint surface. The synovial membrane becomes thickened, with hypertrophy of the villous processes; the joint cavity, however, never becomes totally obliterated, and the synovial membrane does not form adhesions. Inflammation is prominent only in occasional patients with acute interphalangeal joint involvement.

Clinical Findings

A. Symptoms and Signs

The onset is insidious. Initially, there is articular stiffness, seldom lasting more than 15 minutes; this develops later into pain on motion of the affected joint and is made worse by activity or weight bearing and relieved by rest. Deformity may be absent or minimal; however, bony enlargement of the interphalangeal joints is occasionally prominent, and flexion contracture or varus deformity of the knee is not unusual. There is no ankylosis, but limitation of motion of the affected joint or joints is common. Coarse crepitus may often be felt in the joint. Joint effusion and other articular signs of inflammation are mild. There are no systemic manifestations.

B. Laboratory Findings

Elevated sedimentation rate and other laboratory signs of inflammation are not present.

C. Imaging

Radiographs may reveal narrowing of the joint space, sharpened articular margins, osteophyte formation and lipping of marginal bone, and thickened, dense subchondral bone. Bone cysts may also be present.

Differential Diagnosis

Because articular inflammation is minimal and systemic manifestations are absent, degenerative joint disease should seldom be confused with other arthritides. The distribution of joint involvement in the hands also helps distinguish osteoarthritis from rheumatoid arthritis. Osteoarthritis chiefly affects the distal and proximal interphalangeal joints and spares the wrist and metacarpophalangeal joints (except at the thumb); rheumatoid arthritis involves the wrists and metacarpophalangeal joints and spares the distal interphalangeal joints. Furthermore, the joint enlargement is bony-hard and cool in osteoarthritis but spongy and warm in rheumatoid arthritis. Skeletal symptoms due to degenerative changes in joints, especially in the spine, may cause coexistent metastatic neoplasia, osteoporosis, multiple myeloma, or other bone disease to be overlooked.

Prevention

Weight reduction in women reduces the risk of developing symptomatic knee osteoarthritis. Estrogen replacement therapy may reduce the risk of knee and hip

osteoarthritis and maintaining normal vitamin D levels can reduce the occurrence and progression of osteoarthritis.

Treatment

A. General Measures

For patients with mild to moderate osteoarthritis of weight-bearing joints, a supervised walking program may result in clinical improvement of functional status without aggravating the joint pain. Weight loss can also improve the symptoms.

B. Analgesic and Anti-inflammatory Drugs

NSAIDs ([Table 5-6](#)) are more effective (and more toxic) than acetaminophen for osteoarthritis of the knee or hip. Their superiority is most convincing in those with severe disease. Patients with mild disease should start with acetaminophen (2.6-4 g/d). Glucosamine and chondroitin sulfate also appear to be effective and safe. NSAIDs should be considered for patients who fail to respond to acetaminophen, chondroitin sulfate, and glucosamine. (See discussion of NSAID toxicity in the section on treatment of rheumatoid arthritis.) High doses of NSAIDs, as used in more inflammatory arthritides, are unnecessary.

For many patients, it is possible eventually to reduce the dosage or limit use of drugs to periods of exacerbation. For patients with knee osteoarthritis and effusion, intra-articular injection of triamcinolone (20-40 mg) may obviate the need for analgesics or NSAIDs but should not be repeated more than two or three times in a year. Intra-articular injections of sodium hyaluronate reduce symptoms moderately in some patients. Capsaicin cream 0.025% applied twice daily can also reduce knee pain without NSAIDs.

C. Surgical Measures

Total hip replacement provides excellent symptomatic and functional improvement when that joint is seriously afflicted, as indicated by severely restricted walking and pain at rest, particularly at night. Knee replacement is also effective. Arthroscopic surgery for knee osteoarthritis is ineffective. Experimental techniques to repair focal cartilage loss in the knee by autologous chondrocyte transplantation are promising. However, the indications for and limitations of this procedure require further definition.

Prognosis

Marked disability is less common than in rheumatoid arthritis, but symptoms may be quite severe and limit activity considerably (especially with involvement of the hips, knees, and cervical spine).

CRYSTAL DEPOSITION ARTHRITIS

1. Gouty Arthritis

Essentials of Diagnosis

- Acute onset, typically nocturnal and usually monarticular, often involving the first metatarsophalangeal joint.
- Postinflammatory desquamation and pruritus.
- Hyperuricemia in most; identification of urate crystals in joint fluid or tophi is diagnostic.
- Dramatic therapeutic response to NSAIDs or colchicine.
- With chronicity, urate deposits in subcutaneous tissue, bone, cartilage, joints, and other tissues.

General Considerations

Gout is a metabolic disease of heterogeneous nature, often familial, associated with abnormal amounts of urates in the body and characterized early by a recurring acute arthritis, usually monarticular, and later by chronic deforming arthritis. The associated hyperuricemia is due to overproduction or underexcretion of uric acid—sometimes both. The disease is especially common in Pacific islanders, eg, Filipinos and Samoans. It is rarely caused by a specifically determined genetic aberration (eg, Lesch-Nyhan syndrome). Secondary gout, which may have a heritable component, is related to acquired causes of hyperuricemia, eg, medication use (especially diuretics, cyclosporine, low-dose aspirin, and niacin), myeloproliferative disorders, multiple myeloma, hemoglobinopathies, chronic renal disease, hypothyroidism, psoriasis, sarcoidosis, and lead poisoning. Alcohol ingestion promotes hyperuricemia by increasing urate production and decreasing the renal excretion of uric acid. Finally, hospitalized patients frequently suffer attacks of gout because of changes in diet (eg, inability to take oral feedings following abdominal surgery) or medications that lead either to rapid reductions or increases in the serum urate level.

About 90% of patients with primary gout are men, usually over 30 years of age. In women the onset is typically postmenopausal. The characteristic lesion is the tophus, a nodular deposit of monosodium urate monohydrate crystals, with an associated foreign body reaction. These are found in cartilage, subcutaneous and periarticular tissues, tendon, bone, the kidneys, and elsewhere. Urates have been demonstrated in the synovial tissues (and fluid) during acute arthritis; indeed, the acute inflammation of gout is believed to be activated by the phagocytosis by polymorphonuclear cells of urate crystals with the ensuing release from the neutrophils of chemotactic and other substances capable of mediating inflammation. The precise relationship of hyperuricemia to gouty arthritis is still obscure, since chronic hyperuricemia is found in people who never develop gout or uric acid stones ([Table 20-4](#)). Rapid fluctuations in serum urate levels, either increasing or decreasing, are important factors in precipitating acute gout. The mechanism of the late, chronic stage of gouty arthritis is better understood. This is characterized pathologically by tophaceous invasion of the articular and periarticular tissues, with structural derangement and secondary degeneration (osteoarthritis).

Uric acid kidney stones are present in 5-10% of patients with gouty arthritis. Hyperuricemia correlates highly with the likelihood of developing stones, with the risk of stone formation reaching 50% in patients with a serum urate level above 13 mg/dL. Chronic urate nephropathy is caused by the deposition of monosodium urate crystals in the renal medulla and pyramids. Although progressive renal failure occurs in a substantial percentage of patients with chronic gout, the role of hyperuricemia in causing this outcome is controversial, because many patients with gout have numerous confounding risk factors for renal failure (eg, hypertension, alcohol use, lead exposure, and other risk factors for vascular disease).

Unless there is a rapid breakdown of cellular nucleic acid following aggressive treatment of leukemia or lymphoma, uric acid-lowering drugs need not be instituted until arthritis, renal calculi, or tophi become apparent. Asymptomatic hyperuricemia should not be treated.

Clinical Findings

A. Symptoms and Signs

The acute arthritis is characterized by its sudden onset, frequently nocturnal, either without apparent precipitating cause or following rapid fluctuations in serum urate levels, from alcohol excess or medication changes (see above). The metatarsophalangeal joint of the great toe is the most susceptible joint ("podagra"), although others, especially those of the feet, ankles, and knees, are commonly affected. Gouty attacks may develop in periarticular soft tissues such as the arch of the foot. Hips and shoulders are rarely affected. More than one joint may occasionally be affected during the same attack; in such cases, the distribution of the arthritis is usually asymmetric. As the attack progresses, the pain becomes intense. The involved joints are swollen and exquisitely tender and the overlying skin tense, warm, and dusky red. Fever is common and may reach 39 °C. Local desquamation and pruritus during recovery from the acute arthritis are characteristic of gout but are not always present. Tophi may be found in the external ears, hands, feet, olecranon, and prepatellar bursas. They are usually seen only after several attacks of acute arthritis.

Asymptomatic periods of months or years commonly follow the initial acute attack. After years of recurrent severe monarthritis attacks of the lower extremities, gout can evolve into a chronic, deforming polyarthritis of upper and lower extremities that mimics rheumatoid arthritis.

B. Laboratory Findings

The serum uric acid is elevated (> 7.5 mg/dL) in 95% of patients who have serial measurements during the course of an attack. However, a single uric acid determination is normal in up to 25% of cases, so it does not exclude gout, especially in patients taking uricopenic drugs. During an acute attack, the erythrocyte

sedimentation rate and white cell count are frequently elevated. Material aspirated from a tophus shows the typical crystals of sodium urate and confirms the diagnosis. Further confirmation is obtained by identification of sodium urate crystals by compensated polariscopic examination of wet smears prepared from joint fluid aspirates. Such crystals are negatively birefringent and needle-like and may be found free or in neutrophils.

C. Imaging

Early in the disease, radiographs show no changes. Later, punched-out erosions with an overhanging rim of cortical bone ("rat bite") develop. When these are adjacent to a soft tissue tophus, they are diagnostic of gout.

Differential Diagnosis

Acute gout is often confused with cellulitis. Bacteriologic studies usually exclude acute pyogenic arthritis. Pseudogout is distinguished by the identification of calcium pyrophosphate crystals (strong positive birefringence) in the joint fluid, usually normal serum uric acid, the x-ray appearance of chondrocalcinosis, and the relative therapeutic ineffectiveness of colchicine.

Chronic tophaceous arthritis may resemble chronic rheumatoid arthritis; gout is suggested by an earlier history of monarthritis and is established by the demonstration of urate crystals in a suspected tophus. Likewise, hips and shoulders are generally spared in tophaceous gout. Biopsy may be necessary to distinguish tophi from rheumatoid nodules. An x-ray appearance similar to that of gout may be found in rheumatoid arthritis, sarcoidosis, multiple myeloma, hyperparathyroidism, or Hand-Schuller-Christian disease. Chronic lead intoxication may result in attacks of gouty arthritis (saturnine gout); abdominal pain, peripheral neuropathy, renal insufficiency, and basophilic stippling of red cells are clues to the diagnosis.

Treatment

A. Acute Attack

Arthritis is treated first and hyperuricemia later, if at all. Sudden reduction of serum uric acid often precipitates further episodes of gouty arthritis.

1. Nonsteroidal anti-inflammatory drugs—NSAIDs ([Table 5-6](#)) have become the treatment of choice for acute gout. Traditionally, indomethacin has been the most frequently used agent, but all of the other newer NSAIDs are probably equally effective. Indomethacin is initiated at a dosage of 25-50 mg every 8 hours and continued until the symptoms have resolved (usually 5-10 days). Active peptic ulcer disease, impaired renal function, and a history of allergic reaction to NSAIDs are contraindications. For patients at high risk for upper gastrointestinal bleeding, a COX-2 inhibitor may be an appropriate first choice for management of an acute gout attack.

2. Colchicine—Colchicine is less favored, since 80% of treated patients develop abdominal cramping, diarrhea, nausea, or vomiting. Colchicine is thought to work by inhibiting chemotaxis, thereby interfering with the inflammatory response to urate crystals; it is most effective when given in the first few hours after onset of symptoms. The dose is 0.5 mg or 0.6 mg by mouth every hour until pain is relieved or until nausea or diarrhea appears; the drug is then stopped. The usual total dose required is 4-6 mg and should not exceed 8 mg. Oral colchicine should not be used in patients with inflammatory bowel disease. For patients who cannot tolerate oral medications (eg, postoperative patients), colchicine can be administered intravenously. However, local pain, tissue damage from extravasation, and marrow suppression may occur. The initial dose is 2 mg in 20-50 mL of saline solution given through an intravenous catheter. Two additional doses of 1 mg each can be administered at 6-hour intervals. The total dose should not exceed 4 mg, and no additional colchicine should be given by mouth for 3 weeks. Dosages are reduced by at least 50% in the presence of renal or hepatic disease. Combined renal and hepatic disease contraindicates the use of intravenous colchicine.

3. Corticosteroids—Corticosteroids often give dramatic symptomatic relief in acute episodes of gout and will control most attacks. They are best reserved for patients unable to take oral NSAIDs. If the patient's gout is monarticular, intra-articular administration (eg, triamcinolone, 10-40 mg depending on the size of the joint) is most effective. For polyarticular gout, corticosteroids may be given intravenously (eg, methylprednisolone, 40 mg/d tapered over 7 days) or orally (eg, prednisone, 40-60 mg/d tapered over 7 days). Gouty and septic arthritis can coexist, albeit rarely. Therefore, joint aspiration and Gram stain with culture of synovial fluid should be performed before corticosteroids are given.

4. Analgesics—At times the pain of an acute attack may require opioids. Aspirin should be avoided since it aggravates hyperuricemia (see below).

5. Bed rest—Bed rest is important in the management of the acute attack and should be continued for about 24 hours after the acute attack has subsided. Early ambulation may precipitate a recurrence.

B. Management Between Attacks

Treatment during symptom-free periods is intended to minimize urate deposition in tissues, which causes chronic tophaceous arthritis, and to reduce the frequency and severity of recurrences.

1. Diet—Potentially reversible causes of hyperuricemia are a high-purine diet, obesity, alcohol consumption, and use of certain medications (see below). Although dietary purines usually contribute only 1 mg/dL to the serum uric acid level, moderation in eating foods with high-purine content is advisable ([Table 20-5](#)). A high liquid intake and, more importantly, a daily urinary output of 2 L or more will aid urate excretion and minimize urate precipitation in the urinary tract.

2. Avoidance of hyperuricemic medications—Thiazide and loop diuretics inhibit renal excretion of uric acid and should be avoided in patients with gout. Similarly, low doses of aspirin (< 3 g daily) aggravate hyperuricemia, as does niacin.

3. Colchicine—Patients with a single episode of gout who are willing to lose weight and stop drinking alcohol are at low risk of another attack and unlikely to benefit from chronic medical therapy. In contrast, older individuals with mild chronic renal failure who require diuretic use and have a history of multiple attacks of gout are more likely to benefit from pharmacologic treatment. In general, the higher the uric acid level and the more frequent the attacks, the more likely that chronic medical therapy will be beneficial.

There are two indications for daily colchicine administration: (1) It can be used to prevent future attacks. For the person who has mild hyperuricemia and occasional attacks of gouty arthritis, chronic colchicine prophylaxis may be all that is needed. The usual dose is 0.6 mg twice a day. Patients who have coexisting moderate renal insufficiency or heart failure should have the dose reduced to once a day in order to avoid the development of a peripheral neuromyopathy and myositis that can complicate the use of higher doses. (2) It is also used when uricosuric drugs or allopurinol (see below) are started, to suppress attacks precipitated by abrupt changes in the serum uric acid level.

4. Reduction of serum uric acid—Indications include frequent acute arthritis not controlled by colchicine prophylaxis, tophaceous deposits, or renal damage. Hyperuricemia with infrequent attacks of arthritis may not require treatment; asymptomatic hyperuricemia should not be treated. If instituted, the goal of medical treatment is to maintain the serum uric acid below 6 mg/dL, which should prevent crystallization of urate.

Two classes of agents may be used to lower the serum uric acid—the uricosuric drugs and allopurinol (neither is of value in the treatment of acute gout). The choice of one or the other depends on the result of a 24-hour urine uric acid determination. A value under 800 mg/d indicates undersecretion of uric acid, which is amenable to uricosuric agents if renal function is preserved. Patients with more than 800 mg of uric acid in a 24-hour urine collection are overproducers and require allopurinol.

a. Uricosuric drugs—These drugs, by blocking tubular reabsorption of filtered urate and reducing the metabolic pool of urates, prevent the formation of new tophi and reduce the size of those already present. When administered concomitantly with colchicine, they may lessen the frequency of recurrences of acute gout. The indication for uricosuric treatment is the increasing frequency or severity of acute attacks. Uricosuric agents are ineffective in patients with renal insufficiency, with a serum creatinine of more than 2 mg/dL.

The following uricosuric drugs may be employed: (1) Probenecid, 0.5 g daily initially, with gradual increase to 1-2 g daily; or (2) sulfinpyrazone, 50-100 mg twice daily initially, with gradual increase to 200-400 mg twice daily. Hypersensitivity to either with fever and rash occurs in 5% of cases; gastrointestinal complaints are observed in 10%. Probenecid also inhibits the excretion of penicillin, indomethacin, dapsone, and acetazolamide.

Precautions with uricosuric drugs. It is important to maintain a daily urinary output of 2000 mL or more in order to minimize the precipitation of uric acid in the urinary tract. This can be further prevented by giving alkalinizing agents (eg, potassium citrate, 30-80 meq/d) to maintain a urine pH of above 6.0. Uricosuric drugs are avoided in patients with a history of uric acid nephrolithiasis. Aspirin in moderate doses antagonizes the action of uricosuric agents, but low doses (325 mg or less per day) do not; doses greater than 3 g daily are themselves uricosuric.

b. Allopurinol—The xanthine oxidase inhibitor allopurinol promptly lowers plasma urate and urinary uric acid concentrations and facilitates tophus mobilization. The drug is of special value in uric acid overproducers; in tophaceous gout; in patients unresponsive to the uricosuric regimen; and in gouty patients with uric acid renal stones. It should be used in low doses in patients with renal insufficiency and is not indicated in asymptomatic hyperuricemia. The most frequent adverse effect is the precipitation of an acute gouty attack. However, the commonest sign of hypersensitivity to allopurinol (occurring in 2% of cases) is a pruritic rash that may progress to

toxic epidermal necrolysis. Vasculitis and hepatitis are other rare complications.

The daily dose is determined by the serum uric acid response. Initially, 100 mg/d of allopurinol is given for 1 week; the dose is increased if the serum uric acid is still high. A normal serum uric acid level is often obtained with a daily dose of 200-300 mg. Occasionally (and in selected cases) it may be helpful to continue the use of allopurinol with a uricosuric drug.

Allopurinol interacts with other drugs. The combined use of allopurinol and ampicillin causes a drug rash in 20% of patients. Allopurinol can increase the half-life of probenecid, while probenecid increases the excretion of allopurinol. Thus, a patient taking both drugs may need to use slightly higher than usual doses of allopurinol and lower doses of probenecid. Allopurinol potentiates the effect of azathioprine. If allopurinol cannot be avoided, the dose of azathioprine should be reduced by 75% before allopurinol is started.

C. Chronic Tophaceous Arthritis

Tophaceous deposits can be made to shrink and disappear with allopurinol therapy. Resorption of extensive tophi requires maintaining a serum uric acid below 5 mg/dL, which may be achievable only with concomitant use of allopurinol and a uricosuric agent. Surgical excision of large tophi offers mechanical improvement in selected deformities.

D. Gout in the Transplant Patient

Since many transplant patients have decreased renal function and require drugs that inhibit uric acid excretion (especially cyclosporine and diuretics), they commonly develop hyperuricemia and gout. Treating these patients is challenging: NSAIDs are usually contraindicated because of renal impairment; intravenous colchicine should be avoided for the same reason; and corticosteroids are already being used. Often the best approach for monarticular gout—after excluding infection—is injecting corticosteroids into the joint (see above). For polyarticular gout, increasing the dose of systemic corticosteroid may be the only alternative. Since transplant patients often have multiple attacks of gout, long-term relief requires lowering the serum uric acid with allopurinol. Renal impairment seen in many transplant patients would make uricosuric agents ineffective.

Prognosis

Without treatment, the acute attack may last from a few days to several weeks. The intervals between acute attacks vary up to years, but the asymptomatic periods often become shorter if the disease progresses. Chronic gouty arthritis occurs after repeated attacks of acute gout, but only after inadequate treatment. The younger the patient at the onset of disease, the greater the tendency to a progressive course. Destructive arthropathy is rarely seen in patients whose first attack is after age 50.

Patients with gout are anecdotally thought to have an increased incidence of hypertension, renal disease (eg, nephrosclerosis, interstitial nephritis, pyelonephritis), diabetes mellitus, hypertriglyceridemia, and atherosclerosis.

Harris M et al: Effect of low dose daily aspirin on serum urate levels and urinary excretion in patients receiving probenecid for gouty arthritis. *J Rheumatol* 2000;27:2873. [\[PMID: 11128679\]](#)

2. Chondrocalcinosis & Pseudogout (Calcium Pyrophosphate Dihydrate [CPPD] Deposition Disease)

Chondrocalcinosis is the presence of calcium-containing salts in articular cartilage. Diagnosed radiologically, it may be familial and is commonly associated with a wide variety of metabolic disorders, eg, hemochromatosis, hyperparathyroidism, ochronosis, diabetes mellitus, hypothyroidism, Wilson's disease, and gout. Pseudogout, its clinical correlate, is most often seen in persons age 60 or older, is characterized by acute, recurrent and rarely chronic arthritis involving large joints (most commonly the knees and the wrists) and is almost always accompanied by chondrocalcinosis of the affected joints. Other joints frequently affected are the metacarpophalangeals, hips, shoulders, elbows, and ankles. Involvement of the distal interphalangeal and proximal interphalangeal joints is no more common in CPPD deposition disease than in other age-matched controls. Pseudogout, like gout, frequently develops 24-48 hours after major surgery. Identification of calcium pyrophosphate crystals in joint aspirates is diagnostic of pseudogout. With light microscopy, the rhomboid-shaped crystals differ from the needle-shaped gout crystals. A red compensator is used for positive identification, since pseudogout crystals are blue when parallel and yellow when perpendicular to the axis of the compensator. Urate crystals give the opposite pattern. X-ray examination shows not only calcification (usually symmetric) of cartilaginous structures but also signs of degenerative joint disease (osteoarthritis). Unlike gout, pseudogout is usually associated with normal serum urate levels and is not dramatically improved by colchicine.

Treatment of chondrocalcinosis is directed at the primary disease, if present. Some of the nonsteroidal anti-inflammatory agents (salicylates, indomethacin, naproxen, and other drugs) are helpful in the treatment of acute episodes. Patients at increased risk for upper gastrointestinal bleeding may use a COX-2 inhibitor to treat acute attacks of pseudogout. Colchicine, 0.6 mg orally twice daily, is more effective for prophylaxis than for acute attacks. Aspiration of the inflamed joint and intra-articular injection of triamcinolone, 10-40 mg, depending on the size of the joint, are also of value in resistant cases.

■ PAIN SYNDROMES

NECK PAIN

Essentials of Diagnosis

- Most chronic neck pain is caused by degenerative joint disease and responds to conservative approaches.
- Whiplash, the most common type of traumatic injury to the neck, responds to early mobilization.
- Serious erosive disease of joints in the neck that may lead to neurologic complications sometimes occurs in rheumatoid arthritis and occasionally in ankylosing spondylitis; the usual joint involved in these disorders is the atlantoaxial joint (C1-2).

General Considerations

At any point in time, about 15% of adults are experiencing neck pain. The prevalence of neck pain peaks at age 50 and develops more commonly in women than in men. A large group of articular and extra-articular disorders are characterized by pain that may involve simultaneously the neck, shoulder girdle, and upper extremity. Diagnostic differentiation may be difficult. Some represent primary disorders of the cervicobrachial region; others are local manifestations of systemic disease. It is frequently not possible to make a specific diagnosis.

Clinical Findings

A. Symptoms and Signs

Neck pain may be limited to the posterior region or, depending upon the level of the symptomatic joint, may radiate segmentally to the occiput, anterior chest, shoulder girdle, arm, forearm, and hand. It may be intensified by active or passive neck motions. The general distribution of pain and paresthesias corresponds roughly to the involved dermatome in the upper extremity. Radiating pain in the upper extremity is often intensified by hyperextension of the neck and deviation of the head to the involved side. Limitation of cervical movements is the most common objective finding. Neurologic signs depend upon the extent of compression of nerve roots or the spinal cord. Compression of the spinal cord may cause paraparesis or paraplegia.

B. Imaging

The radiographic findings depend on the cause of the pain; many plain x-rays are completely normal in patients who have suffered an acute cervical strain. Loss of cervical lordosis is often seen but is nonspecific. In osteoarthritis, comparative reduction in height of the involved disk space is a frequent finding. The most common late x-ray finding is osteophyte formation anteriorly, adjacent to the disk; other chronic abnormalities occur around the apophysial joint clefts, chiefly in the lower cervical spine.

Use of advanced imaging techniques is indicated in the patient who has severe pain of unknown cause that fails to respond to conservative therapy or in the patient who has evidence of myelopathy. MRI is more sensitive than CT in detecting disk disease, extradural compression, and intramedullary cord disease. CT is preferable for demonstration of fractures.

Differential Diagnosis & Treatment

The causes of neck pain include acute and chronic cervical strain or sprains, herniated nucleus pulposus, osteoarthritis, ankylosing spondylitis, rheumatoid arthritis, osteomyelitis, neoplasms, spinal stenosis, polymyalgia rheumatica, compression fractures, and functional disorders. Referred pain of myocardial ischemia is rare in the neck, but this does happen.

A. Nonspecific Neck Pain

In the absence of trauma or evidence of infection, malignancy, neurologic findings, or systemic inflammation, the patient can be treated conservatively. Conservative therapy can include rest, analgesics, or physical therapy.

B. Acute Cervical Musculotendinous Strain

Cervical strain is generally caused by mechanical postural disorders, overexertion, or injury (eg, whiplash). Acute episodes are associated with pain, decreased cervical spine motion, and paraspinal muscle spasm, resulting in stiffness of the neck and loss of motion. Muscle trigger points can often be localized. After whiplash injury, patients often experience not only neck pain but also shoulder girdle discomfort and headache. Management includes a cervical collar and administration of analgesics. Corticosteroid injection into cervical facet joints is ineffective. Gradual return to full activity is encouraged.

C. Herniated Nucleus Pulposus

Rupture or prolapse of the nucleus pulposus of the cervical disks into the spinal canal causes pain radiating at a C6-7 level. When intra-abdominal pressure is increased by coughing, sneezing, or other movements, symptoms are aggravated, and cervical muscle spasm may occur. Neurologic abnormalities include decreased reflexes of the deep tendons of the biceps and triceps and decreased sensation and muscle atrophy or weakness in the forearm or hand. Cervical traction, bed rest, and other conservative measures are usually successful. Radicular symptoms usually respond to conservative therapy, including NSAIDs, activity modification, intermittent cervical traction, and neck immobilization. Cervical epidural steroid injections may help those who fail. Surgery is indicated for unremitting pain and progressive weakness despite a full trial of conservative therapy and if a surgically correctable abnormality is identified by MRI or CT myelography. Surgical decompression achieves excellent results in 70-80% of such patients.

D. Arthritic Disorders

Cervical spondylosis (degenerative arthritis) is a collective term describing degenerative changes that occur in the apophysial joints and intervertebral disk joints, with or without neurologic signs. Osteoarthritis of the articular facets is characterized by progressive thinning of the cartilage, subchondral osteoporosis, and osteophytic proliferation around the joint margins. Degeneration of cervical disks and joints may occur in adolescents but is more common after age 40. Degeneration is progressive and is marked by gradual narrowing of the disk space, as demonstrated by x-ray. Osteocartilaginous proliferation occurs around the margin of the vertebral body and gives rise to osteophytic ridges that may encroach upon the intervertebral foramina and spinal canal, causing compression of the neurovascular contents.

Osteoarthritis of the cervical spine is often asymptomatic but may cause diffuse neck pain. A minority of patients with neck pain also develop radicular pain or myelopathy. Myelopathy develops insidiously and is manifested by numb, clumsy hands. Some patients also complain of unsteady walking, urinary frequency and urgency, or electrical shock sensations with neck flexion or extension (Lhermitte's sign). Weakness, sensory loss, and spasticity with exaggerated reflexes develop below the level of spinal cord compression. Motor neuron disease, multiple sclerosis, syringomyelia, spinal cord tumors, and tropical spastic paresis from HTLV-1 infection can mimic myelopathy from cervical arthritis. The mainstay of conservative therapy is immobilizing the cervical spine with a collar. With moderate to severe neurologic symptoms, surgical treatment is indicated.

Ankylosing spondylitis is discussed below. Atlantoaxial subluxation may occur in patients with rheumatoid arthritis, regardless of the severity of disease. Inflammation of the synovial structures resulting from erosion and laxity of the transverse ligament can lead to neurologic signs of spinal cord compression. Treatment may vary from use of a cervical collar or more rigid bracing to operative treatment, depending on the degree of subluxation and neurologic progression. Surgical treatment for stabilization of the cervical spine is a last resort.

D. Other Disorders

Osteomyelitis and neoplasms are discussed below. Osteoporosis is discussed in [Chapter 26](#).

THORACIC OUTLET SYNDROMES

Thoracic outlet syndromes result from compression of the neurovascular structures supplying the upper extremity. Patients often have a history of head or neck trauma.

Symptoms and signs arise from intermittent or continuous pressure on elements of the brachial plexus and the subclavian or axillary vessels by a variety of anatomic structures of the shoulder girdle region. The neurovascular bundle can be compressed between the anterior or middle scalene muscles and a normal first thoracic rib or a cervical rib. Descent of the shoulder girdle may continue during adulthood and cause compression. Faulty posture and occupation may be other predisposing factors. The components of the median nerve that encircle the axillary artery may cause compression and vascular symptoms. Sudden or repetitive strenuous physical activity may precipitate thrombosis of the axillary or subclavian vein.

Pain radiates from the point of compression to the base of the neck, the axilla, the shoulder girdle region, arm, forearm, and hand. Paresthesias are common and distributed to the volar aspect of the fourth and fifth digits. Sensory symptoms may be aggravated at night or by prolonged use of the extremities. Weakness and muscle atrophy are the principal motor abnormalities. Vascular symptoms consist of arterial ischemia characterized by pallor of the fingers on elevation of the extremity, sensitivity to cold, and, rarely, gangrene of the digits or venous obstruction marked by edema, cyanosis, and engorgement.

Reflexes are usually not altered. When the site of compression is between the upper rib and clavicle, partial obliteration of subclavian artery pulsation may be demonstrated by abduction of the arm to a right angle with the elbow simultaneously flexed and rotated externally at the shoulder so that the entire extremity lies in the coronal plane. Neck or arm position has no effect on the diminished pulse, which remains constant in the subclavian steal syndrome.

Chest x-ray will identify patients with cervical rib. MRI with the arms held in different positions is useful in identifying sites of impaired blood flow. Intra-arterial or venous obstruction is confirmed by angiography. Determination of conduction velocities of the ulnar and other peripheral nerves of the upper extremity may help to localize the site of their compression.

Thoracic outlet syndrome must be differentiated from osteoarthritis of the cervical spine, tumors of the cervical spinal cord or nerve roots, and peri arthritis of the shoulder.

Treatment is directed toward relief of compression of the neurovascular bundle. Overhead pulley exercises are useful to improve posture. Shoulder bracing, although uncomfortable, provides a constant stimulus to improve posture. When lying down, the shoulder girdle should be bolstered by arranging pillows in an inverted "V" position.

Symptoms may disappear spontaneously or may be relieved by conservative treatment. Operative treatment is more likely to relieve the neurologic rather than the vascular component that causes symptoms.

LOW BACK PAIN

Low back pain is experienced at some time by up to 80% of the population. The differential diagnosis is broad and includes muscular strain, primary spine disease (eg, disk herniation, degenerative arthritis), systemic diseases (eg, metastatic cancer), and regional diseases (eg, aortic aneurysm). A precise diagnosis cannot be made in the majority of cases. Even when anatomic defects—such as vertebral osteophytes or a narrowed disk space—are present, clinical disease cannot be assumed since such defects are common in asymptomatic patients. The majority of patients will improve in 1-4 weeks and need no evaluation beyond the initial history and physical examination. The diagnostic challenge is to identify those patients who require more extensive or urgent evaluation.

In practice, this means identifying those patients with pain caused by (1) infection, (2) cancer, (3) inflammatory back disease such as ankylosing spondylitis, (4) or nonrheumatologic conditions, especially expanding aortic aneurysm. Significant or progressive neurologic deficits also require identification. If there is no evidence of these problems, conservative therapy is called for.

1. Clinical Approach to Diagnosis

General History & Physical Examination

Low back pain is a final common pathway of many processes; the pain of vertebral osteomyelitis, for example, is not very different in quality and intensity from that due

to back strain of the weekend gardener. Historical factors of importance include smoking, weight loss, age over 50, and cancer, all of which are risk factors for vertebral body metastasis. Osteomyelitis most frequently occurs in adults with a history of recurrent urinary tract infections and is especially common in diabetics.

Previous peptic ulcer disease suggests that a patient's back pain is due to a penetrating ulcer. A history of a cardiac murmur should raise concern about endocarditis, since back pain is a not uncommon manifestation. A background of renal stones might indicate another cause of referred back pain.

History of the Back Pain

Certain qualities of a patient's pain can indicate a specific diagnosis. Low back pain radiating down the buttock and below the knee suggests a herniated disk causing nerve root irritation. Other conditions—including sacroiliitis, facet joint degenerative arthritis, spinal stenosis, or irritation of the sciatic nerve from a wallet—also cause this pattern.

The diagnosis of disk herniation is further suggested by physical examination (see below) and confirmed by imaging techniques. Disk herniation can be asymptomatic, so its presence does not invariably link it to the symptom.

Low back pain at night, unrelieved by rest or the supine position, suggests the possibility of malignancy, either vertebral body metastasis (chiefly from prostate, breast, lung, multiple myeloma, or lymphoma) or a cauda equina tumor. Similar pain can also be caused by compression fractures (from osteoporosis or myeloma).

Symptoms of large or rapidly evolving neurologic deficits identify patients who need urgent evaluation for possible cauda equina tumor, epidural abscess, or, rarely, massive disk herniation. Even with a herniated disk and nerve root impingement, pain is the most prominent symptom; numbness and weakness are less commonly reported and when present are of the magnitude consistent with compression of a single nerve root. Thus, symptoms of bilateral leg weakness (from multiple lumbar nerve root compressions) or of saddle area anesthesia, bowel or bladder incontinence, or impotence (indicating multiple sacral nerve root compressions) indicate a cauda equina process.

Low back pain that worsens with rest and improves with activity is characteristic of ankylosing spondylitis or other seronegative spondyloarthropathies, especially when the onset is insidious and begins before age 40. Most degenerative back diseases produce precisely the opposite pattern, with rest alleviating and activity aggravating the pain. Low back pain causing the patient to writhe occurs in renal colic but can also indicate a leaking aneurysm. The pain associated with pseudoclaudication from lumbar spinal stenosis is discussed below.

Physical Examination of the Back

Several physical findings should be sought because they help identify those few patients who need more than conservative management.

Neurologic examination of the lower extremities will detect the small deficits produced by disk disease and the large deficits complicating such problems as cauda equina tumors. A positive straight leg raising test indicates nerve root irritation. The examiner performs the test on the supine patient by passively raising the patient's leg. The test is positive if radicular pain is produced with the leg raised 60 degrees or less. It has a specificity of 40% but is 95% sensitive in patients with herniation at the L4-5 or L5-S1 level (the sites of 95% of disk herniations). It can be falsely negative, especially in patients with herniation above the L4-5 level. The crossed straight leg sign has a sensitivity of 25% but is 90% specific for disk herniation and is positive when raising the contralateral leg reproduces the sciatica.

Detailed examination of the sacral and lumbar nerve roots, especially L5 and S1, is essential for detecting neurologic deficits associated with back pain. Disk herniation produces deficits predictable for the site involved ([Table 20-6](#)). Deficits of multiple nerve roots suggest a cauda equina tumor or an epidural abscess, both requiring urgent evaluation and treatment.

Measurement of spinal motion in the patient with acute pain is rarely of diagnostic utility and usually simply confirms that pain limits motion. An exception is the decreased range of motion in multiple regions of the spine (cervical, thoracic, and lumbar) in a diffuse spinal disease such as ankylosing spondylitis. By the time the patient has such limits, however, the diagnosis is usually straightforward.

If back pain is not severe and does not itself limit motion, Schober's test of lumbar motion is helpful in early diagnosis of ankylosing spondylitis. To perform this test, two marks are made, one 10 cm above S1 and another 5 cm below. The patient then bends forward as far as possible, and the distance between the points is measured. Normally, the distance increases at least 5 cm. Anything less indicates reduced lumbar motion, which in the absence of severe pain is most commonly due to ankylosing spondylitis or other seronegative spondyloarthropathies.

Palpation of the spine usually does not yield diagnostic information. Point tenderness over a vertebral body is reported to suggest osteomyelitis, but this association is uncommon. A step-off noted between the spinous process of adjacent vertebral bodies may indicate spondylolisthesis, but the sensitivity of this finding is extremely low. Tenderness of the soft tissues overlying the greater trochanter of the hip is a manifestation of trochanteric bursitis.

Inspection of the spine is not often of value in identifying serious causes of low back pain. The classic posture of ankylosing spondylitis is a late finding. Scoliosis of mild degree is not associated with an increased risk of clinical back disease. Cutaneous neurofibromas can identify the rare patient with nerve root encasement.

Examination of the hips should be part of the complete examination. While hip arthritis usually produces groin pain, some patients have buttock or low back symptoms.

Further Examination

If the history and physical examination do not suggest the presence of infection, cancer, inflammatory back disease, major neurologic deficits, or pain referred from abdominal or pelvic disease, further evaluation can be eliminated or deferred while conservative therapy is tried. The great majority of patients will improve with conservative care over 1-4 weeks.

Regular radiographs of the lumbosacral spine give 20 times the radiation dose of a chest x-ray and provide limited, albeit important, information. Oblique films double the radiation dose and are not routinely needed. X-rays can provide evidence of vertebral body osteomyelitis, cancer, fractures, or ankylosing spondylitis. Degenerative changes in the lumbar spine are ubiquitous in patients over 40 and do not prove clinical disease. Plain x-rays have very low sensitivity or specificity for disk disease. Thus, plain x-rays are warranted promptly for patients suspected of having infection, cancer, or fractures; selected other patients who fail to improve after 2-4 weeks of conservative therapy are also candidates. The Agency for Health Care Policy and Research guidelines for obtaining lumbar radiographs are summarized in [Table 20-7](#).

MRI provides exquisite anatomic detail but is reserved for patients who are considering surgery or have evidence of a systemic disease. For example, MRI is needed urgently for any patient suspected of having an epidural mass or cauda equina tumor but not if a patient is felt to have a routine disk herniation, since most will improve over 4-6 weeks of conservative therapy. Noncontrast CT does not image cauda equina tumors or other intradural lesions, and if used instead of MRI it must include intrathecal contrast.

Radionuclide bone scanning has limited utility. It is most useful for early detection of vertebral body osteomyelitis or osteoblastic metastases. The bone scan is normal in multiple myeloma because lytic lesions do not take up isotope.

2. Management

While any management plan must be individualized, key elements of most conservative treatments for back pain include analgesia and education. Analgesia can usually be provided with NSAIDs ([Table 5-6](#)), but severe pain may require opioids ([Table 5-7](#)). Rarely does the need for opioids extend beyond 1-2 weeks.

Diazepam, cyclobenzaprine, carisoprodol, and methocarbamol have been prescribed as muscle relaxants, though their sedative effects may contribute. They should be reserved for patients who fail NSAIDs and should also be limited to courses of 1-2 weeks. Their use should be avoided in older patients, who are at risk of falling. All patients should be taught how to protect the back in daily activities—ie, not to lift heavy objects, to use the legs rather than the back when lifting, to use a chair with arm rests, and to rise from bed by first rolling to one side and then using the arms to push to an upright position. Back manipulation for benign, mechanical low back pain appears safe and as effective as therapies provided by physicians.

Rest and back exercises, once thought to be cornerstones of conservative therapy, are now known to be ineffective for acute back pain. Two days of bed rest gives better results than 7 days. Indeed, no bed rest with continuation of ordinary activities as tolerated is superior to either 2 days of bed rest or back mobilizing exercises. The value of corsets or traction is dubious. Epidural corticosteroid injections can provide short-term relief of sciatica but do not improve functional status or reduce the need for surgery. Corticosteroid injections into facet joints are ineffective for chronic low back pain.

Surgical consultation is needed urgently for any patient with a major or evolving neurologic deficit. Surgery for disk disease is indicated when there is documentation of herniation by imaging, persistent pain, and a consistent neurologic deficit that has failed to respond to 4-6 weeks of conservative therapy. Percutaneous lumbar discectomy, performed under local anesthesia, is a safe and effective (up to 75%) alternative to laminectomy. The percutaneous procedure is contraindicated in the

presence of tumor, infection, spondylolisthesis, foraminal stenosis, loose disk fragments, or severe facet joint arthritis.

Complaints without objective findings suggest a psychologic role in symptom formation. Treatment includes reassurance and nonopioid analgesics.

LUMBAR SPINAL STENOSIS

Lumbar spinal stenosis may be congenital or (more commonly) acquired. Narrowing of the spinal canal most frequently results from enlarging osteophytes at the facet joints, hypertrophy of the ligamentum flavum, and protrusion or bulging of intervertebral disks. Exactly how spinal stenosis results in the pain syndromes described below is not defined, but ischemia from compression of nutrient arterioles is one possible mechanism.

Since age is the greatest risk factor for spinal degenerative changes, most patients with lumbar spinal stenosis are over 60 years old. Patients may present either with trouble walking or with back pain. Those with gait disturbances notice the gradual onset of pain, weakness, or unsteadiness in both legs precipitated by walking or prolonged standing and relieved by sitting. The onset of symptoms with standing, the location of the maximal discomfort to the thighs, and the preservation of pedal pulses help distinguish the "pseudoclaudication" of spinal stenosis from true claudication caused by vascular insufficiency. In some patients, unsteadiness of gait is the most prominent complaint. Because the lumbar spinal canal volume increases with back flexion and decreases with extension, some patients observe that they have fewer symptoms walking uphill than down. When low back pain is the chief symptom, it is bilateral and often diffuse over the buttocks.

The back examination in patients with lumbar spinal stenosis is often unimpressive. Fewer than 10% have a positive straight leg raise sign, 25% have diminished deep tendon reflexes, and 60% have slight proximal weakness. Walking with the patient may reveal unsteadiness, though usually the patient's perception of gait disturbance is greater than that of any other observer. The diagnosis of spinal stenosis in a patient with symptoms is best confirmed by MRI. Weight loss and exercises aimed at reducing lumbar lordosis, which aggravates symptoms of spinal stenosis, can help. When disabling symptoms persist, decompressive laminectomy provides at least short-term relief in approximately 80%.

FIBROMYALGIA

Essentials of Diagnosis

- Most frequent in women aged 20-50.
- Chronic widespread musculoskeletal pain syndrome with multiple tender points.
- Fatigue, headaches, numbness common.
- Objective signs of inflammation absent; laboratory studies normal.
- Partially responsive to exercise, tricyclic antidepressants.

General Considerations

Fibromyalgia is one of the most common rheumatic syndromes in ambulatory general medicine affecting 3-10% of the general population. It shares many features with the chronic fatigue syndrome, namely, an increased frequency among women aged 20-50, absence of objective findings, and absence of diagnostic laboratory tests. While many of the clinical features of the two conditions overlap, musculoskeletal pain predominates in fibromyalgia whereas lassitude dominates the chronic fatigue syndrome.

The cause is unknown, but sleep disorders, depression, viral infections, and aberrant perception of normal stimuli have all been proposed. Fibromyalgia can be a rare complication of hypothyroidism, rheumatoid arthritis, or, in men, sleep apnea.

Clinical Findings

The patient complains of chronic aching pain and stiffness, frequently involving the entire body but with prominence of pain around the neck, shoulders, low back, and hips. Fatigue, sleep disorders, subjective numbness, chronic headaches, and irritable bowel symptoms are common. Even minor exertion aggravates pain and increases fatigue. Physical examination is normal except for "trigger points" of pain produced by palpation of various areas such as the trapezius, the medial fat pad of the knee, and the lateral epicondyle of the elbow.

Differential Diagnosis

Fibromyalgia is a diagnosis of exclusion. A detailed history and repeated physical examination can obviate the need for extensive laboratory testing. Rheumatoid arthritis and systemic lupus erythematosus present with objective physical findings or abnormalities on routine testing, including the erythrocyte sedimentation rate and C-reactive protein. Thyroid function tests are useful, since hypothyroidism can produce a secondary fibromyalgia syndrome. Polymyositis produces weakness rather than pain. The diagnosis of fibromyalgia probably should be made hesitantly in a patient over age 50 and should never be invoked to explain fever, weight loss, or any other objective signs. Polymyalgia rheumatica produces shoulder and girdle pain, is associated with anemia and an elevated sedimentation rate, and occurs after age 50. Hypophosphatemic states, such as oncogenic osteomalacia, should also be included in the differential diagnosis of musculoskeletal pain unassociated with physical findings. In contrast to fibromyalgia, oncogenic osteomalacia usually produces pain in only a few areas and is associated with a low serum phosphate level.

Treatment

Patient education is essential. Patients can be comforted that they have a diagnosable syndrome treatable by specific though imperfect therapies and that the course is not progressive. There is modest efficacy of amitriptyline, fluoxetine, chlorpromazine, or cyclobenzaprine. Amitriptyline is initiated at a dosage of 10 mg at bedtime and gradually increased to 40-50 mg depending on efficacy and toxicity. Exercise programs are also beneficial. NSAIDs are generally ineffective. Opioids and corticosteroids are ineffective and should not be used to treat fibromyalgia.

Prognosis

All patients have chronic symptoms. With treatment, however, many do eventually resume increased activities. Progressive or objective findings do not develop.

CARPAL TUNNEL SYNDROME

An entrapment neuropathy, carpal tunnel syndrome is a painful disorder caused by compression of the median nerve between the carpal ligament and other structures within the carpal tunnel. The contents of the tunnel can be increased by organic lesions such as synovitis of the tendon sheaths or carpal joints, recent or malhealed fractures, tumors, and occasionally congenital anomalies. Even though no anatomic lesion is apparent, flattening or even circumferential constriction of the median nerve may be observed during operative section of the ligament. The disorder may occur in pregnancy, is seen in individuals with a history of repetitive use of the hands, and may follow injuries of the wrists. There is a familial type of carpal tunnel syndrome in which no etiologic factor can be identified.

Carpal tunnel syndrome can also be a feature of many systemic diseases: rheumatoid arthritis and other rheumatic disorders (inflammatory tenosynovitis); myxedema,

localized amyloidosis in chronic renal failure, sarcoidosis, and leukemia (tissue infiltration); acromegaly; and hyperparathyroidism.

Clinical Findings

Pain in the distribution of the median nerve, which may be burning and tingling (acroparesthesia), is the initial symptom. Aching pain may radiate proximally into the forearm and occasionally proximally to the shoulder and over the neck and chest. Pain is exacerbated by manual activity, particularly by extremes of volar flexion or dorsiflexion of the wrist. It is most bothersome at night. Impairment of sensation in the median nerve distribution may or may not be demonstrable. Subtle disparity between the affected and opposite sides can be shown by testing for two-point discrimination or by requiring the patient to identify different textures of cloth by rubbing them between the tips of the thumb and the index finger. Tinel's or Phalen's sign may be positive. (Tinel's sign is tingling or shock-like pain on volar wrist percussion; Phalen's sign, pain or paresthesia in the distribution of the median nerve when the patient flexes both wrists to 90 degrees with the dorsal aspects of the hands held in apposition for 60 seconds.) The carpal compression test, in which numbness and tingling are induced by the direct application of pressure over the carpal tunnel, may be more sensitive and specific than the Tinel and Phalen tests. Muscle weakness or atrophy, especially of the thenar eminence, appears later than sensory disturbances. Specific examinations include electromyography and determinations of segmental sensory and motor conduction delay. Sensory conduction delay is evident before motor delay.

Differential Diagnosis

This syndrome should be differentiated from other cervicobrachial pain syndromes, from compression syndromes of the median nerve in the forearm or arm, and from mononeuritis multiplex. When left-sided, it may be confused with angina pectoris.

Treatment

Treatment is directed toward relief of pressure on the median nerve. When a causative lesion is discovered, it is treated appropriately. Otherwise, patients suspected of having causative carpal tunnel syndrome should modify their hand activities and have the affected wrist splinted for 2-6 weeks. Nonsteroidal anti-inflammatory drugs can also be added. Patients who fail to improve or who develop thenar muscle atrophy or weakness should be referred to a specialist for injection of corticosteroid into the carpal tunnel or for operation. Muscle strength returns gradually, but complete recovery cannot be expected when atrophy is pronounced.

DUPUYTREN'S CONTRACTURE

This relatively common disorder is characterized by hyperplasia of the palmar fascia and related structures, with nodule formation and contracture of the palmar fascia. The cause is unknown, but the condition has a genetic predisposition and occurs primarily in white men over 50 years of age. The incidence is higher among alcoholics and patients with chronic systemic disorders (especially cirrhosis). It is also associated with systemic fibrosing syndrome, which includes Peyronie's disease, mediastinal and retroperitoneal fibrosis, and Riedel's struma. The onset may be acute, but slowly progressive chronic disease is more common.

Dupuytren's contracture manifests itself by nodular or cord-like thickening of one or both hands, with the fourth and fifth fingers most commonly affected. The patient may complain of tightness of the involved digits, with inability to satisfactorily extend the fingers, and on occasion there is tenderness. The resulting cosmetic problems may be unappealing, but in general the contracture is well tolerated since it exaggerates the normal position of function of the hand. Fasciitis involving other areas of the body may lead to plantar fibromatosis (10% of patients) or Peyronie's disease (1-2%).

If the palmar nodule is growing rapidly, injections of triamcinolone into the nodule may be of benefit. Surgical intervention is indicated in patients with significant flexion contractures, depending on the location, but recurrence is not uncommon.

REFLEX SYMPATHETIC DYSTROPHY

Reflex sympathetic dystrophy is a syndrome of pain and swelling of an extremity accompanied by signs of skin changes in the extremity (eg, skin atrophy, hyperhidrosis) and signs and symptoms of vasomotor instability. Complex regional pain syndrome may be a more appropriate name. Any extremity can be involved, but the disorder most commonly occurs in the hand and is associated with ipsilateral restricted shoulder motion (shoulder-hand syndrome). The swelling in reflex sympathetic dystrophy is diffuse ("catcher's mitt hand") and not restricted to joints. Pain is often described as burning in quality. The shoulder-hand variant of reflex sympathetic dystrophy sometimes complicates myocardial infarction or injuries to the neck or shoulder. Direct trauma to the hand or foot can also provoke this syndrome. Reflex sympathetic dystrophy may occur after a knee injury or after arthroscopic knee surgery. There are no systemic symptoms, and x-rays reveal severe generalized osteopenia. In the posttraumatic variant, this is known as Sudeck's atrophy. Bone scans also show increased uptake. Symptoms and findings are bilateral in some.

This syndrome should be differentiated from other cervicobrachial pain syndromes, rheumatoid arthritis, and scleroderma, among others.

In addition to addressing the underlying disorder, treatment is directed toward restoration of function. Physical therapy is the cornerstone of treatment. Many patients will also benefit from drug therapies, especially antidepressant agents (eg, nortriptyline initiated at a dosage of 10 mg at bedtime and gradually increased to 40-75 mg at bedtime). In resistant cases, prednisone, 30-40 mg/d for 2 weeks and then tapered over 2 weeks, may be effective. Patients who have restricted shoulder motion may benefit from the treatment described for scapulohumeral periarthritis. The prognosis depends in part upon the stage in which the lesions are encountered and the extent and severity of associated organic disease. Early treatment offers the best prognosis for recovery.

BURSITIS

Inflammation of the synovium-like cellular membrane overlying bony prominences may be secondary to trauma, infection, or arthritic conditions such as gout, rheumatoid arthritis, or osteoarthritis. The most common locations are the subdeltoid, olecranon, ischial, trochanteric, semimembranous-gastrocnemius (Baker's cyst) and prepatellar bursae.

There are several ways to distinguish bursitis from arthritis. Bursitis is more likely than arthritis to begin abruptly and cause focal tenderness and swelling. Olecranon bursitis, for example, causes an oval swelling at the tip of the elbow, whereas elbow joint inflammation produces more diffuse swelling. Similarly, a patient with prepatellar bursitis has a small focus of swelling over the kneecap and no distention of the knee joint itself. Active and passive range of motion are usually much more limited in arthritis than in bursitis. A patient with trochanteric bursitis will have normal internal rotation of the hip, whereas a patient with hip arthritis will not. Bursitis caused by trauma responds to local heat, rest, immobilization, NSAIDs, and local corticosteroid injections.

Bursitis can result from infection. The two most common sites are the olecranon and prepatellar bursae. Acute swelling and redness at either of these two sites calls for aspiration to rule out infection. The absence of fever does not exclude infection; and one-third of those with septic olecranon bursitis are afebrile. A bursal fluid white blood cell count of greater than 1000/uL indicates inflammation from infection, rheumatoid arthritis, or gout. In septic bursitis, the white cell count averages over 50,000/uL. Most cases are caused by *Staphylococcus aureus*; the Gram stain is positive in two-thirds. Treatment involves antibiotics and repeated aspiration for tense effusions.

Chronic, stable olecranon bursa swelling unaccompanied by erythema or other signs of inflammation does not suggest infection and does not require aspiration. Aspiration of the olecranon bursa in rheumatoid arthritis and in gout runs the risk of creating a chronic drainage site, which can be reduced by using a small needle (25-gauge if possible) and pulling the skin over the bursa before introducing it. Applying a pressure bandage may also help prevent chronic drainage. Surgical removal of the bursa is indicated only for cases in which repeated infections occur. Repetitive minor trauma to the olecranon bursa should be eliminated by avoiding resting the elbow on a hard surface or by wearing an elbow pad.

A bursa can also become symptomatic when it ruptures. This is particularly true for Baker's cyst, whose rupture can cause calf pain and swelling that mimic thrombophlebitis. The ruptured cyst can be imaged with sonography, MRI, or arthrography. In most cases, none of these tests are necessary because Baker's cyst or the frequently associated knee effusion is detectable on physical examination. Often it is more important to exclude thrombophlebitis than it is to visualize Baker's cyst.

Treatment of a ruptured cyst includes rest, leg elevation, and injection of triamcinolone, 20-40 mg into the knee (which communicates with the cyst). Rarely, Baker's cyst can compress vascular structures and cause leg edema and true thrombophlebitis.

SPORTS MEDICINE INJURIES

Musculoskeletal problems commonly occur as a result of both serious athletic pursuits and activities of daily living. For most such disorders, the diagnosis is made easily. Physical therapy is an increasingly important adjunct to the management of these disorders.

1. Rotator Cuff Disorders

A substantial majority of shoulder problems stem from disorders of the rotator cuff. The tendons of the rotator cuff form a musculotendinous unit near their insertions into the proximal humerus. As a result of years of cumulative irritation, attenuation of these tendons occurs. Among the relevant muscles, the supraspinatus is most often affected. Distinguishing between the various soft tissue disorders that cause shoulder pain is difficult. Rotator cuff tendinitis, subacromial bursitis, partial and complete rotator cuff tears, and calcific tendinitis frequently cause similar symptoms. In addition, these disorders often occur together, though precise distinction is frequently unimportant for purposes of therapy.

Clinical Findings

Patients usually present with nonspecific pain localized to the shoulder, often noticed more at night when lying on the affected side. Locking sensations occur with motion of the shoulder, particularly through abduction. Because of the shared innervation, symptoms are frequently referred down the proximal lateral arm. With rotator cuff tears, there may be an inability to abduct or flex the shoulder depending on the site of the tear.

The rotator cuff may be palpated just lateral to the head of the acromion. Maximum tenderness is usually noted over the supraspinatus insertion. The acromioclavicular joint may also be tender if there is accompanying degenerative arthritis in that joint. There may be prominent crepitus. Pain with range of motion is most pronounced between 60 and 120 degrees of abduction, the site of greatest impingement of the rotator cuff tissues between the humerus and coracoacromial arch.

For patients with partial rotator cuff tendon ruptures, the findings are identical to those of chronic tendinitis and bursitis. Patients with partial ruptures often demonstrate mild abduction weakness. With complete ruptures, weakness of abduction (and, to a lesser extent, flexion) is substantial, even though full range of motion may be maintained by the shoulder's accessory rotator muscles. Patients with complete tears usually have positive "drop arm" signs: inability to sustain passive abduction of the arm to 90 degrees.

Treatment

For most rotator cuff disorders, the central tenets of therapy are rest and abstention from inciting activities. Temporary use of a sling is occasionally helpful in enforcing rest. NSAIDs and moist heat afford some relief. For patients with symptoms persisting after 2 weeks of conservative management, injections of a corticosteroid preparation (eg, 1 mL of triamcinolone, 40 mg/mL) mixed with 2-3 mL of lidocaine hydrochloride (1-2%) may be useful. Tears or partial tears of the rotator cuff tendons that are believed to be chronic do not preclude a corticosteroid injection. Most patients obtain significant relief with one injection, but the procedure—along with continued rest—may be repeated after 2-3 weeks. Physical therapy is valuable for refractory cases—if the patient fails to maintain the shoulder's normal range of motion, stiffness and impaired function may ensue.

Aside from patients with complete rotator cuff tears, only those who fail to improve after months of conservative therapy are candidates for operation. Persistent symptoms may be a sign of complete tear, which may be diagnosed by MRI. Patients with symptoms that continue in the absence of a complete tear, however, sometimes require surgery to excise the inferolateral portion of the acromion, release obstructed soft tissue, and repair partial tendon tears. Depending on the degree of symptoms and functional status, complete tears may not always require surgical repair. Patients over 75 years of age rarely have symptoms or limitations that necessitate surgery. Moreover, surgical repairs are frequently less successful because of the attrition of the rotator cuff that occurs with aging.

2. Lateral & Medial Epicondylitis

These disorders are better known by their sports associations: "tennis elbow" and "golf elbow," respectively. Lateral epicondylitis is the more common of the two. The conditions are caused by overuse, and the pain results from minor tears in the tendons of the forearm's extensor and flexor muscles.

Clinical Findings

The patient presents with pain at the site of tendon insertion. Tasks that require grasping and squeezing, such as shaking hands or opening jars, are impaired and cause pain.

The diagnoses are easily confirmed on physical examination by elicitation of point tenderness over the involved site. The characteristic pain may also be reproduced by extension or flexion of the wrist against pressure. Clenching the fist and extending the wrist against the pressure of the examiner's palm is a useful maneuver for localizing lateral epicondylitis. Medial epicondylitis may be demonstrated by performing the same maneuver in flexion.

Treatment
