The plaques in the arterial walls of patients with atherosclerosis contain large amounts of cholesterol. The higher the level of LDL cholesterol, the greater the risk of atherosclerotic heart disease; conversely, the higher the HDL cholesterol, the lower the risk of coronary heart disease (CHD). This is true in men and women, in different racial and ethnic groups, and at all ages up to age 75. Because most cholesterol in serum is LDL, high total cholesterol levels are also associated with an increased risk of CHD. Middle-aged men whose serum cholesterol levels are in the highest quintile for age (above about 230 mg/dL) have a risk of coronary death before age 65 of about 10%; men in the lowest quintile (below about 170 mg/dL) have a 3% risk. Death from CHD before age 65 is less common in women, with equivalent risks one-third those of men. In men, each 10-mg/dL increase in cholesterol (or LDL cholesterol) increases the risk of CHD by about 10%; each 5-mg/dL increase in HDL reduces the risk by about 10%. The effect of HDL cholesterol is greater in women, whereas the effects of total and LDL cholesterol are smaller. All of these relationships diminish with age.

The exact mechanism by which LDL particles result in the formation of atherosclerotic plaques—or the means whereby HDL particles protect against their formation—is not known. The model of LDL carrying cholesterol into the walls of arteries with HDL removing it is simple but not established. The natural oxidation of LDL particles may be particularly atherogenic. Receptors on the surface of macrophages within atherosclerotic plaques bind and accumulate oxidized LDL. The formation of antibodies to oxidized LDL may also be important in plaque formation. The size of the LDL molecule may also influence atherogenesis; at the same LDL concentrations, individuals with large numbers of smaller particles appear to be at higher risk for CHD.

The relationship of VLDL cholesterol to atherogenesis is less certain. The number, size, or subtype of VLDL particles—in addition to the total amount in serum—may be important. In addition, HDL and VLDL levels are inversely related. Patients with a high VLDL level are likely to have a low HDL level and thus be at increased risk for CHD for that reason alone.

There are several genetic disorders that provide insight into the pathogenesis of lipid-related diseases. Most important—but rare in the homozygous state (about one per million)—is a condition in which the cell-surface receptors for the LDL molecule are absent or defective, **familial hypercholesterolemia**, resulting in unregulated synthesis of LDL. Patients with two abnormal genes (homozygotes) have extremely high levels—up to eight times normal—and present with atherosclerotic disease in childhood. Homozygotes may require liver transplantation to correct their severe lipid abnormalities. Those with one defective gene (heterozygotes) have LDL concentrations twice normal; persons with this condition may develop CHD in their 30s or 40s.

Another rare condition is caused by an abnormality of lipoprotein lipase, the enzyme that enables peripheral tissues to take up triglyceride from chylomicrons and VLDL particles. Patients with this condition, one cause of **familial hyperchylomicronemia**, have marked hypertriglyceridemia with recurrent pancreatitis and hepatosplenomegaly in childhood.

Numerous other genetic abnormalities of lipid metabolism are named for the abnormality noted when serum is electrophoresed (eg, dysbetalipoproteinemia) or from combinations of lipid abnormalities in families (eg, familial combined hyperlipidemia). Thus, family members of patients with severe lipid disorders are appropriately studied. Other patients have abnormalities in the production of apoproteins, such as increased apoprotein B and its affiliated lipoproteins, LDL and VLDL; reduced apoprotein AII and its affiliated particle; or excess lipoprotein(a). Other mutations occur in lipoprotein lipase and in the gene encoding for cholesterol efflux regulatory protein.

LIPID FRACTIONS & THE RISK OF CORONARY HEART DISEASE

In fasting serum, cholesterol is carried primarily on three different lipoproteins—the VLDL, LDL, and HDL molecules. Total cholesterol equals the sum of these three components:

Total cholesterol = HDL cholesterol + VLDL cholesterol + LDL cholesterol

Most clinical laboratories measure the total cholesterol, the total triglycerides, and the amount of cholesterol found in the HDL fraction, which is easily precipitated from serum. Most triglyceride is found in VLDL particles, which contain five times as much triglyceride by weight as cholesterol. The amount of cholesterol found in the VLDL fraction can be estimated by dividing the triglyceride by 5:

VLDL cholesterol = Triglycerides / 5

Because the triglyceride level is used as a proxy for the amount of VLDL, this formula only works in fasting samples. Furthermore, it only works when the triglyceride level is less than 400-500 mg/dL. At higher triglyceride levels, LDL and VLDL cholesterol levels can be determined after ultracentrifugation or by direct chemical measurement.

The total cholesterol is reasonably stable over time; however, measurements of HDL and especially triglycerides may vary considerably because of analytic error in the laboratory and biologic variation in a patient's lipid level. Thus, the LDL should always be estimated as the mean of at least two determinations; if those two estimates differ by more than 10%, a third lipid profile is obtained and is estimated as follows:

LDL cholesterol = Total cholesterol - HDL cholesterol - Triglycerides / 5

When using SI units, the formula becomes:

LDL cholesterol = Total cholesterol (mmol/L) - HDL cholesterol (mmol/L) - Triglycerides (mmol/L) / 2.2

Understanding the relationships of the different lipid fractions leads to a more accurate understanding of a patient's lipid-related coronary risk than the total cholesterol. Two persons with the same total cholesterol of 275 mg/dL may have very different lipid profiles. One may have an HDL cholesterol of 110 mg/dL with a triglyceride of 150 mg/dL, giving an estimated LDL cholesterol of 135 mg/dL; the other may have an HDL cholesterol of 25 mg/dL with a triglyceride of 200 mg/dL and an LDL cholesterol of 210 mg/dL. The second would have more than a tenfold higher CHD risk than the first, assuming no differences in other factors. Because of high HDL cholesterol levels in women, many with apparently high total cholesterol levels have favorable lipid profiles. Thus, evaluation of the lipid fractions is essential before therapy is initiated.

Some authorities use the ratio of the total to HDL cholesterol as an indicator of lipid-related coronary risk: the lower this ratio is, the better. (In the example above, the first person would have a ratio of 275 ÷ 110 = 2.5, while the second would have a much less favorable ratio of 275 ÷ 25 = 11.) Although ratios are useful predictors within populations of patients, they may obscure important information in individual patients. (A total cholesterol of 300 mg/dL and an HDL of 60 mg/dL results in the same ratio of 5 as a total cholesterol of 150 mg/dL with an HDL of 30 mg/dL.) Moreover, errors in the measurement of HDL cholesterol are common in many laboratories, and the total cholesterol-to-HDL cholesterol ratio magnifies their importance.

There is no true "normal" range for serum lipids. In Western populations, cholesterol values are about 20% higher than in Asian populations and exceed 300 mg/dL in nearly 5% of adults. About 10% of adults have LDL cholesterol levels above 200 mg/dL. Total and LDL cholesterol levels tend to rise with age in persons who are otherwise in good health.

Declines are seen in acute illness, and lipid studies in such patients are of little value with the exception of the serum triglyceride level in a patient with pancreatitis. Cholesterol levels (even when expressed as an age-matched percentile rank, such as the highest 20%) do not remain constant over time, especially from childhood through adolescence and young adulthood. Thus, children and young adults with relatively high cholesterol may have lower levels later in life, whereas those with low cholesterol may show increases.

THERAPEUTIC EFFECTS OF LOWERING CHOLESTEROL

Most studies of the effect of cholesterol lowering have distinguished between primary and secondary prevention. The important distinction is that primary prevention trials enroll healthy subjects who have relatively low rates of coronary disease but in whom other causes of morbidity and mortality are proportionately more common. Secondary prevention trials, on the other hand, follow patients who have a high rate of subsequent coronary disease; other causes of mortality are relatively less important.

Reducing cholesterol levels in healthy middle-aged men without CHD (primary prevention) reduces their risk in proportion to the reduction in LDL cholesterol and the increase in HDL cholesterol. Treated patients have statistically significant and clinically important reductions in the rates of myocardial infarctions, new cases of angina, and need for coronary artery bypass procedures. The West of Scotland Study showed a 31% decrease in myocardial infarctions in middle-aged men treated with pravastatin compared with placebo. The AFCAPS/TexCAPS study showed similar results with lovastatin. As with any primary prevention interventions, large numbers of healthy patients need to be treated to prevent a single event. The numbers of patients needed to treat (NNT) to prevent a nonfatal myocardial infarction or a coronary artery disease death in these two studies were 46 and 50, respectively.

Primary prevention studies have found a less consistent effect on total mortality. Although the West of Scotland study found a 20% decrease in total mortality, tending toward statistical significance, the AFCAPS/TexCAPS study with lovastatin showed no difference in total mortality. The recent Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT-LLT) also showed no reduction either in all-cause mortality or in CHD events when pravastatin was compared with usual care.

In patients with CHD, the benefits of cholesterol lowering are more clear. Major studies with statins have shown significant reductions in cardiovascular events, cardiovascular deaths, and all-cause mortality in men and women with coronary artery disease. The numbers of patients needed to treat (NNT) to prevent a nonfatal myocardial infarction or a coronary artery disease death in these three studies were between 12 and 34. Aggressive cholesterol lowering with these agents causes regression of atherosclerotic plaques in some patients, reduces the progression of atherosclerosis in saphenous vein grafts, and can slow or reverse carotid artery atherosclerosis. Meta-analysis suggests that this latter effect results in a significant decrease in strokes. Results with other classes of medications have been less consistent. For example, gemfibrozil treatment subjects had fewer cardiovascular events, but there was no benefit in all-cause mortality when compared with placebo.

The disparities in results between primary and secondary prevention studies highlight several important points. The benefits and adverse effects of cholesterol lowering appear to be specific to each type of drug; the clinician cannot assume that the effects will generalize to other classes of medication. Second, the net benefits from cholesterol lowering depend upon the underlying risk of CHD and of other disease. In patients with atherosclerosis, morbidity and mortality rates associated with CHD are high, and measures that reduce it are more likely to be beneficial even if they have no effect—or even slightly harmful effects—on other diseases. Third, the full effects of cholesterol lowering in women and in older and younger men are uncertain.

SECONDARY CONDITIONS THAT AFFECT LIPID METABOLISM

Several factors, including drugs, can influence serum lipids ([Table 28-1](#)). These are important for two reasons: Abnormal lipid levels (or changes in lipid levels) may be the presenting sign of some of these conditions, and correction of the underlying condition may obviate the need to treat an apparent lipid disorder. Diabetes and alcohol use, in particular, are commonly associated with high triglyceride levels that decline with improvements in glycemic control or reduction in alcohol use, respectively. Thus, secondary causes of high blood lipids should be considered in each patient with a lipid disorder before lipid-lowering therapy is started. In most instances, special testing is not needed: a history and physical examination are sufficient. However, screening for hypothyroidism in patients with hyperlipidemia is cost-effective.

CLINICAL PRESENTATIONS

Most patients with high cholesterol levels have no specific symptoms or signs. The vast majority of patients with lipid abnormalities are detected by the laboratory, either as part of the workup of a patient with cardiovascular disease or as part of a preventive screening strategy. Extremely high levels of chylomicrons or VLDL particles (triglyceride level above 1000 mg/dL) result in the formation of **eruptive xanthomas** (red-yellow papules, especially on the buttocks). High LDL concentrations result in **tendinous xanthomas** on certain tendons (Achilles, patella, back of the hand). Such xanthomas usually indicate one of the underlying genetic hyperlipidemias. **Lipemia retinalis** (cream-colored blood vessels in the fundus) is seen with extremely high triglyceride levels (above 2000 mg/dL).

SCREENING FOR HIGH BLOOD CHOLESTEROL

All patients with CHD or CHD risk equivalents (other clinical forms of atherosclerosis such as peripheral artery disease, abdominal aortic aneurysm, and symptomatic carotid artery disease; patients with diabetes mellitus; and patients with multiple risk factors that confer a greater than 20% 10-year risk for developing CHD) should be screened for elevated lipids. The only exceptions are patients in whom lipid lowering is not indicated or desirable for other reasons. Patients who already have evidence of atherosclerosis are the group at highest risk of suffering additional manifestations in the near term and thus have the most to gain from reduction of blood lipids. Additional risk reduction measures for atherosclerosis are discussed in [Chapter 10](#); lipid lowering should be just one aspect of a program to reduce the progression and effects of the disease.

Given the high prevalence of lipid abnormalities in patients with cardiovascular disease, a complete lipid profile (total cholesterol, HDL cholesterol, and triglyceride levels) after an overnight fast should be obtained as a screening test. Those whose estimated LDL cholesterol level is high should have at least one repeat measurement. Specific treatments for high LDL cholesterol levels are discussed below. The goal of therapy should be to reduce the LDL cholesterol to below 100 mg/dL, but any reduction in LDL is better than no reduction. Even treatment of only mildly elevated LDL cholesterol is clinically useful. Individuals with LDL cholesterol levels > 175 mg/dL have a 25% reduction in fatal CHD and recurrent myocardial infarctions when the LDL is lowered to 100 mg/dL.

The best screening and treatment strategy for adults who do not have atherosclerotic cardiovascular disease is not clear. Several algorithms have been developed to guide the clinician in treatment decisions, but management decisions are individualized.

Although the National Cholesterol Education Program (NCEP) recommends screening of all adults aged 20 or older for high blood cholesterol, the United States Preventive Services Task Force (USPSTF) suggests beginning at age 35 in men and age 45 in women unless there are other risk factors for coronary heart disease. This strategy focuses cholesterol screening on those at most immediate risk of coronary artery disease and increases the cost-effectiveness of cholesterol screening.

Individuals without cardiovascular disease can then be stratified according to risk factors as defined by the NCEP. Those with two or more risk factors are considered to be at intermediate risk of coronary artery disease, and those with less than two are at low risk. These include age and gender (men aged 45 or older, women aged 55 or older), a family history of premature CHD (myocardial infarction or sudden cardiac death before age 55 in a first-degree male relative or before age 65 in a first-degree female relative), hypertension (whether treated or not), current cigarette smoking (ten or more cigarettes per day), and low HDL cholesterol (< 40 mg/dL). Because HDL cholesterol is protective against CHD, a risk factor is subtracted if the level is greater than 60 mg/dL. Patients with two or more risk factors are then further stratified by evaluating their 10-year risk of developing CHD using Framingham projections of 10-year risk ([Table 28-2](#)).

Several strategies for obtaining the initial cholesterol measurement have been proposed, including (1) measuring total cholesterol alone, (2) measuring total cholesterol and HDL cholesterol, or (3) measuring LDL and HDL cholesterol. Each is acceptable, but treatment decisions are based on the LDL and HDL cholesterol levels. Measurement of the total cholesterol alone is the least expensive strategy and is adequate for low-risk individuals; those with total cholesterol greater than 200 mg/dL should then be reevaluated with a fasting LDL and HDL cholesterol measurement. Measurement of the total cholesterol and HDL cholesterol allows for better characterization of the risk factor profile but also requires reevaluation if the total cholesterol is greater than 200 mg/dL as recommended by the USPSTF. Initial measurement of the LDL and HDL cholesterol is least likely to lead to patient misinformation and misclassification and is the strategy recommended by the NCEP.

Treatment decisions are based upon the LDL cholesterol and the patient's risk factor profile (including the HDL cholesterol level). Patients in the intermediate-risk group (two or more risk factors) are selected for diet therapy (therapeutic lifestyle changes) if LDL cholesterol is greater than 130 mg/dL. If the 10-year risk of CHD is < 10%, drug treatment is recommended if LDL is > 160 mg/dL; if the 10-year CHD risk is between 10% and 20%, drug treatment is recommended if LDL is > 130 mg/dL. Low-risk individuals are selected for diet therapy if LDL cholesterol is greater than 160 mg/dL and for drug therapy if it is greater than 190 mg/dL.

Screening in Women

The foregoing screening and treatment guidelines, based largely on LDL cholesterol levels, are designed for both men and women. Yet observational studies suggest that a low HDL cholesterol is a more important risk factor for CHD in women than a high LDL cholesterol. Meta-analysis of studies including women with known heart disease, however, has found that medications which primarily lower LDL cholesterol do prevent recurrent myocardial infarctions in women. There is insufficient evidence to be certain of a similar effect from LDL-lowering therapy in women without evidence of CHD. Although most experts recommend application of the same primary prevention guidelines for women as for men, clinicians should be aware of the uncertainty in this area.

Screening in Older Patients

Meta-analysis of evidence relating cholesterol to CHD in the elderly suggests that cholesterol is not a risk factor for CHD for persons over age 75. Clinical trials have rarely included such individuals. Although the NCEP recommends continuing treatment in the elderly, many clinicians will prefer to stop screening and treatment in patients age 75 or older who do not have CHD. In patients age 75 or older who have CHD, LDL-lowering therapy can be continued as recommended for younger patients with the disease. Decisions to discontinue therapy should be based on overall functional status and life expectancy, comorbidities, and patient preference and should be made in context with overall therapeutic goals and end-of-life decisions.

TREATMENT OF HIGH LDL CHOLESTEROL (TABLE 28-3)

Reduction of LDL cholesterol is just one part of a program to reduce the risk of cardiovascular disease. Other measures—including smoking cessation, hypertension control, and aspirin—are also of central importance. Less well studied but of potential value is raising the HDL cholesterol level. Quitting smoking reduces the effect of other cardiovascular risk factors (such as a high cholesterol level); it may also increase the HDL cholesterol level. Exercise (and weight loss) may reduce the LDL cholesterol and increase the HDL. Modest alcohol use (1-2 ounces a day) also raises HDL levels and appears to have a salutary effect on CHD rates. While the clinician may not wish to recommend alcohol use to patients, its use in moderation need not be discouraged.

Diet Therapy

Studies of nonhospitalized adults have reported only modest cholesterol-lowering benefits of dietary therapy, typically in the range of a 5-10% decrease in LDL cholesterol, with even less in the long term. The effect of diet therapy, however, varies considerably among individuals, as some patients will have striking reductions in LDL cholesterol—up to a 25-30% decrease—while others will have clinically important increases. Thus, the results of diet therapy should be assessed about 4 weeks after initiation.

Cholesterol-lowering diets may also have a variable effect on lipid fractions. Diets very low in total fat or in saturated fat may lower HDL cholesterol as much as LDL cholesterol. It is not known how these diet-induced changes affect coronary risk.

Several nutritional approaches to diet therapy are available. Most Americans currently eat over 35% of calories as fat, of which 15% is saturated fat. Dietary cholesterol intake averages 400 mg/d. A cholesterol-lowering diet recommends reducing total fat to 25-30% and saturated fat to less than 7% of calories. Dietary cholesterol should be limited to less than 200 mg/d. These diets replace fat, particularly saturated fat, with carbohydrate. In most instances, this approach will also result in fewer total calories consumed and will facilitate weight loss in overweight patients. Other diet plans, including the Dean Ornish Diet, the Pritikin Diet, and most vegetarian diets, restrict fat even further. Low-fat, high-carbohydrate diets may, however, result in reductions in HDL cholesterol.

An alternative strategy is the "Mediterranean diet," which maintains total fat at approximately 35-40% of total calories but replaces saturated fat with monounsaturated fat such as that found in canola oil and in olives, peanuts, avocados, and their oils. This diet is equally effective at lowering LDL cholesterol but is less likely to lead to reductions in HDL cholesterol. This diet is less likely to lead to weight loss. Thus, a traditional low-fat approach is still preferred for patients with lipid disorders who are overweight.

Other dietary changes may also result in beneficial changes in blood lipids. Soluble fiber, such as that found in oat bran or psyllium, may reduce LDL cholesterol by 5-10%. Garlic, soy protein, vitamin C, pecans, and plant sterols may also result in reduction of LDL cholesterol. Because oxidation of LDL cholesterol is a potential initiating event in atherogenesis, diets rich in antioxidant vitamins, found primarily in fruits and vegetables, may be helpful (see [Chapter 29](#)).

Pharmacologic Therapy

All patients whose risk from CHD is considered high enough to warrant pharmacologic therapy of an elevated LDL cholesterol should be given aspirin prophylaxis at a dose of 81-325 mg/d unless there are contraindications such as aspirin sensitivity, bleeding diatheses, or active peptic ulcer disease. The benefit of aspirin in reducing the risk of CHD is equivalent to that of cholesterol lowering. Other CHD risk factors, such as hypertension and smoking, should also be controlled.

If the decision to treat a patient with an LDL-lowering drug is made, a goal for treatment is set. For patients with CHD or CHD risk equivalents, the goal is LDL < 100 mg/dL. For patients with two or more risk factors the goal is LDL < 130 mg/dL. For those with zero or one risk factor the goal is LDL < 160 mg/dL. In each instance, the therapeutic goal is approached slowly, watching for side effects and encouraging continued adherence to nonpharmacologic therapies. Combinations of drugs may be necessary. Once the goal is reached, the lipid profile should be monitored periodically (every 6-12 months), with consideration given to periodic reductions in drug dose. With the exception of niacin (available generically for a few dollars per month), lipid-lowering agents are expensive and may need to be given for decades. Thus, their cost-effectiveness is generally low, especially in primary prevention.

A. Niacin (Nicotinic Acid)

Niacin was the first lipid-lowering agent that was associated with a reduction in total mortality. Long-term follow-up of a secondary prevention trial of middle-aged men with previous myocardial infarction disclosed that about half of those who had been previously treated with niacin had died, compared with nearly 60% of the placebo group. This favorable effect on mortality was not seen during the trial itself, though there was a reduction in the incidence of recurrent coronary events.

Niacin reduces the production of VLDL particles, with secondary reduction in LDL and increases in HDL cholesterol levels. The average effect of full-dose niacin therapy, 3-4.5 g/d, is a 15-25% reduction in LDL cholesterol and a 25-35% increase in HDL cholesterol. Full doses are required to obtain the LDL effect, but the HDL effect is observed at lower doses, eg, 1 g/d. Niacin will also reduce triglycerides by half and will lower lipoprotein(a) (Lp[a]) levels and will increase plasma homocysteine levels. Thus, its effect on blood lipids and CHD risk is nearly optimal. Intolerance to niacin is common; only 50-60% of patients can take full doses. Niacin causes a prostaglandin-mediated flushing that patients may describe as "hot flashes" or pruritus and can be decreased by pretreatment with aspirin (81-325 mg/d) or other nonsteroidal anti-inflammatory agents. Flushing may also be decreased by initiating niacin therapy with a very small dose, eg, 100 mg with the evening meal. The dose can be doubled each week until 1.5 g/d is tolerated. After rechecking blood lipids, the dose is divided and increased until the goal of 3-4.5 g/d is reached. Extended-release niacin is also available and may be better tolerated by some patients. It is not known whether routine monitoring of liver enzymes results in early detection and thus reduced severity of this side effect. Niacin can also exacerbate gout and peptic ulcer disease. Although niacin may increase blood sugar in some patients, clinical trials have shown that niacin can be safely used in diabetics.

B. Bile Acid-Binding Resins (Cholestyramine, Colesevelam, Colestipol)

Treatment with these agents reduces the incidence of coronary events in middle-aged men by about 20%, with no significant effect on total mortality. The resins work by binding bile acids in the intestine. The resultant reduction in the enterohepatic circulation causes the liver to increase its production of bile acids, using hepatic cholesterol to do so. Thus, hepatic LDL receptor activity increases, with a decline in plasma LDL levels. The triglyceride level tends to increase slightly in some patients treated with bile acid-binding resins; they should be used with caution in those with elevated triglycerides and probably not at all in patients who have triglyceride levels above 500 mg/dL. The clinician can anticipate a reduction of 15-25% in the LDL cholesterol level, with insignificant effects on the HDL level.

The usual dose of cholestyramine is 12-36 g of resin per day in divided doses with meals, mixed in water or, more palatably, juice. Doses of colestipol are 20% higher (the packets each contain 5 g of resin). The dose of colesevelam is 625 mg 6-7 tablets per day.

These agents often cause gastrointestinal symptoms, such as constipation and gas. They may interfere with the absorption of fat-soluble vitamins (thereby complicating the management of patients receiving warfarin) and may bind other drugs in the intestine. Concurrent use of psyllium may ameliorate the gastrointestinal side effects.

C. HMG-CoA Reductase Inhibitors (Lovastatin, Pravastatin, Simvastatin, Fluvastatin, Atorvastatin)

These agents work by inhibiting the rate-limiting enzyme in the formation of cholesterol. They reduce myocardial infarctions and total mortality in secondary prevention, as well as in middle-aged men free of CHD. A meta-analysis has demonstrated significant reduction in risk of stroke. Cholesterol synthesis in the liver is reduced, with a compensatory increase in hepatic LDL receptors (presumably so that the liver can take more of the cholesterol that it needs from the blood) and a reduction in the circulating LDL cholesterol level by up to 35%. There are also modest increases in HDL levels and decreases in triglyceride levels.

Doses are as follows: lovastatin, 10-80 mg/d; pravastatin, 10-40 mg/d; simvastatin, 5-40 mg/d; fluvastatin, 20-40 mg/d; and atorvastatin, 10-80 mg/d. These agents are usually given once a day in the evening (most cholesterol synthesis takes place overnight); at the high end of the dose ranges, twice-a-day dosing may be used. Side effects include myositis, whose incidence may be higher in patients concurrently taking fibrates or niacin. Manufacturers recommend monitoring liver and muscle enzymes. Several agents (notably erythromycin, cyclosporine, and azole antifungals) reduce the metabolism of these agents.

D. Fibric Acid Derivatives (Gemfibrozil, Fenofibrate, Clofibrate) BR>Gemfibrozil reduced CHD rates in hypercholesterolemic middle-aged men free of coronary disease in the Helsinki Heart Study. The effect was only observed among those who also had lower HDL cholesterol levels and high triglyceride levels. In a recent VA study, gemfibrozil was also shown to reduce cardiovascular events in men with existing CHD whose primary lipid abnormality was a low HDL cholesterol. There was no effect on all-cause mortality.

The fibrates reduce the synthesis and increase the breakdown of VLDL particles, with secondary effects on LDL and HDL levels. They reduce LDL levels by about 10-15% and triglyceride levels by about 40% and raise HDL levels by about 15-20%. The usual dose of gemfibrozil is 600 mg once or twice a day. Side effects include cholelithiasis, hepatitis, and myositis. The incidence of the latter two conditions may be higher among patients also taking other lipid-lowering agents. In the largest clinical trial that used clofibrate, there were significantly more deaths—especially due to cancer—in the treatment group; it should not be used.

E. Ezetimibe

Ezetimibe is a new lipid-lowering drug that inhibits the intestinal absorption of dietary and biliary cholesterol by blocking passage across the intestinal wall. Ezetimibe reduces LDL cholesterol between 15% and 20% when used as monotherapy and can further reduce LDL in patients on statins who are not yet at therapeutic goal. The effects of ezetimibe on CHD and its long-term safety are not yet known. The usual dose of ezetimibe is 10 mg/d.

Initial Selection of Medication

At present there are no absolute guidelines for selection of available lipid-modifying medications in particular patients. Nonetheless, clinical trials provide guidance ([Table 28-4](#)). For most patients who require a lipid-modifying medication, an HMG-CoA reductase inhibitor is preferred. Although niacin will also have beneficial effects on lipids in both men and women with CHD, there is less evidence demonstrating the desired effects on CHD and all-cause mortality. Resins are the only lipid-modifying medication considered safe in pregnancy.

Combinations of lipid-modifying medications may be more cost-effective than high doses of a single medication (usually an HMG-CoA reductase inhibitor) and may have beneficial effects on lipids. Low-dose niacin (0.5-1 g/d), for example, will substantially increase the HDL cholesterol when added to an HMG-CoA reductase inhibitor. Combinations, however, may increase the risk of severe complications of drug therapy. The combination of gemfibrozil and HMG-CoA reductase inhibitors increases the risk of myopathy more than either drug alone.

HIGH BLOOD TRIGLYCERIDES

Patients with very high levels of serum triglycerides are at risk of pancreatitis. The pathophysiology is not certain, since some patients with very high levels never develop pancreatitis. Most patients with congenital abnormalities in triglyceride metabolism present in childhood; hypertriglyceridemia-induced pancreatitis first presenting in adults is more commonly due to an acquired problem in lipid metabolism.

Although there are no clear triglyceride levels that predict pancreatitis, most clinicians are uncomfortable with fasting levels above 500 mg/dL. The risk of pancreatitis may be more related to the triglyceride level following consumption of a fatty meal. Because postprandial increases in triglyceride are inevitable if fat-containing foods are eaten, fasting triglyceride levels in persons prone to pancreatitis should be kept well below that level.

The primary therapy for high triglyceride levels is dietary, avoiding alcohol and fatty foods and restricting calories. Control of secondary causes of high triglyceride levels (see Table 28-1) may also be helpful. In patients with fasting triglycerides = 500 mg/dL despite adequate dietary compliance—and certainly in those with a previous episode of pancreatitis—therapy with a triglyceride-lowering drug (eg, niacin, a fibric acid derivative, or an HMG-CoA reductase inhibitor) is indicated.

Whether patients with elevated triglycerides (> 150 mg/dL) should be treated to prevent CHD is not known. Meta-analysis of 17 observational studies suggests that after adjustment for other risk factors, elevated triglycerides increased CHD risk in men by 14% and in women by 37%. Triglyceride-rich lipoproteins (partially degraded VLDL, commonly called remnant lipoproteins) have been found in human atheromas, and elevated triglycerides are associated with small dense LDL in most instances. Elevated triglycerides are also an important feature of the **metabolic syndrome**, found in an estimated 25% of Americans—defined by three or more of the following five abnormalities: waist circumference > 102 cm in men or > 88 cm in women, serum triglyceride level of at least 150 mg/dL, HDL level of < 40 mg/dL in men or < 50 mg/dL in women, blood pressure of at least 130/85 mm Hg, and serum glucose level of at least 110 mg/dL. Other data, however, suggest that triglyceride measurements do not improve discrimination between those with and without CHD events, and clinical trial data are not available to support the routine treatment of high triglycerides in all patients.

The recent NCEP Adult Treatment Panel III (ATP III) report, however, recommends an aggressive approach to triglyceride management. For those with borderline levels (150-199 mg/dL), emphasis is placed on calorie restriction and exercise. For patients with high triglycerides (> 200 mg/dL), the non-HDL cholesterol should be measured (total cholesterol - HDL cholesterol). The ATP III report recommends that non-HDL cholesterol should be treated with diet and medications to result in levels 30 mg/dL higher than the LDL goal. The ATP III report does not differentiate between primary and secondary prevention. A reasonable approach might be to use this approach for patients with CHD and risk equivalents for that disease but not for lower-risk patients.

29. Nutrition - Robert B. Baron, MD, MS

■ NUTRITIONAL REQUIREMENTS

Approximately 40 nutrients are required by the human body. Nutrients are essential if they cannot be synthesized by the body and if a deficiency causes recognizable abnormalities that disappear when the deficit is corrected. Required nutrients include the essential amino acids, water-soluble vitamins, fat-soluble vitamins, minerals, and the essential fatty acids. The body also requires an adequate energy substrate, a small amount of metabolizable carbohydrate, indigestible carbohydrate (fiber), additional nitrogen, and water.

Nutritional requirements have been most commonly expressed by recommended dietary allowances (RDAs). Published and periodically reviewed by the Food and Nutrition Board of the National Academy of Sciences, the RDAs were initially designed to meet the known nutritional needs of practically all healthy persons. RDAs have been established for energy and protein; the water-soluble vitamins thiamin, riboflavin, niacin, vitamin B₆, folic acid, vitamin B₁₂, and vitamin C; the fat-soluble vitamins A, D, and K; and the minerals calcium, phosphorus, magnesium, iron, zinc, iodine, and selenium ([Table 29-1](#)).

Recently, the Food and Nutrition Board has developed a broader approach to defining nutritional adequacy. Known as dietary reference intakes (DRIs), these new guidelines go beyond the prevention of classic nutritional deficiency diseases and address the role of nutrients and other food components in long-term health and the reduction of risk of chronic diseases. The DRIs consist of four reference intakes: the RDA, the estimated average requirement (EAR), the tolerable upper intake level (UL), and the adequate intake (AI). The RDA remains the dietary intake that is sufficient to meet the nutritional requirements of nearly all individuals in an age- and gender-specific group. RDAs are intended as goals for individuals. The EAR is the intake value that is estimated to meet the requirements of 50% of individuals in an age- and gender-specific group. The UL is the maximum level of daily nutrient intake that is unlikely to pose health risks to most individuals. The AI is determined when insufficient data are available to establish the EAR and RDA for a given nutrient. It is based on fewer data and more expert opinion but is also intended as goals for individuals. DRIs are divided into seven nutrient groups: (1) calcium, vitamin D, phosphorus, magnesium and fluoride; (2) folate and other B vitamins; (3) antioxidants (eg, vitamins C and E and selenium); (4) macronutrients (eg, protein, fat, carbohydrates); (5) trace elements (eg, iron and zinc); (6) electrolytes and water; and (7) other food components (eg, fiber, phytoestrogens).

ENERGY

The body requires energy to support normal functions and physical activity, growth, and repair of damaged tissues. Energy is provided by oxidation of dietary protein, fat, carbohydrate, and alcohol. Oxidation of 1 g of each provides 4 kcal of energy from protein and carbohydrate, 9 kcal from fat, and 7 kcal from alcohol.

In healthy adults, energy expenditure is primarily determined by three factors: basal energy expenditure (BEE), thermic effect of food (TEF), and physical activity.

The BEE is the amount of energy required to maintain basic physiologic functions. It is measured while the subject is resting in a warm room, not having eaten for 12 hours. In healthy persons, the BEE (in kcal/24 h) can be estimated by the Harris-Benedict equation, which will correctly predict measured BEE in 90% + 10% of healthy subjects. In clinical practice, patients rarely meet the strict criteria for BEE measurement. Instead, energy expenditure is measured in individuals at rest without food for 2 hours. This measurement, the resting energy expenditure (REE), is about 10% greater than BEE.

TEF is the amount of energy expended during and following the ingestion of food. TEF averages approximately 10% of the BEE.

Physical activity has a major impact on energy expenditure. The average energy expenditure per hour by adults engaged in typical activities is shown in [Table 29-2](#).

Daily recommended energy intakes for healthy individuals are shown in [Table 29-3](#).

PROTEIN

Protein is required for growth and for maintenance of body structure and function. Although the nutritional requirement is commonly stated in grams of protein, the true requirement is for nine **essential amino acids** plus additional nitrogen for protein synthesis. The essential amino acids are leucine, isoleucine, lysine, methionine, phenylalanine, threonine, tryptophan, valine, and histidine.

Adequate protein must be consumed each day to replace essential amino acids lost through protein turnover. On a protein-free diet, the average male loses 3.8 g of nitrogen per day—equivalent to 24 g of protein. Allowing for differences in protein quality and utilization and for individual variability, the RDA for protein is 56 g/d for men and 45 g/d for women.

Protein and energy requirements are closely related. Diets that provide insufficient energy will require additional protein to maintain nitrogen equilibrium.

CARBOHYDRATE

As long as adequate energy and protein are provided in the diet, there is no specific requirement for dietary carbohydrate. A small amount of carbohydrate—approximately 100 g/d—is necessary to prevent ketosis. In practice, however, most dietary energy should be provided by carbohydrate. The average American diet contains 45% of calories as carbohydrate. Current recommendations are to increase carbohydrate intakes to 55-60% of total calories in the diet.

Dietary carbohydrates include simple sugars, complex carbohydrates (starches), and indigestible carbohydrates (dietary fiber). Although simple sugars and starches provide equal amounts of calories, the bulk of dietary carbohydrates should be derived from starches. Simple sugars—particularly sucrose—are concentrated sources of calories without other sources of essential nutrients. Sucrose consumption is also thought to be an important factor in the development of tooth decay. Starches, when unrefined, provide carbohydrate calories and vitamins, minerals, and dietary fiber.

Dietary fiber is that portion of plant foods that cannot be digested by the human intestine. Fiber increases the bulk of the stool and facilitates excretion. Diets high in dietary fiber are associated with a lower incidence of digestive and cardiovascular diseases. The more insoluble fibers, such as those found in wheat bran, have the greatest effect on colonic function. Soluble fibers such as those found in legumes, oats, and fruit result in lower blood sugar levels in diabetics and lower blood cholesterol.

FAT

Dietary fat is the most concentrated source of food energy. Like energy from dietary carbohydrate, energy derived from fat can support protein synthesis. Dietary fat also provides the essential fatty acid linoleic acid. Other than the need for adequate quantities of linoleic acid, there is no specific requirement for dietary fat as long as the diet provides adequate nutrients oxidizable for energy. Although the average American diet contains 35-40% of calories as fat, most current recommendations are to limit dietary fat to 30% or less of total calories. Diets containing as little as 5-10% of total calories as fat appear to be safe and well tolerated.

Dietary fats are composed chiefly of fatty acids and dietary cholesterol. Fatty acids contain either no double bonds (saturated), one double bond (monounsaturated), or more than one double bond (polyunsaturated). Current recommendations are to decrease total fat and replace saturated fats with monounsaturated fatty acids and complex carbohydrates. Saturated fatty acids are associated with increased serum cholesterol, while polyunsaturated and monounsaturated fatty acids lower serum cholesterol. Saturated fats are solid at room temperature and in general are derived from animal foods; unsaturated fats are liquid at room temperature and in general are derived from plant foods.

The polyunsaturated fatty acid **linoleic acid** is an essential nutrient, required by the body for the synthesis of arachidonic acid, the major precursor of prostaglandins. Deficiency of linoleic acid results in dermatitis, hair loss, and impaired wound healing. For individuals with average energy requirements, approximately 5 g of linoleic acid per day—1-2% of total calories—is required to prevent essential fatty acid deficiency.

Cholesterol is a major constituent of cell membranes. It is synthesized by the body and is not an essential nutrient. Diets that contain large amounts of cholesterol partially inhibit endogenous cholesterol synthesis but result in a net increase in serum cholesterol concentrations because of suppression of synthesis of low-density lipoprotein receptors. Average American diets contain approximately 450 mg/d of cholesterol, but 300 mg or less per day is recommended.

VITAMINS

Vitamins are a heterogeneous group of organic molecules required by the body for a variety of essential metabolic functions. They are grouped as **water-soluble vitamins**: thiamin, riboflavin, niacin, vitamin B₆ (pyridoxine), vitamin B₁₂ (cobalamin), folate, pantothenic acid, biotin, and vitamin C (ascorbic acid); and **fat-soluble**

vitamins: A, D, E, and K. Disorders of vitamin metabolism are discussed below.

MINERALS

The body also requires a number of inorganic minerals, commonly grouped as the **major minerals** calcium, magnesium, and phosphorus; the **electrolytes** sodium, potassium, and chloride; and the **trace elements** iron, zinc, copper, manganese, molybdenum, fluoride, iodine, cobalt, chromium, and selenium. Important characteristics of major minerals and electrolytes are summarized in [Table 29-4](#).

DRUG-NUTRIENT INTERACTIONS

Many medications affect nutritional requirements. A variety of drugs induce nutrient deficiencies by appetite suppression, intestinal malabsorption, and alterations in nutrient metabolism or excretion. The effects of selected drugs on nutrient absorption and metabolism are summarized in [Table 29-5](#).

DIETARY RECOMMENDATIONS

Prior to 1980, the emphasis in diet planning was to ensure that the RDAs were met by diets containing a wide variety of foods. The most important tool used for this purpose was *The Four Food Groups*, published by the United States Department of Agriculture (USDA). According to this model, two servings per day from both the milk group and the meat group and four servings per day from both the fruit and vegetable group and the cereal group would meet the minimal nutritional requirements for most individuals. This model, however, did not guarantee that selected foods were of high quality. The effects of food processing on the nutrient density of food, the balance of macronutrients, and the character of macronutrients (simple versus complex carbohydrate; saturated versus unsaturated fat) are omitted.

In the last 2 decades, numerous authorities have published dietary recommendations that address these issues. Although attention has been directed to the differences between these reports, most agree on the basic principles of eating a wide variety of foods; increasing the consumption of foods containing complex carbohydrates; reducing the intake of sugar, fat (particularly saturated fat), cholesterol, salt, and alcohol; maintaining an ideal body weight, and being physically active each day.

A nutrition education guide, the "Food Guide Pyramid" ([Figure 29-1](#)), has been published by the USDA to guide food choices. The Pyramid emphasizes consumption of bread, cereal, rice, and pasta (six to eleven servings); vegetables (three to five servings); and fruit (two to four servings). It places lesser emphasis on milk, yogurt, and cheese (two or three servings) and meat, poultry, fish, dry beans, eggs, and nuts (two or three servings), and recommends that fats, oils, and sweets be used sparingly. "Food guide pyramids" have also been developed recently for use with older individuals and with children.

■ ASSESSMENT OF NUTRITIONAL STATUS

No single biochemical test or clinical technique is sufficiently accurate to serve as a reliable test for malnutrition. Techniques of nutritional assessment utilize a combination of methods, including evaluation of dietary intake, anthropometric measurements, clinical examination, and laboratory tests.

DIETARY HISTORY

Patients undergoing a history and physical examination should be asked questions to help identify those high-risk patients who require further evaluation for malnutrition. Of particular importance are the regularity and availability of meals; who does the shopping and food preparation; recent changes in appetite, intake, or body weight; use of special diets or dietary supplements; use of alcohol, drugs, or medications; food preferences and food allergies; and the presence of illnesses affecting nutritional intakes, losses, or requirements. Elderly and adolescent patients, pregnant or lactating women, and the poor and socially isolated are at particular risk for nutritional problems.

Further quantification of dietary intake can be performed using a variety of techniques. **Twenty-four-hour diet recalls** provide rough estimates of nutrient intakes. Patients are asked to describe their dietary intake over the preceding day, including snacks, beverages, and alcohol. Problems with this technique include poor patient recall, difficulties in estimating serving sizes, and the inaccuracy associated with generalizing from a single day's intake. More accurate information can be obtained by asking patients to complete a **3- to 5-day diet record**. Nutrient composition can then be analyzed with the aid of standard handbooks or computer software. Although prospective and less likely to be invalidated by memory lapses, omissions are still common, and the usual difficulties in estimating serving sizes persist.

CLINICAL EXAMINATION

A nutritionally focused physical examination should be performed on each patient at risk for nutritional problems. The examination targets body weight, muscle wasting, fat stores, volume status, and signs of micronutrient deficiencies ([Table 29-6](#)).

Evaluation of body weight is particularly useful. Body weight in relation to height can be assessed as the **relative weight** (the current weight/desirable weight × 100), or as the **body mass index**—weight (in kilograms)/height (in meters)² ([Table 29-7](#)). In adult patients, however, a recent change in body weight is usually a better index of undernutrition than a low relative weight or a low body mass index. This change is best expressed as a percentage of usual weight lost per unit of time. A weight loss of 10% or more of usual weight within a period of 1-2 months is generally considered to be predictive of a poor clinical outcome.

Evaluation of body composition—particularly fat stores and skeletal muscle—can be performed by visual inspection or, more quantitatively, by using **anthropometric measurements**. The most commonly used are the triceps skin fold, and mid arm muscle circumference. Because of variations in measurement, they have limited clinical utility.

A number of more sophisticated techniques are available for assessment of body composition. Most have little role in patient care. These include bioelectrical impedance, dual-energy x-ray absorptiometry, air-displacement plethysmography, hydrodensitometry, spectroscopy and mass spectrometry, neutron activation analysis, and MRI and body line scanners.

LABORATORY TESTS

Serum albumin is the most important laboratory test for the diagnosis of protein-calorie undernutrition. Most patients with severe protein depletion will have low serum albumin levels. Many nonnutritional conditions can also reduce serum albumin—particularly liver disease and severe illness in general. Other serum proteins with shorter half-lives (such as transferrin, transthyretin, and prealbumin) may reflect short-term changes in nutritional status but suffer from similar shortcomings.

Tests of cellular immunity are also abnormal in many patients with protein-calorie undernutrition. Measurements of the **total lymphocyte count** and **delayed hypersensitivity reactions** to common skin test antigens are nonspecific; abnormalities may be due to nonnutritional factors.

Despite their poor specificity, these tests are useful prognostically. Patients with abnormal nutritional assessment parameters have a markedly increased risk of poor clinical outcomes.

Despite the use of a nutritionally focused history, physical examination, and laboratory tests, it is often difficult to confirm a diagnosis of malnutrition. Monitoring dietary intakes with **calorie counts** during hospitalization may be necessary.

■ NUTRITIONAL DISORDERS

PROTEIN-ENERGY MALNUTRITION

Essentials of Diagnosis

- History of decreased intake of energy or protein, increased nutrient losses, or increased nutrient requirements.
- Manifestations range from weight loss and growth failure to distinct syndromes, kwashiorkor, and marasmus.
- In severe cases, virtually all organ systems affected.
- Protein loss correlates with weight loss. Thirty-five to 40% total body weight loss is usually fatal.

General Considerations

Protein-energy malnutrition occurs as a result of a relative or absolute deficiency of energy and protein. It may be primary, due to inadequate food intake, or secondary, as a result of other illness. For most developing nations, primary protein-energy malnutrition remains among the most significant health problems. Protein-energy malnutrition has been described as two distinct syndromes. **Kwashiorkor**, caused by a deficiency of protein in the presence of adequate energy, is typically seen in weaning infants at the birth of a sibling in areas where foods containing protein are insufficiently abundant. **Marasmus**, caused by combined protein and energy deficiency, is most commonly seen where adequate quantities of food are not available.

In industrialized societies, protein-energy malnutrition is most often secondary to other diseases. **Kwashiorkor-like secondary protein-energy malnutrition** occurs primarily in association with hypermetabolic acute illnesses such as trauma, burns, and sepsis. **Marasmus-like secondary protein-energy malnutrition** typically results from chronic diseases such as COPD, congestive heart failure, cancer, or AIDS. These syndromes have been estimated to be present in at least 20% of hospitalized patients. A substantially greater number of patients have risk factors that could result in these syndromes. In both syndromes, protein-energy malnutrition is caused either by decreased intake of energy and protein, increased nutrient losses, or increased nutrient requirements dictated by the underlying illness. For example, diminished oral intake may result from poor dentition or various gastrointestinal disorders. Loss of nutrients results from malabsorption and diarrhea as well as from glycosuria. Nutrient requirements are increased by fever, surgery, neoplasia, and burns.

Pathophysiology

Protein-energy malnutrition affects every organ system. The most obvious results are loss of body weight, adipose stores, and skeletal muscle mass. Weight losses of 5-10% are usually tolerated without loss of physiologic function; losses of 35-40% of body weight usually result in death. Loss of protein from skeletal muscle and internal organs is usually proportionate to weight loss. Protein mass is lost from the liver, gastrointestinal tract, kidneys, and heart.

As protein-energy malnutrition progresses, organ dysfunction develops. Hepatic synthesis of serum proteins decreases, and depressed levels of circulating proteins are observed. Cardiac output and contractility are decreased, and the ECG may show decreased voltage and a rightward axis shift. Autopsies of patients who die with severe undernutrition show myofibrillar atrophy and interstitial edema of the heart.

Respiratory function is affected primarily by weakness and atrophy of the muscles of respiration. Vital capacity and tidal volume are depressed, and mucociliary clearance is abnormal. The gastrointestinal tract is affected by mucosal atrophy and loss of villi of small intestine, resulting in malabsorption. Intestinal disaccharidase deficiency and mild pancreatic insufficiency also occur.

Changes in immunologic function are among the most important changes seen in protein-calorie undernutrition. T lymphocyte number and function are depressed. Changes in B cell function are more variable. Impaired complement activity, granulocyte function, and anatomic barriers to infection are noted, and wound healing is poor.

Clinical Findings

The clinical manifestations of protein-energy malnutrition range from mild growth retardation and weight loss to a number of distinct clinical syndromes. Children in the developing world manifest marasmus and kwashiorkor. In secondary protein-energy malnutrition as seen in industrialized nations, clinical manifestations are affected by the degree of protein and energy deficiency, the underlying illness that resulted in the deficiency, and the patient's nutritional status prior to illness.

In marasmus-like secondary protein-energy malnutrition, most patients typically develop progressive wasting that begins with weight loss and proceeds to more severe cachexia. In the most severe form of this disorder, virtually all body fat stores disappear and muscle mass decreases, most noticeably in the temporalis and interosseus muscles. Laboratory studies may be unremarkable—serum albumin, for example, may be normal or slightly decreased, rarely decreasing to < 2.8 g/dL. In contrast, owing to its rapidity of onset, kwashiorkor-like secondary protein-energy malnutrition may develop in patients with normal subcutaneous fat and muscle mass or, if the patient is obese, in patients with excess fat and muscle. The serum protein level, however, typically declines and the serum albumin is often < 2.8 g/dL. Dependent edema, ascites, or anasarca may develop. As with primary protein-energy malnutrition, combinations of the marasmus-like and kwashiorkor-like syndromes can occur simultaneously, typically in patients with progressive chronic disease who develop a superimposed acute illness.

Treatment

The treatment of severe protein-energy malnutrition is a slow process requiring great care. Initial efforts should be directed at correcting fluid and electrolyte abnormalities and infections. Of particular concern are depletion of potassium, magnesium, and calcium and acid-base abnormalities. The second phase of treatment is directed at repletion of protein, energy, and micronutrients. Treatment is started with modest quantities of protein and calories calculated according to the patient's actual body weight. Adult patients are given 1 g of protein and 30 kcal per kilogram. Concomitant administration of vitamins and minerals is obligatory. Either the enteral or parenteral route can be used, although the former is preferable. Enteral fat and lactose are withheld initially. Patients with less severe protein-calorie undernutrition can be given calories and protein simultaneously with the correction of fluid and electrolyte abnormalities. Similar quantities of protein and calories are recommended for initial treatment.

Patients treated for protein-energy malnutrition require close follow-up. In adults, both calories and protein are advanced as tolerated, adults to 1.5 g/kg/d of protein and 40 kcal/kg/d of calories.

Patients who are refed too rapidly may develop a number of untoward clinical sequelae. During refeeding, circulating potassium, magnesium, phosphorus, and glucose move intracellularly and can result in low serum levels of each. The administration of water and sodium with carbohydrate refeeding can overload hearts with depressed cardiac function and result in congestive heart failure. Enteral refeeding can lead to malabsorption and diarrhea due to abnormalities in the gastrointestinal tract.

Refeeding edema is a benign condition to be differentiated from congestive heart failure. Changes in renal sodium reabsorption and poor skin and blood vessel integrity result in the development of dependent edema without other signs of heart disease. Treatment includes reassurance, elevation of the dependent area, and modest sodium restriction. Diuretics are usually ineffective, may aggravate electrolyte deficiencies, and should not be used.

The prevention and early detection of protein-energy malnutrition in hospitalized patients require awareness of its risk factors and early symptoms and signs. Patients at risk require formal assessment of nutritional status and close observation of dietary intake, body weight, and nutritional requirements during the hospital stay.

OBESITY

Essentials of Diagnosis

- Excess adipose tissue, resulting in body mass index > 30.
- Upper body obesity (abdomen and flank) of greater health consequence than lower body obesity (buttocks and thighs).
- Associated with multiple metabolic and structural disorders, including diabetes mellitus, hypertension, and hyperlipidemia.

General Considerations

Obesity is one of the most common disorders in medical practice and among the most frustrating and difficult to manage. Little progress has been made in treatment, yet major changes have occurred in our understanding of its causes and its implications for health.

Definition & Measurement

Obesity is defined as an excess of adipose tissue. Accurate quantification of body fat requires sophisticated techniques not usually available in clinical practice. Physical examination is usually sufficient to detect excess body fat. Two methods commonly used for more quantitative evaluation are relative weight (RW) and body mass index (BMI).

Relative weight (RW) is the measured body weight divided by the "desirable weight" × 100. Desirable weight is defined as the midpoint value recommended for a given height in the weight tables published by the United States government ([Table 29-7](#)). There is controversy over which table best reflects the relationship between body weight and health. Weight tables published every few years since 1983 have varied significantly in their recommendations.

Because the RW does not differentiate between excess fat or excess muscle, the **body mass index (BMI)** can be used to more accurately reflect the presence of excess adipose tissue. The BMI is calculated by dividing measured body weight in kilograms by the height in meters squared.

The National Institutes of Health define a normal BMI as 18.5-24.9. Overweight is defined as BMI = 25-29.9. Class I obesity is 30-34.9, class II obesity is 35-39.9, and class III (extreme) obesity is BMI > 40. Other factors besides total weight, however, are also important. Upper body obesity (excess fat around the waist and flank) is a greater health hazard than lower body obesity (fat in the thighs and buttocks). Obese patients with increased abdominal circumference (> 102 cm in men and 88 cm in women) or with high waist-hip ratios (> 1.0 in men; > 0.85 in women) have a greater risk of diabetes mellitus, stroke, coronary artery disease, and early death than equally obese patients with lower ratios. Further differentiation of the location of excess fat suggests that visceral fat within the abdominal cavity is more hazardous to health than subcutaneous fat around the abdomen.

The National Health and Nutrition Exam Survey III (NHANES III) found that 59.4% of men and 49.9% of women are overweight and that 19.9% of men and 25.1% of women are obese. Blacks—particularly black women—are more apt to be obese than whites, and the poor are more obese than the rich regardless of race.

Health Consequences of Obesity

Obesity is associated with significant increases in both morbidity and mortality. A great many disorders occur with greater frequency in obese people. The most important and common of these are hypertension, type II diabetes mellitus, hyperlipidemia, coronary artery disease, degenerative joint disease, and psychosocial disability. Certain cancers (colon, rectum, and prostate in men; uterus, biliary tract, breast, and ovary in women), thromboembolic disorders, digestive tract diseases (gallstones, reflux esophagitis), and skin disorders are also more prevalent in the obese. Surgical and obstetric risks are greater. Obese patients also have a greater risk of pulmonary functional impairment, endocrine abnormalities, proteinuria, and increased hemoglobin concentration.

In young and middle-aged adults, mortality from all causes and mortality from cardiovascular disease increase in proportion to the degree of obesity. The relative risk associated with obesity, however, decreases with age, and weight is no longer a risk factor in adults over age 75.

Etiology

Until recently, obesity was considered to be the direct result of a sedentary lifestyle plus chronic ingestion of excess calories. Although these factors are undoubtedly the principal cause in some cases, there is now evidence for strong genetic influences on the development of obesity. Adopted children demonstrate a close relationship between their body mass index and that of their biologic parents. No such relationship is found between the children and their adoptive parents. Twin studies also demonstrate substantial genetic influences on body mass index with little influence from the childhood environment. As much as 40-70% of obesity may be explained by genetic influences.

Genetic determinants of some types of obesity have now been established. Five genes affecting control of appetite have been identified in mice. Mutations of each gene result in obesity, and each has a human homolog. One gene codes for a protein expressed by adipose tissue—leptin—and another for the leptin receptor in the brain. The other three genes affect brain pathways downstream from the leptin receptor. Numerous other candidate genes for human obesity have been identified. Only a very small number of humans, however, have been found with similar single gene mutations. Most human obesity undoubtedly develops from the interactions of multiple genes, environmental factors, and behavior.

Medical Evaluation of the Obese Patient

Historical information should be obtained about age at onset, recent weight changes, family history of obesity, occupational history, eating and exercise behavior, cigarette and alcohol use, previous weight loss experience, and psychosocial factors. Particular attention should be directed at use of laxatives, diuretics, hormones, nutritional supplements, and over-the-counter medications.

Physical examination should assess the degree and distribution of body fat, overall nutritional status, and signs of secondary causes of obesity.

Less than 1% of obese patients have an identifiable secondary cause of obesity. Hypothyroidism and Cushing's syndrome are important examples that can usually be diagnosed by physical examination in patients with unexplained recent weight gain. Such patients require further endocrinologic evaluation, including serum TSH determination and dexamethasone suppression testing (see [Chapter 26](#)).

All obese patients should be assessed for medical consequences of their obesity. Fasting levels of glucose, cholesterol, and triglycerides should be measured.

Treatment

Using conventional techniques, only 20% of patients will lose 20 lb and maintain the loss for over 2 years; 5% will maintain a 40-lb loss. Continued close provider-patient contact appears to be more important for success of treatment than the specific features of any given treatment regimen. Careful patient selection will improve success rates and lessen frustration of both patients and therapists. Only sufficiently motivated patients should enter treatment programs. Specific attempts to identify motivated patients—eg, requesting a 3-day diet record—are often useful.

Most successful programs employ a multidisciplinary approach to weight loss, with hypocaloric diets, behavior modification to change eating behavior, aerobic exercise, and social support. Emphasis must be on *maintenance* of weight loss.

Dietary instructions for most patients incorporate the same principles that apply to healthy people who are not obese, ie, a low-fat, high-complex carbohydrate, high-fiber diet. This is achieved by emphasizing intake of a wide variety of predominantly "unprocessed" foods. Special attention is usually paid to limiting foods that provide large amounts of calories without other nutrients, ie, fat, sucrose, and alcohol. There is no special advantage to diets that restrict carbohydrates, advocate relatively larger amounts of protein or fats, or recommend ingestion of foods one at a time. In some instances, however, diets that are restricted in carbohydrates can be effective in achieving a lower total calorie intake.

Long-term changes in eating behavior are required to maintain weight loss. Although formal **behavior modification** programs are available to which patients can be referred, the clinician caring for obese patients can teach a number of useful behavioral techniques. The most important technique is to emphasize planning and record keeping. Patients can be taught to plan menus and exercise sessions and to record their actual behavior. Record keeping not only aids in behavioral change; the availability of records also helps the provider to make specific suggestions for problem solving. Patients can be taught to recognize "eating cues" (emotional, situational, etc) and how to avoid or control them. Reward systems and refundable financial contracts are also useful for many patients.

Exercise offers a number of advantages to patients trying to lose weight and keep it off. Aerobic exercise directly increases the daily energy expenditure and is particularly useful for long-term weight maintenance. Exercise will also preserve lean body mass and partially prevent the decrease in basal energy expenditure seen with semistarvation.

Social support is essential for a successful weight loss program. Continued close contact with the therapist and involvement of the family and peer group are useful techniques for reinforcing behavioral change and preventing social isolation.

Patients with severe obesity may require more aggressive treatment regimens. **Very low-calorie diets** (= 800 kcal/d) result in rapid weight loss and marked improvement in obesity-related metabolic complications. Patients are commonly maintained on such programs for 4-6 months and lose an average of 2-4 lb per week. Long-term weight maintenance is less predictable and requires concurrent behavior modification and exercise. Side effects such as fatigue, orthostatic hypotension, cold intolerance, and fluid and electrolyte disorders are observed in proportion to the degree of calorie reduction and require regular supervision by a physician. Other less common complications include gout, gallbladder disease, and cardiac arrhythmias. Although weight loss is more rapidly achieved with very low-calorie diets as compared with traditional diets, long-term outcomes are equivalent.

Medications for the treatment of obesity are available both over the counter and by prescription. Medications can be classified as catecholaminergic or serotonergic. Catecholaminergic medications include amphetamines (with high abuse potential) and the nonamphetamine schedule IV appetite suppressants phentermine, diethylpropion, and mazindol. The September 1997 withdrawal from the market of fenfluramine and dexfenfluramine has made true serotonergic appetite medications unavailable. The SSRI antidepressants, eg, fluoxetine and sertraline, also have serotonergic activity but are not approved by the FDA for weight loss.

Two newer medications are approved for weight loss: sibutramine and orlistat. Sibutramine blocks uptake of both serotonin and norepinephrine in the central nervous system. Orlistat reduces fat absorption in the gastrointestinal tract.

Considerable controversy exists as to the appropriate use of medications for obesity. The 1998 NIH clinical obesity guidelines state that obesity drugs may be used as part of a comprehensive weight loss program for patients with BMI > 30 or those with BMI > 27 with obesity-related risk factors. Nonetheless, use of medications has decreased in the United States since the withdrawal from the market in 1997 of dexfenfluramine and fenfluramine after multiple reports of medication-associated valvular heart disease. Although recent studies have estimated the risk of valvular heart disease to be substantially less than the 30% prevalence first reported, this

experience has led to considerable caution in the use of anorectic medications.

Several medications remain available for treatment of obesity. Older catecholaminergic medications (eg, phentermine, diethylpropion, mazindol) are approved for short-term use only and have limited utility. **Sibutramine**, typically at doses of 10 mg/d, results in average weight losses of 3-5 kg more than placebo in studies extending over 6-12 months. Sibutramine also appears to improve 1-year outcomes in patients on very low-calorie diets. Side effects include dry mouth, anorexia, constipation, insomnia, and dizziness. In some patients (< 5%), sibutramine may substantially increase blood pressure.

Orlistat is the first approved medication for obesity that works in the gastrointestinal tract rather than the central nervous system. By inhibiting intestinal lipase, orlistat reduces fat absorption. As expected, orlistat may result in diarrhea, gas, and cramping and perhaps also reduced absorption of fat-soluble vitamins. In randomized trials with up to 2 years of follow-up, orlistat has resulted in 2-4 kg greater weight loss than placebo. The recommended dose of orlistat is 120 mg three times daily with meals.

Despite FDA approval of sibutramine and orlistat and NIH guidelines supporting their use, long-term clinical benefits have not been demonstrated. Although these medications result in some additional weight loss at the end of 1- and 2-year clinical trials and, in some studies, improved obesity-related metabolic parameters, the impact of these medications on obesity-related clinical outcomes is unknown.

Although surgery is the last resort for treatment of obesity, large numbers of patients have had bariatric surgery. In the United States, gastric operations are considered the procedures of choice. Most popular are the vertical banded gastroplasty (VBG) and roux-en-Y gastric bypass (GBP). In some centers, these procedures can be done laparoscopically. Both operations lead to substantial amounts of weight loss—close to 50% of initial body weight in some studies. Direct comparisons of the two operations suggest that GBP is the more effective procedure. Complications occur in up to 50% of subjects undergoing both operations and include peritonitis due to anastomotic leak, abdominal wall hernias, staple line disruption, gallstones, neuropathy, marginal ulcers, stomal stenosis, wound infections, thromboembolic disease, and various nutritional deficiencies and gastrointestinal symptoms. Within 30 days operative mortality rates are nil to 1%. NIH consensus panel recommendations are to limit obesity surgery to patients with BMIs over 40, or over 35 if obesity-related comorbidities are present. Many third-party payers now cover obesity surgery.

■ EATING DISORDERS

ANOREXIA NERVOSA

Essentials of Diagnosis

- Disturbance of body image and intense fear of becoming fat.
- Weight loss leading to body weight 15% below expected.
- In females, absence of three consecutive menstrual cycles.

General Considerations

Anorexia nervosa begins in the years between adolescence and young adulthood. Ninety percent of patients are females, most from the middle and upper socioeconomic strata. The diagnosis is based on weight loss leading to body weight 15% below expected, a distorted body image, fear of weight gain or of loss of control over food intake, and, in females, the absence of at least three consecutive menstrual cycles. Other medical or psychiatric illnesses that can account for anorexia and weight loss must be excluded.

The prevalence of anorexia nervosa is greater than previously suggested. In Rochester, Minnesota, for example, the prevalence per 100,000 population is estimated to be 270 for females and 22 for males. Many other adolescent girls have features of the disorder without the severe weight loss.

The cause of anorexia nervosa is not known. Although multiple endocrinologic abnormalities exist in these patients, most authorities believe they are secondary to malnutrition and not primary disorders. Most authors favor a primary psychiatric origin, but no hypothesis explains all cases. The patient characteristically comes from a family whose members are highly goal- and achievement-oriented. Interpersonal relationships may be inadequate or destructive. The parents are usually overly directive and concerned with slimness and physical fitness, and much of the family conversation centers around dietary matters. One theory holds that the patient's refusal to eat is an attempt to regain control of her body in defiance of parental control. The patient's unwillingness to inhabit an "adult body" may also represent a rejection of adult responsibilities and the implications of adult interpersonal relationships. Patients are commonly perfectionistic in behavior and exhibit obsessional personality characteristics. Marked depression or anxiety may be present.

Clinical Findings

A. Symptoms and Signs

Patients with anorexia nervosa may exhibit severe emaciation and may complain of cold intolerance or constipation. Amenorrhea is almost always present. Bradycardia, hypotension, and hypothermia may be present in severe cases. Examination demonstrates loss of body fat, dry and scaly skin, and increased lanugo body hair. Parotid enlargement and edema may also occur.

B. Laboratory Findings

Laboratory findings are variable but may include anemia, leukopenia, electrolyte abnormalities, and elevations of BUN and serum creatinine. Serum cholesterol levels are often increased. Endocrine abnormalities include depressed levels of luteinizing and follicle-stimulating hormones and impaired response of LH to luteinizing hormone-releasing hormone.

Diagnosis & Differential Diagnosis

The diagnosis can be difficult, since many common social and cultural factors promote and maintain anorexic behavior. The diagnosis depends upon identification of the common behavioral features and exclusion of medical disorders that would account for weight loss.

Behavioral features required for the diagnosis include intense fear of becoming obese, disturbance of body image, weight loss of at least 15%, and refusal to exceed a minimal normal weight.

The differential diagnosis includes endocrine and metabolic disorders such as panhypopituitarism, Addison's disease, hyperthyroidism, and diabetes mellitus; gastrointestinal disorders such as Crohn's disease and celiac sprue; chronic infections and cancers such as tuberculosis and lymphoma; and rare central nervous system disorders such as hypothalamic tumors.

Treatment

The goal of treatment is restoration of normal body weight and resolution of psychologic difficulties. Hospitalization may be necessary. Treatment programs conducted by experienced teams are successful in about two-thirds of cases, restoring normal weight and menstruation. One-half continue to experience difficulties with eating behavior and psychiatric problems. Occasional patients with anorexia develop obesity after treatment. Two to 6% of patients die from the complications of the disorder or commit suicide.

Various treatment methods have been used without clear evidence of superiority of one over another. Supportive care by physicians and nurses is probably the most important feature of therapy. Structured behavioral therapy, intensive psychotherapy, and family therapy may be tried. A variety of medications including tricyclic antidepressants, selective serotonin reuptake inhibitors, and lithium carbonate are effective in some cases; overall, however, clinical trial results have been disappointing. Patients with severe malnutrition must be hemodynamically stabilized and may require enteral or parenteral feeding. Forced feedings should be reserved for life-threatening situations, since the goal of treatment is to reestablish normal eating behavior.

BULIMIA NERVOSA

Essentials of Diagnosis

- Uncontrolled episodes of binge eating at least twice weekly for 3 months.
- Recurrent inappropriate compensation to prevent weight gain such as self-induced vomiting, laxatives, diuretics, fasting, or excessive exercise.
- Overconcern with weight and body shape.

General Considerations

Bulimia nervosa is the episodic uncontrolled ingestion of large quantities of food followed by recurrent inappropriate compensatory behavior in order to prevent weight gain such as self-induced vomiting, diuretic or cathartic use, or strict dieting or vigorous exercise.

Like anorexia nervosa, bulimia nervosa is predominantly a disorder of young, white middle- and upper-class women. It is more difficult to detect than anorexia, and some studies have estimated that the prevalence may be as high as 19% in college-age women.

Clinical Findings

Patients with bulimia nervosa typically consume large quantities of easily ingested high-calorie foods, usually in secrecy. Some patients may have several such episodes a day for a few days; others report regular and persistent patterns of binge eating. Binging is usually followed by vomiting, cathartics, or diuretics and is usually accompanied by feelings of guilt or depression. Periods of binging may be followed by intervals of self-imposed starvation. Body weights may fluctuate but generally are within 20% of desirable weights.

Some patients with bulimia nervosa also have a cryptic form of anorexia nervosa with significant weight loss and amenorrhea. Family and psychologic issues are generally similar to those encountered among patients with anorexia nervosa. Bulimics, however, have a higher incidence of premorbid obesity, greater use of cathartics and diuretics, and more impulsive or antisocial behavior. Menstruation is usually preserved.

Medical complications are numerous. Gastric dilatation and pancreatitis have been reported after binges. Vomiting can result in poor dentition, pharyngitis, esophagitis, aspiration, and electrolyte abnormalities. Cathartic and diuretic abuse also cause electrolyte abnormalities or dehydration. Constipation and hemorrhoids are common.

Treatment

Treatment of bulimia nervosa and bulimarexia requires supportive care and psychotherapy. Individual, group, family, and behavioral therapy have all been utilized. Antidepressant medications may be helpful. The best results have been with fluoxetine hydrochloride and other selective serotonin reuptake inhibitors. Although death from bulimia is rare, the long-term psychiatric prognosis in severe bulimia is worse than that in anorexia nervosa.

■ DISORDERS OF VITAMIN METABOLISM

Deficiencies of single vitamins are less often encountered than those of multiple vitamins. Although any cause of protein-calorie undernutrition can result in concurrent vitamin deficiency, most deficiencies are associated with malabsorption, alcoholism, medications, hemodialysis, total parenteral nutrition, food faddism, or inborn errors of metabolism.

Vitamin deficiency syndromes develop gradually. Symptoms are commonly nonspecific, and the physical examination is rarely helpful in early diagnosis. Most characteristic physical findings are seen late in the course of the syndrome. Other characteristic physical findings, such as glossitis and cheilosis, are seen with deficiencies of many B vitamins. Such abnormalities suggest the presence of a nutritional deficiency but do not indicate which nutrient is deficient.

Despite the relative ease of meeting the recommended daily allowances with a mixed diet, many adults in the United States take vitamin supplements. In fact, syndromes of vitamin excess may be more common than deficiency syndromes, particularly those due to excess of vitamins A, D, and B₆. Most claims for significant health benefits of such supplements, particularly those taken in megadoses, remain unsubstantiated.

Some vitamins can be used efficaciously as drugs. Derivatives of vitamin A are used to treat cystic acne and, more recently, skin wrinkles. Niacin is an effective medication for hyperlipidemia. Vitamin-responsive inborn errors of metabolism also commonly require pharmacologic doses of vitamins.

THIAMIN (B₁)

The primary role of thiamin is as precursor of thiamin pyrophosphate, a coenzyme required for several important biochemical reactions necessary for carbohydrate oxidation. Thiamin is also thought to have an independent role in nerve conduction in peripheral nerves. The recommended daily allowances of thiamin are listed in [Table 29-1](#). There is no known toxicity of thiamin.

Thiamin Deficiency

A. Clinical Findings

Most thiamin deficiency in the United States is due to alcoholism. Chronic alcoholics may have poor dietary intakes of thiamin and impaired thiamin absorption, metabolism, and storage. Thiamin deficiency is also associated with malabsorption, dialysis, and other causes of chronic protein-calorie undernutrition. Thiamin deficiency can be precipitated in patients with marginal thiamin status with intravenous dextrose solutions.

Early manifestations of thiamin deficiency include anorexia, muscle cramps, paresthesias, and irritability. Advanced deficiency affects chiefly the cardiovascular system ("wet beriberi") or the nervous system ("dry beriberi"). Wet beriberi occurs in thiamin deficiency accompanied by severe physical exertion and high carbohydrate intakes. Dry beriberi occurs in thiamin deficiency accompanied by inactivity and low calorie intake.

Wet beriberi is characterized by marked peripheral vasodilation resulting in high-output heart failure with dyspnea, tachycardia, cardiomegaly, and pulmonary and peripheral edema, with warm extremities mimicking cellulitis.

Dry beriberi involves both the peripheral and the central nervous systems. Peripheral nerve involvement is typically a symmetric motor and sensory neuropathy with pain, paresthesias, and loss of reflexes. The legs are affected more than the arms. Central nervous system involvement results in Wernicke-Korsakoff syndrome. Wernicke's encephalopathy consists of nystagmus progressing to ophthalmoplegia, truncal ataxia, and confusion. Korsakoff's syndrome includes amnesia, confabulation, and impaired learning.

B. Diagnosis

A variety of biochemical tests are available to assess thiamin deficiency. In most instances, however, the clinical response to empirical thiamine therapy is used to support a diagnosis of thiamin deficiency. The most commonly used and widely available biochemical tests are measurement of erythrocyte transketolase activity and urinary thiamin excretion. A transketolase activity coefficient greater than 15-20% suggests thiamin deficiency.

C. Treatment

Thiamin deficiency is treated with large parenteral doses of thiamine. Fifty to 100 mg/d is administered for the first few days, followed by daily oral doses of 5-10 mg/d. All patients should simultaneously receive therapeutic doses of other water-soluble vitamins. Although treatment results in complete resolution in one-half of patients (one-fourth immediately and another one-fourth over days), the other half obtain only partial resolution or no benefit.

Shin RK et al: Wernicke encephalopathy. Arch Neurol 2000; 57:405. [PMID: 10714669]

RIBOFLAVIN (B₂)

Riboflavin—as the coenzymes flavin mononucleotide and flavin adenine dinucleotide—participates in a variety of important oxidation-reduction reactions and is an essential component of a number of other enzymes. The recommended daily allowances of riboflavin are listed in [Table 29-1](#). There is no known toxicity of riboflavin.

Riboflavin Deficiency

A. Clinical Findings

Riboflavin deficiency almost always occurs in combination with deficiencies of other vitamins. Dietary inadequacy, interactions with a variety of medications, alcoholism, and other causes of protein-calorie undernutrition are the most common causes of riboflavin deficiency.

Manifestations of riboflavin deficiency include cheilosis, angular stomatitis, glossitis, seborrheic dermatitis, weakness, corneal vascularization, and anemia.

B. Diagnosis

Riboflavin deficiency is usually treated empirically when the diagnosis is suspected. Deficiency can be confirmed by measuring the riboflavin-dependent enzyme erythrocyte glutathione reductase. Activity coefficients greater than 1.2-1.3 are suggestive of riboflavin deficiency. Urinary riboflavin excretion and serum levels of plasma and red cell flavins can also be measured.

C. Treatment

Riboflavin deficiency is easily treated with foods such as meat, fish, and dairy products or with oral preparations of the vitamin. Administration of 5-15 mg/d until clinical findings are resolved is usually adequate. Riboflavin can also be given parenterally, but it is poorly soluble in aqueous solutions.

Riboflavin Toxicity

There is no known toxicity of riboflavin.

Powers HJ: Current knowledge concerning optimum nutritional status of riboflavin, niacin and pyridoxine. Proc Nutr Soc 1999;58:435. [PMID: 10466188]

NIACIN

Niacin is a generic term for nicotinic acid and other derivatives with similar nutritional activity. Unlike most other vitamins, niacin can be synthesized from the amino acid tryptophan. Niacin is an essential component of the coenzymes nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP), which are involved in many oxidation-reduction reactions. The recommended daily allowances of niacin are listed in [Table 29-1](#); major food sources are protein foods containing tryptophan and numerous cereals, vegetables, and dairy products.

Niacin in the form of nicotinic acid is used therapeutically for the treatment of hypercholesterolemia and hypertriglyceridemia. Daily doses of 3-6 g can result in significant reductions in levels of low-density lipoproteins (LDL) and very low-density lipoproteins (VLDL) and in elevation of high-density lipoproteins (HDL). Niacinamide (the form of niacin usually used to treat niacin deficiency) does not exhibit the lipid-lowering effects of nicotinic acid.

Niacin Deficiency

A. Clinical Findings

Historically, niacin deficiency occurred when corn, which is relatively deficient in both tryptophan and niacin, was the major source of calories. Currently, niacin deficiency is more commonly due to alcoholism and nutrient-drug interactions. Niacin deficiency can also occur in inborn errors of metabolism.

As with other B vitamins, the early manifestations of niacin deficiency are nonspecific. Common complaints include anorexia, weakness, irritability, mouth soreness, glossitis, stomatitis, and weight loss. More advanced deficiency results in the classic triad of pellagra: dermatitis, diarrhea, and dementia. The dermatitis is symmetric, involving sun-exposed areas. Skin lesions are dark, dry, and scaling. The dementia begins with insomnia, irritability, and apathy and progresses to confusion, memory loss, hallucinations, and psychosis. The diarrhea can be severe and may result in malabsorption due to atrophy of the intestinal villi. Advanced pellagra can result in death.

B. Diagnosis

In advanced cases, the diagnosis of pellagra can be made on clinical grounds. In early deficiency, diagnosis requires a high index of suspicion and attempts at confirmation of niacin deficiency. Niacin metabolites, particularly *N*-methylnicotinamide, can be measured in the urine. Low levels suggest niacin deficiency but may also be found in patients with generalized undernutrition. Serum and red cell levels of NAD and NADP are also low but are similarly nonspecific.

C. Treatment

Niacin deficiency can be effectively treated with oral niacin, usually given as nicotinamide. Doses ranging from 10 mg/d to 150 mg/d have been used without difficulty.

Niacin Toxicity

At the high doses of niacin used to treat hyperlipidemia, side effects are common. These include cutaneous flushing (partially prevented by pretreatment with aspirin, 325 mg/d, and use of extended-release preparations) and gastric irritation. Elevation of liver enzymes, hyperglycemia, and gout are less common untoward effects.

VITAMIN B₆ (PYRIDOXINE)

Vitamin B₆ (pyridoxine) is actually a group of closely related substances involved in intermediary metabolism. These include pyridoxine itself, pyridoxal, pyridoxamine, and their 5-phosphate esters. As the major coenzyme involved in the metabolism of amino acids, pyridoxal 5-phosphate is the most important. Pyridoxal phosphate is also required for the synthesis of heme. The recommended daily allowances of vitamin B₆ are listed in [Table 29-1](#).

Vitamin B₆ Deficiency

A. Clinical Findings

Vitamin B₆ deficiency most commonly occurs as a result of interactions with medications—especially isoniazid, cycloserine, penicillamine, and oral contraceptives—or of alcoholism. A number of inborn errors of metabolism and other pyridoxine-responsive syndromes, particularly pyridoxine-responsive anemia, are not clearly due to vitamin deficiency but commonly respond to high doses of the vitamin.

Vitamin B₆ deficiency results in a clinical syndrome similar to that seen with deficiencies of other B vitamins, including mouth soreness, glossitis, cheilosis, weakness, and irritability. Severe deficiency can result in peripheral neuropathy, anemia, and seizures.

B. Diagnosis

The diagnosis of vitamin B₆ deficiency can be confirmed by measurement of pyridoxal phosphate in blood. Normal levels are greater than 50 ng/mL.

C. Treatment

Vitamin B₆ deficiency can be effectively treated with oral vitamin B₆ supplements. Doses of 10-20 mg/d are usually adequate, though some patients taking medications that interfere with pyridoxine metabolism may need doses as high as 100 mg/d. Inborn errors of metabolism and the pyridoxine-responsive syndromes often require up to 600 mg/d.

Vitamin B₆ should be routinely prescribed for patients receiving medications (such as isoniazid) that interfere with pyridoxine metabolism to prevent vitamin B₆ deficiency. This is particularly true for elderly patients, the urban poor, and alcoholics, who are more likely to have diets marginally adequate in vitamin B₆.

Vitamin B₆ Toxicity

A sensory neuropathy, at times irreversible, occurs in patients receiving large doses of vitamin B₆. Although most patients have taken 2 g or more per day, some patients have taken only 200 mg/d.

VITAMIN B₁₂ & FOLATE

Vitamin B₁₂ (cobalamin) and folate are discussed in [Chapter 13](#). The recommended daily allowances of vitamin B₁₂ and folate are listed in [Table 29-1](#). Vitamin B₁₂ is abundant in meat and dairy products; fresh fruits and vegetables supply ample folic acid.

VITAMIN C (ASCORBIC ACID)

Vitamin C is a potent antioxidant involved in many oxidation-reduction reactions and is also required for the synthesis of collagen. It increases the absorption of nonheme iron and is involved in tyrosine metabolism, wound healing, and drug metabolism. With the exception of collagen synthesis, the mechanism of action for these functions is poorly understood. The recommended daily allowances of vitamin C are listed in [Table 29-1](#); major food sources are fresh fruits and vegetables.

Vitamin C Deficiency

A. Clinical Findings

Most cases of vitamin C deficiency seen in the United States are due to dietary inadequacy in the urban poor, the elderly, and chronic alcoholics. Patients with chronic illnesses such as cancer and chronic renal failure and individuals who smoke cigarettes are also at risk.

Early manifestations of vitamin C deficiency are nonspecific and include malaise and weakness. In more advanced stages, the typical features of scurvy develop. Manifestations include perifollicular hemorrhages, perifollicular hyperkeratotic papules, petechiae and purpura, splinter hemorrhages, bleeding gums, hemarthroses, and subperiosteal hemorrhages. Periodontal signs do not occur in edentulous patients. Anemia is common, and wound healing is impaired. The late stages of scurvy are characterized by edema, oliguria, neuropathy, intracerebral hemorrhage, and death.

B. Diagnosis

The diagnosis of advanced scurvy can be made clinically on the basis of the skin lesions in the proper clinical situation. Atraumatic hemarthrosis is also highly suggestive. The diagnosis can be confirmed with decreased plasma ascorbic acid levels, typically below 0.1 mg/dL.

C. Treatment

Adult scurvy can be treated with 300-1000 mg of ascorbic acid per day. Improvement typically occurs within days. Some studies have suggested that high intakes of vitamin C are associated with a decreased risk of cancer. Vitamin C may also protect against coronary heart disease by modifying blood cholesterol levels and preventing LDL cholesterol from oxidation. A decrease in all-cause and coronary heart disease mortality in individuals with high intakes (approximately 300-400 mg/d) has been reported.

Vitamin C Toxicity

Very large doses of vitamin C can cause gastric irritation, flatulence, or diarrhea. Oxalate kidney stones are of theoretic concern because ascorbic acid is metabolized to oxalate, but stone formation has not been frequently reported. Vitamin C can also confound common diagnostic tests by causing false-negative tests for fecal occult blood and both false-negative and false-positive tests for urine glucose.

VITAMIN A

Vitamin A (retinol) is a high-molecular-weight alcohol either ingested preformed or synthesized from plant carotenoids, particularly β -carotene. Isomers and derivatives

of retinol are commonly called retinoids. Vitamin A is essential for normal retinal function and plays an important but still not fully understood role in cell growth and differentiation, particularly of epithelial cells. Vitamin A is also necessary for normal wound healing. The recommended daily allowances of vitamin A are listed in [Table 29-1](#); the principal food sources are highly pigmented vegetables.

Because of its role in cell differentiation, vitamin A has been postulated to have a role in cancer prevention. The role of retinoids for chemoprevention of cancer is under intense investigation. The provitamin β -carotene may play an even more important role in prevention of cancer and heart disease by virtue of its antioxidant activity.

Vitamin A Deficiency

A. Clinical Findings

Vitamin A deficiency is one of the most common vitamin deficiency syndromes, particularly in developing countries. In many such regions, it is the most common cause of blindness. In the United States, vitamin A deficiency is usually due to fat malabsorption syndromes or mineral oil laxative abuse and occurs most commonly in the elderly and urban poor.

Night blindness is the earliest symptom. Dryness of the conjunctiva (xerosis) and the development of small white patches on the conjunctiva (Bitot's spots) are early signs. Ulceration and necrosis of the cornea (keratomalacia), perforation, endophthalmitis, and blindness are late manifestations. Xerosis and hyperkeratinization of the skin and loss of taste may also occur.

B. Diagnosis

Abnormalities of dark adaptation are strongly suggestive of vitamin A deficiency. Serum levels below the normal range of 30-65 mg/dL are commonly seen in advanced deficiency.

C. Treatment

Night blindness, poor wound healing, and other signs of early deficiency can be effectively treated with 30,000 IU of vitamin A daily for 1 week. Advanced deficiency with corneal damage calls for administration of 20,000 units/kg for at least 5 days. The potential antioxidant effects of β -carotene can be achieved with supplements of 25,000-50,000 IU of β -carotene.

Vitamin A Toxicity

Excess intake of β -carotenes (hypercarotenosis) results in staining of the skin a yellow-orange color but is otherwise benign. Skin changes are most marked on the palms and soles, while the scleras remain white, clearly distinguishing hypercarotenosis from jaundice.

Excessive vitamin A (hypervitaminosis A), on the other hand, can be quite toxic. Chronic toxicity usually occurs after ingestion of daily doses of over 50,000 units/d for more than 3 months. Early manifestations include dry, scaly skin, hair loss, mouth sores, painful hyperostoses, anorexia, and vomiting. More serious findings include hypercalcemia; increased intracranial pressure, with papilledema, headaches, and decreased cognition; and hepatomegaly, occasionally progressing to cirrhosis. Excessive vitamin A has also recently been related to increased risk of hip fracture. Acute toxicity can result from ingestion of massive doses of vitamin A, such as in drug overdoses or consumption of polar bear liver. Manifestations include nausea, vomiting, abdominal pain, headache, papilledema, and lethargy.

The diagnosis can be confirmed by elevations of serum vitamin A levels. The only treatment is withdrawal of vitamin A from the diet. Most symptoms and signs improve rapidly.

VITAMIN D

Vitamin D is discussed in [Chapter 26](#). The recommended daily allowances of vitamin D are listed in [Table 29-1](#); a major food source is fortified milk, but sunlight on the skin is a prime resource as well.

VITAMIN E

Vitamin E activity is derived from at least eight naturally occurring tocopherols, the most potent of which is α -tocopherol. Although the exact function and mechanism of action of vitamin E in humans are unclear, it is commonly thought to function as an antioxidant, protecting cell membranes and other cellular structures from attack by free radicals. Dietary selenium and other antioxidants work in conjunction with vitamin E and may partially spare its requirement and reverse signs of vitamin E deficiency in animals. The recommended daily allowances of vitamin E are listed in [Table 29-1](#); the major food source is vegetable seed oil.

Vitamin E, like β -carotene and vitamin C, may also play a role in protection against cancer, coronary heart disease, Alzheimer's disease, and cataracts through its antioxidant function.

Vitamin E Deficiency

A. Clinical Findings

Clinical deficiency of vitamin E is most commonly due to severe malabsorption, the genetic disorder abetalipoproteinemia, or, in children with chronic cholestatic liver disease, biliary atresia or cystic fibrosis. Manifestations of deficiency include areflexia, disturbances of gait, decreased proprioception and vibration, and ophthalmoplegia.

B. Diagnosis

Plasma vitamin E levels can be measured; normal levels are 0.5-0.7 mg/dL or higher. Since vitamin E is normally transported in lipoproteins, the serum level should be interpreted in relation to circulating lipids.

C. Treatment

The optimum therapeutic dose of vitamin E has not been clearly defined. Large doses, often administered parenterally, can be used to improve the neurologic complications seen in abetalipoproteinemia and cholestatic liver disease. The potential antioxidant benefits of vitamin E can be achieved with supplements of 100-400 units/d. Clinical trials of supplemental vitamin E to prevent cardiovascular disease, however, have mostly shown no beneficial effects.

Vitamin E Toxicity

Vitamin E is the least toxic of the fat-soluble vitamins. Large doses—20-80 times the recommended daily requirement—have been taken for extended periods of time without apparent harm, though nausea, flatulence, and diarrhea have been reported. Large doses of vitamin E can increase the vitamin K requirement and can result in bleeding in patients taking oral anticoagulants.

BR>■ DIET THERAPY

Specific therapeutic diets can be designed to facilitate the medical management of most common illnesses. In most cases, consultation with a registered dietitian is necessary in order to design and implement major dietary changes. Physicians should be familiar with the indications for special diets and their basic composition to facilitate patient referrals and to maximize patient compliance. Diet therapy is a difficult process, and not all patients are able to cooperate fully. Requesting the patient to record dietary intake for 3-5 days may provide useful insight into the patient's motivation.

Therapeutic diets can be divided into three groups: (1) diets that alter the consistency of food, (2) diets that restrict or otherwise modify dietary components, and (3) diets that supplement dietary components.

DIETS THAT ALTER CONSISTENCY

Clear Liquid Diet

This diet provides adequate water, 500-1000 kcal as simple sugar, and some electrolytes. It is fiber-free and requires minimal digestion or intestinal motility.

A clear liquid diet is useful for patients with resolving postoperative ileus, acute gastroenteritis, partial intestinal obstruction, and as preparation for diagnostic gastrointestinal procedures. It is commonly used as the first diet for patients who have been taking nothing by mouth for long periods. Because of the low calorie and minimal protein content of the clear liquid diet, it is used only for short periods.

Full Liquid Diet

The full liquid diet provides adequate water and can be designed to provide adequate calories and protein. Vitamins and minerals—especially folic acid, iron, and vitamin B₆—may be inadequate and should be provided in the form of supplements. Dairy products, soups, eggs, and soft cereals are used to supplement clear liquids. Commercial oral supplements can also be incorporated into the diet or used alone.

This diet is low in residue and can be used in many instances instead of the clear liquid diet described above—especially in patients with difficulty in chewing or swallowing, with partial obstructions, or in preparation for some diagnostic procedures. Full liquid diets are commonly used following clear liquid diets to advance diets in patients who have been taking nothing by mouth for long periods.

Soft Diets

Soft diets are designed for patients unable to chew or swallow hard or coarse food. Tender foods are used, and most raw fruits and vegetables and coarse breads and cereals are eliminated. Soft diets are commonly used to assist in progression from full liquid diets to regular diets in postoperative patients, in patients who are too weak or those whose dentition is too poor to handle a general diet, in head and neck surgical patients, in patients with esophageal strictures, and in other patients who have difficulty with chewing or swallowing.

The soft diet can be designed to meet all nutritional requirements.

DIETS THAT RESTRICT NUTRIENTS

Diets can be designed to restrict (or eliminate) virtually any nutrient or food component. The most commonly used restricted diets are those that limit sodium, fat, and protein. Other restrictive diets include gluten restriction in sprue, potassium and phosphate reduction in renal insufficiency, and various elimination diets for food allergies.

Sodium-Restricted Diets

Low-sodium diets are useful in the management of hypertension and in conditions in which sodium retention and edema are prominent features, particularly congestive heart failure, chronic liver disease, and chronic renal failure. Sodium restriction is beneficial with or without diuretic therapy. When used in conjunction with diuretics, sodium restriction allows lower dosage of the diuretic medication and may prevent side effects. Potassium excretion, in particular, is directly related to distal renal tubule sodium delivery, and sodium restriction will decrease diuretic-related potassium losses.

Typical American diets contain a minimum of 4-6 g (175-260 meq) of sodium per day. A no-added-salt diet contains approximately 3 g (132 meq) of sodium per day. Further restriction can be achieved with sodium diets of 2 g or 1 g per day. Diets with more severe restriction are poorly accepted by patients and are rarely used.

Dietary sodium includes sodium naturally occurring in foods, sodium added during food processing, and sodium added by the consumer during cooking and at the table. About a third of current dietary intake is derived from each. Diets that allow 2000 mg of sodium daily are easiest to design and implement. Such diets generally eliminate added salt, most processed foods, and selected foods with particularly high sodium content. Patients who follow such diets for 2-3 months lose their craving for salty foods and can often continue to restrict their sodium intake indefinitely. Many patients with mild hypertension will achieve significant reductions in blood pressure (approximately 5 mm Hg diastolic) with this degree of sodium restriction. Other patients require more severe sodium restriction (approximately 1000 mg of sodium per day) for reduction in blood pressure.

Diets allowing 1000 mg of sodium require further restriction of commonly eaten foods. Special "low-sodium" products are now available to facilitate such diets. These diets are difficult for most people to follow and are generally reserved for hospitalized patients and highly motivated outpatients—most commonly those with severe liver disease and ascites.

Fat-Restricted Diets

Traditional fat-restricted diets are useful in the treatment of fat malabsorption syndromes. Such diets will improve the symptoms of diarrhea with steatorrhea independently of the primary physiologic abnormality by limiting the quantity of fatty acids that reach the colon. The degree of fat restriction necessary to control symptoms must be individualized. Patients with severe malabsorption can be limited to 40-60 g of fat per day. Diets containing 60-80 g of fat per day can be designed for patients with less severe abnormalities.

In general, fat-restricted diets require broiling, baking, or boiling meat and fish; discarding the skin of poultry and fish and using those foods as the main protein source; using nonfat dairy products; and avoiding desserts, sauces, and gravies.

Low-Cholesterol, Low-Saturated- Fat Diets

Fat-restricted diets that specifically restrict saturated fats and dietary cholesterol are the mainstay of dietary treatment of hyperlipidemia (see [Chapter 28](#)). Similar diets are recommended also for diabetes ([Chapter 27](#)) and for the prevention of coronary artery disease ([Chapter 10](#)). Current recommendations for the prevention of cancer by dietary modification also include fat restriction.

The aim of these diets is to restrict total fat to 30% of calories and to achieve a normal body weight by caloric restriction. Saturated fat is restricted to 10% of calories

and dietary cholesterol to 300 mg/d. Saturated fat can be replaced either with complex carbohydrates or, if energy balance permits, with monounsaturated fats. Saturated fat, total fat, and dietary cholesterol can be restricted further, but studies suggest that more extreme restriction offers little further advantage in overall modification of serum lipids.

Protein-Restricted Diets

Protein-restricted diets are most commonly used in patients with hepatic encephalopathy due to chronic liver disease and in patients with renal failure to slow the progression of early disease and to decrease symptoms of uremia in more severe disease. Patients with selected inborn errors of amino acid metabolism and other abnormalities resulting in hyperammonemia also require restriction of protein or of specific amino acids.

Protein restriction is intended to limit the production of nitrogenous waste products. Energy intake must be adequate to facilitate the efficient use of dietary protein. Proteins must be of high biologic value and be provided in sufficient quantity to meet minimal requirements. For most patients, the diet should contain at least 0.6 g/kg/d of protein. Patients with encephalopathy who fail to respond to this degree of restriction are unlikely to respond to more severe restriction.

DIETS THAT SUPPLEMENT NUTRIENTS

High-Fiber Diet

Dietary fiber is a diverse group of plant constituents that are resistant to digestion by the human digestive tract. Typical American diets contain about 5-10 g of dietary fiber per day. Epidemiologic evidence has suggested that populations consuming greater quantities of fiber have a lower incidence of certain gastrointestinal disorders, including diverticulitis and colon cancer. Most authorities currently recommend higher intakes of dietary fiber for health maintenance.

Diets high in dietary fiber (20-35 g/d) are also commonly used in management of a variety of gastrointestinal disorders, particularly irritable bowel syndrome and recurrent diverticulitis. Diets high in fiber may also be useful to reduce blood sugar in patients with diabetes and to reduce cholesterol levels in patients with hypercholesterolemia. Such diets include greater intakes of fresh fruits and vegetables, whole grains, legumes and seeds, and bran products. For some patients, the addition of psyllium seed (2 tsp per day) or natural bran (1/2 cup per day) may be preferable.

High-Potassium Diets

Potassium-supplemented diets are used most commonly to compensate for potassium losses caused by diuretics. Although potassium losses can be partially prevented by using lower doses of diuretics, concurrent sodium restriction, and potassium-sparing diuretics, some patients require additional potassium to prevent hypokalemia. High-potassium diets may also have a direct antihypertensive effect. Typical American diets contain about 3 g (80 meq) of potassium per day. High-potassium diets commonly contain 4.5-7 g (120-180 meq) of potassium per day.

Most fruits, vegetables, and their juices contain high concentrations of potassium (see [Chapter 21](#)). Supplemental potassium can also be provided with potassium-containing salt substitutes (up to 20 meq in 1/4 tsp) or as potassium chloride in solution or capsules, but this is rarely necessary if the above measures are followed to prevent potassium losses and supplement dietary potassium.

High-Calcium Diets

Additional intakes of dietary calcium have recently been recommended for the prevention of postmenopausal osteoporosis, the prevention and treatment of hypertension, and the prevention of colon cancer. Although the evidence in each case is preliminary, authorities recommend intakes of 1 g of calcium per day for most adults and 1.5 g/d for postmenopausal women. Average American daily intakes are approximately 700 mg/d.

Low-fat and nonfat dairy products are the mainstay of supplemental calcium intakes. Patients with lactose intolerance who cannot tolerate liquid dairy products may be able to tolerate nonliquid products such as cheese and yogurt. Leafy green vegetables and canned fish with bones also contain high concentrations of calcium, although the latter is also very high in sodium.

■ NUTRITIONAL SUPPORT

Nutritional support is the provision of nutrients to patients who cannot meet their nutritional requirements by eating standard diets. Nutrients may be delivered enterally, using oral nutritional supplements, nasogastric and nasoduodenal feeding tubes, and tube enterostomies, or parenterally, using lines or catheters placed in peripheral or central veins, respectively. Current nutritional support techniques permit adequate nutrient delivery to virtually any patient. Nutrition support should only be utilized, however, if it is likely to improve the patient's clinical outcome. The financial costs and risks of side effects must be balanced against the potential advantages of improved nutritional status in each clinical situation.

INDICATIONS FOR NUTRITIONAL SUPPORT

The precise indications for nutritional support remain controversial. Most authorities agree that nutritional support is indicated for at least four groups of adult patients: (1) those with inadequate bowel syndromes, (2) those with severe prolonged hypercatabolic states (eg, due to extensive burns, multiple trauma, mechanical ventilation), (3) those requiring prolonged therapeutic bowel rest, and (4) those with severe protein-calorie undernutrition with a treatable disease who have sustained a

loss of over 25% of body weight.

It has been difficult to prove the efficacy of nutritional support in the treatment of most other conditions. In most cases it has not been possible to show a clear advantage of treatment by means of nutritional support over treatment without such support.

The American Society for Parenteral and Enteral Nutrition (ASPEN) has published recommendations for the rational use of nutritional support. The recommendations emphasize the need to individualize the decision to begin nutritional support, weighing the risks and costs against the benefits to each patient. They also reinforce the need to identify high-risk malnourished patients by nutritional assessment.

NUTRITIONAL SUPPORT METHODS

Selection of the most appropriate nutritional support method involves consideration of gastrointestinal function, the anticipated duration of nutritional support, and the ability of each method to meet the patient's nutritional requirements. The method chosen should meet the patient's nutritional needs with the lowest risk and lowest cost possible. For most patients, enteral feeding is safer and cheaper and offers significant physiologic advantages. An algorithm for selection of the most appropriate nutritional support method is presented in [Figure 29-2](#).

Prior to initiating specialized enteral nutritional support, efforts should be made to supplement food intake. Attention to patient preferences, timing of meals and diagnostic procedures and use of medications, and the use of foods brought to the hospital by family and friends can often increase oral intake. Patients unable to eat enough at regular mealtimes to meet nutritional requirements can be given **oral supplements** as snacks or to replace low-calorie beverages. Oral supplements of differing nutritional composition are available for the purpose of individualizing the diet in accordance with specific clinical requirements (see below). Fiber and lactose content, caloric density, protein level, and amino acid profiles can all be modified as necessary.

Patients unable to take adequate oral nutrients who have functioning gastrointestinal tracts and who meet the criteria for nutritional support are candidates for **tube feedings**. Small-bore feeding tubes are placed via the nose into the stomach or duodenum. Patients able to sit up in bed who can protect their airways can be fed into the stomach. Because of the increased risk of aspiration, patients who cannot adequately protect their airways should be fed nasoduodenally. Feeding tubes can usually be passed into the duodenum by leaving an extra length of tubing in the stomach and placing the patient in the right decubitus position. Metoclopramide, 10 mg intravenously, can be given 20 minutes prior to insertion and continued every 6 hours thereafter to facilitate passage through the pylorus. Occasionally patients will require fluoroscopic or endoscopic guidance to insert the tube distal to the pylorus. Placement of nasogastric and, particularly, nasoduodenal tubes should be confirmed radiographically before delivery of feeding solutions.

Feeding tubes can also be placed directly into the gastrointestinal tract using **tube enterostomies**. Most tube enterostomies are placed in patients who require long-term enteral nutritional support. Gastrostomies have the advantage of allowing bolus feedings, while jejunostomies require continuous infusions. Gastrostomies—like nasogastric feeding—should only be used in patients at low risk for aspiration. Gastrostomies can also be placed percutaneously with the aid of endoscopy. These tubes can then be advanced to jejunostomies. Tube enterostomies can also be placed surgically.

Patients who require nutritional support but whose gastrointestinal tracts are nonfunctional should receive **parenteral nutritional support**. Most patients receive parenteral feedings via a central vein—most commonly the subclavian vein. Peripheral veins can be used in some patients, but because of the high osmolality of parenteral solutions this is rarely tolerated for more than a few weeks.

Peripheral vein nutritional support is most commonly used in patients with nonfunctioning gastrointestinal tracts who require immediate support but whose clinical status is expected to improve within 1-2 weeks, allowing enteral feeding. Peripheral vein nutritional support is administered via standard intravenous lines. Solutions should always include lipid and dextrose in combination with amino acids to provide adequate nonprotein calories. Serious side effects are infrequent, but there is a high incidence of phlebitis and infiltration of intravenous lines.

Central vein nutritional support is delivered via intravenous catheters placed percutaneously using aseptic technique. Proper placement in the superior vena cava is documented radiographically before the solution is infused. Catheters must be carefully maintained by experienced nursing personnel and used solely for nutritional support to prevent infection and other catheter-related complications.

NUTRITIONAL REQUIREMENTS

Each patient's nutritional requirements should be determined independently of the method of nutritional support. In most situations, solutions of equal nutrient value can be designed for delivery via enteral and parenteral routes, but differences in absorption must be considered. A complete nutritional support solution must contain water, energy, amino acids, electrolytes, vitamins, minerals, and essential fatty acids.

Water

For most patients, water requirements can be calculated by allowing 1500 mL for the first 20 kg of body weight plus 20 mL for every kilogram over 20. Additional losses should be replaced as they occur. For average-sized adult patients, fluid needs are about 30-35 mL/kg, or approximately 1 mL/kcal of energy required (see below).

Energy

Energy requirements can be estimated by one of three methods: (1) by using standard equations to calculate resting energy expenditure (REE) plus additional calories for activity and illness, (2) by applying a simple calculation based on calories per kilogram of body weight, or (3) by measuring energy expenditure with indirect calorimetry.

Resting energy expenditure (REE) can be calculated by the **Harris-Benedict equation**: for men, $REE = 666 + (13.7 \times \text{weight in kg}) + (5 \times \text{height in cm}) - (6.8 \times \text{age in years})$. For women, $REE = 655 + (9.5 \times \text{weight in kg}) + (1.8 \times \text{height in cm}) - (4.7 \times \text{age})$. For undernourished patients, actual body weight should be used; for obese patients, ideal body weight should be used. For most patients, an additional 20-50% of REE is administered as nonprotein calories to accommodate energy expenditures during activity or relating to the illness. Occasional patients are noted to have energy expenditures greater than 150% of REE.

Energy requirements can be estimated also by multiplying actual body weight in kilograms (for obese patients, ideal body weight) by 30-35 kcal.

Both of these methods provide imprecise estimates of actual energy expenditures, especially for the markedly underweight, overweight, and critically ill patient. Studies using indirect calorimetry have demonstrated that as many as 30-40% of patients will have measured expenditures 10% above or below estimated values. For accurate determination of energy expenditure, indirect calorimetry should be used.

Protein

Protein and energy requirements are closely related. If adequate calories are provided, most patients can be given 0.8-1.2 g of protein per kilogram per day. Patients undergoing moderate to severe stress should receive up to 1.5 g/kg/d. As in the case of energy requirements, actual weights should be used for normal and underweight patients and ideal weights for patients with significant obesity.

Patients who are receiving protein without adequate calories will catabolize protein for energy rather than utilizing it for protein synthesis. Thus, when energy intake is low, excess protein is needed for nitrogen balance. If both energy and protein intakes are low, extra energy will have a more significant positive effect on nitrogen balance than extra protein.

Electrolytes & Minerals

Requirements for sodium, potassium, and chloride vary widely. Most patients require 45-145 meq/d of each. The actual requirement in individual patients will depend on the patient's cardiovascular, renal, endocrine, and gastrointestinal status as well as measurements of serum concentration.

Patients receiving enteral nutritional support should receive adequate vitamins and minerals according to the recommended daily allowances ([Table 29-1](#)). Most premixed enteral solutions provide adequate vitamins and minerals as long as adequate calories are administered.

Patients receiving parenteral nutritional support require smaller amounts of minerals: calcium, 10-15 meq/d; phosphorus, 15-20 meq per 1000 nonprotein calories; and magnesium, 16-24 meq/d. Most patients receiving nutritional support do not require supplemental iron because body stores are adequate. Iron nutrition should be monitored closely by following the hemoglobin concentration, MCV, and iron studies. Parenteral administration of iron is associated with a number of adverse effects and should be reserved for iron-deficient patients unable to take oral iron.

Patients receiving parenteral nutritional support should be given the trace elements zinc (about 5 mg/d) and copper (about 2 mg/d). Patients with diarrhea will require additional zinc to replace fecal losses. Additional trace elements—especially chromium, manganese, and selenium—are provided to patients receiving long-term parenteral nutrition.

Parenteral vitamins are provided daily. Standardized multivitamin solutions are currently available to provide adequate quantities of vitamins A, B₁₂, C, D, E, thiamin, riboflavin, niacin, pantothenic acid, pyridoxine, folic acid, and biotin. Vitamin K is not given routinely but administered when the prothrombin time becomes abnormal.

Essential Fatty Acids

Patients receiving nutritional support should be given 2-4% of their total calories as linoleic acid to prevent essential fatty acid deficiency. Most prepared enteral solutions contain adequate linoleic acid. Patients receiving parenteral nutrition should be given at least 250 mL of a 20% intravenous fat (emulsified soybean or safflower oil) about two or three times a week. Intravenous fat can also be used as an energy source in place of dextrose.

ENTERAL NUTRITIONAL SUPPORT SOLUTIONS

Most patients who require enteral nutritional support can be given commercially prepared enteral solutions ([Table 29-8](#)). Nutritionally complete solutions have been designed to provide adequate proportions of water, energy, protein, and micronutrients. Nutritionally incomplete solutions are also available to provide specific macronutrients (eg, protein, carbohydrate, and fat) to supplement complete solutions for patients with unusual requirements or to design solutions that are not available commercially.

Nutritionally complete solutions are characterized as follows: (1) by osmolality (isotonic or hypertonic), (2) by lactose content (present or absent), (3) by the molecular form of the protein component (intact proteins; peptides or amino acids), (4) by the quantity of protein and calories provided, and (5) by fiber content (present or absent). For most patients, isotonic solutions containing no lactose or fiber are preferable. Such solutions generally contain moderate amounts of fat and intact protein. Most commercial isotonic solutions contain 1000 kcal and about 37-45 g of protein per liter.

Solutions containing hydrolyzed proteins or crystalline amino acids and with no significant fat content are called elemental solutions, since macronutrients are provided in their most "elemental" form. These solutions have been designed for patients with malabsorption, particularly pancreatic insufficiency and limited fat absorption. Elemental diets are extremely hypertonic and often result in more severe diarrhea. Their use should be limited to patients who cannot tolerate isotonic solutions.

Although formulas have been designed for specific clinical situations—solutions containing primarily essential amino acids (for renal failure), medium-chain triglycerides (for fat malabsorption), more fat (for respiratory failure and CO₂ retention), and more branched-chain amino acids (for hepatic encephalopathy and severe trauma)—they have not been shown to be superior to standard formulas for most patients.

Enteral solutions should be administered via continuous infusion, preferably with an infusion pump. Isotonic feedings should be started at full strength at about 25-33% of the estimated final infusion rate. Feedings can be advanced by similar amounts every 12 hours as tolerated. Hypertonic feedings should be started at half strength. The strength and the rate can then be advanced every 6 hours as tolerated.

COMPLICATIONS OF ENTERAL NUTRITIONAL SUPPORT

Minor complications of tube feedings occur in 10-15% of patients. Gastrointestinal complications include diarrhea (most common), inadequate gastric emptying, emesis, esophagitis, and occasionally gastrointestinal bleeding. Diarrhea associated with tube feeding may be due to intolerance to the osmotic load or to one of the macronutrients (eg, fat, lactose) in the solution. Patients being fed in this way may also have diarrhea from other causes (as side effects of antibiotics or other drugs, associated with infection, etc), and these possibilities should always be investigated in appropriate circumstances.

Mechanical complications of tube feedings are potentially the most serious. Of particular importance is aspiration. All patients receiving nasogastric tube feedings are at risk for this life-threatening complication. Limiting nasogastric feedings to those patients who can adequately protect their airway and careful monitoring of patients being fed by tube should limit these serious complications to 1-2% of cases. Minor mechanical complications are common and include tube obstruction and dislodgment.

Metabolic complications during enteral nutritional support are common but in most cases easily managed. The most important problem is hypernatremic dehydration, most commonly seen in elderly patients given excessive protein intake who are unable to respond to thirst. Abnormalities of potassium, glucose, and acid-base balance may also occur.

PARENTERAL NUTRITIONAL SUPPORT SOLUTIONS

Parenteral nutritional support solutions can be designed to deliver adequate nutrients to virtually any patient. The basic parenteral solution is composed of dextrose, amino acids, and water. Electrolytes, minerals, trace elements, vitamins, and medications can also be added. Most commercial solutions contain the monohydrate form of dextrose that provides 3.4 kcal/g. Crystalline amino acids are available in a variety of concentrations, so that a broad range of solutions can be made up that will contain specific amounts of dextrose and amino acids as required.

Typical solutions for central vein nutritional support contain 25-35% dextrose and 2.75-6% amino acids depending upon the patient's estimated nutrient and water requirements. These solutions typically have osmolalities in excess of 1800 mosm/L and require infusion into a central vein. A typical formula for patients without organ failure is shown in [Table 29-9](#).

Solutions with lower osmolalities can also be designed for infusion into peripheral veins. Typical solutions for peripheral infusion contain 5-10% dextrose and 2.75-4.25% amino acids. These solutions have osmolalities between 800 and 1200 mosm/L and result in a high incidence of thrombophlebitis and line infiltration. These solutions will provide adequate protein for most patients but inadequate energy. Additional energy must be provided in the form of emulsified soybean or safflower oil. Such intravenous fat solutions are currently available in 10% and 25% solutions providing 1.1 and 2.2 kcal/mL, respectively. Intravenous fat solutions are isosmotic and well tolerated by peripheral veins. Typical patients are given 200-500 mL of a 20% solution each day. As much as 60% of total calories can be administered in this manner.

Intravenous fat can also be provided to patients receiving central vein nutritional support. In this instance, dextrose concentrations should be decreased to provide a fixed concentration of energy. Intravenous fat has been shown to be equivalent to intravenous dextrose in providing energy to spare protein. Intravenous fat is associated with less glucose intolerance, less production of carbon dioxide, and less fatty infiltration of the liver and has been increasingly utilized in patients with hyperglycemia, respiratory failure, and liver disease. Intravenous fat has also been increasingly used in patients with large estimated energy requirements. Recent studies suggest that the maximum glucose utilization rate is approximately 5-7 mg/min/kg. Patients who require additional calories can be given them as fat to prevent excess administration of dextrose. Intravenous fat can also be used to prevent essential fatty acid deficiency. The optimal ratio of carbohydrate and fat in parenteral nutritional support has not been determined.

Infusion of parenteral solutions should be started slowly to prevent hyperglycemia and other metabolic complications. Typical solutions are given initially at a rate of 50 mL/h and advanced by about the same amount every 24 hours until the desired final rate is reached.

COMPLICATIONS OF PARENTERAL NUTRITIONAL SUPPORT

Complications of central vein nutritional support occur in up to 50% of patients. Although most are minor and easily managed, about 5% of patients will develop significant complications. Complications of central vein nutritional support can be divided into catheter-related complications and metabolic complications.

Catheter-related complications can occur during insertion or while the catheter is in place. Pneumothorax, hemothorax, arterial laceration, air emboli, and brachial plexus injury can occur during catheter placement. The incidence of these complications is inversely related to the experience of the physician performing the procedure but will occur in at least 1-2% of cases even in major medical centers. Each catheter placement should be documented by chest radiograph prior to initiation of nutritional support.

Catheter thrombosis and catheter-related sepsis are the most important complications of indwelling catheters. Patients with indwelling central vein catheters who develop fever without an apparent source should have their lines changed over a wire or removed immediately, the tip quantitatively cultured, and antibiotics begun empirically. Quantitative tip cultures and blood cultures will help guide further antibiotic therapy. Catheter-related sepsis occurs in 2-3% of patients even if maximal efforts are made to prevent infection.

Metabolic complications of central vein nutritional support occur in over 50% of patients ([Table 29-10](#)). Most are minor and easily managed, and termination of support is seldom necessary.

PATIENT MONITORING DURING NUTRITIONAL SUPPORT

Every patient receiving enteral or parenteral nutritional support should be followed closely. Formal nutritional support teams composed of a physician, a nurse, a dietitian, and a pharmacist have been shown to decrease the rate of complications.

Patients should be monitored both for the adequacy of treatment and to prevent complications or detect them early when they occur. Because estimates of nutritional requirements are imprecise, frequent reassessment is necessary. Daily intakes should be recorded and compared with estimated requirements. Body weight, hydration status, and overall clinical status should be followed. Patients who do not appear to be responding as anticipated can be evaluated for nitrogen balance by means of the following equation:

$$\text{Nitrogen balance} = \frac{24 \text{ hour protein intake (g)}}{6.25} - \left(\frac{25\text{-hour urinary nitrogen (g)}}{4} \right)$$

Patients with positive nitrogen balances can be continued on their current regimens; patients with negative balances should receive moderate increases in calorie and protein intake and then be reassessed. Monitoring for metabolic complications includes daily measurements of electrolytes; serum glucose, phosphorus, magnesium, calcium, and creatinine; and BUN until the patient is stabilized. Once the patient is stabilized, electrolytes, phosphorus, calcium, magnesium, and glucose should be obtained at least twice weekly. Red blood cell folate, zinc, and copper should be checked at least once a month.

Table 29-4. Essential macrominerals: Summary of major characteristics.¹

Elements	Functions	Deficiency Disease or Symptoms	Toxicity Disease or Symptoms ²
Calcium	Constituent of bones, teeth; regulation of nerve, muscle function.	Children: rickets. Adults: osteomalacia. May contribute to osteoporosis.	Occurs with excess absorption due to hypervitaminosis D or hypercalcemia due to hyper-parathyroidism or other causes of hypercalcemia.
Phosphorus	Constituent of bones, teeth, ATP, phosphorylated metabolic intermediates. Nucleic acids.	Children: rickets. Adults: osteomalacia.	Low serum Ca ²⁺ :P _i ratio stimulates secondary hyperparathyroidism; may lead to bone loss.
Sodium	Principal cation in extracellular fluid. Regulates plasma volume, acid-base balance, nerve and muscle function, Na ⁺ -K ⁺ ATPase.	Unknown on normal diet, secondary to injury or illness.	Hypertension (in susceptible individuals).
Potassium	Principal cation in intracellular fluid; nerve and muscle function, Na ⁺ -K ⁺ ATPase.	Occurs secondary to illness, injury, or diuretic therapy; muscular weakness, paralysis, mental confusion.	Cardiac arrest, small bowel ulcers.
Chloride	Fluid and electrolyte balance; gastric fluid.	Infants fed salt-free formula. Secondary to vomiting, diuretic therapy, renal disease.	Cardiac arrest, small bowel ulcers.
Magnesium	Constituent of bones, teeth; enzyme cofactor (kinases, etc).	Secondary to malabsorption or diarrhea, alcoholism.	Depressed deep tendon reflexes and respiration.

Table 29-5. Effect of drugs on nutrient absorption and metabolism.

Drug	Effect
Analgesics and anti-inflammatories	
Salicylates	Decrease serum ascorbic acid; increase urinary loss of ascorbic acid, potassium, and amino acids.
Sulfasalazine	Impairs folate absorption and antagonizes folate supplementation.
Antacids	
Aluminum antacids	Decrease absorption of phosphate and vitamin A.
H ₂ blockers	Decrease iron and vitamin B ₁₂ absorption.
Octreotide acetate	Hypo- and hyperglycemia; decreases fat and carotene absorption.
Anticonvulsants	
Phenobarbital deficiency.	Decreases serum folate; increases vitamin D and vitamin K turnover and may cause
Phenytoin	Decreases serum folate; increases vitamin D and vitamin K turnover and may cause deficiency.
Primidone	Decreases serum folate and vitamins B ₆ and B ₁₂ ; decreases calcium absorption; increases vitamin D and vitamin K turnover and may cause anxiety.
Antimicrobials	
Neomycin	Binds bile acids. Decreases absorption of fat and carotene; of vitamins A, D, K, and B ₁₂ ; and of potassium, sodium, calcium, and nitrogen.
Amphotericin B	Decreases serum magnesium and potassium.
Aminosalicylic acid	Increases absorption of folate, vitamin B ₁₂ , iron, cholesterol, and fat.
Chloramphenicol	Increases need for vitamins B ₂ , B ₆ , B ₁₂ ; increases serum iron.
Penicillin	Hypokalemia; renal potassium wasting.
Tetracycline	Calcium, iron, magnesium inhibit drug absorption; decreases vitamin K synthesis.
Cycloserine	May decrease absorption of calcium, magnesium; may decrease serum folate and vitamins B ₆ and B ₁₂ ; decreases protein synthesis.
Isoniazid	Vitamin B ₆ antagonist; may cause deficiency.
Sulfonamide	Decreases absorption of folate; decreases serum folate, iron.
Nitrofurantoin	Decreases serum folate.
Pyrimethamine	Decreases serum B ₁₂ and folate.
Antimitotics	
Methotrexate	Decreases activation of folate.
Colchicine	Decreases absorption of vitamin B ₁₂ , carotene, fat, sodium, potassium, cholesterol, lactose, nitrogen.
Cathartics	
Phenolphthalein	Malabsorption, hypokalemia; deficiency of vitamin D, calcium.
Mineral oil	Malabsorption; decreased absorption of vitamins A, D, K.
Diuretics	
	Some cause hypokalemia, hypomagnesemia; may increase urinary excretion of vitamins B ₁ and B ₆ ; calcium, magnesium, potassium.
Hypocholesterolemics	
Cholestyramine	Binds bile acids; decreases absorption of fat, carotene; vitamins A, D, K, and B ₁₂ ; folate, iron.
Clofibrate	Decreases absorption of carotene, vitamin B ₁₂ , iron, glucose.
Hypotensives	
Hydralazine	Vitamin B ₆ deficiency.
Captopril	May cause hyponatremia, hyperkalemia; decreases taste acuity.
Oral contraceptives	
	Vitamin B ₆ , folate deficiency; may increase the need for other nutrients.

30. General Problems in Infectious Diseases - *Richard A. Jacobs, MD, PhD*

INTRODUCTION

Most infections are confined to specific organ systems, and many of the important infectious disease entities are discussed in chapters dealing with the relevant anatomic areas. In this chapter are discussed some important general problems related to infectious diseases that are not covered elsewhere.

FEVER OF UNKNOWN ORIGIN (FUO)

To fulfill the original criteria for FUO, a patient must have had an illness of at least 3 weeks' duration, fever over 38.3°C on several occasions, and remain undiagnosed after 1 week of study in the hospital. The intervals specified are arbitrary ones intended to exclude patients with protracted but self-limited viral illnesses and to allow time for the usual radiographic, serologic, and cultural studies to be performed. Because of costs of hospitalization and the availability of most screening tests on an outpatient basis, the criterion requiring 1 week of hospitalization has been modified to accept patients who remain undiagnosed after three outpatient visits or 3 days of hospitalization.

Several additional categories of FUO have been added: (1) Nosocomial FUO refers to the hospitalized patient with fever of 38.3°C or higher on several occasions, due to a process not present or incubating at the time of admission, in whom initial cultures are negative and the diagnosis remains unknown after 3 days of investigation (see Nosocomial Infections, below). (2) Neutropenic FUO includes patients with fever of 38.3°C or higher on several occasions with less than 500 neutrophils per milliliter in whom initial cultures are negative and the diagnosis remains uncertain after 3 days (see [Chapter 4](#) and Infections in the Immunocompromised Patient, below). (3) HIV-associated FUO pertains to HIV-positive patients with fever of 38.3°C or higher who have been febrile for 4 weeks or more as an outpatient or 3 days as an inpatient, in whom the diagnosis remains uncertain after 3 days of investigation with at least 2 days for cultures to incubate (see [Chapter 31](#)). Although not usually considered separately, FUO in solid organ transplant recipients is a common scenario with a unique differential diagnosis and is discussed below.

For a general discussion of fever, see the section on fever and hyperthermia in [Chapter 1](#).

Etiologic Considerations

A. Common Causes

Most cases represent unusual manifestations of common diseases and not rare or exotic diseases—eg, tuberculosis, endocarditis, gallbladder disease, and HIV (primary infection or opportunistic infection) are more common causes of FUO than Whipple's disease or familial Mediterranean fever.

B. Age of Patient

In adults, infections (25-40% of cases) and cancer (25-40% of cases) account for the majority of FUOs. In children, infections are the most common cause of FUO (30-50% of cases) and cancer a rare cause (5-10% of cases). Autoimmune disorders occur with equal frequency in adults and children (10-20% of cases), but the diseases differ. Juvenile rheumatoid arthritis is particularly common in children, whereas systemic lupus erythematosus, Wegener's granulomatosis, and polyarteritis nodosa are more common in adults. Adult Still's disease, giant cell arteritis, and polymyalgia rheumatica occur exclusively in adults. In the elderly (over 65 years of age), multisystem immune-mediated diseases such as temporal arteritis, polymyalgia rheumatica, sarcoidosis, rheumatoid arthritis, and Wegener's granulomatosis account for 25-30% of all FUOs.

C. Duration of Fever

The cause of FUO changes dramatically in patients who have been febrile for 6 months or longer. Infection, cancer, and autoimmune disorders combined account for only 20% of FUOs in these patients. Instead, other entities such as granulomatous diseases (granulomatous hepatitis, Crohn's disease, ulcerative colitis) and factitious fever become important causes. One-fourth of patients who say they have been febrile for 6 months or longer actually have no true fever or underlying disease. Instead, the usual normal circadian variation in temperature (temperature 0.5-1°C higher in the afternoon than in the morning) is interpreted as abnormal. Patients with episodic or recurrent fever (ie, those who meet the criteria for FUO but have fever-free periods of 2 weeks or longer) are similar to those with prolonged fever. Infection, malignancy, and autoimmune disorders account for only 20-25% of such fevers, whereas various miscellaneous diseases (Crohn's disease, familial Mediterranean fever, allergic alveolitis) account for another 25%. Approximately 50% remain undiagnosed but have a benign course with eventual resolution of symptoms.

D. Immunologic Status

In the neutropenic patient, fungal infections and occult bacterial infection are important causes of FUO. In the patient taking immunosuppressive medications (particularly organ transplant patients), cytomegalovirus infections are a frequent cause of fever, as are fungal infections, nocardiosis, *Pneumocystis jiroveci* (formerly *P. carinii*) pneumonia, and mycobacterial infections.

E. Classification of Causes of FUO

Most patients with FUO will fit into one of five categories.

1. Infection—Both systemic and localized infections can cause FUO. Tuberculosis and endocarditis are the most common systemic infections, but mycoses, viral diseases (particularly infection with Epstein-Barr virus and cytomegalovirus), toxoplasmosis, brucellosis, Q fever, cat-scratch disease, salmonellosis, malaria, and many other less common infections have been implicated. Primary infection with human immunodeficiency virus (HIV) or opportunistic infections associated with the acquired immunodeficiency syndrome (AIDS)—particularly mycobacterial infections—can also present as FUO. The most common form of localized infection causing FUO is an occult abscess. Liver, spleen, kidney, brain, and bone are organs in which abscess may be difficult to find. A collection of pus may form in the peritoneal cavity or in the subdiaphragmatic, subhepatic, paracolic, or other areas. Cholangitis, osteomyelitis, urinary tract infection, dental abscess, or paranasal sinusitis may cause prolonged fever.

2. Neoplasms—Many cancers can present as FUO. The most common are lymphoma (both Hodgkin's and non-Hodgkin's) and leukemia. Other diseases of lymph nodes, such as angioimmunoblastic lymphoma and Castleman's disease, can also cause FUO. Primary and metastatic tumors of the liver are frequently associated with fever, as are renal cell carcinomas. Atrial myxoma is an often forgotten neoplasm that can result in fever. Chronic lymphocytic leukemia and multiple myeloma are rarely associated with fever, and the presence of fever in patients with these diseases should prompt a search for infection.

3. Autoimmune disorders—Still's disease, systemic lupus erythematosus, cryoglobulinemia, and polyarteritis nodosa are the most common autoimmune causes of FUO. Giant cell arteritis and polymyalgia rheumatica are seen almost exclusively in patients over 50 years of age and are nearly always associated with an elevated erythrocyte sedimentation rate (> 40 mm/h).

4. Miscellaneous causes—Many other conditions have been associated with FUO but less commonly than the foregoing types of illness. Examples include thyroiditis, sarcoidosis, Whipple's disease, familial Mediterranean fever, recurrent pulmonary emboli, alcoholic hepatitis, drug fever, and factitious fever.

5. Undiagnosed FUO—Despite extensive evaluation, in 10-15% of patients the diagnosis remains elusive. In about three-fourths of these patients, the fever abates spontaneously and the clinician never knows the cause; in the remainder, more classic manifestations of the underlying disease appear over time.

Approach to Diagnosis of FUO

Because the evaluation of a patient with FUO is costly and time-consuming, it is imperative to first document the presence of fever. This is done by observing the patient while the temperature is being taken to ascertain that fever is not factitious (self-induced). Associated findings that accompany fever include tachycardia, chills, and piloerection. A thorough history—including family, occupational, social (sexual practices, use of intravenous drugs), dietary (unpasteurized products, raw meat), exposures (animals, chemicals), and travel—may give clues to the diagnosis. Repeated physical examination may reveal subtle, evanescent clinical findings essential to diagnosis.

In addition to routine laboratory studies, blood cultures should always be obtained, preferably when the patient has been off antibiotics for several days, and should be held by the laboratory for 2 weeks to detect slow-growing organisms. Cultures on special media are requested if legionella, bartonella, or nutritionally deficient streptococci are considered possible pathogens. "Screening tests" with immunologic or microbiologic serologies ("febrile agglutinins") are of low yield and should not be done. Specific serologic tests are helpful if the history or physical examination suggests a specific diagnosis. A single elevated titer rarely allows one to make a diagnosis of infection; instead, one must demonstrate a fourfold rise or fall in titer to confirm a specific infectious cause. Because infection is the most common cause of FUO, other body fluids are usually cultured, ie, urine, sputum, stool, cerebrospinal fluid, and morning gastric aspirates (if one suspects tuberculosis). Direct examination of blood smears may establish a diagnosis of malaria or relapsing fever (borrelia).

All patients with FUO should have a chest radiograph. Studies such as sinus films, upper gastrointestinal series with small bowel follow-through, barium enema, proctosigmoidoscopy, and evaluation of gallbladder function are reserved for patients who have symptoms, signs, or a history that suggest disease in these body

regions. CT scan of the abdomen and pelvis is also frequently performed and is particularly useful for looking at the liver, spleen, and retroperitoneum. When the CT scan is positive, the findings often lead to a specific diagnosis. A negative CT scan is not quite as useful; more invasive procedures such as biopsy or exploratory laparotomy may be needed. The role of MRI in the investigation of FUO has not been evaluated. In general, however, MRI is better than CT for detecting lesions of the nervous system. Ultrasound is sensitive for detecting lesions of the kidney, pancreas, and biliary tree. Echocardiography should be used if one is considering endocarditis or atrial myxoma. Transesophageal echocardiography is more sensitive than surface echocardiography for detecting valvular lesions, but even a negative transesophageal study does not exclude endocarditis (10% false-negative rate). The usefulness of radionuclide studies has not been extensively studied in FUO. Theoretically, a gallium scan would be more helpful than an indium-labeled white blood cell scan, because gallium is useful for detecting infection and neoplasm whereas the indium scan is useful only for detecting infection. Indium-labeled immunoglobulin may prove to be useful in detecting infection and neoplasm and can be used in the neutropenic patient. It is not sensitive for lesions of the liver, kidney, and heart because of high background activity. Positron emission tomography (PET scan) may prove useful in diagnosis. In general, radionuclide scans are plagued by high rates of false-positive and false-negative results that are not useful when used as screening tests and, if done at all, are limited to those patients whose history or examination suggests local inflammation or infection.

Invasive procedures are often required for diagnosis. Any abnormal finding should be aggressively evaluated: Headache calls for lumbar puncture to rule out meningitis; skin from a rash should be biopsied to look for cutaneous manifestations of collagen vascular disease or infection; and enlarged lymph nodes should be aspirated or biopsied and examined for cytologic features to rule out neoplasm and sent for culture. Bone marrow aspiration with biopsy is a relatively low-yield procedure (except in HIV-positive patients, in whom mycobacterial infection is a common cause of FUO), but the risk is low and the procedure should be done if other less invasive tests have not yielded a diagnosis. Liver biopsy will yield a specific diagnosis in 10-15% of patients with FUO. One considers in any patient with abnormal liver function tests even if the liver is normal in size. The role of exploratory laparotomy is debatable since the advent of CT scanning and MRI. One should consider laparotomy or laparoscopy in the deteriorating patient if the diagnosis is elusive despite extensive evaluation.

Therapeutic Trials

Therapeutic trials are indicated if a diagnosis is strongly suspected—eg, it is reasonable to give antituberculous drugs if one suspects tuberculosis, or tetracycline if brucellosis is suspected. However, if there is no clinical response in several weeks, it is imperative to stop therapy and reevaluate the patient. In the seriously ill or rapidly deteriorating patient, empirical therapy is often given. Antituberculosis medications (particularly in the elderly or foreign-born) and broad-spectrum antibiotics are reasonable in this setting.

Empirical administration of corticosteroids should be discouraged; they can suppress fever if given in high enough doses, but they can also exacerbate many infections, and infection remains a leading cause of FUO.

INFECTIONS IN THE IMMUNOCOMPROMISED PATIENT

A description of the cellular basis of immune response, the role of various host responses in maintaining health, and the methods used for detection of deficiencies in the immune system can be found in [Chapter 19](#).

Compromised hosts are individuals who have one or more defects in their natural defense mechanisms that put them at an increased risk of developing infections. Not only is the risk of infection greater in these individuals, but once established it is often severe, rapidly progressive, and life-threatening. In addition, microorganisms not usually pathogens in the noncompromised patient may cause serious disease in the compromised patient. Individuals are most commonly so impaired because of dysfunction of their immune system (granulocytopenia, T and B cell deficiency, hypogammaglobulinemia), but the presence of coexisting illness can also predispose to infection.

Granulocytopenia is common following bone marrow transplantation—as a result of myelosuppressive chemotherapy—and in acute leukemias. The risk of infection begins to increase when the absolute granulocyte count falls below 1000/uL, with a dramatic increase in frequency and severity when the granulocyte count falls below 100/uL. The granulocytopenic patient is particularly susceptible to infections with gram-negative enteric organisms, pseudomonas, gram-positive cocci (particularly *Staphylococcus aureus*, *Staphylococcus epidermidis*, and viridans streptococci), candida, aspergillus, and other fungi that have recently emerged as pathogens such as trichosporon, scedosporium, fusarium, and pseudallescheria.

Defects in humoral immunity are often congenital, though hypogammaglobulinemia can occur in multiple myeloma and chronic lymphocytic leukemia. Patients with ineffective humoral immunity lack opsonizing antibodies and are at particular risk of infection with encapsulated organisms such as *Haemophilus influenzae* and *Streptococcus pneumoniae*.

Patients with cellular immune deficiency encompass a large and heterogeneous group, including patients with HIV infection (see [Chapter 31](#)), those with lymphoreticular malignancies such as Hodgkin's disease, and patients receiving immunosuppressive medications such as corticosteroids, cyclosporine, tacrolimus, and other cytotoxic drugs. This latter group—the immunosuppressed as a result of medications—includes transplant patients, many solid tumor patients receiving therapy, and patients receiving prolonged high-dose corticosteroid treatment (for asthma, temporal arteritis, systemic lupus, etc). Patients with cellular immune dysfunction are susceptible to infections by a large number of organisms, particularly ones that replicate intracellularly. Examples include bacteria such as listeria, legionella, salmonella, and mycobacterium; viruses such as herpes simplex, varicella, and cytomegalovirus; fungi such as cryptococcus, coccidioides, histoplasma, and pneumocystis; and protozoa such as toxoplasma.

Patients functionally or anatomically asplenic fail to clear organisms from the bloodstream and are at an increased risk of overwhelming bacteremia with encapsulated bacteria (primarily *S pneumoniae* but also *H influenzae* and *Neisseria meningitidis*).

Finally, a large group of patients who are not specifically immunodeficient are at increased risk of infection because of debilitating injury (eg, burns or severe trauma), invasive procedures (eg, hyperalimentation lines, Foley catheters, dialysis catheters), central nervous system dysfunction (which predisposes to aspiration pneumonia and decubitus ulcers), obstructing lesions (eg, pneumonia due to an obstructed bronchus, pyelonephritis due to nephrolithiasis, cholangitis secondary to cholelithiasis), and use of broad-spectrum antibiotics.

Despite these generalizations, any pathogen can cause infection in any immunosuppressed patient at any time. Thus, a systematic evaluation to identify a specific organism is required.

Organisms not usually pathogens in the noncompromised host may cause serious life-threatening infection in the compromised patient (eg, *S epidermidis*, *Corynebacterium jeikeium*, *Propionibacterium acnes*, *Bacillus* species). Therefore, one must interpret culture results with caution and not disregard isolates as mere contaminants. A contaminating organism in an immunocompetent individual may be a pathogen in an immunocompromised one.

Approach to Diagnosis

Not all fevers are due to infection. Transplant rejection, organ ischemia and necrosis, thrombophlebitis, and lymphoma (posttransplant lymphoproliferative disease) may all present as fever and must be considered in the differential diagnosis.

Because infections in the immunocompromised patient can be rapidly progressive and life-threatening, diagnostic procedures must be done promptly, and empirical therapy is usually instituted before a specific diagnostic agent has been isolated:

(1) Routine evaluation includes complete blood count with differential, chest x-ray, and blood cultures; urine and sputum cultures should be obtained if indicated clinically or radiographically. Any focal complaints (localized pain, headache, rash) should prompt imaging and cultures appropriate to the site.

(2) Patients who remain febrile without an obvious source should be evaluated for viral infection (cytomegalovirus blood cultures or antigen test), abscesses (which usually occur near previous operative sites), candidiasis involving the liver or spleen, or aspergillosis. Serologic evaluation may be helpful if toxoplasmosis is a possible pathogen.

(3) One also considers special diagnostic procedures. The cause of pulmonary infiltrates can be easily determined with simple techniques in some situations—eg, induced sputum yields a diagnosis of pneumocystis pneumonia in 50-80% of AIDS patients with this infection. In other situations, more invasive procedures may be required (bronchoalveolar lavage, transbronchial biopsy, or even open lung biopsy). Other investigations such as skin, liver, or bone marrow biopsy may be helpful in establishing a diagnosis.

(4) In patients who have undergone solid organ transplants, immediate postoperative infections often involve the transplanted organ. Following lung transplantation, pneumonia and mediastinitis are particularly common; following liver transplantation, intra-abdominal abscess, cholangitis, and peritonitis; after renal transplantation,

urinary tract infections, perinephric abscesses, and infected lymphoceles. In contrast to solid organ transplants, in bone marrow transplant patients the source of fever cannot be found in 60-70% of patients.

(5) The time of occurrence of infection, particularly following solid organ transplantation, can be helpful in determining the infectious origin. Most infections that occur in the first 2-4 weeks posttransplant are related to the operative procedure and to hospitalization itself (wound infection, intravenous catheter infection, urinary tract infection from a Foley catheter) or are related to the transplanted organ (see paragraph [4], above). Infections that occur between the first and sixth months are often related to immunosuppression. During this period, reactivation of viruses occurs, and herpes simplex, varicella-zoster, and CMV infections are quite common. Opportunistic infections with fungi (candida, aspergillus, cryptococcus, pneumocystis, and others), *Listeria monocytogenes*, nocardia, and toxoplasma are also common. After 6 months, when immunosuppression has been reduced to maintenance levels, infections that are found in any population occur.

Prevention of Infection

There is great interest in preventing infection with prophylactic antimicrobial regimens but no uniformity of opinion about optimal drugs or dosage regimens.

Trimethoprim-sulfamethoxazole (TMP-SMZ), one double-strength tablet three times a week, one double-strength tablet twice daily on weekends, or one single-strength tablet daily for 3-6 months, is frequently used to prevent pneumocystis infections in transplant patients. It may also decrease the incidence of bacterial pneumonia, urinary tract infections, nocardia infections, and toxoplasmosis. In patients allergic to trimethoprim-sulfamethoxazole, aerosolized pentamidine is used in a dosage of 300 mg once a month, as is dapsone, 50 mg daily or 100 mg three times weekly. (G6PD levels should be determined before therapy with the latter is instituted.) Acyclovir prevents herpes simplex infections in bone marrow and solid organ transplant recipients and is given to seropositive patient who are not receiving acyclovir or ganciclovir for CMV prophylaxis. The usual dose is 200 mg orally three times daily for 4 weeks (bone marrow transplants) to 12 weeks (other solid organ transplants).

Prevention of CMV is more difficult, and no uniformly accepted approach has been adopted. Prevention strategies often depend on the serologic status of the donor and recipient and the organ transplanted, which determines the level of immunosuppression after transplant. In solid organ transplants (liver, kidney, heart, lung), the greatest risk of developing CMV disease is in seronegative patients who receive organs from seropositive donors. These high-risk patients usually receive ganciclovir, 2.5-5 mg/kg intravenously twice daily, during hospitalization (usually about 10 days) and then are placed on a regimen of oral ganciclovir, 1 g three times daily, for 3 months. Other solid organ transplant recipients (seropositive recipients) are at lower risk for developing CMV disease and usually receive intravenous ganciclovir while in the hospital followed by either high-dose oral acyclovir at a dosage of 800 mg four times daily or oral ganciclovir for 3 months. Both ganciclovir and acyclovir prevent herpesvirus reactivation. Because immunosuppression is increased during periods of rejection, patients treated for rejection usually receive intravenous ganciclovir during rejection therapy.

Recipients of bone marrow transplants are more severely immunosuppressed than recipients of solid organ transplants, are at greater risk for developing serious CMV infection, and thus usually receive more aggressive prophylaxis. Two approaches have been used: universal prophylaxis or preemptive therapy. In the former, all high-risk patients (seropositive patients who receive allogeneic transplants) receive 5 mg/kg of intravenous ganciclovir every 12 hours for a week, followed by oral ganciclovir, 1 g three times daily to day 100. This method is costly and associated with significant toxicity and is therefore being used less frequently. Alternatively, patients can be followed without specific therapy and have blood sampled weekly for the presence of CMV. If CMV is detected by an antigenemia assay, preemptive therapy with ganciclovir is given (5 mg/kg intravenously twice daily for 7-14 days, followed by oral ganciclovir). This approach is effective but does miss a small number of patients who subsequently develop CMV disease. Other preventive strategies include use of CMV-negative or leukocyte-depleted blood products for CMV-seronegative recipients.

Routine decontamination of the gastrointestinal tract to prevent bacteremia in the neutropenic patient is not recommended. Prophylactic administration of antibiotics in the afebrile, asymptomatic neutropenic patient is controversial, though many centers have adopted this strategy. Rates of bacteremia are decreased, but overall mortality is not affected and emergence of resistant organisms is a common problem. Use of intravenous immunoglobulin is reserved for the small number of patients with severe hypogammaglobulinemia following bone marrow transplantation and should not be routinely administered to all transplant patients.

Prophylaxis with antifungal agents to prevent invasive mold (primarily aspergillus) and yeast (primarily candida) infections is routinely used, but the optimal agent, dose, and duration have not been standardized. Moderate-dose (0.5 mg/kg/d) and low-dose (0.1-0.25 mg/kg/d) amphotericin B, liposomal preparations of amphotericin B, aerosolized amphotericin B, and itraconazole (capsules and solution) have all been used with varying success in the neutropenic patient. Because voriconazole appears to be more effective than amphotericin for documented aspergillus infections, one approach to prophylaxis is to use fluconazole for patients at low risk for developing fungal infections (those who receive autologous bone marrow transplants) and voriconazole for those at high risk (allogeneic transplants). In solid organ transplant recipients, the risk of invasive fungal infection varies considerably (1-2% in liver, pancreas, and kidney transplants and 6-8% in heart and lung transplants). Whether universal prophylaxis or observation with preemptive therapy is the best approach has not been determined. Although fluconazole is effective in preventing yeast infections, emergence of resistant strains of *Candida krusei*, other *Candida* species, and molds (*fusarium*, *aspergillus*, *mucor*) has raised concerns about its routine use as a prophylactic agent.

Hand washing is the simplest and most effective means of decreasing nosocomial infections in *all* patients, especially the compromised host. Invasive devices such as central and peripheral lines and Foley catheters are a potential source of infection.

Approach to Treatment

Reduction or discontinuation of immunosuppressive medication may jeopardize the viability of the transplanted organ, but in life-threatening infections it is necessary as an adjunct to effective antimicrobial therapy. Hematopoietic growth factors (granulocyte and granulocyte-macrophage colony-stimulating factors) stimulate proliferation of bone marrow stem cells, resulting in an increase in peripheral leukocytes. These agents shorten the period of neutropenia and have been associated with fewer infections. Use of growth factors in patients with prolonged neutropenia (> 7 days) is an effective means of reversing immunosuppression.

Antimicrobial drug therapy is rationally based on culture results (see [Chapter 37](#)). Therapy should be specific for isolated pathogens, and bactericidal agents should be used. Combinations of antimicrobials are often required to provide synergy, to prevent resistance, or to serve as broad-spectrum coverage of multiple pathogens (since infections in these patients are often polymicrobial).

Empirical therapy is often instituted at the earliest sign of infection in the immunosuppressed patient because prompt therapy favorably affects outcome. The antibiotic or combination of antibiotics used depends on the type of immunocompromise and the site of infection. For example, in the febrile neutropenic patient, one is concerned primarily about bacterial and fungal infections. Often in this patient population an algorithmic approach to therapy is used, with initial treatment directed at gram-positive and gram-negative organisms. If the patient fails to respond, broader-spectrum antibiotics and antifungal drugs are added. Although a number of different agents can be used, choices should be based on local microbiologic trends. One example would be to initiate therapy with a fluoroquinolone active against gram-positive organisms (such as levofloxacin, gatifloxacin, or moxifloxacin) when the absolute neutrophil count falls below 500/uL. If fever develops, cultures are obtained and vancomycin, 10-15 mg/kg every 12 hours, is given (to cover methicillin-resistant *S aureus*, *S epidermidis*, and enterococcus). If after 48-72 hours fever continues, antifungal coverage can be increased by changing to voriconazole, 200 mg twice daily (if the patient was on fluconazole prophylaxis), and broader-spectrum antibiotics can be added sequentially. For example, to better cover acinetobacter, citrobacter, and pseudomonas, the fluoroquinolone may be switched to cefipime, 2 g every 8 hours intravenously; with continued fever, imipenem, 500 mg every 6 hours (or meropenem, 1 g every 8 hours), with or without tobramycin, 1.8 mg/kg every 8 hours, may be used in place of cefipime. If fevers persist, trimethoprim-sulfamethoxazole at 10 mg/kg/d (of trimethoprim) in three divided doses can be added to cover *stenotrophomonas*. Regardless of whether the patient becomes afebrile, therapy is continued until resolution of neutropenia. Failure to continue antibiotics through the period of neutropenia is associated with a high incidence of relapse that can be associated with septic shock. Patients with fever and neutropenia who are at low risk for developing complications (neutropenia expected to persist for less than 10 days, no comorbid complications requiring hospitalization, and cancer adequately treated) can be treated with oral antibiotic regimens (ciprofloxacin, 750 mg every 12 hours, plus amoxicillin-clavulanic acid, 500 mg every 8 hours). In the organ transplant patient with interstitial infiltrates, one is concerned mainly about *Pneumocystis* or *Legionella* species, so that empirical treatment with a macrolide and trimethoprim-sulfamethoxazole would be reasonable. If the patient fails to respond to empirical treatment, one must often decide between empirical addition of more antimicrobial agents or undertaking invasive procedures (see above) to make a specific diagnosis. By making a specific diagnosis, therapy can be specific and polypharmacy with multiple potentially toxic agents avoided.

NOSOCOMIAL INFECTIONS

Nosocomial infections are by definition those acquired during the course of hospitalization. In the United States, approximately 5% of patients who enter the hospital free of infection acquire a nosocomial infection resulting in prolongation of the hospital stay, increase in cost of care, significant morbidity, and a 5% mortality rate. Although most such fevers are due to infections, about 25% of patients will have fever of noninfectious origin. Causes include drug fever, nonspecific postoperative fevers (atelectasis, tissue damage or necrosis), hematoma, pancreatitis, pulmonary embolus, myocardial infarction, and ischemic bowel disease. The most common infections are urinary tract infections, usually associated with Foley catheters or urologic procedures; bloodstream infections, most commonly from indwelling catheters but also from secondary sites such as surgical wounds, abscesses, pneumonia, the genitourinary tract, and the gastrointestinal tract; pneumonia in intubated patients or those with altered levels of consciousness; surgical wound infections; and *C difficile* colitis.

Some general principles are helpful in preventing, diagnosing, and treating nosocomial infections:

(1) Many infections are a direct result of the use of invasive devices for monitoring or therapy such as intravenous catheters, Foley catheters, shunts, surgical drains, catheters placed by interventional radiology for drainage, nasogastric tubes and orotracheal or nasotracheal tubes for ventilatory support. Early removal reduces the possibility of infection.

(2) Patients who develop nosocomial infections are often critically ill, have been hospitalized for extended periods, and have received several courses of broad-spectrum antibiotic therapy. As a result, nosocomial infections are often caused by organisms that are multidrug-resistant and are different from those encountered in community-acquired infections. Examples are *S aureus* and *S epidermidis* (a frequent cause of prosthetic device infection) that may be resistant to nafcillin and cephalosporins and require vancomycin for therapy; *Enterococcus faecium* resistant to ampicillin and vancomycin; gram-negative infections caused by pseudomonas, citrobacter, enterobacter, acinetobacter, and stenotrophomonas, which may be sensitive only to fluoroquinolones, carbapenems, aminoglycosides, or trimethoprim-sulfamethoxazole. When choosing antibiotics to treat the seriously ill patient with a nosocomial infection, one must consider the previous antimicrobial the patient has received as well as the "local ecology." It is often necessary to institute therapy with vancomycin, a carbapenem, an aminoglycoside, or a fluoroquinolone until a specific agent is isolated and sensitivities are known, at which time the least toxic and most cost-effective drug can be used.

One promising approach to preventing the development of multidrug-resistant organisms is antibiotic cycling. By changing the class of antibiotic primarily used every 6-12 months (eg, a cephalosporin, then fluoroquinolones, then carbapenems), selection pressure is decreased and less resistance emerges.

Because widespread use of antimicrobial drugs contributes to the selection of drug-resistant organisms that cause nosocomial infections, every effort should be made to limit the use of antibiotics to treat documented infections. All too often, unreliable or uninterpretable specimens are obtained for culture that result in unnecessary use of antibiotics. The best example of this principle is the diagnosis of line-related or bloodstream infection in the febrile patient. Blood cultures from unidentified sites, a single blood culture from any site, or a blood culture through an existing line will often be positive for *S epidermidis* and will result in therapy with vancomycin. The likelihood that such a culture represents a true bacteremia is 10-20%. Unless two separate venipuncture cultures are obtained—*not* through catheters—interpretation of results is impossible and unnecessary therapy is given. Every such "pseudobacteremia" increases laboratory costs, antibiotic use, and length of stay and increases costs of hospitalization by about \$4500. To avoid unnecessary use of antibiotics, thoughtful consideration of culture results is mandatory. A positive wound culture without signs of inflammation or infection, a positive sputum culture without pulmonary infiltrates on chest x-ray, or a positive urine culture in a catheterized patient without signs or symptoms of pyelonephritis are all likely to represent colonization, not infection.

Prevention is of paramount importance in controlling nosocomial infections. The concept of universal precautions emphasizes that all patients are treated as though they have a potential blood-borne transmissible disease, and thus all body secretions are handled with care to prevent spread of disease. Almost all hospitals have implemented body substance isolation, which requires use of gloves whenever a health care worker anticipates contact with blood or other body secretions. The use of gloves is intended to prevent contamination of the hands of health care workers with infected secretions and subsequent spread of infection to other patients by direct contact. Hand washing is the easiest and most effective means of preventing nosocomial infections and should be done routinely even when gloves are utilized. Peripheral intravenous lines should be replaced every 3 days and arterial lines every 4 days. Lines in the central venous circulation (including those placed peripherally) can be left in indefinitely and are changed or removed when they are clinically suspected of being infected, when they are nonfunctional, or when they are no longer needed. Silver alloy-impregnated Foley catheters reduce the incidence of catheter-associated bacteriuria, and antibiotic-impregnated (minocycline plus rifampin or chlorhexidine plus silver sulfadiazine) venous catheters reduce line infections and bacteremia. Whether the increased cost of these devices justifies their routine use should be determined by individual institutions based on local infection rates. Selective decontamination of the digestive tract with nonabsorbable antibiotics to prevent nosocomial pneumonia is widely used in Europe, but the therapeutic efficacy of this expensive intervention is controversial. Attentive nursing care (positioning to prevent decubitus ulcers, wound care, elevating the head during tube feedings to prevent aspiration) is critical in preventing nosocomial infections. In addition, monitoring of high-risk areas by hospital epidemiologists detects increases in infection rates early and is a key factor in prevention of these types of infections.

Several highly efficacious vaccines have been approved by the FDA that add to our armamentarium for prevention of certain nosocomial infections. Hepatitis A, hepatitis B, and the varicella vaccine should be considered in the appropriate setting. (See section below on Immunization Against Infectious Diseases.)

INFECTIONS OF THE CENTRAL NERVOUS SYSTEM

Infections of the central nervous system can be caused by almost any infectious agent, including bacteria, mycobacteria, fungi, spirochetes, protozoa, helminths, and viruses. Certain symptoms and signs are common to all types of central nervous system infection: headache, fever, sensorial disturbances, neck and back stiffness, positive Kernig and Brudzinski signs, and cerebrospinal fluid abnormalities. Although it is rare for all of these manifestations to be present in any one individual, the presence of even one should suggest the possibility of a central nervous system infection.

Central nervous system infection is a medical emergency. Immediate diagnostic steps must be instituted to establish the specific cause. Normally, these include the history, physical examination, blood count, blood culture, lumbar puncture followed by careful study and culture of the cerebrospinal fluid, and a chest film. The fluid must be examined for cell count, glucose, and protein, and a smear stained for bacteria (and acid-fast organisms when appropriate) and cultured for pyogenic organisms and for mycobacteria and fungi when indicated. Latex agglutination tests can detect antigens of encapsulated organisms (*S pneumoniae*, *H influenzae*, *N meningitidis*, and *Cryptococcus neoformans*) but are rarely used except for detection of cryptococcus or in partially treated patients. Polymerase chain reaction (PCR) testing of cerebrospinal fluid has been employed to detect bacteria (*S pneumoniae*, *H influenzae*, *N meningitidis*, *Mycobacterium tuberculosis*, *Borrelia burgdorferi*, and *Tropheryma whippelii*) and viruses (herpes simplex, varicella-zoster, cytomegalovirus, Epstein-Barr virus, and enteroviruses) in patients with meningitis. The greatest experience is with PCR for herpes simplex and varicella-zoster, and the tests are very sensitive (> 95%) and specific. Tests to detect the other organisms may not be any more sensitive than culture, but the real value is the rapidity with which results are available, ie, hours compared with days or weeks. At present, with the exception of PCR for herpes simplex, these tests are performed only in reference laboratories. Although it is difficult to prove with existing clinical data that early antibiotic therapy improves outcome in bacterial meningitis, prompt therapy is still recommended.

Since performing a lumbar puncture in the presence of a space-occupying lesion (brain abscess, subdural hematoma, subdural abscess) may result in brain stem herniation, a CT scan is performed prior to lumbar puncture if a space-occupying lesion is suspected on the basis of papilledema, coma, seizures, or focal neurologic findings. If delays are encountered in obtaining a CT scan and bacterial meningitis is suspected, blood cultures should be drawn and antibiotics and corticosteroids administered even before cerebrospinal fluid is obtained for culture to avoid delay in treatment (Table 30-1). Antibiotics given within 4 hours before obtaining cerebrospinal fluid probably do not affect culture results.

Etiologic Classification

Central nervous system infections can be divided into several categories that usually can be readily distinguished from each other by cerebrospinal fluid examination as the first step toward etiologic diagnosis (Table 30-2).

A. Purulent Meningitis

Patients with bacterial meningitis usually present acutely within hours or 1-2 days after onset of symptoms. The organisms responsible depend primarily on the age of the patient as summarized in Table 30-1. The diagnosis is usually based on the Gram-stained smear (positive in 60-80%) or culture (positive in over 90%).

B. Chronic Meningitis

Patients with chronic meningitis present less acutely with a history of symptoms lasting weeks to months. The most common pathogens are *Mycobacterium*

tuberculosis, atypical mycobacteria, fungi (cryptococcus, coccidioides, histoplasma), and spirochetes (*Treponema pallidum* and *Borrelia burgdorferi*, the cause of Lyme disease). The diagnosis is made by culture or in some cases by serologic tests (cryptococcosis, coccidioidomycosis, syphilis, Lyme disease).

C. Aseptic Meningitis

Aseptic meningitis—a much more benign and self-limited syndrome than purulent meningitis—is caused principally by viruses, especially mumps virus and the enterovirus group (including coxsackieviruses and echoviruses). Infectious mononucleosis may be accompanied by aseptic meningitis. Leptospiral infection is also usually placed in the aseptic group because of the lymphocytic cellular response and its relatively benign course. This type of meningitis also occurs during secondary syphilis and stage 2 Lyme disease.

D. Encephalitis

Encephalitis (due to herpesviruses, arboviruses, rabies virus, flaviviruses [West Nile encephalitis, Japanese encephalitis], and many others) produces disturbances of the sensorium, seizures, and many other manifestations. Patients are more ill than those with aseptic meningitis. Cerebrospinal fluid may be entirely normal or may show some lymphocytes and in some instances (eg, herpes simplex) red cells as well.

E. Partially Treated Bacterial Meningitis

Previous effective antibiotic therapy given for 12-24 hours will decrease the rate of positive Gram stain results by 20% and culture by 30-40% but will have little effect on cell count, protein, or glucose. Occasionally, previous antibiotic therapy will change a predominantly polymorphonuclear response to a lymphocytic pleocytosis, and some of the cerebrospinal fluid findings may be similar to those seen in aseptic meningitis.

F. Neighborhood Reaction

As noted in [Table 30-2](#), this term denotes a purulent infectious process in close proximity to the central nervous system that spills some of the products of the inflammatory process—white blood cells or protein—into the cerebrospinal fluid. Such an infection might be a brain abscess, osteomyelitis of the vertebrae, epidural abscess, subdural empyema, or bacterial sinusitis or mastoiditis.

G. Noninfectious Meningeal Irritation

Carcinomatous meningitis, sarcoidosis, systemic lupus erythematosus, chemical meningitis, and certain drugs—NSAIDs, muromonab-CD3 (OKT3), trimethoprim-sulfamethoxazole, and others—can also produce symptoms and signs of meningeal irritation with associated cerebrospinal fluid pleocytosis, increased protein, and low or normal glucose. Meningismus with normal cerebrospinal fluid findings occurs in the presence of other infections such as pneumonia and shigellosis.

H. Brain Abscess

Brain abscess presents as a space-occupying lesion; symptoms may include vomiting, fever, change of mental status, or focal neurologic manifestations. When brain abscess is suspected, a CT scan should be performed. If positive, lumbar puncture should *not* be performed since results rarely provide clinically useful information and herniation can occur. The bacteriology of brain abscess is usually polymicrobial and includes *S aureus*, gram-negative bacilli, streptococci, and anaerobes (including anaerobic streptococci and *Prevotella* species).

I. Amebic Meningoencephalitis

These infections are caused by free-living amebas and present as two distinct syndromes. The diagnosis is confirmed by culture or identification of the organism in cerebrospinal fluid or on biopsy specimens. No effective therapy is available.

Primary amebic meningoencephalitis is caused by *Naegleria fowleri* and is an acute fulminant disease characterized by signs of meningeal irritation that rapidly progresses to encephalitis and death. Rare cases have been reported with intravenous and intraventricular administration of amphotericin B.

Granulomatous amebic encephalitis is caused by *Acanthamoeba* species. It is an indolent disease characterized by headache, nausea, vomiting, cranial neuropathies, seizures, and hemiparesis.

Treatment

Increased intracranial pressure due to brain edema often requires therapeutic attention. Hyperventilation, mannitol (25-50 g as a bolus intravenous infusion), and even drainage of cerebrospinal fluid by repeated lumbar punctures or by placement of ventricular catheters have been employed to control cerebral edema and increased intracranial pressure. Dexamethasone (4 mg every 4-6 hours) may also decrease cerebral edema. In purulent meningitis, the identity of the causative microorganism may remain unknown or doubtful for a few days and initial antibiotic treatment as set forth in [Table 30-1](#) should be directed against the microorganisms most common for each age group.

The duration of therapy for bacterial meningitis varies depending upon the etiologic agent: *H influenzae*, 7 days; *N meningitidis*, 7 days; *S pneumoniae*, 10-14 days; *L monocytogenes*, 14-21 days; and gram-negative bacilli 21 days.

Dexamethasone therapy is standard in infants and children with meningitis and is now recommended for adults with pneumococcal meningitis. Ten milligrams of dexamethasone administered 15-20 minutes before or simultaneously with the first dose of antibiotics and continued every 6 hours for 4 days decreases morbidity and mortality. The number of patients with meningitis due to *N meningitidis* and other bacterial pathogens studied does not support similar conclusions. However, because adverse effects of dexamethasone for short periods are few and because potential benefits are great, many would advocate dexamethasone even if *N meningitidis* is the causative agent.

Therapy of brain abscess consists of drainage (excision or aspiration) in addition to 3-4 weeks of systemic antibiotics directed against organisms isolated. A regimen often used includes metronidazole, 500 mg intravenously or orally every 8 hours, plus ceftizoxime, 2 g intravenously every 8 hours, or ceftriaxone, 2 g every 12 hours. In cases where abscesses are less than 2 cm in size, where there are multiple abscesses that cannot be drained, or if an abscess is located in an area where significant neurologic sequelae would result from drainage, antibiotics for 6-8 weeks without drainage can be employed.

Therapy of other types of meningitis is discussed elsewhere in this book (fungal meningitis, [Chapter 36](#); syphilis and Lyme borreliosis, [Chapter 33](#); tuberculous meningitis, [Chapter 34](#); herpes encephalitis, [Chapter 32](#)).

ANIMAL & HUMAN BITE WOUNDS

About 900 dog bite injuries require emergency department attention each day, most often in urban areas. Dog bites occur most commonly in the summer months. Biting animals are usually known by their victims, and most biting incidents are provoked (ie, bites occur while playing with the animal or after surprising the animal or waking it abruptly from sleep). Failure to elicit a history of provocation is important, because an unprovoked attack raises the possibility of rabies. Human bites are usually inflicted by children while playing or fighting; in adults, bites are associated with alcohol use and closed-fist injuries that occur during fights.

The animal inflicting the bite, the location of the bite, and the type of injury inflicted are all important determinants of whether they become infected. Cat bites are more likely to become infected than human bites—between 30% and 50% of all cat bites become infected. Infections following human bites are variable: Those inflicted by children rarely become infected because they are superficial, and bites by adults become infected in 15-30% of cases, with a particularly high rate of infection in closed-fist injuries. Dog bites, for unclear reasons, become infected only 5% of the time. Bites of the head, face, and neck are less likely to become infected than bites on the extremities. Puncture wounds become infected more frequently than lacerations, probably because the latter are easier to irrigate and debride.

The bacteriology of bite infections depends upon the biting animal and when the infection occurs after the biting incident. Early infections (within 24 hours after the bite) following dog and cat bites are most frequently caused by *Pasteurella multocida*. These infections are characterized by rapid onset and progression, fevers, chills, cellulitis, and local adenopathy. Early infections following human bites are usually caused by mixed aerobic and anaerobic mouth flora and can produce a rapidly progressive necrotizing infection. Late infections (longer than 24 hours after the bite) are caused mainly by staphylococci, streptococci, and anaerobes (fusobacterium, bacteroides, prevotella), but innumerable organisms have been implicated. *Capnocytophaga canimorsus* (formerly called a DF2 organism), a gram-negative organism that is part of canine oral flora; *Eikenella corrodens*, another gram-negative organism that can be part of human mouth flora and has been recovered in up to 25% of infections following human bites; *Haemophilus* species, *Pseudomonas* species, and other gram-negative organisms—all have been implicated in bite infections.

There have been no documented cases of HIV transmission by human bites.

Treatment

A. Local Care

Vigorous cleansing and irrigation of the wound as well as debridement of necrotic material are the most important factors in decreasing the incidence of infections. X-rays should be obtained to look for fractures and the presence of foreign bodies. Careful examination to assess the extent of the injury (tendon laceration, joint space penetration) is critical to appropriate care.

B. Suturing

If wounds require closure for cosmetic or mechanical reasons, suturing can be done. However, one should never suture an infected wound, and wounds of the hand should generally not be sutured since a closed-space infection of the hand can result in loss of function.

C. Prophylactic Antibiotics

Prophylaxis is indicated in high-risk bites, eg, cat bites in any location (dicloxacillin, 0.5 g orally four times a day for 3-5 days) and hand bites by any animal or by humans (penicillin V, 0.5 g orally four times a day for 3-5 days). Despite this, there is concern about their use because of their narrow spectrum of activity. Based on the microbiology of bite wounds, other agents less adequately studied but that have broader spectrums of activity may be better as prophylactic agents. Examples include cefuroxime, amoxicillin-clavulanic acid, and, in the penicillin-allergic patient, clindamycin plus a fluoroquinolone. Immunocompromised patients and especially individuals without functional spleens are at risk for developing overwhelming bacteremia and sepsis following animal bites and should also receive prophylaxis, even for low-risk bites.

D. Antibiotics

For wounds that are infected, antibiotics are clearly indicated. How they are given (orally or intravenously) and the need for hospitalization are individualized clinical decisions. In general, *P multocida* is best treated with penicillin or a tetracycline. Other active agents include second- and third-generation cephalosporins, fluoroquinolones, or azithromycin and clarithromycin. Response to therapy is slow, and therapy should be continued for at least 2-3 weeks. Human bites frequently require intravenous therapy with a β -lactam plus a β -lactamase inhibitor combination (Unasyn, Timentin, Zosyn), a second-generation cephalosporin with anaerobic activity (cefoxitin, cefotetan, cefmetazole), or, in the penicillin-allergic patient, clindamycin plus a fluoroquinolone. Because the bacteriology of these infections is so variable, one should always culture infected wounds and adjust therapy appropriately, especially if the patient is not responding to initial empirical treatment.

E. Tetanus and Rabies

All patients must be evaluated for the need for tetanus (see [Chapter 33](#)) and rabies (see [Chapter 32](#)) prophylaxis.

SEXUALLY TRANSMITTED DISEASES

Some infectious diseases are transmitted most commonly—or most efficiently—by sexual contact. Most of the infectious agents that cause sexually transmitted diseases are fairly easily inactivated when exposed to a harsh environment. They are thus particularly suited to transmission by contact with mucous membranes. They may be bacteria, spirochetes, chlamydiae, viruses, or protozoa. In most infections caused by these agents, early lesions occur on genitalia or other sexually exposed mucous membranes; however, wide dissemination may occur, and involvement of nongenital tissues and organs may mimic many noninfectious disorders. All sexually transmitted diseases have subclinical or latent phases that play an important role in long-term persistence of the infection or in its transmission from infected (but largely asymptomatic) persons to other contacts. Laboratory examinations are of particular importance in the diagnosis of such asymptomatic patients. Simultaneous infection by several different agents is common, and any person with a sexually transmitted disease should be tested for syphilis; a repeat study should be done in 3 months if negative, since seroconversion is delayed after primary infection.

For each patient, there are one or more sexual contacts who require diagnosis and treatment. As a rule, sexual partners should be treated simultaneously to avoid prompt reinfection. The commonest sexually transmitted diseases are gonorrhea,* syphilis,* condyloma acuminatum, chlamydial genital infections, herpesvirus genital infections, trichomonas vaginitis, chancroid,* granuloma inguinale,* scabies, louse infestation, and bacterial vaginosis (among lesbians). However, shigellosis,* hepatitis A, B, and C,* amebiasis,* giardiasis, cryptosporidiosis, salmonellosis,* and campylobacteriosis may also be transmitted by sexual (oral-anal) contact, especially in homosexual males. Homosexual contact is a typical method of transmission of HIV, though bidirectional heterosexual transmission is occurring more commonly (see [Chapter 31](#)).

The risk of developing a sexually transmitted disease following a sexual assault has not been established. Victims of assault have a high baseline rate of infection (*N gonorrhoeae*, 6%, *C trachomatis*, 10%, *T vaginalis*, 15%, and bacterial vaginosis, 34%), and the risk of acquiring infection as a result of the assault is significant but is often lower than the preexisting rate (*N gonorrhoeae*, 6-12%, *C trachomatis*, 4-17%, *T vaginalis*, 12%, syphilis, 0.5-3%, and bacterial vaginosis, 19%). Victims should be evaluated within 24 hours after the assault, and cultures for *N gonorrhoeae* and *C trachomatis* (if culture is not available, nonculture tests, such as nucleic acid amplification tests, are acceptable. If the test is positive, it must be confirmed with a second test using a different target sequence). Vaginal secretions are cultured and examined for trichomonas. If a discharge is present, if there is itching, or if secretions are malodorous, a wet mount should be examined for candida and bacterial vaginosis. In addition, a blood sample should be obtained for immediate serologic testing for syphilis, hepatitis B, and HIV. Follow-up examination for sexually transmitted disease should be repeated within 1-2 weeks, since concentrations of infecting organisms may not have been sufficient to produce a positive culture at the time of initial examination. If prophylactic treatment was given (see below), tests should be repeated only if the victim has symptoms. If prophylaxis was not administered, the individual should be seen in 1 week so that any positive tests can be treated. Follow-up serologic testing for syphilis and HIV infection should be performed in 6, 12, and 24 weeks if the initial tests are negative. The usefulness of presumptive therapy is controversial, some feeling that all patients should receive it and others that it should be limited to those in whom follow-up cannot be ensured or to patients who request it. If therapy is given, a reasonable regimen would be hepatitis B vaccination (without hepatitis B immune globulin, the first dose given at the initial evaluation and follow-up doses at 1-2 months and 4-6 months) and one dose of ceftriaxone, 125 mg intramuscularly, plus metronidazole, 2 g orally as a single dose, plus doxycycline, 100 mg orally twice daily for 7 days, or azithromycin, 1 g orally as a single dose. In premenopausal women, azithromycin should be used instead of doxycycline until the pregnancy status is determined; if the pregnancy test is positive, metronidazole should be given only after the first trimester.

Although seroconversion to HIV has been reported following sexual assault when this was the only known risk, this risk is felt to be low. The likelihood of HIV transmission from anal or vaginal receptive intercourse when the source is known to be HIV positive is 1-3 per 1000. Because prophylactic antiretroviral therapy has not been studied in this setting, firm recommendations cannot be made and the decision to institute therapy should be individualized. If therapy is given, it should be prompt, and certainly no later than 72 hours.

*Reportable to public health authorities.

INFECTIONS IN DRUG USERS

The use of parenterally administered recreational drugs has increased enormously in recent years. There are now an estimated 300,000 or more intravenous drug users in the United States.

Common Infections That Occur with Greater Frequency in Drug Users

(1) **Skin infections** are associated with poor hygiene and use of nonsterile technique when injecting drugs. *S aureus* (including methicillin-resistant strains) and oral flora (streptococci, eikenella, fusobacterium, peptostreptococcus) are the most common organisms, with enteric gram-negatives less common and seen in those who inject into the groin. Cellulitis and subcutaneous abscesses occur most commonly, particularly in association with subcutaneous ("skin-popping") or intramuscular injections and the use of cocaine and heroin mixtures (probably due to ischemia). Myositis, clostridial myonecrosis, and necrotizing fasciitis occur infrequently but are life-threatening. Wound botulism in association with black tar heroin occurs sporadically but often in clusters.

(2) **Hepatitis** is very common among habitual drug users and is transmissible both by the parenteral (hepatitis B, C, and D) and by the fecal-oral route (hepatitis A). Multiple episodes of hepatitis with different agents can occur.

(3) **Aspiration pneumonia** and its complications (lung abscess, empyema, brain abscess) result from altered consciousness associated with drug use. Mixed aerobic and anaerobic mouth flora are usually involved.

(4) **Tuberculosis** also occurs in drug users, and infection with HIV has fostered the spread of tuberculosis in this population. Morbidity and mortality rates are increased in HIV-infected individuals with tuberculosis. Classic radiographic findings are often absent; any patient with infiltrates who does not respond to antibiotics is suspect.

(5) **Pulmonary septic emboli** may originate from venous thrombi or right-sided endocarditis.

(6) **Sexually transmitted diseases** are not directly related to drug use, but the practice of exchanging sex for drugs has resulted in an increased frequency of sexually transmitted diseases. Syphilis, gonorrhea, and chancroid are the most common.

(7) **AIDS** has a high incidence among intravenous drug users and their sexual contacts and among the offspring of infected women (see [Chapter 31](#)).

(8) **Infective endocarditis.** The organisms that cause infective endocarditis in those who use drugs intravenously are most commonly *S aureus*, candida (especially *Candida parapsilosis*), *Enterococcus faecalis*, other streptococci, and gram-negative bacteria (especially pseudomonas and *Serratia marcescens*). A number of complications of endocarditis can occur, including splenic abscesses, central nervous system infections (meningitis, brain abscess, subdural empyema, epidural abscess), and endophthalmitis. Involvement of the right side of the heart is common, and infection of more than one valve is not infrequent. Right-sided involvement, especially in the absence of murmurs, is often suggested by the presence of septic pulmonary emboli. The diagnosis must be established by blood culture. Therapy, including empirical treatment, is discussed in [Chapter 33](#).

(9) **Other vascular infections** include septic thrombophlebitis and mycotic aneurysms. Mycotic aneurysms resulting from direct trauma to a vessel with secondary infection most commonly occur in femoral arteries and less commonly in arteries of the neck. Aneurysms resulting from hematogenous spread of organisms frequently involve intracerebral vessels and thus are seen in association with endocarditis.

(10) **Osteomyelitis and septic arthritis.** Osteomyelitis involving vertebral bodies, sternoclavicular joints, the pubic symphysis, the sacroiliac joints, and other sites usually results from hematogenous distribution of injected organisms or septic venous thrombi. Pain and fever precede radiographic changes, sometimes by several weeks. While staphylococci—often methicillin-resistant—are common organisms, *serratia*, *pseudomonas*, candida (usually not *C albicans*), and other pathogens rarely encountered in spontaneous bone or joint disease are found in intravenous drug users.

Infections Rare in United States

A. Tetanus

In the 1950s and 1960s, tetanus was commonly seen in drug users, especially in unimmunized women who injected drugs subcutaneously ("skin-popping"). Increased tetanus immunization among drug users has resulted in a decline in this disease, though cases are still reported.

B. Malaria

Needle transmission occurs from intravenous drug users who acquired the infection in malaria-endemic areas outside the United States.

C. Melioidosis

This chronic pulmonary infection caused by *Burkholderia pseudomallei* is occasionally seen in debilitated drug users. It occurs occasionally in debilitated drug users, but most cases are reported in Asia and Australia.

Approach to the Patient

A common and difficult clinical problem is management of the parenteral drug user who presents with fever. In general, after obtaining appropriate cultures (blood, urine, and sputum if the chest x-ray is abnormal), empirical therapy is begun. If the chest x-ray is suggestive of a community-acquired pneumonia (consolidation), therapy for outpatient pneumonia is begun with a second- or third-generation cephalosporin (many would add azithromycin or doxycycline to this regimen). If the chest x-ray is suggestive of septic emboli (nodular infiltrates), therapy for presumed endocarditis is initiated, usually with a combination of nafcillin (or vancomycin if there is a high prevalence of methicillin-resistant *S aureus* or if enterococcus is a consideration) and gentamicin. If the chest x-ray is normal and no focal site of infection can be found, endocarditis is presumed. While awaiting the results of blood cultures, empirical treatment with nafcillin (or vancomycin) and gentamicin is started. If blood cultures are positive for organisms that frequently cause endocarditis in drug users (see above), endocarditis is presumed to be present and treated accordingly. If blood cultures are positive for an organism that is an unusual cause of endocarditis, evaluation for an occult source of infection should go forward. In this setting, a transesophageal echocardiogram may be quite helpful since it is 90% sensitive in detecting vegetations and a negative study is strong evidence against endocarditis. If blood cultures are negative and the patient responds to antibiotics, therapy should be continued for 7-14 days (oral therapy can be given once an initial response has occurred). In every patient, careful examination for an occult source of infection (genitourinary, dental, sinus, gallbladder, etc) should be done.

Infections in injection drug users are the subject matter of a series of articles in *Infectious Disease Clinics of North America*, Volume 16, No. 3, September 2002. The subject is dealt with also in [Chapter 31](#), page 3112 (Levine DP, Brown PD), of *Principles and Practice of Infectious Diseases*, 5th ed, Mandell GL, Bennett JR, Dolin R (editors), Churchill Livingstone, 2000.

ACUTE INFECTIOUS DIARRHEA

Diarrheal syndromes are arbitrarily divided into acute (those lasting less than 2 weeks) and chronic diseases and are said to be mild if there are three or fewer stools per day, moderate if there are four or more stools in association with local symptoms (abdominal cramps, nausea, tenesmus), and severe if there are four or more stools per day with systemic symptoms (fevers, chills, dehydration). Acute diarrhea can be caused by a number of different factors, including emotional stress, food intolerance, inorganic agents (eg, sodium nitrite), organic substances (eg, mushrooms, shellfish), drugs, and infectious agents (including viruses, bacteria, and protozoa). From a diagnostic and therapeutic standpoint, it is helpful to classify infectious diarrhea into syndromes that produce inflammatory or bloody diarrhea and those that are noninflammatory, nonbloody, or watery. In general, the term "inflammatory diarrhea" suggests colonic involvement by invasive bacteria or parasites or by toxin production. Patients present with frequent bloody, small-volume stools, often associated with fever, abdominal cramps, tenesmus, and fecal urgency. Common causes of this syndrome include shigella, salmonella, campylobacter, yersinia, invasive strains of *E coli*, *E coli* O157:H7, *Entamoeba histolytica*, and *Clostridium difficile*. Tests for fecal leukocytes are frequently positive, and definitive etiologic diagnosis requires stool culture. Noninflammatory diarrhea is generally milder and is caused by viruses or toxins that affect the small intestine and interfere with salt and water balance, resulting in large-volume watery diarrhea, often with nausea, vomiting, and cramps. Common causes of this syndrome include viruses (eg, rotavirus, Norwalk virus, enteric adenoviruses, astrovirus, coronavirus), vibrios (*V cholerae*, *V parahaemolyticus*), enterotoxin-producing *E coli*, *Giardia lamblia*, cryptosporidia, and agents that can cause food-borne gastroenteritis.

The term "food poisoning" denotes diseases caused by toxins present in consumed foods. When the incubation period is short (1-6 hours after consumption), the toxin is usually preformed. Vomiting is usually a major complaint, and fever is usually absent. Examples include intoxication from *S aureus* or *Bacillus cereus*, and toxin can be detected in the food. When the incubation period is longer—between 8 hours and 16 hours—the organism is present in the food and produces toxin after being ingested. Vomiting is less prominent, abdominal cramping is frequent, and fever is often absent. The best example of this disease is that due to *Clostridium perfringens*. Toxin can be detected in food or stool specimens.

The inflammatory and noninflammatory diarrheas discussed above can also be transmitted by food and water and usually have incubation periods between 12 and 72 hours. Cyclospora, cryptosporidia, and isospora are protozoans capable of causing disease in both immunocompetent and immunocompromised patients. Characteristics of disease include profuse watery diarrhea that is prolonged but usually self-limited (1-2 weeks) in the immunocompetent patient but can be chronic in the compromised host. Epidemiologic features may be helpful in determining etiology. Recent hospitalization or antibiotic use suggests *C difficile*; recent foreign travel suggests salmonella, shigella, campylobacter, *E coli*, or *V cholerae*; undercooked hamburger suggests *E coli*, especially O157:H7; and fried rice consumption is associated with *B cereus* toxin. Prominent features of some of these causes of diarrhea are listed in [Table 30-3](#).

Treatment usually consists of replacement of fluids and electrolytes and, very rarely, management of hypovolemic shock and respiratory compromise. In mild diarrhea, increasing ingestion of juices and clear soups is adequate. In more severe cases of dehydration (postural lightheadedness, decreased urination), oral glucose-based rehydration solutions can be used (Ceralyte, Pedialyte). In general, most cases of acute gastroenteritis are self-limited and do not require therapy other than supportive measures. When symptoms persist beyond 3-4 days, initial presentation is accompanied by fever or bloody diarrhea, or the patient is immunocompromised, cultures of stool are usually obtained. Symptoms have often resolved by the time cultures are completed. In this case, even if a pathogen is isolated, therapy is not needed (except for shigella, since the infecting dose is so small that therapy to eradicate organisms from the stool is indicated for epidemiologic reasons). If symptoms persist and a pathogen is isolated, it is reasonable to institute specific treatment even though therapy has not been conclusively shown to alter the natural history of disease for most pathogens. Exceptions include gastroenteritis due to salmonella (where therapy may prolong the carrier state and increase the number of relapses), infections

with *E coli* O157:H7 (antibiotic therapy does not ameliorate symptoms and may increase the risk of developing hemolytic-uremic syndrome), and campylobacter infections (early therapy shortens the course of disease). Ciprofloxacin, 500 mg every 12 hours for 5 days, is effective in shortening the course of illness compared with placebo. However, because of concerns about selecting for resistant organisms (especially campylobacter, where increasing resistance to fluoroquinolones has been documented and erythromycin is the drug of choice) coupled with the fact that most infectious diarrhea is self-limited, routine use of antibiotics for all patients with diarrhea is not recommended. Antibiotics should be considered in patients with evidence of invasive disease (white cells in stool, dysentery), with symptoms 3-4 days or more in duration, with multiple stools (eight to ten or more per day), and in those with impaired immune responses. Antimotility drugs may relieve cramping and decrease diarrhea in mild cases. Their use should be limited to patients without fever and without dysentery (bloody stools), and they should be used in low doses because of the risk of producing toxic megacolon.

Therapeutic recommendations for specific agents can be found elsewhere in this book.

Ilnyckyj A: Clinical evaluation and management of acute infectious diarrhea in adults. Gastroenterol Clin North Am 2001;30:599. [\[PMID: 11586547\]](#)

TRAVELER'S DIARRHEA

Whenever a person travels from one country to another—particularly if the change involves a marked difference in climate, social conditions, or sanitation standards and facilities—diarrhea is likely to develop within 2-10 days. There may be up to ten or even more loose stools per day, often accompanied by abdominal cramps, nausea, occasionally vomiting, and rarely fever. The stools do not usually contain mucus or blood, and aside from weakness and dehydration there are no systemic manifestations of infection. The illness usually subsides spontaneously within 1-5 days, although 10% remain symptomatic for a week or longer, and in 2% symptoms persist for longer than a month.

Bacteria cause 80% of cases of traveler's diarrhea, with enterotoxigenic *E coli*, *Shigella* species, and *Campylobacter jejuni* being the most common pathogens. Less common are aeromonas, salmonella, noncholera vibrios, *Entamoeba histolytica*, and *Giardia lamblia*. Contributory causes include unusual food and drink, change in living habits, occasional viral infections (adenoviruses or rotaviruses), and change in bowel flora. In patients with fever and bloody diarrhea, stool culture may be indicated, but in most cases cultures are reserved for those who do not respond to antibiotics. Chronic watery diarrhea may be due to amebiasis or giardiasis or, rarely, tropical sprue.

For most individuals, the affliction is short-lived, and symptomatic therapy with opioids or loperamide is all that is required provided the patient is not systemically ill (fever = 39°C) and does not have dysentery (bloody stools), in which case antimotility agents should be avoided. Packages of oral rehydration salts to treat dehydration are available over the counter in the United States (Infalyte, Pedialyte, others) and in many foreign countries. Avoidance of fresh foods and water sources that are likely to be contaminated is recommended for travelers to developing countries, where infectious diarrheal illnesses are endemic. Prophylaxis is recommended for those with significant underlying disease (inflammatory bowel disease, AIDS, diabetes, heart disease in the elderly, conditions requiring immunosuppressive medications) and for those whose full activity status during the trip is so essential that even short periods of diarrhea would be unacceptable. Prophylaxis is started upon entry into the destination country and is continued for 1 or 2 days after leaving. For stays of more than 3 weeks, prophylaxis is not recommended because of the cost and increased toxicity. For prophylaxis, bismuth subsalicylate is effective but turns the tongue and the stools black and can interfere with doxycycline absorption, which may be needed for malaria prophylaxis; it is rarely used. Numerous antimicrobial regimens for once-daily prophylaxis are effective, such as norfloxacin, 400 mg, ciprofloxacin, 500 mg, ofloxacin, 300 mg, or trimethoprim-sulfamethoxazole, 160/800 mg. Because not all travelers will have diarrhea and because most episodes are brief and self-limited, an alternative approach currently recommended is to provide the traveler with a supply of antimicrobials to be taken if significant diarrhea occurs during the trip. Loperamide (4 mg loading dose, then 2 mg after each loose stool to a maximum of 16 mg/d) with a single dose of ciprofloxacin (750 mg), levofloxacin (500 mg), or ofloxacin (300 mg) cures most cases of traveler's diarrhea. If diarrhea is severe, associated with fever or bloody stools, or persists despite single-dose ciprofloxacin treatment, then 3-5 days of ciprofloxacin, 500 mg twice daily, levofloxacin, 500 mg once daily, norfloxacin, 400 mg twice daily, or ofloxacin, 300 mg twice daily, can be given. Trimethoprim-sulfamethoxazole, 160/800 mg twice daily, can be used as an alternative, but resistance is common in many areas.

■ ACTIVE IMMUNIZATION AGAINST INFECTIOUS DISEASES

RECOMMENDED IMMUNIZATION OF INFANTS, CHILDREN, & ADOLESCENTS

The recommended schedules and dosages of vaccination change often, so that one should always consult the manufacturer's package inserts.

The schedule for active immunizations in children is presented in [Table 30-4](#). All adolescents should see a health care provider to ensure vaccination of those who have not received varicella or hepatitis B vaccine, to make certain that a second dose of measles-mumps-rubella (MMR) has been given as well as a booster for tetanus and diphtheria (Td), and to provide immunizations (influenza and pneumococcal vaccines) that may be indicated for certain high-risk individuals.

RECOMMENDED IMMUNIZATION OF ADULTS

Several vaccines are recommended for adults depending upon the individual's previous vaccination status and the risks of exposure to certain diseases. Recommendations are summarized in [Table 30-5](#).

Tetanus-Diphtheria Toxoid

All should receive a primary series of immunizations against tetanus and diphtheria once ([Table 30-4](#)). Adults who have not previously been immunized should receive two doses of Td 1-2 months apart, followed by a booster dose 6-12 months later. Adults partially immunized in childhood with DTP need only a total of three doses of tetanus and diphtheria toxoid. The historical recommendation has been to give booster doses of Td every 10 years throughout life. An alternative approach emphasizes ensuring that all adults receive primary immunization and recommending a single midlife (age 50 years) booster dose of Td to those who have received the full pediatric immunization, including the booster in the teenage years. If booster doses are given too frequently, an Arthus reaction with severe local pain and swelling can occur. An acellular pertussis vaccine, which is highly immunogenic but associated with far fewer adverse effects than the whole cell vaccine, is now included with tetanus-diphtheria toxoid for use in childhood immunization (DTaP). The acellular vaccine appears to date to be well tolerated in adolescents and adults. Even though adolescents and adults with waning immunity may be reservoirs for *B pertussis*—making immunization attractive—routine immunization of this population with the acellular vaccine is not recommended pending further study.

For tetanus prophylaxis in wound management see [Chapter 33](#).

Measles

Adults born before 1957 are considered immune to measles. Adults born in 1957 or later who lack documentation of immunization after age 1 or who do not have a physician-documented history or laboratory evidence of previous infection should receive at least one dose of vaccine. Persons born between 1963 and 1967—a period when inactivated measles vaccine was the only product available—should also receive one dose of live attenuated vaccine. Persons vaccinated before their first birthday should also receive a single dose of vaccine. Because most adults do not have detailed information about childhood immunization or illnesses, a practical approach is to administer a single dose of MMR to all healthy adults born after 1956. Because outbreaks of measles have occurred in young adults who have received a single dose of measles vaccine, revaccination is recommended, particularly before going to college, entering a health care profession, or embarking on foreign travel to areas where measles is endemic. Even though birth before 1957 implies immunity, unvaccinated health care workers (especially women of childbearing age) who do not have a history of measles or laboratory evidence of immunity should be vaccinated. Entrants to colleges and universities and employees of health care institutions who have not previously been vaccinated should receive two doses of vaccine at least 1 month apart. Revaccination of an immune person is not associated with adverse effects—if the vaccination status is unknown and an indication for vaccination exists, it can be safely done. Vaccination of susceptible adults within 72 hours after exposure to an active case of measles is protective.

About 5-15% of unimmunized individuals will develop fever and about 5% a mild rash 5-12 days after vaccination. Fever and rash are self-limiting, lasting only 2-3 days. Local swelling and induration are particularly common in individuals previously vaccinated with inactivated vaccine. Pregnant women and immunosuppressed persons should not be vaccinated (with the exception of asymptomatic HIV-infected individuals who are not severely immunosuppressed [CD4 count < 200/uL], who should be vaccinated if susceptible). It is felt that MMR vaccine can be safely given to patients with a history of egg allergy even when severe. A single 0.5 mL dose

can be given without prior skin testing or desensitization as long as postvaccination observation for 90 minutes is possible.

Rubella

The purpose of rubella vaccination is to prevent transmission to the fetus. Immunization is recommended for all adults but particularly for women of childbearing age not previously immunized. Although persons born before 1957 are considered immune, this is not an acceptable criterion of immunity for women who could become pregnant. Thus, premenopausal women born before 1957 who might become pregnant should be vaccinated. In addition, both male and female hospital workers who may be exposed to patients with rubella or who might have contact with pregnant patients should be immunized. A single immunization is given. MMR trivalent vaccine is recommended, but if immunity to one or more of the components can be demonstrated, monovalent or bivalent vaccines can be used. Because of its expense and because revaccination of immune individuals is not associated with adverse effects, serologic testing is not required prior to vaccination.

Adverse effects are usually mild. Up to 40% of unvaccinated adults (usually women) experience joint pain, often worse than that associated with natural infection. Symptoms begin 1-3 weeks after vaccination and are self-limited, lasting 3-10 days. Frank arthritis is rare. Although vaccination of pregnant women is *not* recommended, with the currently available RA27/3 vaccine strain the congenital rubella syndrome does not occur in the offspring of those inadvertently vaccinated during pregnancy or within 3 months before conception. Persons immunosuppressed by virtue of disease or medication should not receive vaccine. HIV infection is an exception—it should be given to asymptomatic individuals who do not have evidence of severe immunosuppression (CD4 count < 200/uL) and may be considered in symptomatic patients. Since the vaccine contains trace amounts of neomycin, a history of anaphylaxis to this agent is a contraindication.

Mumps

Mumps vaccine is recommended for all adults thought to be susceptible. Persons born before 1957 are considered to be naturally immune. Those born in 1957 or later are felt to be susceptible unless they can document infection, prove vaccination, or have laboratory evidence of immunity. Vaccination in those already immune is not associated with an increased incidence of adverse effects.

Mumps vaccine is generally safe. It should not be given to those who are immunosuppressed (except HIV-infected individuals) or who have a history of anaphylaxis to neomycin.

Influenza

Influenza vaccination is recommended yearly. Those at greatest risk for severe complications of influenza should have priority in vaccination programs: (1) Adults and children with chronic cardiopulmonary disease, including asthmatics. (2) Residents of chronic care facilities. (3) Healthy adults 50 years of age or older. (4) Adults and children who have required either regular medical follow-up or hospitalization in the last year for chronic metabolic disorders (including diabetes) or renal disease, those with hemoglobinopathies, and those receiving immunosuppressive drugs. (5) Children and teenagers (age 6 months to 18 years) who are on long-term aspirin therapy and would be at increased risk for developing Reye's syndrome following influenza. (6) Women who will be in the second or third trimester of pregnancy during the influenza season.

Certain high-risk groups of patients (the elderly, persons with AIDS, transplant patients) may have a poor antibody response to vaccine, but there is no reason not to vaccinate them. Concern that vaccination of HIV-positive patients may result in a brief (2- to 4-week) period of increased HIV viremia and viral replication has been raised. The clinical significance is probably minimal, as progression of disease after vaccination has not been observed. Thus, the potential benefit of vaccination of HIV-positive individuals outweighs any theoretic risks. To prevent disease in high-risk patients, vaccination is advised for household members and health care providers who have contact with these high-risk patients. Vaccination is recommended also for otherwise healthy adults who provide essential community services and for any individual who wishes to decrease the risk of becoming ill with influenza.

Local reactions (erythema and tenderness) at the site of injection are common, but fevers, chills, and malaise (which last in any case only 2-3 days) are rare. Like measles, mumps, and yellow fever vaccines, influenza vaccine is prepared using embryonated chicken eggs, and persons with a history of anaphylaxis to eggs should not be vaccinated. The risk of Guillain-Barre syndrome is not increased following vaccination. Influenza vaccination may be associated with multiple false-positive serologic tests to HIV, HTLV-1, and hepatitis C, but it is self-limited, lasting 2-5 months.

A trivalent live attenuated influenza vaccine administered as a single-dose intranasal spray may be effective in preventing disease; it may be available for the 2004 influenza season. Two neuraminidase inhibitors (zanamivir and oseltamivir) are used for therapy of influenza A and B, and oseltamivir for prophylaxis. The dose is 75 mg/d, and the duration of treatment depends on the clinical setting. Amantadine and rimantadine are also effective but only against influenza A.

Pneumococcal Pneumonia

Pneumococcal vaccine contains purified polysaccharide from 23 of the most common strains of *S pneumoniae*, which cause 90% of bacteremic episodes in the United States. Antibody response following vaccination is dependent upon the patient's immune status and the presence of concomitant disease. Healthy adults have an excellent antibody response, as do patients who are postsplenectomy and those with sickle cell disease. Elderly individuals and those with chronic diseases (diabetes mellitus, alcoholic cirrhosis, chronic obstructive pulmonary disease, lupus erythematosus, rheumatoid arthritis) have less vigorous response than young healthy adults. Patients with Hodgkin's disease respond to vaccination if it is given before splenectomy, radiation, or chemotherapy, whereas patients with leukemia, lymphoma, and HIV infection respond sluggishly.

Although the efficacy of pneumococcal vaccine has been questioned, most authorities believe that vaccination is about 60-70% effective in preventing bacteremic disease in immunocompetent persons. Fifty percent efficacy is observed in patients with underlying diseases (not severely immunocompromised), and less in immunocompromised patients (10%), largely because of inability to mount an antibody response in this population. It is presently recommended for patients at increased risk for developing severe pneumococcal disease, especially asplenic patients and those with sickle cell disease. It is also indicated for adults at increased risk of developing pneumococcal disease, including those with chronic illnesses (eg, cardiopulmonary disease, alcoholism, cirrhosis, chronic renal failure, nephrotic syndrome, cerebrospinal fluid leaks), those who are immunocompromised (eg, patients with Hodgkin's disease, lymphoma, chronic lymphocytic leukemia, multiple myeloma, congenital immunodeficiency, asymptomatic or symptomatic HIV infection, organ or bone marrow transplant recipients), and those receiving immunosuppressive therapy, including long-term systemic corticosteroids, alkylating agents, and antimetabolites. Because of the apparent increased risk of developing pneumococcal meningitis following cochlear implants, patients receiving these implants should be given age-appropriate vaccination. Although not currently recommended for smokers and black adults, some feel that these groups should be routinely immunized because of an increased risk of developing invasive disease. In addition, it is recommended for all individuals over 65 years of age. Whether 65 is the appropriate age to vaccinate healthy adults is unclear. Antibody response declines with age, and some have suggested routine immunization at age 50 similar to the recommendation for tetanus (see above). A single dose of vaccine usually confers lifelong immunity. One-time revaccination 5 years after initial vaccination is recommended for those at highest risk (see list above). In addition, a single revaccination is recommended for those 65 or more years of age who received the vaccine 5 years or more previously and were under age 65 at the time of primary vaccination. Elderly individuals with unknown vaccination status should be immunized once. Revaccination should also be considered for high-risk individuals previously immunized with the older 14-valent vaccine. Since immunocompetent patients respond best to the vaccine, it should be given 2 weeks before splenectomy or before starting chemotherapy if that can be anticipated.

A protein-conjugated heptavalent pneumococcal vaccine used in children under 2 years of age has not been studied in adults.

Mild reactions (erythema and tenderness) to pneumococcal vaccine occur in up to 50% of recipients, but systemic reactions are uncommon. Similarly, revaccination at least 5 years after initial vaccination is associated with mild self-limited local but not systemic reactions.

Hepatitis B

Recombinant hepatitis B vaccine is given intramuscularly in the deltoid (gluteal injection often results in deposition of vaccine in fat rather than muscle, with fewer serologic conversions) on three separate occasions: the first two doses 1 month apart and the last dose 5 months after the second one. It is recommended for all individuals at increased risk of developing hepatitis B. These include injection drug users, men who have sex with men, individuals who have had more than one sex partner in the last 6 months, and persons with sexually transmitted diseases or who attend STD clinics. Family (household and sexual contacts of hepatitis B carriers) or occupational factors (frequent exposure to blood and blood products, hemodialysis patients and staff, residents, medical students, laboratory technicians, morticians) also serve as indications. Others who should be considered for vaccination are those who work at or inhabit institutions for the developmentally disabled, travelers spending more than 6 months in high-risk areas, and inmates of correctional institutions. For immunosuppressed patients, those being maintained on hemodialysis, and chronic alcoholics, seroresponse to standard doses of vaccine is low, and for that reason preparations delivering a higher vaccine dose (40 ug/mL) are administered. In addition to higher vaccine doses, these patients may require more frequent immunizations, and some authorities recommend annual screening to determine whether booster doses are needed. Although most often used for preexposure prophylaxis, the vaccine is also given as postexposure prophylaxis along with hepatitis B immunoglobulin following needlestick injury or mucous membrane exposure to blood from an individual who is HBsAg-positive. It is also given along with hepatitis B immunoglobulin to infants of mothers who are HBsAg-positive ([Table 30-4](#)). Immunity wanes with time, but periodic serologic monitoring is not recommended, and routine administration of booster doses is not necessary. Adverse reactions are minor and limited to local soreness.

Following vaccination, 90-95% of healthy young individuals develop protective antibodies. A number of factors decrease serologic response, including increasing age over 30, renal failure, HIV infection, diabetes, chronic liver disease, obesity, and smoking. Postvaccination serologic testing is not routinely performed. It is reserved for those whose clinical management would be influenced by their immune status (eg, health care workers, infants born to HBsAg-positive mothers, dialysis patients), and those who may have an impaired response. Those who do not respond should receive a second three-dose vaccine series with serologic testing 1-2 months after completion. Those who fail to respond are unlikely to respond to further vaccination even with a different recombinant vaccine and should be considered susceptible; if exposed, they should receive hepatitis B immune globulin.

Varicella

A live attenuated varicella virus vaccine is currently recommended as part of routine childhood immunization ([Table 30-4](#)). Although only 10% of adults remain susceptible, varicella in adolescents and adults is a more serious disease. Only about 2% of all cases of varicella occur in adults, but almost 50% of all deaths are in adults. Thus, susceptible adolescents and adults should be immunized, with special emphasis on certain high-risk groups, ie, health care workers; household contacts of immunosuppressed individuals; persons who live or work in environments where transmission can occur, eg, teachers in day care centers or elementary schools, residents and workers in institutional settings such as military and correctional institutions, college students; nonpregnant women of childbearing age; and international travelers. The role of the present vaccine in postexposure prophylaxis has not been widely studied, but it has been suggested that it is 90% effective in preventing varicella in an outbreak, particularly when given within 3-5 days after exposure. The Advisory Committee on Immunization Practices (ACIP) now recommends vaccination in susceptible persons following exposure. The vaccine is very immunogenic. Seroconversion occurs in 95% of children after a single dose. In adolescents (older than 12 years of age) and adults, seroconversion is seen in 78% after one dose and 99% after two doses. For this reason, two doses given 4-8 weeks apart are recommended in persons 12 years of age and older. The duration of immunity is not known but is probably 10 years. Although the vaccine is very effective in preventing disease, breakthrough infections do occur—but are much milder than in unvaccinated individuals (usually less than 50 lesions, with milder systemic symptoms). Although the vaccine is very safe, adverse reactions can occur as late as 4-6 weeks after vaccination. Tenderness and erythema at the injection site are seen in 25%, fever in 10-15%, and a localized maculopapular or vesicular rash in 5%; a smaller percentage develop a diffuse rash, usually with five or fewer vesicular lesions. Spread of virus from vaccinees to susceptible individuals is possible, but the risk of such transmission even to immunocompromised patients is small and disease, when it develops, is mild and treatable with acyclovir. Nonetheless, the vaccine, being a live attenuated virus, should not be given to immunocompromised individuals, including HIV-positive children and adults, or pregnant women. It is contraindicated in persons allergic to neomycin. For theoretic reasons, it is recommended that following vaccination salicylates should be avoided for 6 weeks (to prevent Reye's syndrome). Several unresolved issues remain, including the need for booster doses, whether universal childhood vaccination will shift the incidence of disease to adolescence or adulthood with the possibility of more severe disease, and whether vaccination might prevent development of herpes zoster.

Hepatitis A

Two inactivated hepatitis A vaccines (Havrix, VAQTA) are approved for use in the United States. They are indicated for individuals 2 years of age or older who are at an increased risk of developing hepatitis A. Potential vaccinees include travelers (including military personnel) to areas where hepatitis is endemic (Africa, Asia, Central and South America, Mexico, parts of the Caribbean); certain populations that experience outbreaks (such as indigenous Alaskans, certain American Indian reservations, various religious communities and states where the risk of hepatitis A is high among children); employees of day care centers, caretakers for developmentally impaired institutionalized individuals, and laboratory workers who handle live hepatitis A virus or work closely with nonhuman primates; men who have sex with men; illicit drug users; persons who receive clotting factor concentrates; and those with chronic liver disease. The role of hepatitis A vaccine in controlling outbreaks in day care centers, hospitals, and institutions for the disabled has not been investigated, and immune globulin is used in those settings. A single intramuscular injection of vaccine in adults elicits antibodies in 55-60% of individuals at 2 weeks and 95% by 1 month. The different formulations come in different strengths, and dosage depends on the age of the vaccinee and the preparation used (see package insert). In general, two doses are required, the second 6-18 months after the first. The duration of immunity may be lifelong, and at present repeat vaccination is not recommended. Adverse effects are minimal and consist mainly of pain at the injection site. If vaccine is not available, temporary passive immunity may be induced by the intramuscular injection of immune globulin, 0.02 mL/kg every 2-3 months or 0.1 mL/kg every 6 months. Protection with immune globulin is recommended for persons traveling to areas where sanitation is poor and the risk of exposure to hepatitis A high because of contaminated food and water supplies and contact with infected persons. Preparation of immunoglobulin from plasma involves steps that inactivate HIV, thus making it incapable of transmitting HIV infection.

Combined Hepatitis A & B Vaccine

A combined hepatitis A and B vaccine is approved for use in individuals 18 years of age and older. The components are identical to individual vaccines. It is highly immunogenic and should be used in individuals who have an indication for both hepatitis A and B vaccination, as noted above. The product is safe, and adverse effects are similar to those of the individual components.

Smallpox

Smallpox vaccination, discontinued in the United States in the early 1970s, has been reinstituted because of concerns about bioterrorism. The vaccine is a live vaccinia virus derived through serial passage of cowpox and does not contain the actual smallpox virus. Vaccine is administered with a bifurcated needle, making 15 puncture wounds in a small area of the skin (5 mm) just deep enough to cause bleeding. Because the inoculation site is contagious, it should be covered with gauze or a semipermeable dressing such as OpSite. If vaccination is successful, the site goes through a characteristic evolution: In 3-4 days the site becomes red, itchy, and indurated; a vesicle umbilicates and evolves into a well-formed pustule by day 6-11; the pustule scabs over between week 2 and week 3; and by the end of the third week the scab falls off, leaving a scar. At the end of the first week, fever for several days, tenderness at the vaccination site, and localized axillary adenopathy occur in 10-20% of first-time vaccinees, but these reactions are less common in those who have been previously vaccinated within the last 10 years. Successful vaccination is indicated by the presence of a pustular lesion at day 7 in a nonimmune individual and by the presence of a pustule or area of induration in a previously vaccinated person. Failure to see these reactions is an indication for revaccination.

In general, adverse effects are more common in children under 5 years of age and in first-time vaccinees. Other than the local reactions, the most common adverse effect (estimated at 1:2000) is autoinoculation to another site, most commonly the face, eyelid, mouth, and genitalia. These lesions usually are self-limited and heal without specific therapy. Generalized vaccinia occurs in 1:5000 vaccinees and is characterized by widespread lesions appearing 6-9 days after vaccination, the result of hematogenous spread. The lesions usually heal without therapy in immunocompetent individuals but can be life-threatening in the immunosuppressed. Eczema vaccinatum occurs in patients with active or healed eczema and can progress to involve all areas of the skin involved with the skin disorder. Although uncommon (1:25,000), this is a potentially fatal complication. Progressive vaccinia or vaccinia necrosum is seen in immunocompromised individuals. The vaccination site fails to heal and the virus spreads to surrounding areas with progressive necrosis and gangrene, a serious complication with a high mortality. Postvaccination encephalitis occurs 1-2 weeks after vaccination, is usually seen in those under 1 year of age, occurs in 1:300,000 vaccinations, and is associated with death in 25% and severe disability in another 25%.

Vaccinia immune globulin is available from the CDC but is in limited supply. It is recommended for severe adverse reactions such as eczema vaccinatum, progressive vaccinia, severe generalized vaccinia, and inadvertent inoculation of the eye or eyelid without vaccinia keratitis. It is not recommended for postvaccination encephalitis. Cidofovir, a nucleotide analog used to treat CMV infections, has activity against variola virus and has been effective in animal models for the therapy of vaccinia infections. It should be considered for those with serious adverse effects.

Routine vaccination—in the absence of a case of smallpox—is not recommended for those under 18 years of age. It is also not recommended for those with a history of or active eczema or household associates of such individuals. Those with other skin diseases (atopic dermatitis, impetigo) may also be at risk of complications and should not be vaccinated until skin lesions have healed. Pregnancy, altered immune states as described above, and allergy to vaccine components (neomycin, streptomycin, polymyxin, chlortetracycline) are contraindications to smallpox vaccination. Household contacts of individuals with altered immunity should also not be vaccinated.

RECOMMENDED IMMUNIZATIONS FOR TRAVELERS

Individuals traveling to other countries frequently require immunizations in addition to those listed above and may benefit from chemoprophylaxis against various diseases. These are listed in *Health Information for International Travel*, published by the Centers for Disease Control. An updated version is published yearly and is available from the Superintendent of Documents, United States Government Printing Office, Washington, DC 20402, or on the Internet: <http://www.cdc.gov/nip/home.html>.

Various vaccines can be given simultaneously at different sites. Some, such as cholera, plague, and typhoid vaccine, cause significant discomfort and are best given at different times. In general, live attenuated vaccines (measles, mumps, rubella, yellow fever, and oral typhoid vaccine) should not be given to immunosuppressed individuals or household members of immunosuppressed people or to pregnant women. Immunoglobulin should not be given for 3 months before or at least 2 weeks after live virus vaccines, because it may attenuate the antibody response.

Chemoprophylaxis of malaria is discussed in [Chapter 35](#).

Cholera

Because cholera among travelers is rare and the vaccine marginally effective, the World Health Organization does not require immunization for persons traveling to endemic areas. Although no country officially requires it, some local authorities may require documentation of vaccination.

Cholera vaccine contains a suspension of killed vibrios of prevalent antigenic types. Two injections are given intramuscularly 2-6 weeks apart, followed by booster injections every 6 months during periods of possible exposure. Protection depends largely on booster doses. A more effective inactivated oral vaccine is not available in the United States. A live attenuated oral vaccine is being investigated. The WHO certificate is valid for 6 months only.

Hepatitis B

Persons traveling to and spending more than 6 months in endemic areas of HBV infection who will have close contact with the local population should be considered for vaccination. Short-term travelers to areas of moderate or high endemic infection (Southeast Asia, China, most of the Middle East, Haiti, the Dominican Republic, and most of Africa) who will be in contact with potentially infected body secretions of residents should be vaccinated. Vaccination should begin at least 6 months before travel to allow for completion of the series.

Hepatitis A

As indicated above, susceptible individuals traveling to areas of high or intermediate endemicity for hepatitis A (eg, anywhere except Canada, western Europe, Japan, Australia, and New Zealand) should be vaccinated. The vaccine is given at least 4 weeks prior to travel, as protective antibodies develop in 95% of vaccinees by that time. If given 2 weeks before travel, up to 45% will not have protective antibodies, and if the person is traveling to a high-risk area, intramuscular immune globulin (0.02 mL/kg) should be administered at a separate site.

Meningococcal Meningitis

If travel is contemplated to an area where meningococcal meningitis is epidemic (Nepal, sub-Saharan Africa, the "meningitis belt" from Senegal in the west to Ethiopia in the east, northern India) or highly endemic, polysaccharide vaccines from types A, C, W-135, and Y may be indicated. (Saudi Arabia requires immunization for pilgrims to Mecca.) Although the need for revaccination has not been determined, antibody levels decline over 2-3 years, and revaccination is reasonable in 3-5 years if risk continues.

Plague

Plague vaccine is a suspension of killed plague bacilli given intramuscularly. Three injections are given—the second, 4 weeks after the first; the third, 5 months after the second. The risk of acquiring plague is so low that vaccination is reserved for travelers who will have exposure to rodents or rabbits in rural areas where plague is endemic (parts of South America, Southeast Asia, the southwestern states of the United States). For continuing exposures, booster doses at intervals of 1-2 years are recommended.

Poliomyelitis

Adult travelers to tropical or developing countries who have not previously been immunized against poliomyelitis should receive a primary series of three doses of inactivated enhanced-potency poliovaccine (IPV), as follows: two doses of 0.5 mL subcutaneously 4-8 weeks apart and then a third dose 6-12 months after the second dose. If more than 8 weeks will elapse before travel, three doses of IPV can be given 4 weeks apart. If 4-8 weeks will elapse before travel, two doses are given 4 weeks apart, and if less than 4 weeks will elapse, a single dose is given. Vaccination can be completed upon return if continued or future exposure to polio is anticipated. Travelers who have previously been fully immunized with OPV or IPV should receive a one-time booster dose with IPV. Data do not indicate the need for more than one adult booster. Live attenuated poliovaccine is no longer recommended because of the risk of vaccine-associated disease.

Rabies

For travelers to areas where rabies is common in domestic animals (eg, India, Asia, Mexico), preexposure prophylaxis with human diploid cell vaccine (HDCV), rabies vaccine adsorbed (RVA), or purified chick embryo cell culture (PCEC) vaccine should be considered. It usually consists of two intramuscular (deltoid area) injections of 1 mL given 1 week apart with a booster dose 2-3 weeks later. Alternatively, two intradermal injections of 0.1 mL of human diploid cell vaccine are given 1 week apart, with a booster dose given 2-3 weeks later. Chloroquine can blunt the immunologic response to rabies vaccine. If malaria prophylaxis with chloroquine is required, vaccination should be given intramuscularly (*not* intradermally) to ensure adequate antibody response. Until further studies are done, interaction between mefloquine and rabies vaccine, while not established, makes intramuscular administration prudent if mefloquine is to be given.

Typhoid

Typhoid vaccination is recommended for travelers to developing countries (especially Latin America, Africa, and Asia) who will have prolonged exposure to contaminated food and water. Three preparations of approximately equal efficacy (50-75% effective) are available: (1) a heat-phenol-inactivated vaccine for parenteral use, (2) an oral live-attenuated Ty21a vaccine supplied as enteric-coated capsules, and (3) a Vi capsular polysaccharide (Vi CPS) vaccine for parenteral use. The phenol-inactivated preparation that has been historically used is associated with more side effects and is not recommended unless the other preparations are not available. The Ty21a vaccine is given as one capsule every other day for four doses. The capsules must be refrigerated and taken with cool liquids (37°C or less) at least 1 hour before meals. All four doses must be taken for maximum protection. Adverse effects are minimal and consist primarily of gastrointestinal upset. The Vi CPS vaccine is given as a single intramuscular injection. Adverse effects consist mainly of local irritation at the site of injection, but fever and headache occur. If continued or repeated exposures are anticipated, boosters are recommended. A dose of the heat-inactivated vaccine is recommended every 3 years, the Vi CPS every 2 years. The optimal booster dose of the Ty21a is not known, but the manufacturer recommends repeating the four-dose series every 5 years. The live attenuated vaccine should not be used in immunosuppressed patients, including those with HIV infection.

Yellow Fever

The live attenuated yellow fever virus vaccine is administered once subcutaneously. Although the risk of yellow fever is low for most travelers, a number of countries require vaccination for all visitors and others require it for travelers to or from endemic areas (mainly equatorial Africa and parts of South and Central America). The WHO certificate requires registration of the manufacturer and the batch number of the vaccine. Vaccination is available in the United States only at approved centers; the local health department should be contacted for available resources. Reimmunization is recommended at 10-year intervals if continued risk exists.

Because it is a live attenuated vaccine prepared in embryonated eggs, the yellow fever vaccine should not be given to immunosuppressed individuals or those with a history of anaphylaxis to eggs. Pregnancy is a relative contraindication to vaccination.

Between 1996 and 2001, seven cases of fever, jaundice, and multiple organ system failure following yellow fever vaccination were reported. As a result of heightened surveillance since June 2001, two additional cases have been reported as well as four cases of encephalitis. These reactions may have been the result of an aberrant host response to the vaccine rather than direct invasion of the vaccine virus. Because yellow fever is a severe disease and deaths have been reported in travelers, vaccination is still recommended but limited to those traveling to areas reporting epidemic or endemic yellow fever. (Current information about the vaccine and yellow fever activity can be found at <http://www.cdc.gov/travel/yfever.htm>)

Japanese B Encephalitis

Japanese B encephalitis is a mosquito-borne viral encephalitis that affects primarily children and older adults (65 years and older) and usually occurs from May to September. It is the leading cause of encephalitis in Asia. Because the risk of infection is low and because adverse effects of the vaccine can be serious, not all travelers to Asia should be vaccinated. Vaccine should be given to travelers to endemic areas who will be staying at least 30 days and who are traveling during the transmission season, particularly if they are visiting rural areas. Travelers who spend less than 30 days in the region should be considered for vaccination if they intend to visit areas of epidemic transmission or if extensive outdoor activities are planned in rural rice-growing areas. The recommended primary immunization schedule is 1 mL of vaccine administered subcutaneously on days 0, 7, and 30. If time constraints are compelling, the last dose can be given on day 14. The last dose should be given at least 10 days before embarkation because urticaria and angioedema have been described, occurring from minutes up to 10 days after vaccination. Following vaccination, patients should be observed for 30 minutes and advised of the possibility of delayed reactions of angioedema and urticaria. In addition, local reactions have been reported in 20% of vaccinees and systemic reactions (fever, chills, malaise, headache) in 10%.

HYPERSENSITIVITY TESTS & DESENSITIZATION

One should test for hypersensitivity before injecting antitoxin, materials derived from animal sources, or drugs (eg, penicillin) to which a patient has had a severe reaction in the past. If the test described below is negative, desensitization is not necessary, and a full dose of the material may be given. If the test is positive, alternative drugs should be strongly considered. If that is not feasible, desensitization is necessary.

Intradermal Test for Hypersensitivity

Penicillin is the drug that most frequently serves as an indication for sensitivity testing and desensitization. A clinical history of penicillin allergy has a positive predictive value of only 15%. In determining whether allergy testing should be performed, its nature should be determined. Immunoglobulin G-mediated delayed reactions such as erythematous or maculopapular skin rash or serum sickness should be distinguished from immediate-type immunoglobulin E-mediated reactions such as urticaria, angioedema, and anaphylaxis. Only patients with the latter history who require penicillin or a cephalosporin should undergo hypersensitivity testing. Skin testing requires two preparations: PPL (penicilloyl-polylysine) and a minor determinant mixture. Several points should be emphasized in performing and interpreting these tests. Whenever possible, both PPL and a minor determinant should be used, since 85% of skin test reactors are positive to PPL but 15% react only to the minor determinant mixture. In addition, if penicillin G is used instead of the minor determinant mixture, some allergic patients will be missed. About 25% of individuals who react to minor determinant mixture may not react to penicillin G, and such patients may still have an anaphylactic or accelerated reaction to penicillin. A pinprick test is performed with each solution at different sites by placing a small drop of solution on the skin and making small indentations of the skin with a needle. If there is no reaction within 10 minutes, 0.01-0.02 mL is injected intradermally, raising a small bleb. Development of a wheal greater than 5 mm in diameter is considered a positive test and an indication for desensitization. Even if the test is negative, about 1-2% of patients will have an immediate or accelerated reaction, but an anaphylactic reaction is rare. Thus, if the test is negative, the drug can be administered with relative safety, but the first dose should be medically supervised and the patient observed for 1 hour (serious reactions after 1 hour are rare).

Patients with a history of allergy to penicillin are also at an increased risk of having a reaction to cephalosporins. A common approach to these patients is to assess the severity of the reaction. If an IgE-mediated reaction can be excluded by history, a cephalosporin can be administered. When the history justifies concern about an immediate-type reaction, penicillin skin testing should be performed. If the test is negative, a cephalosporin can be given. If the test is positive, cephalosporin desensitization should be performed.

Desensitization

A. Precautions

1. The desensitization procedure is not innocuous—deaths from anaphylaxis have been reported. If extreme hypersensitivity is suspected, it is advisable to use an alternative structurally unrelated drug and to reserve desensitization for situations when treatment cannot be withheld and no alternative drug is available.
2. An antihistaminic drug (25-50 mg of hydroxyzine or diphenhydramine intramuscularly or orally) should be administered before desensitization is begun in order to lessen any reaction that occurs.
3. Desensitization should be conducted in an intensive care unit where cardiac monitoring and emergency endotracheal intubation can be performed.
4. Epinephrine, 1 mL of 1:1000 solution, must be ready for immediate administration.

B. Desensitization Method

Several methods of desensitization have been described for penicillin, including use of both oral and intravenous preparations. All methods start with very small doses of drug and gradually increase the dose until therapeutic doses are achieved. For penicillin, 1 unit of drug is given intravenously and the patient observed for 15-30 minutes. If there is no reaction, some recommend doubling the dose while others recommend increasing it tenfold every 15-30 minutes until a dosage of 2 million units is reached; then give the remainder of the desired dose.

For recommendations on skin testing and desensitization for other preparations (botulism antitoxin, diphtheria antitoxin, etc), one should consult the manufacturer's package inserts.

Treatment of Reactions

A. Mild Reactions

If a mild reaction occurs, drop back to the next lower dose and continue with desensitization. If a severe reaction occurs, administer epinephrine (see below) and discontinue the drug unless treatment is urgently needed. If desensitization is imperative, continue slowly, increasing the dosage of the drug more gradually.

B. Severe Reactions

If bronchospasm occurs, epinephrine, 0.3-0.5 mL of 1:1000 dilution, should be given subcutaneously every 10-20 minutes. The following can also be given if symptoms persist: inhaled metaproterenol (0.3 mL of a 5% solution in 2.5 mL of saline), intravenous aminophylline (0.3-0.9 mL/kg/h maintenance after a 6 mg/kg loading dose over 30 minutes), or corticosteroids (250 mg of hydrocortisone or 50 mg of methylprednisolone intravenously every 6 hours for two to four doses). Hypotension should be treated with intravenous fluids (saline or colloid), epinephrine (1 mL of 1:1000 dilution in 500 mL of D₅W intravenously at a rate of 0.5-5 ug/min), and antihistamines (25-50 mg of hydroxyzine or diphenhydramine intramuscularly or orally every 6-8 hours as needed). Cutaneous reactions, manifested as urticaria or angioedema, respond to epinephrine subcutaneously and antihistamines in the doses set forth above.

Table 30-1. Initial antimicrobial therapy for purulent meningitis of unknown cause.

Age Group	Common Microorganisms	Standard Therapy
18-50 years	<i>S pneumoniae</i> , ¹ <i>N meningitidis</i>	Cefotaxime or ceftriaxone ²
Over 50 years	<i>S pneumoniae</i> , ¹ <i>N meningitidis</i> , <i>L monocytogenes</i> , gram-negative bacilli	Ampicillin, ³ cefotaxime, or ceftriaxone ²
Impaired cellular immunity	<i>L monocytogenes</i> , gram-negative bacilli, <i>S pneumoniae</i>	Ampicillin ³ plus ceftazidime ⁴
Postsurgical or posttraumatic	<i>S aureus</i> , <i>S pneumoniae</i> , ¹ gram-negative bacilli	Vancomycin ⁵ plus ceftazidime ⁴

¹In areas where penicillin-resistant pneumococcus is prevalent, vancomycin, 10-15 mg/kg every 6 hours, should be included in the regimen.

²The usual dose of cefotaxime is 2 g every 6 hours and that of ceftriaxone is 2 g every 12 hours. If the organism is sensitive to penicillin, 3-4 million units IV every 4 hours is given.

³The dose of ampicillin is usually 2 g IV every 4 hours.

⁴Ceftazidime is given in a dose of 50-100 mg/kg every 8 hours up to 2 g every 8 hours.

⁵The dose of vancomycin is 10-15 mg/kg every 6 hours.

Spirochetal meningitis	100-1000, mostly lymphocytes ³	Normal	Moderately high (> 50)	Normal to slightly elevated
Aseptic meningitis, viral or meningoencephalitis ⁴	25-2000, mostly lymphocytes ³	Normal or low	High (> 50)	Slightly elevated
"Neighborhood reaction" ⁵	Variably increased	Normal	Normal or high	Variable

¹Cerebrospinal fluid glucose must be considered in relation to blood glucose level. Normally, cerebrospinal fluid glucose is 20-30 mg/dL lower than blood glucose, or 50-70% of the normal value of blood glucose.

²Organisms in smear or culture of cerebrospinal fluid; counterimmunoelectrophoresis or latex agglutination may be diagnostic.

³Polymorphonuclear neutrophils may predominate early.

⁴Viral isolation from cerebrospinal fluid early; antibody titer rise in paired specimens of serum; PCR for herpesvirus.

⁵May occur in mastoiditis, brain abscess, epidural abscess, sinusitis, septic thrombus, brain tumor. Cerebrospinal fluid culture results usually negative.

Table 30-3. Acute bacterial diarrheas and "food poisoning."

Organism	Incubation Period (hours)	Vomiting	Diarrhea	Fever	Microbiology	Pathogenesis	Clinical Features and Treatment
Staphylococcus	1-8, rarely up to 18	+++	+	-	Staphylococci grow in meats and in dairy and bakery products and produce enterotoxin.	Enterotoxin acts on receptors in gut that transmit impulses to medullary centers.	Abrupt onset, intense vomiting for up to 6 hours, followed by regular recovery in 24-48 hours. Occurs in persons eating the same food. No treatment usually necessary except to restore fluid and electrolytes.
Bacillus cereus	1-8, rarely up to 18	+++	+	-	Reheated fried rice causes vomiting or diarrhea.	Enterotoxins formed in food or in gut from growth of B cereus.	After 1-6 hours, mainly vomiting. After 6-12 hours, mainly diarrhea. Both self-limited to less than 1 day.
Clostridium perfringens	8-16	±	+++	-	Clostridia grow in rewarmed meat dishes and produce an enterotoxin.	Enterotoxin produced in food and in gut causes hypersecretion in small intestine.	Abrupt onset of profuse diarrhea; vomiting occurs occasionally. Recovery usual without treatment in 1-4 days. Many clostridia in cultures of feces of patients.
Clostridium botulinum	24-96	±	Rare	-	Clostridia grow in anaerobic foods and produce toxin.	Toxin absorbed from gut blocks acetylcholine at neuromuscular junction.	Diplopia, dysphagia, dysphonia, respiratory paralysis, and ventilation, and intravenous polyvalent antitoxin (see text). Toxin present in food and stool. Mortality rate high.
Clostridium difficile	?	-	+++	+	Associated with antimicrobial drugs, eg, clindamycin.	Enterotoxin causes epithelial necrosis in colon; pseudomembranous colitis.	Especially after abdominal surgery, antibiotic therapy, diarrhea and fever. Toxin in stool. Oral vancomycin or metronidazole useful in severe cases.
Escherichia coli (some strains)	24-72	±	+	-	Organisms grow in gut and produce toxin. May also invade superficial epithelium.	Enterotoxin causes hypersecretion in small intestine.	Usually abrupt onset of diarrhea; vomiting occurs in serious infection in neonates. In adults, "acute diarrhea" is usually self-limited to 1-3 days and does respond to a fluoroquinolone.
Vibrio parahaemolyticus	6-96	+	+	±	Organisms grow in seafood and in gut and produce toxin or invade.	Hypersecretion in small intestine; stools may be bloody.	Abrupt onset of diarrhea in groups consuming the same food, especially crabs and other shellfish. Recovery is usually complete in 1-3 days and stool cultures are positive.
Vibrio cholerae(mild cases)	24-72	+	+++	-	Organisms grow in gut and produce toxin.	Enterotoxin causes hypersecretion in small intestine. Infectivedose: 10 ⁷ -10 ⁹ organisms.	Abrupt onset of liquid diarrhea in endemic areas. Needs prompt replacement of fluids and electrolytes intravenously or orally. Treatment shortens excretion of vibrios. Stool cultures positive.
Campylobacter jejuni	2-10 days	-	+++	+	Organisms grow in jejunum and ileum.	Invasion and enterotoxin production uncertain.	Fever, diarrhea; PMNs and fresh blood in stools, especially in children. Usually self-limited. Media needed for culture at 43 °C. Give fluoroquinolone in severe cases with invasion. Recovery in 5-8 days is usual.
Shigella species (mild cases)	24-72	±	+	+	Organisms grow in superficial gut epithelium and gut lumen and produce toxin.	Organisms invade epithelial cells; blood, mucus, and PMNs in stools. Infective dose: 10 ² -10 ³ organisms	Abrupt onset of diarrhea, often with blood in stools, cramps, tenesmus, and lethargy. Stool cultures are positive. Therapy depends on sensitivity testing, but the fluoroquinolone is most effective. Do not give opioids. Onset is abrupt and self-limited.
Salmonella species	8-48	±	+	+	Organisms grow in gut. Do not produce toxin.	Superficial infection of gut, little invasion. Infective dose: 10 ⁵ organisms.	Gradual or abrupt onset of diarrhea and low-grade fever. No antimicrobials unless systemic dissemination is suspected, in which case give a fluoroquinolone. Stool cultures positive. Prolonged carriage is common.
Yersinia enterocolitica	?	±	+	+	Fecal-oral transmission (occasionally). Food-borne. In pets.	Gastroenteritis or mesenteric adenitis. Occasional bacteremia. Enterotoxin produced.	Severe abdominal pain, diarrhea, fever, and blood in stool; polyarthritides, erythema nodosum in children. If severe, give tetracycline or gentamicin. Keep stool at 4 °C before culture.

Essentials of Diagnosis

- Risk factors: sexual contact with an infected person, parenteral exposure to infected blood by transfusion or needle sharing, perinatal exposure.
- Prominent systemic complaints such as sweats, diarrhea, weight loss, and wasting.
- Opportunistic infections due to diminished cellular immunity—often life-threatening.
- Aggressive cancers, particularly Kaposi's sarcoma and extranodal lymphoma.
- Neurologic manifestations, including dementia, aseptic meningitis, and neuropathy.

General Considerations

When AIDS was first recognized in the United States in 1981, cases were identified by finding severe opportunistic infections such as pneumocystis pneumonia that indicated profound defects in cellular immunity in the absence of other causes of immunodeficiency. When the syndrome was found to be caused by the human immunodeficiency virus (HIV), it became obvious that severe opportunistic infections and unusual neoplasms were at one end of a spectrum of disease, while healthy seropositive individuals were at the other end.

The Centers for Disease Control and Prevention AIDS case definition ([Table 31-1](#)) includes opportunistic infections and malignancies that rarely occur in the absence of severe immunodeficiency (eg, pneumocystis pneumonia, central nervous system lymphoma). It also classifies persons as having AIDS if they have positive HIV serology and certain infections and malignancies that can occur in immunocompetent hosts but which are more common among persons infected with HIV (pulmonary tuberculosis, invasive cervical cancer). Several nonspecific conditions, including dementia and wasting (documented weight loss)—in the presence of a positive HIV serology—are considered AIDS. The definition includes criteria for both definitive and presumptive diagnoses of certain infections and malignancies. Finally, persons with positive HIV serology who have ever had a CD4 lymphocyte count below 200 cells/uL or a CD4 lymphocyte percentage below 14% are considered to have AIDS. Inclusion of persons with low CD4 counts as AIDS cases reflects the recognition that immunodeficiency is the defining characteristic of AIDS. The choice of a cutoff point at 200 cells/uL is supported by several cohort studies showing that over 80% of persons with counts below this level will develop AIDS within 3 years in the absence of effective antiretroviral therapy. The 1993 definition was also expanded to include persons with positive HIV serology and pulmonary tuberculosis, recurrent pneumonia, and invasive cervical cancer. Dramatic increases in the efficacy of antiretroviral treatments—especially those regimens that include protease inhibitors or nonnucleoside reverse transcriptase inhibitors—have improved the prognosis of persons with HIV/AIDS. One consequence is that fewer persons with HIV ever develop an infection or malignancy or have a low enough CD4 count to classify them as having AIDS, which means that the CDC definition has become a less useful measure of the impact of HIV/AIDS in the United States. Conversely, persons who had been diagnosed with AIDS based on a serious opportunistic infection, malignancy, or immunodeficiency may now be markedly healthier, with high CD4 counts, due to the use of highly active antiretroviral therapy. Therefore, the Social Security Administration as well as most social service agencies focus on functional assessment for determining eligibility for benefits rather than the simple presence or absence of an AIDS-defined illness.

Clinicians with limited experience in HIV/AIDS need to educate themselves about disease manifestations and treatment. Resources are available to help clinicians care for HIV-infected persons. Clinicians should call their state medical associations for a list of local resources.

Extra efforts should be made to obtain specialty consultation for patients failing their current regimens, intolerant of standard antiviral drugs, those in need of systemic chemotherapy, and those with complicated opportunistic infections, particularly when invasive procedures or experimental therapies are needed. In many cases, a single consultation with follow-up to the primary care clinician will provide the needed expertise while ensuring continuity in care.

Epidemiology

The modes of transmission of HIV are similar to those of hepatitis B, in particular with respect to sexual, parenteral, and vertical transmission. Although certain sexual practices (eg, receptive anal intercourse) are significantly riskier than other sexual practices (eg, oral sex), it is difficult to quantify per-contact risks. The reason is that studies of sexual transmission of HIV show that most people at risk for HIV infection engage in a variety of sexual practices and have sex with multiple persons, only some of whom may actually be HIV-infected. Thus, it is difficult to determine which practice with which person actually resulted in HIV transmission.

Nonetheless, the best available estimates indicate that the risk of HIV transmission with receptive anal intercourse is between 1:100 and 1:30, with insertive anal intercourse 1:1000, with receptive vaginal intercourse 1:1000, with insertive vaginal intercourse 1:10,000, and with receptive fellatio with ejaculation 1:1000. The per-contact risk of HIV transmission with other behaviors, including receptive fellatio without ejaculation, insertive fellatio, and cunnilingus, are not known.

All per-contact risk estimates assume that the source is HIV-infected. If the HIV status of the source is unknown, the risk of transmission is the risk of transmission multiplied by the probability that the source is HIV-infected. This would vary by risk practices, age, and geographic area. A number of cofactors are known to increase the risk of HIV transmission during a given encounter, including the presence of ulcerative or inflammatory sexually transmitted diseases, trauma, menses, and lack of male circumcision.

The risk of acquiring HIV infection from a needlestick with infected blood is approximately 1:300. Factors known to increase the risk of transmission include depth of penetration, hollow bore needles, visible blood on the needle, and advanced stage of disease in the source. The risk of HIV transmission from a mucosal splash with infected blood is unknown but is assumed to be significantly lower.

The risk of acquiring HIV infection from illicit drug use with sharing of needles from an HIV-infected source is estimated to be 1:150. Use of clean needles markedly decreases the chance of HIV transmission but does not eliminate it if other drug paraphernalia are shared (eg, cookers).

When blood transfusion from an HIV-infected donor occurs, the risk of transmission is 95%. Fortunately, since 1985, blood donor screening using the HIV enzyme-linked immunosorbent assay (ELISA) has been universally practiced in the United States. Also, persons who have recently engaged in unsafe behaviors (eg, sex with a person at risk for HIV, injection drug use) are not allowed to donate. This eliminates donations from persons who are HIV-infected but have not yet developed antibodies (ie, persons in the "window" period). In recent years, HIV antigen and viral load testing have been added to the screening of blood to further lower the chance of HIV transmission. With these precautions, the chance of HIV transmission with receipt of blood transfusion is about 1:1,000,000.

In the absence of perinatal HIV prophylaxis, between 13% and 40% of children born to HIV-infected mothers contract HIV infection. The risk is higher with vaginal than with cesarean delivery, higher among mothers with high viral loads, and higher among those who breast-feed their children. The risk can be decreased by administering antiretroviral treatment to the mother during pregnancy and to the infant immediately after birth (see below).

HIV has not been shown to be transmitted by respiratory droplet spread, by vectors such as mosquitoes, or by casual nonsexual contact.

Current estimates are that about 700,000 Americans are infected with HIV. Estimates of the number of people who developed AIDS in the 1990s have been scaled down from prior estimates, based on recent AIDS incidence data. In 2000, there were 315,000 persons in the United States living with AIDS. Fifty-one percent of those are gay or bisexual men; 28% are heterosexual injection drug users; and 18% are heterosexual noninjection drug users. Women account for 24% of cases.

The rapid increase of AIDS cases among women is of great concern. In 1985, women represented only 7% of new AIDS cases; in 2000, women represented 24% of new cases. Intravenous drug use and heterosexual contact with an infected partner are the two major risk factors for women.

In general, the progression of HIV-related illness is similar in men and women. However, there are some important differences. Women appear later than men for medical care. They are at risk for gynecologic complications of HIV, including recurrent candidal vaginitis, pelvic inflammatory disease, and cervical dysplasia. Violence directed against women, pregnancy, and frequent occurrence of drug use and poverty all complicate the treatment of HIV-infected women. Although "safer sex" campaigns dramatically decreased the rates of seroconversions among gay men living in metropolitan areas in the United States by the mid-1980s, there is concern that relapse to unsafe sexual practices will result in an increase in the number of new seroconversions. Several studies have reported recent increases in the rates of unsafe sexual behaviors and sexually transmitted diseases among gay men in several large cities in the United States and in western Europe. The higher rates of unsafe sex appear to be related to decreased concern about acquiring HIV due to the availability of highly active antiretroviral treatment. Fatigue with following safe sex recommendations also appears to be playing a role in the increased unsafe sex rates.

There are an estimated 10 million persons infected worldwide. In Central and East Africa in some urban areas, as many as one-third of sexually active adults are infected. HIV infection began to spread in Asia in the late 1980s. The most common mode of transmission is bidirectional heterosexual spread. The reason for the greater risk for transmission with heterosexual intercourse in Africa and Asia than in the United States may relate to cofactors such as general health status, the

presence of genital ulcers, the number of sexual partners, and different HIV serotypes.

Etiology

HIV, like other retroviruses, depends upon a unique enzyme, reverse transcriptase (RNA-directed DNA-polymerase), to replicate within host cells. The other major pathogenic human retrovirus, HTLV-I, is associated with lymphoma, while HIV is not directly oncogenic. The HIV genomes contain genes for three basic structural proteins and at least five other regulatory proteins; *gag* codes for group antigen proteins, *pol* codes for polymerase, and *env* codes for the external envelope protein. The greatest variability in strains of HIV occurs in the viral envelope. Since neutralizing activity is found in antibodies directed against the envelope, this variability presents problems for vaccine development.

In addition to the classic AIDS virus (HIV-1), a group of related viruses, HIV-2, have been isolated in West African patients. HIV-2 has the same genetic organization as HIV-1, but there are significant differences in the envelope glycoproteins. Some infected individuals exhibit AIDS-like illnesses, but most West Africans infected with HIV-2 are currently asymptomatic. HIV-2 has been found in several people in the United States. Thus, this variant may be less pathogenic or have a longer period of latency preceding disease. Cases have been documented in which AIDS-like illnesses have occurred in the absence of HIV infection or other known infectious causes of immunodeficiency.

Pathogenesis

The hallmark of symptomatic HIV infection is immunodeficiency caused by continuing viral replication. The virus can infect all cells expressing the T4 (CD4) antigen, which HIV uses to attach to the cell. Chemokine receptors (CCR5 and CXCR4) are important for virus import, and individuals with CCR5 deletions are less likely to become infected, and, once infected, the disease is more likely to progress slowly. Once it enters a cell, HIV can replicate and cause cell fusion or death. A latent state is also established, with integration of the HIV genome into the cell's genome. The cell principally infected is the CD4 (helper-inducer) lymphocyte, which directs many other cells in the immune network. With increasing duration of infection, the number of CD4 lymphocytes falls. Some of the immunologic defects, however, are explained not by *quantitative* abnormalities of lymphocyte subsets but by *qualitative* defects in CD4 responsiveness induced by HIV.

Other cells in the immune network that are infected by HIV include B lymphocytes and macrophages. The defect in B cells is partly due to disordered CD4 lymphocyte function. These direct and indirect effects can lead to generalized hypergammaglobulinemia and can also depress B cell responses to new antigen challenges. Because of these defects, the immunodeficiency of HIV is mixed. Elements of humoral and cellular immunodeficiency are present, especially in children. Macrophages act as a reservoir for HIV and serve to disseminate it to other organ systems (eg, the central nervous system).

Apart from the immunologic effects of HIV, the virus can also directly cause a variety of neurologic effects. Neuropathology largely results from the release of cytokines and other neurotoxins by infected macrophages. Perturbations of excitatory neurotransmitters and calcium flux may contribute to neurologic dysfunction. Direct HIV infection of renal tubular cells and gastrointestinal epithelium may contribute to these organ system manifestations of infection.

Pathophysiology

Clinically, the syndromes caused by HIV infection are usually explicable by one of three known mechanisms.

A. Immunodeficiency

Immunodeficiency is a direct result of the effects of HIV upon immune cells. A spectrum of infections and neoplasms is seen, as in other congenital or acquired immunodeficiency states. Two remarkable features of HIV immunodeficiency are the low incidence of certain infections such as listeriosis and aspergillosis and the frequent occurrence of certain neoplasms such as lymphoma or Kaposi's sarcoma. This latter complication has been seen primarily in gay or bisexual men, and its incidence has steadily declined through the first 15 years of the epidemic. A herpesvirus (KSHV or HHV-8) is the cause of Kaposi's sarcoma.

B. Autoimmunity

Autoimmunity can occur as a result of disordered cellular immune function or B lymphocyte dysfunction. Examples of both lymphocytic infiltration of organs (eg, lymphocytic interstitial pneumonitis) and autoantibody production (eg, immunologic thrombocytopenia) occur. These phenomena may be the only clinically apparent disease or may coexist with obvious immunodeficiency.

C. Neurologic, Renal, and Gastrointestinal Dysfunction

See discussion in Pathogenesis, above.

Clinical Findings

The complications of HIV-related infections and neoplasms affect virtually every organ. The general approach to the HIV-infected person with symptoms is to evaluate the organ systems involved, aiming to diagnose treatable conditions rapidly. As can be seen in [Figure 31-1](#), the CD4 lymphocyte count provides very important prognostic information. Certain infections may occur at any CD4 count, while others rarely occur unless the CD4 lymphocyte count has dropped below a certain level. For example, a patient with a CD4 count of 600 cells/uL, cough, and fever may have a bacterial pneumonia but would be very unlikely to have pneumocystis pneumonia.

A. Symptoms and Signs

Many individuals with HIV infection remain asymptomatic for years even without antiretroviral therapy, with a mean time of approximately 10 years between exposure and development of AIDS. When symptoms occur, they may be remarkably protean and nonspecific. Since virtually all the findings may be seen with other diseases, a combination of complaints is more suggestive of HIV infection than any one symptom.

Physical examination may be entirely normal. Abnormal findings range from completely nonspecific to highly specific for HIV infection. Those that are predictive of HIV infection include hairy leukoplakia of the tongue, disseminated Kaposi's sarcoma, and cutaneous bacillary angiomatosis.

1. Systemic complaints—Fever, night sweats, and weight loss are common symptoms in HIV-infected patients and may occur without a complicating opportunistic infection. Patients with persistent **fever** and no localizing symptoms should nonetheless be carefully examined, and evaluated with a chest radiograph (pneumocystis pneumonia can present without respiratory symptoms), bacterial blood cultures if the fever is greater than 38.5°C, serum cryptococcal antigen, and mycobacterial cultures of the blood. Sinus CT scans or sinus radiographs should be considered to evaluate occult sinusitis. If these studies are normal, patients should be observed closely. Antipyretics are useful to prevent dehydration.

Weight loss is a particularly distressing complication of long-standing HIV infection. Patients typically have disproportionate loss of muscle mass, with maintenance or less substantial loss of fat stores. The mechanism of HIV-related weight loss is not completely understood but appears to be multifactorial.

AIDS patients frequently suffer from anorexia, nausea, and vomiting, all of which contribute to weight loss by decreasing caloric intake. In some cases, these symptoms are secondary to a specific infection, such as viral hepatitis. In other cases, however, evaluation of the symptoms yields no specific pathogen, and it is assumed to be due to a primary effect of HIV. Malabsorption also plays a role in decreased caloric intake. Patients may suffer diarrhea from infections with bacterial, viral, or parasitic agents.

Exacerbating the decrease in caloric intake, many AIDS patients have an increased metabolic rate. This increased rate has been shown to exist even among asymptomatic HIV-infected persons, but it accelerates with disease progression and secondary infection. AIDS patients with secondary infections also have decreased protein synthesis, which makes maintaining muscle mass difficult.

Several strategies have been developed to slow AIDS wasting. Food supplementation with high-calorie drinks may enable patients with not much appetite to maintain their intake. Selected patients with otherwise good functional status and weight loss due to unrelenting nausea, vomiting, or diarrhea may benefit from total parenteral nutrition. It should be noted, however, that TPN is more likely to increase fat stores than to reverse the muscle wasting process.

Two pharmacologic approaches for increasing appetite and weight gain are the progestational agent megestrol acetate (80 mg four times a day) and the antiemetic agent dronabinol (2.5-5 mg three times a day). Side effects from megestrol acetate are rare, but thromboembolic phenomena, edema, nausea, vomiting, and rash have been reported. Euphoria, dizziness, paranoia, and somnolence and even nausea and vomiting have been reported in 3-10% of patients using dronabinol. Dronabinol contains only one of the active ingredients in smoked marijuana, and many patients report better relief of nausea and improvement of appetite with smoking marijuana. Several states allow physicians to recommend the use of smoked marijuana to their patients. However, it is still illegal in the United States to sell marijuana. Thus, a physician's recommendation may at best decrease the chance that patients will be prosecuted for use of marijuana. Unfortunately, neither megestrol acetate or dronabinol increases lean body mass.

Two regimens that have resulted in increases in lean body mass are growth hormone and anabolic steroids. Growth hormone at a dose of 0.1 mg/kg/d subcutaneously for 12 weeks has resulted in modest increases in lean body mass; its cost is approximately \$150 per day. Anabolic steroids also increase lean body mass among HIV-infected patients. They seem to work best for patients who are able to do weight training. The most commonly used regimens are testosterone enanthate or testosterone cypionate (100- 200 mg intramuscularly every 2-4 weeks). Testosterone patches (4-6 mg/d) applied to the shaved scrotum and a testosterone gel that can be applied directly to the skin are also available. A transdermal delivery system (2.5 mg/d) is also available that can be applied to nonhairy parts of the body. Unfortunately, the patches tend to fall off, and the transdermal system often causes a local skin reaction. The anabolic steroid oxandrolone (20 mg orally in two divided doses) has also been found to increase lean body mass.

Nausea leading to weight loss is sometimes due to esophageal candidiasis. Patients with oral candidiasis and nausea should be empirically treated with an oral antifungal agent. Patients with weight loss due to nausea of unclear origin may benefit from use of antiemetics prior to meals (prochlorperazine, 10 mg three times daily; metoclopramide, 10 mg three times daily; or ondansetron, 8 mg three times daily). Effective fever control decreases the metabolic rate and may slow the pace of weight loss. Dronabinol (5 mg three times daily) can also be used to increase appetite. Depression and adrenal insufficiency are two potentially treatable causes of weight loss.

2. Sinopulmonary disease—

a. Pneumocystis pneumonia—(See also discussions in [Chapter 36](#).) *Pneumocystis jiroveci* pneumonia is the most common opportunistic infection associated with AIDS. Pneumocystis pneumonia may be difficult to diagnose because the symptoms—fever, cough, and shortness of breath—are nonspecific. Furthermore, the severity of symptoms ranges from fever and no respiratory symptoms through mild cough or dyspnea to frank respiratory distress.

Hypoxemia may be severe, with a PO₂ less than 60 mm Hg. The cornerstone of diagnosis is the chest radiograph. Diffuse or perihilar infiltrates are most characteristic, but only two-thirds of patients with pneumocystis pneumonia have this finding. Normal chest radiographs are seen in 5-10% of patients with pneumocystis pneumonia, while the remainder have atypical infiltrates. Apical infiltrates are commonly seen among patients with pneumocystis pneumonia who have been receiving aerosolized pentamidine prophylaxis. Large pleural effusions are uncommon with pneumocystis pneumonia; their presence suggests bacterial pneumonia, other infections such as tuberculosis, or pleural Kaposi's sarcoma.

Definitive diagnosis can be obtained in 50-80% of cases by Wright-Giemsa stain of induced sputum. Sputum induction is performed by having patients inhale an aerosolized solution of 3% saline produced by an ultrasonic nebulizer. Patients should not eat for at least 8 hours and should not use toothpaste or mouthwash prior to the procedure since they can interfere with test interpretation. The next step for patients with negative sputum examinations still suspected of having pneumocystis pneumonia should be bronchoalveolar lavage. This technique establishes the diagnosis in over 95% of cases.

In patients with symptoms suggestive of pneumocystis pneumonia but with negative or atypical chest radiographs and negative sputum examinations, other diagnostic tests may provide additional information in deciding whether to proceed to bronchoalveolar lavage. Elevation of serum lactate dehydrogenase occurs in 95% of cases of pneumocystis pneumonia, but the specificity of this finding is at best 75%. Either a normal diffusing capacity of carbon monoxide (D_L CO) or a high-resolution CT scan of the chest that demonstrates no interstitial lung disease makes the diagnosis of pneumocystis pneumonia very unlikely. In addition, a CD4 count above 250 cells/uL within 2 months prior to evaluation of respiratory symptoms makes a diagnosis of pneumocystis pneumonia unlikely; only 1-5% of cases occur above this CD4 count level ([Figure 31-1](#)). This is true even if the patient previously had a CD4 count lower than 200 cells/uL but has had an increase with antiretroviral therapy.

Pneumothoraces are common in HIV-infected patients with a history of pneumocystis pneumonia, especially if they have received aerosolized pentamidine treatment. Because patients may have a pneumothorax as their presenting symptom of recurrent pneumocystis pneumonia, such patients who have not had therapy for pneumocystis pneumonia in the preceding 3 months may need evaluation for pneumocystis. Pneumothoraces in HIV-infected individuals should be treated initially in the same fashion as in other patients. Unfortunately, they frequently recur with clamping or removal of the chest tube. Sclerosis with bleomycin or talc is the treatment of choice for recurrent pneumothoraces, but it is not uniformly successful even when multiple treatments are performed. If sclerosis fails, thoroscopic stapling or thoracotomy may be required.

b. Other infectious pulmonary diseases—Other infectious causes of pulmonary disease in AIDS patients include bacterial, mycobacterial, and viral pneumonias. Community-acquired pneumonia is the most common cause of pulmonary disease in HIV-infected persons. An increased incidence of pneumococcal pneumonia with septicemia and *Haemophilus influenzae* pneumonia has been reported. *Pseudomonas aeruginosa* is an important respiratory pathogen in advanced disease. The incidence of infection with *Mycobacterium tuberculosis* has markedly increased in metropolitan areas because of HIV infection as well as homelessness. Tuberculosis occurs in an estimated 4% of persons in the United States who have AIDS. Apical infiltrates and disseminated disease occur more commonly than among immunocompetent hosts. Although a PPD test should be performed on all HIV-infected persons in whom a diagnosis of tuberculosis is being considered, the lower the CD4 cell count, the greater the likelihood of anergy. Because "anergy" skin test panels do not accurately classify those patients who are infected with tuberculosis but unreactive to the PPD, they are not recommended. Treatment of HIV-infected persons with active tuberculosis is similar to treatment of HIV-uninfected tubercular individuals (see [Chapter 9](#)). However, rifampin should not be given to patients receiving indinavir, nelfinavir, amprenavir, lopinavir, or delavirdine. In these cases, rifabutin may be substituted, but it may require dosing modifications depending upon the antiretroviral regimen. Multidrug-resistant tuberculosis is a major problem in several metropolitan areas. Noncompliance with prescribed antituberculous drugs is a major risk factor. Several of the reported outbreaks appear to implicate nosocomial spread. The emergence of drug resistance makes it essential that antibiotic sensitivities be performed on all positive cultures. Drug therapy should be individualized. Patients with multidrug-resistant *M tuberculosis* infection should receive at least three drugs to which their organism is sensitive. Atypical mycobacteria can cause pulmonary disease in AIDS patients with or without preexisting lung disease and responds variably to treatment. Making a distinction between *M tuberculosis* and atypical mycobacteria requires culture of sputum specimens. If culture of the sputum produces acid-fast bacilli, definitive identification may take several weeks using traditional techniques. DNA probes allow for presumptive identification usually within days of a positive culture. While awaiting definitive diagnosis, clinicians should err on the side of treating patients as if they have *M tuberculosis* infection. In cases where the risk of atypical mycobacteria is very high (eg, a person without risk for tuberculosis exposure with a CD4 count under 50 cells/uL—see [Figure 31-1](#)), clinicians may wait for definitive diagnosis if the person is smear-negative for acid-fast bacilli, clinically stable, and not living in a communal setting. Isolation of cytomegalovirus from bronchoalveolar lavage fluid occurs commonly in AIDS patients but does not establish a definitive diagnosis. Diagnosis of cytomegalovirus pneumonia requires biopsy; response to treatment is poor. Histoplasmosis, coccidioidomycosis, and cryptococcal disease should also be considered in the differential diagnosis of unexplained pulmonary infiltrates.

c. Noninfectious pulmonary diseases—Noninfectious causes of lung disease include Kaposi's sarcoma, non-Hodgkin's lymphoma, and interstitial pneumonitis. In patients with known Kaposi's sarcoma, pulmonary involvement complicates the course in approximately one-third of cases. However, pulmonary involvement is rarely the presenting manifestation of Kaposi's sarcoma. Non-Hodgkin's lymphoma may involve the lung as the sole site of disease but more commonly involves other organs as well, especially the brain, liver, and gastrointestinal tract. Both of these processes may show nodular or diffuse parenchymal involvement, pleural effusions, and mediastinal adenopathy on chest radiographs.

Nonspecific interstitial pneumonitis may mimic pneumocystis pneumonia. Lymphocytic interstitial pneumonitis seen in lung biopsies has a variable clinical course. Typically, these patients present with several months of mild cough and dyspnea; chest radiographs show interstitial infiltrates. Many patients with this entity undergo transbronchial biopsies in an attempt to diagnose pneumocystis pneumonia. Instead, the tissue shows interstitial inflammation ranging from an intense lymphocytic infiltration (consistent with lymphoid interstitial pneumonitis) to a mild mononuclear inflammation. Corticosteroids may be helpful in some cases refractory to antiretroviral therapy.

d. Sinusitis—Chronic sinusitis can be a frustrating problem for HIV-infected patients. Symptoms include sinus congestion and discharge, headache, and fever. Some patients may have radiographic evidence of sinus disease on sinus CT scan or sinus x-ray in the absence of significant symptoms. Nonsmoking patients with purulent drainage should be treated with amoxicillin (500 mg orally three times a day). Patients who smoke should be treated with amoxicillin-potassium clavulanate (500 mg orally three times a day) to cover *H influenzae*. Prolonged treatment (3-6 weeks) with an antibiotic and guaifenesin (600 mg orally twice daily) to decrease sinus congestion may be required. For patients not responding to amoxicillin-potassium clavulanate, levofloxacin should be tried (400 mg orally daily). Some patients may require referral to an otolaryngologist for sinus drainage.

3. Central nervous system disease—Central nervous system disease in HIV-infected patients can be divided into intracerebral space-occupying lesions, encephalopathy, meningitis, and spinal cord processes. Many of these complications have declined markedly in prevalence in the era of highly active antiretroviral therapy.

a. Toxoplasmosis—Toxoplasmosis is the most common space-occupying lesion in HIV-infected patients. Patients may present with headache, focal neurologic deficits, seizures, or altered mental status. The diagnosis is usually made presumptively based on the characteristic appearance of cerebral imaging studies in an

individual known to be seropositive for toxoplasma. Typically, toxoplasmosis appears as multiple contrast-enhancing lesions on CT scan. Lesions tend to be peripheral, with a predilection for the basal ganglia.

Single lesions are atypical of toxoplasmosis. When a single lesion has been detected by CT scanning, MRI scanning—because of its greater sensitivity—may reveal multiple lesions. If a patient has a single lesion on MRI and is neurologically stable, clinicians may pursue a 2-week empirical trial of toxoplasmosis therapy. A repeat scan should be performed at 2 weeks. If the lesion has not diminished in size, biopsy of the lesion should be performed. Since many HIV-infected patients will have detectable titers, a positive toxoplasma serologic test does not confirm the diagnosis. Conversely, as many as 15% of patients with toxoplasmosis have negative titers by enzyme immunoassay or immunofluorescence assays.

b. Central nervous system lymphoma—Primary non-Hodgkin's lymphoma is the second most common space-occupying lesion in HIV-infected patients. Symptoms are similar to those with toxoplasmosis. While imaging techniques cannot distinguish these two diseases with certainty, lymphoma more often is solitary. Other less common lesions should be suspected if there is preceding bacteremia, positive tuberculin test, fungemia, or intravenous drug use. These include bacterial abscesses, cryptococcomas, tuberculomas, and nocardia lesions.

Because techniques for stereotactic brain biopsy have improved, this procedure plays an increasing role in diagnosing cerebral lesions. Biopsy should be strongly considered if lesions are solitary or do not respond to toxoplasmosis treatment, especially if they are easily accessible. Diagnosis of lymphoma is important because many patients benefit from treatment (radiation therapy). In the future, it may be possible to avoid brain biopsy by utilizing PCR assay of cerebrospinal fluid for Epstein-Barr virus DNA, which is present in 90% of cases.

c. AIDS dementia complex—The diagnosis of AIDS dementia complex (HIV-associated cognitive-motor complex) is one of exclusion based on a brain imaging study and on spinal fluid analysis that excludes other pathogens. Neuropsychiatric testing is helpful in distinguishing patients with dementia from those with depression. Patients with AIDS dementia complex typically have difficulty with cognitive tasks and exhibit diminished motor speed. Patients may first notice a deterioration in their handwriting. The manifestations of dementia may wax and wane, with persons exhibiting periods of lucidity and confusion over the course of a day. Many patients improve with effective antiretroviral treatment. Metabolic abnormalities may also cause changes in mental status: hypoglycemia, hyponatremia, hypoxia, and drug overdose are important considerations in this population. Other less common infectious causes of encephalopathy include progressive multifocal leukoencephalopathy (discussed below), cytomegalovirus, syphilis, and herpes simplex encephalitis.

d. Cryptococcal meningitis—Cryptococcal meningitis typically presents with fever and headache. Less than 20% of patients have meningismus. Diagnosis is based on a positive latex agglutination test (CRAG) or positive culture of spinal fluid for cryptococcus. Seventy to 90% of patients with cryptococcal meningitis have a positive serum CRAG. Thus, a negative serum CRAG test makes a diagnosis of cryptococcal meningitis unlikely and can be useful in the initial evaluation of a patient with headache, fever, and normal mental status. HIV meningitis, characterized by lymphocytic pleocytosis of the spinal fluid with negative culture, is common early in HIV infection.

e. HIV myelopathy—Spinal cord function may also be impaired in HIV-infected individuals. HIV myelopathy presents with leg weakness and incontinence. Spastic paraparesis and sensory ataxia are seen on neurologic examination. Myelopathy is usually a late manifestation of HIV disease, and most patients will have concomitant HIV encephalopathy. Pathologic evaluation of the spinal cord reveals vacuolation of white matter. Because HIV myelopathy is a diagnosis of exclusion, symptoms suggestive of myelopathy should be evaluated by lumbar puncture to rule out cytomegalovirus polyradiculopathy (described below) and an MRI or CT scan to exclude epidural lymphoma.

f. Progressive multifocal leukoencephalopathy (PML)—PML is a viral infection of the white matter of the brain seen in patients with very advanced HIV infection. It typically results in focal neurologic deficits such as aphasia, hemiparesis, and cortical blindness. Imaging studies are strongly suggestive of the diagnosis if they show nonenhancing white matter lesions without mass effect. Extensive lesions may be difficult to differentiate from the changes caused by HIV. Several patients have stabilized or improved after the institution of combination antiretroviral therapy or cidofovir.

4. Peripheral nervous system—Peripheral nervous system syndromes include inflammatory polyneuropathies, sensory neuropathies, and mononeuropathies.

An inflammatory demyelinating polyneuropathy similar to Guillain-Barre syndrome occurs in HIV-infected patients, usually prior to frank immunodeficiency. The syndrome in many cases improves with plasmapheresis, supporting an autoimmune basis of the disease. Cytomegalovirus can cause an ascending polyradiculopathy characterized by lower extremity weakness and a neutrophilic pleocytosis on spinal fluid analysis with a negative bacterial culture. Transverse myelitis can be seen with herpes zoster or cytomegalovirus.

Peripheral neuropathy is common among HIV-infected persons. Patients typically complain of numbness, tingling, and pain in the lower extremities. Symptoms are disproportionate to findings on gross sensory and motor evaluation. The most common cause is prior antiretroviral therapy with stavudine or didanosine. Patients who report these symptoms should be switched to an alternative agent if possible. Caution should be used when administering these agents to patients with a history of peripheral neuropathy. Unfortunately, drug-induced neuropathy is not always reversed when the offending agent is discontinued. Patients with advanced disease may also develop peripheral neuropathy even if they have never taken antiretroviral therapy. Evaluation should rule out other causes of sensory neuropathy such as alcoholism, thyroid disease, vitamin B₁₂ deficiency, and syphilis.

Treatment of peripheral neuropathy is aimed at symptomatic relief. Patients should be initially treated with gabapentin (start at 300 mg at bedtime and increase to 300-900 mg orally three times a day). Although many clinicians initiate a trial of amitriptyline (10-25 mg orally at bedtime), responses to this agent are uncommon.

5. Rheumatologic manifestations—Arthritis, involving single or multiple joints, with or without effusion, has been commonly noted in HIV-infected patients. Involvement of large joints is most common. While the cause of HIV-related arthritis is unknown, most patients will respond to nonsteroidal anti-inflammatory agents. Patients with a sizable effusion, especially if the joint is warm or erythematous, should have the joint tapped, followed by culture of the fluid to rule out suppurative arthritis as well as fungal and mycobacterial disease.

Several rheumatologic syndromes, including reactive arthritis (Reiter's syndrome), psoriatic arthritis, sicca syndrome, and systemic lupus erythematosus, have been reported in HIV-infected patients ([Chapter 19](#)). However, it is unclear if the prevalence is greater than in the general population.

6. Myopathy—Myopathies are increasingly noted in HIV-infected patients. Proximal muscle weakness is typical, and patients may have varying degrees of muscle tenderness. The most important clinical distinction is between myopathy due to the primary effect of HIV and that due to zidovudine. Patients with symptomatic myopathy, especially with creatine kinase levels greater than 1000 units/L, should have their dose of zidovudine decreased or stopped and be considered for alternative antiviral therapy. A muscle biopsy can distinguish HIV myopathy from zidovudine myopathy and should be considered in patients for whom continuation of zidovudine is essential.

7. Retinitis—Complaints of visual changes must be evaluated immediately in HIV-infected patients. Cytomegalovirus retinitis, characterized by perivascular hemorrhages and fluffy exudates, is the most common retinal infection in AIDS patients and can be rapidly progressive. In contrast, cotton wool spots, which are also common in HIV-infected people, are benign, remit spontaneously, and appear as small indistinct white spots without exudation or hemorrhage. This distinction may be difficult at times for the nonspecialist, and patients with visual changes should be seen by an ophthalmologist. Other rare retinal processes include other herpesvirus infections or toxoplasmosis.

8. Oral lesions—The findings of oral candidiasis and hairy leukoplakia are significant for several reasons. First, these lesions are highly suggestive of HIV infection. Second, several studies have indicated that patients with these lesions have a high rate of progression to AIDS even with statistical adjustment for CD4 count.

Hairy leukoplakia is caused by the Epstein-Barr virus. The lesion is not usually troubling to patients and sometimes regresses spontaneously. Hairy leukoplakia is commonly seen as a white lesion on the lateral aspect of the tongue. It may be flat or slightly raised, is usually corrugated, and has vertical parallel lines with fine or thick ("hairy") projections. Oral candidiasis can be bothersome to patients, many of whom report an unpleasant taste or mouth dryness. There are two types of oral candidiasis: pseudomembranous (removable white plaques) and erythematous (red friable plaques). Treatment is with topical agents such as clotrimazole 10-mg troches (one troche four or five times a day). Patients with candidiasis that does not respond to topical antifungals can be treated with fluconazole (50-100 mg orally once a day for 3-7 days). Chronic suppression of oral candidiasis with fluconazole has been associated with development of candidiasis resistant to all available azoles and thus should be avoided except in frequently recurring cases.

Angular cheilitis—fissures at the sides of the mouth—is usually due to candida as well and can be treated topically with ketoconazole cream (2%) twice a day.

Gingival disease is common in HIV-infected patients and is thought to be due to an overgrowth of microorganisms. It usually responds to professional dental cleaning and chlorhexidine rinses. Some HIV-infected patients will develop a particularly aggressive gingivitis or periodontitis; these patients should be started on antibiotics that cover anaerobic oral flora (eg, metronidazole, 250 mg four times a day for 4 or 5 days) and referred to oral surgeons with experience with these entities.

Aphthous ulcers are painful and may interfere with eating. They can be treated with fluocinonide (0.05% ointment mixed 1:1 with plain Orabase and applied six times a day to the ulcer). For lesions that are difficult to reach, patients should use dexamethasone swishes (0.5 mg in 5 mL elixir three times a day). The pain of the ulcers can

be relieved with use of an anesthetic spray (10% lidocaine). For patients with refractory ulcers, thalidomide, starting at a dose of 50 mg orally daily and increasing to 100-200 mg daily, has proved useful. It should only be administered to patients at zero risk of procreation. The most common side effects are sedation and peripheral neuropathy. Other lesions seen in the mouths of HIV-infected patients include Kaposi's sarcoma (usually on the hard palate) and warts.

9. Gastrointestinal manifestations—

a. Candidal esophagitis—(See also discussion in [Chapter 14](#).) Esophageal candidiasis is a common AIDS infection. In a patient with characteristic symptoms, empirical antifungal treatment is begun with fluconazole (200 mg daily for 10-14 days). Further evaluation to identify other causes of esophagitis (herpes simplex, cytomegalovirus) is reserved for patients who do not improve with treatment.

b. Hepatic disease—Autopsy studies have demonstrated that the liver is a frequent site of infections and neoplasms in HIV-infected patients. However, many of these infections are not clinically symptomatic. Clinicians may note elevations of alkaline phosphatase and aminotransferases on routine chemistry panels. Mycobacterial disease, cytomegalovirus, hepatitis B virus, hepatitis C virus, and lymphoma cause liver disease and can present with varying degrees of nausea, vomiting, and right upper quadrant abdominal pain. Sulfonamides, imidazole drugs, antituberculous medications, pentamidine, clarithromycin, and didanosine (ddI) have also been associated with hepatitis. HIV-infected patients with chronic hepatitis may have more rapid progression of liver disease because of the concomitant immunodeficiency or hepatotoxicity of antiretroviral therapy. Percutaneous liver biopsy may be helpful in diagnosing liver disease, but the cause can frequently be determined by other tests (eg, blood culture, biopsy of a more accessible site). Moreover, because the majority of hepatic infections do not respond well to treatment (eg, *M avium* complex), liver biopsy should be reserved for people with persistent symptoms and laboratory abnormalities in whom no other cause for illness can be determined.

c. Biliary disease—Cholecystitis presents with manifestations similar to those seen in immunocompetent hosts but is more likely to be acalculous. Sclerosing cholangitis and papillary stenosis have also been increasingly reported in HIV-infected patients. Typically, the syndrome presents with severe nausea, vomiting, and right upper quadrant pain. Liver function tests generally show alkaline phosphatase elevations disproportionate to elevation of the aminotransferases. Although dilated ducts can be seen on ultrasound, the diagnosis is made by endoscopic retrograde cholangiopancreatography, which reveals intraluminal irregularities of the proximal intrahepatic ducts with "pruning" of the terminal ductal branches. Stenosis of the distal common bile duct at the papilla is commonly seen with this syndrome. Cytomegalovirus, cryptosporidium, and microsporidia are thought to play inciting roles in this syndrome. Initial reports of symptomatic improvement with performance of sphincterotomies were encouraging, but many patients had recurrence of symptoms.

d. Enterocolitis—Enterocolitis is a common problem in HIV-infected individuals. Organisms known to cause enterocolitis include bacteria (campylobacter, salmonella, shigella), viruses (cytomegalovirus, adenovirus), and protozoans (cryptosporidium, *Entamoeba histolytica*, giardia, isospora, Microsporida). HIV itself may cause enterocolitis. Several of the organisms causing enterocolitis in HIV-infected individuals also cause diarrhea in immunocompetent hosts. However, HIV-infected patients tend to have more severe and more chronic symptoms, including high fevers and severe abdominal pain that can mimic acute abdominal catastrophes. Bacteremia and concomitant biliary involvement are also more common with enterocolitis in HIV-infected patients. Relapses of enterocolitis following adequate therapy have been reported with both salmonella and shigella infections.

Because of the wide range of agents known to cause enterocolitis, a stool culture and multiple stool examinations for ova and parasites (including modified acid-fast staining for cryptosporidium) should be performed. Those patients who have cryptosporidium in one stool with improvement in symptoms in less than 1 month should not be considered to have AIDS, as cryptosporidium is a cause of self-limited diarrhea in HIV-negative hosts. More commonly, HIV-infected patients with cryptosporidium have persistent enterocolitis with profuse watery diarrhea.

To date, no consistently effective treatments have been developed for cryptosporidium infection. The most effective treatment of cryptosporidiosis is to improve immune function through the use of effective antiretroviral treatment. The diarrhea can be treated symptomatically with diphenoxylate with atropine (one or two tablets orally three or four times a day). Those who do not respond may be given paregoric with bismuth (5-10 mL orally three or four times a day). Octreotide in escalating doses (starting at 0.05 mg subcutaneously every 8 hours for 48 hours) has been found to ameliorate symptoms in approximately 40% of patients with cryptosporidia or idiopathic HIV-associated diarrhea.

Patients with a negative stool examination and persistent symptoms should be evaluated with colonoscopy and biopsy. Patients whose symptoms last longer than 1 month with no identified cause of diarrhea are considered to have a presumptive diagnosis of AIDS enteropathy. Patients may respond to institution of effective antiretroviral treatment. Upper endoscopy with small bowel biopsy is not recommended as a routine part of the evaluation.

e. Other disorders—Two other important gastrointestinal abnormalities in HIV-infected patients are gastropathy and malabsorption. It has been documented that some HIV-infected patients do not produce normal levels of stomach acid and therefore are unable to absorb drugs that require an acid medium. This decreased acid production may explain, in part, the susceptibility of HIV-infected patients to campylobacter, salmonella, and shigella, all of which are sensitive to acid concentration. There is no evidence that *Helicobacter pylori* is more common in HIV-infected persons.

A malabsorption syndrome occurs commonly in HIV-infected patients. It can be due to infection of the small bowel with *M avium* complex, cryptosporidium, or microsporidia.

10. Endocrinologic manifestations—The adrenal gland is the most commonly afflicted endocrine gland in patients with AIDS. Abnormalities demonstrated on autopsy include infection (especially with cytomegalovirus and *M avium* complex), infiltration with Kaposi's sarcoma, and injury from hemorrhage and presumed autoimmunity. The prevalence of clinically significant adrenal insufficiency is low. Patients with suggestive symptoms should undergo a cosyntropin stimulation test.

While frank deficiency of cortisol is rare, an isolated defect in mineralocorticoid metabolism may lead to salt-wasting and hyperkalemia. Such patients should be treated with fludrocortisone (0.1-0.2 mg daily).

AIDS patients appear to have abnormalities of thyroid function tests different from those of patients with other chronic diseases. AIDS patients have been shown to have high levels of triiodothyronine (T₃), thyroxine (T₄), and thyroid-binding globulin and low levels of reverse triiodothyronine (rT₃). The causes and clinical significance of these abnormalities are unknown.

11. Skin manifestations—HIV-infected patients commonly develop skin manifestations that can be grouped into viral, bacterial, fungal, neoplastic, and nonspecific dermatitides.

Herpes simplex infections occur more frequently, tend to be more severe, and are more likely to disseminate in AIDS patients than in immunocompetent hosts. Because of the risk of progressive local disease, all herpes simplex attacks should be treated with acyclovir (400 mg orally three times a day for 7 days), famciclovir (500 mg orally twice daily for 7 days), or valacyclovir (500 mg orally twice daily for 7 days). To avoid the complications of attacks, many clinicians recommend suppressive therapy for HIV-infected patients with a history of recurrent herpes. Options for suppressive therapy include acyclovir (400 mg orally twice daily), famciclovir (250 mg orally twice daily), and valacyclovir (500 mg orally daily).

Herpes zoster is a common manifestation of HIV infection. As with herpes simplex infections, patients with zoster should be treated with acyclovir to prevent dissemination (800 mg orally four or five times per day for 7 days). Alternatively, famciclovir (500 mg orally three times a day) or valacyclovir (500 mg three times a day) may be used. Vesicular lesions should be cultured if there is any question about their origin, since herpes simplex responds to much lower doses of acyclovir. Disseminated zoster and cases with ocular involvement should be treated with intravenous (10 mg/kg every 8 hours for 7-10 days) rather than oral acyclovir.

Molluscum contagiosum is seen in HIV-infected patients, as in other immunocompromised patients. Lesions have a propensity for spreading widely over the patient's skin and should be treated with topical liquid nitrogen.

Staphylococcus is the most common bacterial cause of skin disease in HIV-infected patients; it usually presents as **folliculitis**, **superficial abscesses (furuncles)**, or **bullous impetigo**. Because dissemination with sepsis has been reported, attempts should be made to treat these lesions aggressively. Folliculitis is initially treated with topical clindamycin or mupirocin, and patients may benefit from regular washing with an antibacterial soap such as chlorhexidine. Intranasal mupirocin has been used successfully for staphylococcal decolonization in other settings. In HIV-infected patients with recurrent staphylococcal infections, weekly intranasal mupirocin should be considered in addition to topical care and systemic antibiotics. Abscesses often require incision and drainage. Patients may need antistaphylococcal antibiotics such as dicloxacillin, 250-500 mg orally four times daily, or erythromycin, 250 mg orally four times daily (with rifampin, 600 mg orally daily for 10 days for nasal staphylococcal decolonization), for severe folliculitis.

Bacillary angiomatosis is a well-described entity in HIV-infected patients. It is caused by two closely related organisms: *Bartonella henselae* and *Bartonella quintana*. The epidemiology of *B henselae* infection suggests zoonotic transmission from young cats. *B quintana* may be harbored by fleas. The most common manifestation is raised, reddish, highly vascular skin lesions that can mimic the lesions of Kaposi's sarcoma. Fever is a common manifestation of this infection; involvement of bone, lymph nodes, and liver has also been reported. The infection responds to doxycycline, 100 mg orally twice daily, or erythromycin, 250 mg orally four times daily. Therapy is continued for at least 14 days, and patients who are seriously ill with visceral involvement may require months of therapy.

The majority of **fungal rashes** afflicting AIDS patients are due to dermatophytes and candida. These are particularly common in the inguinal region but may occur anywhere on the body. Fungal rashes generally respond well to topical clotrimazole (1% twice a day) or ketoconazole (2% twice a day).

Kaposi's sarcoma lesions are red or purple, flat or raised papules that generally do not blanch. Since they may be confused with lesions of bacillary angiomatosis, biopsy for definitive diagnosis should be performed. Individual lesions can be treated with radiation or with intralesional injection of vinblastine, 0.01-0.02 mg in 0.1 mL of saline. Other dermatologic malignancies seen disproportionately among HIV-infected persons include basal cell and squamous cell carcinomas.

Seborrheic dermatitis is more common in HIV-infected patients. Scrapings of seborrhea have revealed *Malassezia furfur* (*Pityrosporum ovale*), implying that the seborrhea is caused by this fungus. Consistent with the isolation of this fungus is the clinical finding that seborrhea responds well to topical clotrimazole (1% cream) as well as hydrocortisone (1% cream).

Xerosis presents in HIV-infected patients with severe pruritus. The patient may have no rash, or nonspecific excoriations from scratching. Treatment is with emollients (eg, absorption base cream) and antipruritic lotions (eg, camphor 9.5% and menthol 0.5%).

Psoriasis can be very severe in HIV-infected patients. Phototherapy and etretinate (0.25-9.75 mg/kg/d orally in divided doses) may be used for recalcitrant cases in consultation with a dermatologist. Because of the underlying immunodeficiency, methotrexate should be avoided.

12. HIV-related malignancies—Four cancers are currently included in the CDC classification of AIDS: Kaposi's sarcoma, non-Hodgkin's lymphoma, primary lymphoma of the brain, and invasive cervical carcinoma. Epidemiologic studies have shown that between 1973 and 1987 among single men in San Francisco, the risk of Kaposi's sarcoma increased more than 5000-fold and the risk of non-Hodgkin's lymphoma more than tenfold. The increase in incidence of malignancies is probably a function of impaired cell-mediated immunity.

Kaposi's sarcoma lesions may appear anywhere; careful examination of the eyelids, conjunctiva, pinnae, palate, and toe webs is mandatory to locate potentially occult lesions. In light-skinned individuals, Kaposi's lesions usually appear as purplish, nonblanching lesions that can be papular or nodular. In dark-skinned individuals, the lesions may appear more brown. In the mouth, lesions are most often palatal papules, though exophytic lesions of the tongue and gingivae may also be seen. Kaposi's lesions may be confused with other vascular lesions such as angiomas and pyogenic granulomas. About 40% of patients with dermatologic Kaposi's sarcoma will develop visceral disease (eg, gastrointestinal, pulmonary). Rapidly progressive dermatologic or visceral disease is best treated with systemic chemotherapy. Liposomally encapsulated doxorubicin given intravenously every 3 weeks has a response rate of approximately 70%. Alpha interferon (10 million units subcutaneously three times a week) also has activity against Kaposi's sarcoma. However, symptoms such as malaise and anorexia limit the utility of this therapy. Bulky lesions of the lower extremities accompanied by lymphedema are a common presentation of Kaposi's sarcoma. Radiation and conservative measures (eg, leg elevation, elastic stockings) may be helpful.

Non-Hodgkin's lymphoma in HIV-infected persons tends to be very aggressive. The malignancies are usually of B cell origin and characterized as diffuse large-cell tumors. Over 70% of the malignancies are extranodal.

The prognosis of patients with systemic non-Hodgkin's lymphoma depends primarily on the degree of immunodeficiency at the time of diagnosis. Patients with high CD4 counts do markedly better than those diagnosed at a late stage of illness. Patients with primary central nervous system lymphoma are treated with radiation. Response to treatment is good, but prior to the availability of highly active antiretroviral treatment, most patients died within a few months after diagnosis due to their underlying disease. Systemic disease is treated with chemotherapy. Common regimens are CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) and modified M-BACOD (methotrexate, bleomycin, doxorubicin, cyclophosphamide, vincristine, and dexamethasone). Granulocyte colony-stimulating factor (G-CSF; filgrastim) is used to maintain white blood counts with this latter regimen. Intrathecal chemotherapy is administered to prevent or treat meningeal involvement.

Although **Hodgkin's disease** is not included as part of the CDC definition of AIDS, studies have found that HIV infection is associated with a fivefold increase in the incidence of Hodgkin's disease. HIV-infected persons with Hodgkin's disease are more likely to have mixed cellularity and lymphocyte depletion subtypes of Hodgkin's disease and to present at an advanced stage of disease.

Anal dysplasia and squamous cell carcinoma have been noted in HIV-infected homosexual men. These lesions have been strongly correlated with previous infection by human papillomavirus (HPV). While many of the infected men report a history of anal warts or have visible warts, a significant percentage have silent papillomavirus infection. Cytologic (using Papanicolaou smears) and papillomavirus DNA studies can easily be performed on specimens obtained by anal swab. The growing frequency of these problems and the risk of progression from dysplasia to cancer in immunocompromised patients suggest that annual anal swabs for cytologic examination should be done in all HIV-infected persons who have engaged in receptive anal intercourse. An anal Pap smear is performed by rotating a moistened Dacron swab about 2 cm into the anal canal. The swab is immediately inserted into a cytology bottle.

HPV also appears to play a causative role in **cervical dysplasia and neoplasia**. The incidence and clinical course of cervical disease in HIV-infected women are discussed below.

13. Gynecologic manifestations—Vaginal candidiasis, cervical dysplasia and neoplasia, and pelvic inflammatory disease are more common in HIV-infected women than in uninfected women. These manifestations also tend to be more severe when they occur in association with HIV infection. Therefore, HIV-infected women need frequent gynecologic care. Vaginal candidiasis may be treated with topical agents (see [Chapter 36](#)). However, HIV-infected women with recurrent or severe vaginal candidiasis may need systemic therapy.

The incidence of cervical dysplasia in HIV-infected women is 40%. Because of this finding, HIV-infected women should have Papanicolaou smears every 6 months (as opposed to the AHRQ Guideline recommendation for every 12 months). Some clinicians recommend routine colposcopy or cervicography because cervical intraepithelial neoplasia has occurred in women with negative Papanicolaou smears. Cone biopsy is indicated in cases of serious cervical dysplasia.

Cervical neoplasia appears to be more aggressive among HIV-infected women. Most HIV-infected women with cervical cancer die of that disease rather than of AIDS. Because of its frequency and severity, cervical neoplasia was added to the CDC definition of AIDS in 1993.

While pelvic inflammatory disease appears to be more common in HIV-infected women, the bacteriology of this condition appears to be the same as among HIV-uninfected women. At present, HIV-infected women with pelvic inflammatory disease should be treated with the same regimens as uninfected women (see [Chapter 17](#)). However, inpatient therapy is generally recommended.

14. Inflammatory reactions—With initiation of highly active antiretroviral treatment, some patients experience inflammatory reactions based on immune reconstitution. Inflammatory reactions usually involve unusual presentations of opportunistic infections. For example, patients with cytomegalovirus retinitis have developed vitreitis after being treated with highly active antiretroviral treatment. *M. avium* can present as focal lymphadenitis or granulomatous masses in patients receiving highly active antiretroviral treatment. Tuberculosis may paradoxically worsen. PML and cryptococcal meningitis may also behave atypically. Clinicians should be alert to new complications in patients with recovering immune function.

B. Laboratory Findings

Specific tests for HIV include antibody and antigen detection ([Table 31-2](#)). Screening serology is done by enzyme-linked immunosorbent assay (ELISA). Positive specimens are then confirmed by a different method (eg, Western blot). The sensitivity of screening serologic tests is greater than 99.5%. The specificity of positive results by two different techniques approaches 100% even in low-risk populations. False-positive screening tests may occur as normal biologic variants or in association with recent influenza vaccination or other disease states, such as connective tissue disease. These are usually detected by negative confirmatory tests. Molecular biology techniques (polymerase chain reaction) show a small incidence of individuals (< 1%) who are infected with HIV for up to 36 months without generating an antibody response. However, 95% of persons will develop antibodies detectable by screening serologic tests within 6 weeks after infection.

Nonspecific laboratory findings with HIV infection may include anemia, leukopenia (particularly lymphopenia), and thrombocytopenia in any combination, elevation of the erythrocyte sedimentation rate, polyclonal hypergammaglobulinemia, and hypocholesterolemia. Cutaneous anergy is common.

Several laboratory markers are available to provide prognostic information and guide therapy decisions ([Table 31-2](#)). The most widely used marker is the absolute CD4 lymphocyte count. As counts decrease, the risk of serious opportunistic infection over the subsequent 3-5 years increases ([Figure 31-1](#)).

There are many limitations to using the CD4 count, including diurnal variation, depression with intercurrent illness, and intra- and interlaboratory variability. Therefore, the trend is more important than a single determination. The frequency of performance of counts depends on the patient's health status. Patients whose CD4 counts are substantially above the threshold for initiation of antiviral therapy (350 cells/uL) should have counts performed every 6 months. Those who have counts near or below 350 cells/uL should have counts performed every 3 months. This is necessary for evaluating the efficacy of antiviral therapy and for initiating *P. jiroveci* prophylactic therapy when the CD4 count drops below 200 cells/uL. Some studies suggest that the percentage of CD4 lymphocytes is a more reliable indicator of prognosis than the absolute counts because the percentage does not depend on calculating a manual differential. While the CD4 count measures immune dysfunction, it does not provide a measure of how actively HIV is replicating in the body. HIV viral load tests (discussed below) assess the level of viral replication and provide useful prognostic information which is independent of the information provided by CD4 counts.

Differential Diagnosis

HIV infection may mimic a variety of other medical illnesses. Specific differential diagnosis depends upon the mode of presentation. In patients presenting with constitutional symptoms such as weight loss and fevers, differential considerations include cancer, chronic infections such as tuberculosis and endocarditis, and endocrinologic diseases such as hyperthyroidism. When pulmonary processes dominate the presentation, acute and chronic lung infections must be considered as well as other causes of diffuse interstitial pulmonary infiltrates. When neurologic disease is the mode of presentation, conditions that cause mental status changes or neuropathy—eg, alcoholism, liver disease, renal dysfunction, thyroid disease, and vitamin deficiency—should be considered. If a patient presents with headache and a cerebrospinal fluid pleocytosis, other causes of chronic meningitis enter the differential. When diarrhea is a prominent complaint, infectious enterocolitis, antibiotic-associated colitis, inflammatory bowel disease, and malabsorptive symptoms must be considered.

Prevention

A. Primary Prevention

Until vaccination is a reality, prevention of HIV infection will depend upon effective precautions regarding sexual practices and intravenous drug use, use of perinatal HIV prophylaxis, screening of blood products, and infection control practices in the health care setting. Primary care clinicians should routinely obtain a sexual history and provide risk factor assessment of their patients and, when appropriate, screening for HIV infection with pre- and posttest counseling. Pretest counseling should include review of risk factors for HIV infection, discussion of safe sex and safe needle use, and the meaning of a positive test. Posttest counseling should include a review of the importance of safe sex and needle use practices. For persons who test positive, information on available medical and mental health services should be provided as well as guidance for contacting sexual or needle-sharing partners. It is the duty of clinicians to counsel HIV-negative patients on how to avoid exposure to HIV. Patients should be counseled not to exchange bodily fluids unless they are in a long-term mutually monogamous relationship with someone who has tested HIV antibody-negative and has not engaged in unsafe sex, injection drug use, or other HIV risk behaviors for at least 6 months prior to or at any time since the negative test.

Only latex condoms should be used, along with a water-soluble lubricant. Although nonoxynol-9, a spermicide, kills HIV, it is contraindicated because in some patients it may cause genital ulcers that could facilitate HIV transmission. Patients should be counseled that condoms are not 100% effective. They should be made familiar with the use of condoms, including, specifically, the advice that condoms must be used every time, that space should be left at the tip of the condom as a receptacle for semen, that intercourse with a condom should not be attempted if the penis is only partially erect, that men should hold on to the base of the condom when withdrawing the penis to prevent slippage, and that condoms should not be reused. Although anal intercourse remains the sexual practice at highest risk of transmitting HIV, seroconversions have been documented with vaginal and oral intercourse as well. Therefore, condoms should be used when engaging in these activities. Women as well as men should understand how to use condoms so as to be sure that their partners are using them correctly.

Persons using intravenous drugs should be cautioned never to exchange needles or other drug paraphernalia. When sterile needles are not available, bleach does appear to inactivate HIV and should be used to clean needles.

Current efforts to screen blood and blood products have lowered the risk of HIV transmission with transfusion of a unit of blood to 1:1,000,000.

In the hospital, concerns about nosocomial infection have led to the recommendation for universal body fluid precautions. This involves the rigorous use of gloves when handling any body fluid and the addition of gown, mask, and goggles for procedures that may result in splash or droplet spread as well as the use of specially designed needles with sheath devices to decrease the risk of needle sticks. Reports of transmission of drug-resistant tuberculosis in health care settings also have had infection control implications. All patients with cough in outpatient settings should be encouraged to wear masks. Hospitalized HIV-infected patients with cough should be placed in respiratory isolation until tuberculosis can be excluded by chest x-ray and sputum smear examination.

Primate model data have suggested that development of a protective vaccine may be possible, but clinical trials in humans using gp120 or its precursor gp160 have shown development of neutralizing antibodies to laboratory but not field isolates of HIV and may not be protective of infection. Many scientists have abandoned the quest for a fully protective HIV vaccine and are focusing on developing a vaccine that would reduce the chances of HIV transmission given a particular exposure.

B. Secondary Prevention

In the era prior to the development of highly effective antiretroviral treatment, cohort studies of individuals with documented dates of seroconversion demonstrate that approximately 50% of untreated seropositive persons develop AIDS within 10 years. Recent improvements in treatment would be expected to substantially improve this prognosis. Too few persons have been treated with these regimens prior to the development of AIDS to provide good data on progression of disease with these new regimens. Nevertheless, decreases in the incidence of AIDS reflecting successful treatment of HIV and successful HIV prevention efforts have been reported in the United States and western Europe.

There is substantial evidence that medical intervention with antiretroviral and prophylactic regimens can prevent opportunistic infections and improve survival. Prophylaxis and early intervention prevent several infectious diseases, including tuberculosis and syphilis, which are transmissible to others. Recommendations are listed in [Table 31-3](#).

Because of the increased occurrence of tuberculosis among HIV-infected patients, all such individuals should undergo PPD testing. Although anergy is common among AIDS patients, the likelihood of a false-negative result is much lower when the test is done early in infection. Those with positive tests (defined for HIV-infected patients as > 5 mm of induration) need a chest x-ray. Patients with an infiltrate in any location, especially if accompanied by mediastinal adenopathy, should have sputum sent for acid-fast staining. Patients with a positive PPD but negative evaluations for active disease should receive isoniazid (300 mg daily) with pyridoxine (50 mg daily) for 9 months to a year. An alternative regimen of rifampin plus pyrazinamide for 2 months is no longer recommended because of the high associated incidence of hepatotoxicity. Recent analysis suggests also that HIV-infected individuals at high risk for tuberculosis should receive a course of isoniazid prophylaxis regardless of the PPD status. This may include homeless individuals and injection drug users.

Because of recent increases in the number of cases of syphilis among men who have sex with men, including those who are HIV-infected, all such men should be screened for syphilis by RPR or VDRL every 6 months. Increases of syphilis cases among HIV-infected persons are of particular concern because these individuals are at increased risk of reactivation of syphilis and progression to tertiary syphilis despite standard treatment. Because the only widely available tests for syphilis are serologic and because HIV-infected individuals are known to have disordered antibody production, there is concern about the interpretation of these titers. This concern has been fueled by a report of an HIV-infected patient with secondary syphilis and negative syphilis serologic testing. Furthermore, HIV-infected individuals may lose FTA-ABS reactivity after treatment for syphilis, particularly if they have low CD4 counts. Thus, in this population, a nonreactive treponemal test does not rule out a past history of syphilis. In addition, persistence of treponemes in the spinal fluid after one dose of benzathine penicillin has been demonstrated in HIV-infected patients with primary and secondary syphilis. Therefore, the CDC has recommended an aggressive diagnostic approach to HIV-infected patients with reactive RPR or VDRL tests of greater than 1 year or unknown duration. All such patients should have a lumbar puncture with cerebrospinal fluid cell count and CSF-VDRL. Those with a normal cerebrospinal fluid evaluation are treated as having late latent syphilis (benzathine penicillin G, 2.4 million units intramuscularly weekly for 3 weeks) with follow-up titers. Those with a pleocytosis or a positive CSF-VDRL test are treated as having neurosyphilis (aqueous penicillin G, 2-4 million units intravenously every 4 hours, or procaine penicillin G, 2.4 million units intramuscularly daily, with probenecid, 500 mg four times daily, for 10 days). Some clinicians take a less aggressive approach to patients who have low titers (less than 1:8), a history of having been treated for syphilis, and a normal neurologic examination. Close follow-up of titers is mandatory if such a course is taken. For a more detailed discussion of this topic, see [Chapter 34](#).

The efficacy of pneumococcal vaccine is debated, but since it is safe, HIV-infected individuals should receive it. Patients without evidence of hepatitis B surface antigen or surface antibody should receive hepatitis B vaccination. Live vaccines, such as yellow fever vaccine, should be avoided. Measles vaccination, while a live virus vaccine, appears relatively safe when administered to HIV-infected individuals and should be given if the patient has never had measles or been adequately vaccinated.

HIV-infected individuals should be counseled with regard to safe sex. Because of the risk of transmission, they should be warned to use condoms with sexual

intercourse, including oral intercourse. Partners of HIV-infected women should use latex barriers such as dental dams (available at dental supply stores) to prevent direct oral contact with vaginal secretions. Substance abuse treatment should be recommended for persons who are using recreational drugs. They should be warned to avoid consuming raw meat or eggs to avoid infections with toxoplasma, campylobacter, and salmonella. HIV-infected patients should wash their hands thoroughly after cleaning cat litter or should forgo this household chore to avoid possible exposure to toxoplasmosis. To reduce the likelihood of infection with bartonella species, patients should avoid activities that might result in cat scratches or bites. Although the data are not conclusive, many clinicians recommend that HIV-infected persons—especially those with low CD4 counts—drink bottled water instead of tap water to prevent cryptosporidia infection.

Because of the emotional impact of HIV infection and subsequent illness, many patients will benefit from supportive counseling.

C. HIV Risk for Health Care Professionals

Epidemiologic studies show that needle sticks occur commonly among health care professionals, especially among surgeons performing invasive procedures, inexperienced hospital house staff, and medical students. Efforts to reduce needle sticks should focus on avoiding recapping needles and use of safety needles whenever doing invasive procedures under controlled circumstances. The risk of HIV transmission from a needle stick with blood from an HIV-infected patient is about 1:300. The risk is higher with deep punctures, large inocula, and source patients with high viral loads. The risk from mucous membrane contact is too low to quantitate.

Health care professionals who sustain needle sticks should be counseled and offered HIV testing as soon as possible. HIV testing is done to establish a negative baseline for worker's compensation claims in case there is a subsequent conversion. Follow-up testing is usually performed at 6 weeks, 3 months, and 6 months.

A case-control study by the Centers for Disease Control and Prevention indicates that administration of zidovudine following a needle stick decreases the rate of HIV seroconversion by 79%. Therefore, providers should be offered therapy with Combivir (zidovudine 300 mg plus lamivudine 150 mg orally twice daily). Providers who have exposures to persons who are likely to have antiretroviral drug resistance (eg, persons receiving therapy who have detectable viral loads) should have their therapy individualized, using at least two drugs to which the source is unlikely to be resistant. Some clinicians recommend triple combination regimens, including a protease inhibitor for all occupational exposures, because of uncertainty about drug resistance. Others save these more aggressive regimens for the higher-risk exposures listed above. Since reports have noted hepatotoxicity due to nevirapine in this setting, this agent should be avoided. Therapy should be started as soon as possible after exposure and continued for 4 weeks. Unfortunately, there have been documented cases of seroconversion following potential parenteral exposure to HIV despite prompt use of zidovudine prophylaxis. Counseling of the provider should include "safe sex" guidelines.

D. Postexposure Prophylaxis for Sexual and Drug Use Exposures to HIV

Following publication of a case-control study indicating that antiretroviral therapy decreased the odds of seroconversion among health care workers who had occupational exposure, some experts have recommended offering antiretroviral therapy following potential exposure to HIV through sexual activity or drug use. While there are no efficacy data to support this practice, there are similarities between the immune response following transcutaneous and transmucosal exposures. The goal of postexposure prophylaxis is to reduce or prevent local viral replication prior to dissemination such that the infection can be aborted.

The choice of antiretroviral agents and the duration of treatment are the same as those for exposures that occur through the occupational route (see above). In contrast to those with occupational exposures, some individuals may present very late after exposure. Because the likelihood of success declines with length of time from HIV exposure, it is not recommended that treatment be offered after 72 hours. In addition, because the psychosocial issues involved with postexposure prophylaxis for sexual and drug use exposures are complex, it should be offered only in the context of prevention counseling. Counseling should focus on how to prevent future exposures.

E. Preventing Perinatal Transmission of HIV

A multicenter trial showed that when zidovudine is administered to women during pregnancy, labor, and delivery and to their newborns, the rate of HIV transmission is decreased by two-thirds. An observational trial demonstrated that zidovudine treatment is almost as effective when begun during labor or when administered only to the infant, as long as treatment is begun within 48 hours after birth. Nonetheless, treatment begun by at least the second trimester is still recommended. Many women are currently being offered combination antiretroviral treatment to further lower the risk of transmission. The availability of treatment makes it essential that all women who are pregnant or considering pregnancy be offered HIV counseling and testing. Many obstetricians recommend combination antiretroviral treatment, especially if zidovudine resistance is suspected. HIV-infected women receiving antiretroviral therapy in whom pregnancy is recognized during the first trimester should be counseled about the benefits and potential risks to the fetus of treatment during the first trimester. Since healthy mothers make healthy babies, continuation of therapy should be strongly considered. Because about half of fetal infections in non-breast-feeding women occur shortly before or during the birth process, antiretroviral therapy should be administered whenever a woman initiates perinatal care even if she did not begin therapy in the second trimester. Breast feeding is thought to increase the rate of transmission by 10-20% and should be avoided.

Treatment

Treatment for HIV infection can be divided into four categories: therapy for opportunistic infections and malignancies, antiretroviral treatment, hematopoietic stimulating factors, and prophylaxis of opportunistic infections.

Experimental treatment regimens for HIV infection are constantly changing. Clinicians may obtain up-to-date information on experimental treatments by calling the AIDS Clinical Trials Information Service (ACTIS), 800-TRIALS-A (English and Spanish), and the National AIDS Hot Line, 800-342-AIDS (English), 800-344-SIDA (Spanish), and 800-AIDS-TTY (hearing-impaired).

A. Therapy for Opportunistic Infections and Malignancies

Treatment of common HIV infections and malignancies is detailed in [Table 31-4](#). In the era prior to the use of highly active antiretroviral treatment (HAART), patients required lifelong treatment for many infections, including cytomegalovirus retinitis, toxoplasmosis, and cryptococcal meningitis. However, among patients who have a good response to HAART, maintenance therapy for some opportunistic infections can be terminated. For example, in consultation with an ophthalmologist, maintenance treatment for CMV infection can be discontinued in persons with durable suppression of viral load on HAART who have a CD4 count > 100-150 cells/uL. Similar results have been observed in patients with *M avium* complex bacteremia.

The emergence of resistance is more common for some infections of HIV-infected people (eg, acyclovir-resistant herpes simplex) than among immunocompetent individuals. In addition, HIV-infected patients have an increased incidence of side effects to standard drugs such as trimethoprim-sulfamethoxazole.

Treating patients with repeated episodes of the same opportunistic infection can pose difficult therapeutic challenges. For example, patients with second or third episodes of pneumocystis pneumonia may have developed allergic reactions to standard treatments with a prior episode. Fortunately, there are several alternatives available for the treatment of pneumocystis infection. Trimethoprim with dapsone—and primaquine and clindamycin—are two combinations that often are tolerated in patients with a prior allergic reaction to trimethoprim-sulfamethoxazole and intravenous pentamidine. On the positive side, patients who develop second episodes of pneumocystis pneumonia while taking prophylaxis tend to have milder courses.

Well-established alternative regimens now also exist for most AIDS-related opportunistic infections: amphotericin B or fluconazole for cryptococcal meningitis; ganciclovir, cidofovir, or foscarnet for cytomegalovirus infection; and sulfadiazine or clindamycin with pyrimethamine for toxoplasmosis.

Corticosteroids. Although conceptually it would seem that corticosteroid therapy should be avoided in HIV-infected patients, steroid use has been shown to improve the course of patients with moderate to severe pneumocystosis (oxygen saturation < 90%, PO₂ < 65 mm Hg) when administered within 72 hours after diagnosis. The mechanism of action is presumed to be a decrease in alveolar inflammation.

B. Antiretroviral Therapy

The availability of agents that alone and in combination suppress HIV replication ([Table 31-5](#)) has had a profound impact on the natural history of HIV infection. Patients who achieve excellent suppression of HIV generally have stabilization or improvement of their clinical course which results from partial immunologic reconstitution and a subsequent decrease in complications of immunosuppression. The best time to initiate antiretroviral treatment remains controversial. The

recognition of continuous viral replication during early HIV infection and the considerable risk of disease progression in individuals with even low levels of circulating HIV RNA gave impetus to the concept of treating the majority of infected individuals with antiretroviral therapy even if the CD4 lymphocyte count was normal. The rationale for hitting the virus "early and hard" was based on the hope that such a strategy might eradicate HIV infection. Even if HIV could not be eradicated, it was thought that this strategy would preserve immune function over time. With greater experience, it is clear that HAART does not eradicate HIV. While these regimens are generally successful in maintaining immune function, the development of severe drug side effects—especially lipodystrophy and other metabolic complications—has significantly qualified enthusiasm for these regimens. Current recommendations are to initiate treatment for symptomatic HIV disease or asymptomatic HIV disease with a CD4 cell count of < 200 cells/uL. For asymptomatic persons with CD4 counts > 200/uL, the decision to initiate treatment should be individualized. In general, treatment would rarely be indicated with CD4 counts > 350 cells/uL. Patients with rapidly dropping CD4 counts or very high viral loads (> 50,000/uL) should be considered for earlier treatment. For those patients who might have difficulty adhering to treatment or who are at higher risk of toxicity (eg, underlying liver disease), waiting until the CD4 count nears 200 cells/uL may be a better strategy.

Patients who were begun on treatment at higher CD4 levels than are currently recommended for initiation of treatment are usually maintained on their regimens if they are doing well and are not suffering side effects from the treatment. However, a strategy of treatment interruption is being studied in this population.

Once a decision to initiate therapy has been made, several important principles should guide therapy. First, since HIV develops drug resistance to antiretroviral agents, a major goal of therapy should be total suppression of viral replication as measured by the serum viral load, which has been shown to correlate with antiviral effect in other compartments. To achieve this and maintain virologic control over time, aggressive combination therapy is essential, and partially suppressive combinations such as dual nucleoside therapy should be avoided. Similarly, if toxicity develops, it is preferable to interrupt the entire regimen rather than reduce individual doses. The current standard is to use at least three agents simultaneously. Since the number of drugs and potential combinations is finite and the development of drug resistance may severely compromise the efficacy of treatment, patients must be able to adhere to these regimens. Patients should be counseled that if they think they will miss many doses of treatment, it would be preferable to defer starting therapy until they are able to adhere to the regimen. Adherence can be promoted through the use of medication boxes with compartments (eg, Medisets), supportive counseling, or daily supervision of therapy. Therefore, decisions to withhold treatment should not be based upon a patient's circumstances (eg, active drug use or housing status) alone. Often, a trial intervention such as offering pneumocystis pneumonia prophylaxis may be helpful in determining the likelihood of adherence to a more complex antiretroviral regimen.

Monitoring of antiretroviral therapy has two goals. Laboratory evaluation for toxicity depends upon the specific drugs in the combination but generally should be done approximately every 3 months once a patient is on a stable regimen. The second aspect of monitoring is to regularly measure objective markers of efficacy. The CD4 cell count and HIV viral load should be repeated 1-2 months after the initiation or change of antiretroviral regimen and every 3-4 months thereafter in clinically stable patients. Reasons for changing antiretroviral regimens include intolerable adverse reactions, rising or persistently high viral loads, the clinical progression of disease, and continued immunologic deterioration as reflected by a declining CD4 cell count. Although a rebound in HIV viral load is cited as an indication to change therapy, exact parameters have not been established, and many patients appear to have continued clinical benefit in the face of rising viral load measurements. When therapy is modified, clinicians should attempt to start at least two agents to which an individual has not been exposed. Conversely, there is a risk to stopping a single medication because of the possibility of its causing a side effect if the remaining regimen contains too few medications to prevent rapid development of resistance.

Drug resistance testing is recommended for patients who are experiencing treatment failure (persistent or rising viral load despite adherence to an efficacious regimen). It is also recommended for guiding therapy in HIV-infected women who are pregnant. Resistance testing can also be considered when starting HAART in newly infected individuals living in areas where transmission of drug-resistant HIV is common. Of the two methods of resistance testing available, genotypic testing is more easily performed and less expensive. However, the interpretation of genotypic testing is complicated. In some cases, a single mutation will make a drug ineffective; in other cases, multiple genetic mutations are necessary to achieve high-grade resistance. Furthermore, some mutations that confer resistance to a particular agent may make the virus more susceptible to other agents. For example, HIV variants with the M184V mutation are resistant to lamivudine but more sensitive to other agents such as zidovudine, stavudine, and tenofovir. In a case such as this, it is advantageous to continue the lamivudine despite the fact that resistance testing shows the virus being resistant to it. The presence of certain genetic mutations confers resistance to particular agents. Although phenotypic testing would appear to be more relevant than genotypic testing since it offers the promise of determining how a patient's virus actually responds to different agents, it is expensive and its superiority has not been proved in most situations.

Both methods of resistance testing are limited by the fact that they may measure resistance in only some of the viral strains present in an individual. Resistance results may also be misleading if a patient is not taking antiretroviral medications at the time of testing. Thus, resistance results must be viewed cumulatively—ie, if resistance is reported to an agent on one test, it should be presumed to be present thereafter even if subsequent tests do not give the same result.

Although the ideal combination of drugs has not yet been defined, possible choices can be better understood after a review of the available agents. These drugs can be grouped into three major categories: nucleoside and nucleotide analogs, protease inhibitors, and nonnucleoside reverse transcriptase inhibitors.

1. Nucleoside and nucleotide analogs—

a. Zidovudine—Zidovudine (azidothymidine; AZT) was the first approved antiviral drug for HIV infection and remains an important agent. It is administered at a dose of 300 mg orally twice daily. A combination of zidovudine 300 mg and lamivudine 150 mg (Combivir) allows more convenient dosing of medication for individuals taking both of these agents. The cost of zidovudine (at a dose of 600 mg/d) is approximately \$270 a month. Side effects seen with zidovudine are listed in [Table 31-5](#). Approximately 40% of patients experience subjective side effects which usually remit within 6 weeks. The common dose-limiting side effects are anemia and neutropenia, which can be exacerbated by other drugs such as ganciclovir that cause bone marrow suppression. Anemia is usually mild, indolent in course, and characterized by macrocytosis. It is unresponsive to vitamin B₁₂ or folate supplementation. A minority of patients have the more rapid onset of red cell aplasia. Bone marrow toxicity is generally reversible with cessation of the drug. Erythropoietin (epoetin alfa), at a starting dose of 8000 units subcutaneously three times a week, and G-CSF (filgrastim), at a dose of 300 ug subcutaneously one to three times a week, can ameliorate these side effects in situations where alternatives to zidovudine therapy are limited. Long-term zidovudine administration may also be complicated by myopathy, with wasting and weakness usually most prominent in the gluteus and quadriceps muscles.

In monitoring patients receiving zidovudine, complete blood counts—with platelet and differential counts—should be done monthly for the first 2 months of therapy and then every 3 months. Creatine phosphokinase levels should be checked every 6 months. Zidovudine can be taken concomitantly with other medicines except probenecid, which prolongs the serum half-life of zidovudine. Long-term administration of zidovudine with ganciclovir can pose a difficult problem. Only 15% of patients tolerate this combination without significant hematologic toxicity. One approach to neutropenia is to add G-CSF (filgrastim) to the regimen; another is to substitute another agent for zidovudine.

b. Didanosine (ddI)—This agent also proved to have significant antiviral activity in early monotherapy trials and now is incorporated into combination regimens. Didanosine is available in three formulations: enteric-coated capsule, pill, and powder. Patients must take the medication on an empty stomach (1 hour before or 2-3 hours after meals). Indinavir and didanosine should be taken at least 1 hour apart.

For adults weighing at least 60 kg, the most convenient dosing is with the enteric-coated capsule (400 mg orally daily). Twice-daily dosing of didanosine with tablets or powder is by weight. For adults weighing < 60 kg, dosing is 125 mg (tablets) or 167 mg (powder) twice a day; for adults weighing = 60 kg, 200 mg (tablets) or 250 mg (powder) twice a day. To ensure adequate buffering agent, the pills should be taken two at a time and thoroughly chewed or dissolved in water. Diarrhea (due to the buffering agent used) is more common with the powder.

Unlike zidovudine, didanosine does not cause anemia but may cause neutropenia. It has also been associated with pancreatitis. The incidence of pancreatitis with didanosine is 5-10%—of fatal pancreatitis, less than 0.4%. Patients with a history of pancreatitis, as well as those taking other medications associated with pancreatitis (including trimethoprim-sulfamethoxazole and intravenous pentamidine) are at higher risk of this complication. Patients should be warned to use alcohol judiciously while taking didanosine. Clinicians should also teach patients to watch for the symptoms of pancreatitis and to stop treatment if they develop abdominal pain, nausea, or vomiting while taking didanosine until it can be determined if they have pancreatitis. Other common side effects with didanosine include a dose-related, reversible, painful peripheral neuropathy, which occurs in about 15% of patients, and dry mouth. Fulminant hepatic failure and electrolyte abnormalities, including hypokalemia, hypocalcemia, and hypomagnesemia, have been reported in patients taking didanosine.

c. Stavudine—Stavudine (d4T) has shown good activity as an antiretroviral drug. Side effects noted are peripheral neuropathy and, rarely, hepatitis. Pancreatitis has been reported in patients taking stavudine, but it is unclear if the drug was the cause of the pancreatitis. The dose is 40 mg orally twice daily for individuals weighing more than 70 kg.

d. Lamivudine—Lamivudine (3TC) is a safe and well-tolerated agent. The dosage is 150 mg orally twice daily. There are no significant side effects with this agent, and it has activity also against hepatitis B.

e. Abacavir—A daily dose of 300 mg orally twice daily results in potent antiretroviral activity. Abacavir retains activity against some HIV strains that have become resistant to other nucleoside drugs. Abacavir is formulated with zidovudine and lamivudine in a single pill (Trizivir, one tablet orally twice daily). Although this is the simplest triple-drug regimen available, it is not as efficacious as combining two nucleoside analogs with a protease inhibitor or an NNRTI and should be used only for patients who cannot comply with a more complicated regimen. The main toxicity of abacavir is a hypersensitivity syndrome in about 5% of patients, characterized by a flu-like syndrome with rash and fever that worsens with successive doses; individuals who develop this syndrome *should not* be rechallenged with this agent.

f. Zalcitabine—Zalcitabine (ddC) is thought to be one of the least effective antiretroviral agents and is therefore not commonly used. Its advantages are that it is inexpensive, easy to administer, and has no known hematologic side effects. The usual dosage of zalcitabine is approximately 0.005-0.01 mg/kg orally every 8 hours. This drug is formulated in 0.375-mg and 0.75-mg tablets.

Zalcitabine, like didanosine, may cause peripheral neuropathy. It is also associated with aphthous ulcers, rash, and rare cases of pancreatitis.

g. Tenofovir—Tenofovir is the only licensed nucleotide analog. It is given as a single daily oral dose of 300 mg and is generally well tolerated. Like lamivudine, it is active also against hepatitis B. Because HIV variants which are resistant to other nucleoside analogs are often sensitive to tenofovir, that drug is often included in second- and third-line treatment regimens.

2. Protease inhibitors—Six protease inhibitors—indinavir, nelfinavir, ritonavir, amprenavir, saquinavir, and lopinavir (in combination with ritonavir)—have been approved for use. Protease inhibitors have been shown to potently suppress HIV replication in vitro and in vivo and are always administered as part of a combination regimen, using either one or two agents from this class. If only one protease inhibitor is chosen as part of a regimen, possible choices include indinavir, amprenavir, or nelfinavir.

All the protease inhibitors—to differing degrees—are metabolized by the cytochrome P450 system, and each can inhibit and induce various P450 isoenzymes. Therefore, drug interactions are common and difficult to predict. Clinicians should consult the product inserts before prescribing protease inhibitors with other medications. Drugs such as rifabutin that are known to induce the P450 system should be avoided.

The fact that the protease inhibitors are dependent on metabolism through the cytochrome P450 system has led to some innovative dosing strategies. In particular, ritonavir dramatically inhibits the hepatic clearance of saquinavir, thereby enhancing its antiviral effect; the combination has demonstrated potent suppression of HIV. When the drugs are used together, the doses are reduced to 200 mg of ritonavir twice daily and 400 mg of saquinavir (soft gel) twice daily. The only additional toxicity observed with this combination has been elevation of hepatic aminotransferases. Thus, liver enzymes should be regularly monitored, especially in patients who have underlying liver disease. Similar strategies combine ritonavir with indinavir, nelfinavir, or amprenavir, allowing twice-daily dosing of these protease inhibitors.

When any protease inhibitor is used incorrectly, drug resistance develops rapidly. Protease inhibitors should never be used alone, and they should not be dose-escalated.

Protease inhibitors and nucleoside analogs have been linked to a constellation of metabolic abnormalities. These abnormalities include elevated cholesterol levels, elevated triglyceride levels, insulin resistance, diabetes mellitus, and changes in body fat composition (eg, abdominal obesity, skeletal wasting). The lipid abnormalities and body habitus changes are referred to as lipodystrophy. Its prevalence is known to be increased among persons treated with protease inhibitors, but it has been seen also in HIV-infected persons who have never been treated with these agents. The changes in body habitus are particularly disturbing to patients who are trying to maintain a positive body image. Of the different manifestations of lipodystrophy, the dyslipidemias that occur are of particular concern because of the likelihood that increased levels of cholesterol and triglycerides will result in increased prevalence of heart disease. All patients taking protease inhibitors or NRTIs should have a fasting cholesterol, LDL, and triglyceride level performed every 3-6 months. Until there is longer follow-up of HIV-infected persons with elevated cholesterol levels, treatment decisions should be the same as those for uninfected persons (see [Chapter 28](#)). HIV-infected persons who do not respond to dietary interventions should be started on pravastatin (20 mg daily orally) or atorvastatin (10 mg daily orally). Lovastatin and simvastatin should be avoided because of their interactions with protease inhibitors. Patients with fasting serum triglyceride levels > 1000 mg/dL who do not respond to dietary intervention should be treated with gemfibrozil (600 mg twice daily prior to the morning and evening meals).

a. Indinavir—The standard dose of indinavir is 800 mg orally three times a day. Twice-daily dosing of indinavir is feasible in combination with ritonavir or nelfinavir. It is recommended that indinavir be taken without food but with water 1 hour before or 2 hours after a meal. Nausea and headache are common complaints with this drug. Indinavir crystals are present in the urine in approximately 40% of patients; this results in clinically apparent nephrolithiasis in about 15% of patients receiving indinavir. Lower urinary tract symptoms and renal failure have been increasingly reported. Patients taking this drug should be instructed to drink at least 48 ounces of fluid a day to ensure adequate hydration in an attempt to avoid these complications, but if stones occur repeatedly, an alternative protease inhibitor may be needed. Mild indirect hyperbilirubinemia is also commonly observed in patients taking indinavir but is not an indication for discontinuation of the drug.

b. Nelfinavir—This agent appears to have slightly less potent antiviral activity than either indinavir or ritonavir but has shown short-term benefit in combination regimens. The dose of nelfinavir is 750 mg orally three times daily or 1250 mg orally twice daily. Diarrhea is a side effect in 25% of patients taking nelfinavir, and this symptom may be controlled in the majority of patients with over-the-counter antidiarrheal agents.

c. Ritonavir—Use of this potent protease inhibitor has been limited by its inhibition of the cytochrome P450 pathway causing a large number of drug-drug interactions and by its frequent side effects of fatigue, nausea, and paresthesias when the full dose of 600 mg orally twice daily is given. One of the major benefits of ritonavir is that it increases the bioavailability of other protease inhibitors (eg, saquinavir, lopinavir).

d. Saquinavir—As a single agent, in its original capsule formulation, saquinavir had limited bioavailability, which greatly curtailed its antiviral activity. However, it can be used in combination with ritonavir (400 mg of saquinavir and 200 mg of ritonavir twice daily). A soft-gel capsule formulation of saquinavir (Fortovase) is available and can be used as the sole protease inhibitor (ie, without ritonavir boosting) at a dosage of 1200 mg three times daily with food. However, because of the large pill burden and because of the necessity for three-times-daily dosing with food, saquinavir is not commonly used as the sole protease inhibitor. The most common side effects with saquinavir are diarrhea, nausea, dyspepsia, and abdominal pain. Soft-gel capsules of saquinavir do not require refrigeration if the capsules are kept at room temperature and used within 30 days.

e. Amprenavir—Amprenavir has efficacy and side effects similar to those of other protease inhibitors. Common side effects are nausea, vomiting, diarrhea, rash, and perioral paresthesia. The dose is 1200 mg orally twice daily. This requires that the patient take 16 capsules a day. When used in combination with ritonavir, the recommended doses are amprenavir 1200 mg with ritonavir 200 mg daily or amprenavir 600 mg with ritonavir 100 mg twice daily.

f. Lopinavir—This protease inhibitor appears to have less cross-resistance with other protease inhibitors. It is formulated with a low dose of ritonavir to maximize the bioavailability of lopinavir. It has been shown to be as effective as nelfinavir when used in combination with stavudine and lamivudine. The usual dose is 400 mg lopinavir with 100 mg of nelfinavir (three capsules) orally twice daily with food. When given along with efavirenz or nevirapine, a higher dose (533 mg/133 mg—four capsules) is needed. The most common side effect is diarrhea.

Second-generation protease inhibitors such as tipranavir and atazanavir retain activity against viral isolates resistant to the older drugs, but as of February 2003 none had been licensed in the United States.

3. Nonnucleoside reverse transcriptase inhibitors (NNRTIs)—These agents inhibit reverse transcriptase at a site different from that of the nucleoside and nucleotide agents described above. All three have shown antiviral activity as measured by HIV viral load and CD4 responses. The major advantage of the NNRTIs is that two of them (nevirapine and efavirenz) have potencies comparable to that of protease inhibitors—with less toxicity. In particular, they do not appear to cause lipodystrophy; patients with cholesterol and triglyceride elevations who are switched from a protease inhibitor to an NNRTI may have improvement in their symptoms. The resistance patterns of the NNRTIs are distinct from those of the protease inhibitors, so their use still leaves open the option for future protease inhibitor use.

The NNRTIs can be used with protease inhibitors in patients who are difficult to suppress on simpler regimens or when it is difficult to identify at least two agents to which the patient is not resistant. Because these agents may cause alterations in the clearance of protease inhibitors, dose modifications may be necessary when these two classes of medications are administered concomitantly. Resistance to one drug in this class uniformly predicts resistance to other drugs in the class, though second-generation drugs are being developed. There is no therapeutic reason for using more than one NNRTI at the same time.

a. Nevirapine—The target dose of nevirapine is 200 mg orally twice daily, but it is initiated at a dose of 200 mg once a day to decrease the incidence of rash, which is as high as 40% when full doses are begun immediately. If rash develops while the patient is taking 200 mg a day, the dose should not be increased until the rash resolves. Patients with mild rash can continue to be treated with nevirapine. Diphenhydramine (25-50 mg orally three or four times daily) may provide symptomatic relief.

b. Efavirenz—The major advantage of this agent is that can be given once daily in a single dose (600 mg orally). The side effects are neurologic, with patients reporting symptoms ranging from lack of concentration and strange dreams to delusions and mania. Fortunately, the neurologic side effects of efavirenz subside over time, usually within a month.

c. Delavirdine—Of the three available NNRTIs, delavirdine is least used. It does not appear to be as potent as nevirapine or efavirenz. The dosage is 400 mg orally three times a day, which makes it less convenient for patients than the other two medications in this class. As with nevirapine, the major side effect with delavirdine is rash, but the incidence of rash is lower with delavirdine.

4. Novel agents—

a. Entry inhibitors—Peptide T-20 (enfuvirtide) is the first drug in the new class of fusion inhibitors, which block the entry of HIV into cells. Phase III studies have demonstrated significant decreases in viral load when T-20 is administered in combination with an individualized antiretroviral regimen compared with patients left on an individualized antiretroviral regimen without T-20. The primary side effect of T-20 is a reaction at the injection site. T-20 is expected to be available in pharmacies in 2003. Other entry inhibitors are being developed, including inhibitors of chemokine receptors.

b. Other agents—Drugs that inhibit HIV's integrase, messenger RNA processing, and accessory gene functions are being developed.

5. Constructing regimens—There is now little debate about the necessity for combining drugs to achieve long-term suppression of HIV and its associated clinical benefit. Only combinations of drugs have been able to decrease HIV viral load by 2-3 logs and allow suppression of HIV RNA to below the threshold of detection for longer than 4 years in some individuals. However, the ideal regimens for initial and second-line therapy have not yet been defined, so clinicians and their patients face difficult decisions in selecting therapy.

Several general principles should guide the choice of combinations. The most important determinant of treatment efficacy is adherence to the regimen. Therefore, it is vitally important that the regimen chosen be one that is easy for the patient to adhere to. In general, patients are more compliant with medication regimens that are once or twice a day only, do not require special timing with regard to meals, can be taken at the same time as other medications, do not require refrigeration or special preparation, and do not have bothersome side effects. Second, it is desirable to prescribe combinations that have demonstrated clinical benefit; since these data do not exist for many combinations, it is reassuring to know that the combination under consideration has shown beneficial effects upon HIV viral load levels in short-term studies. To the extent possible, agents to which the patient has not been exposed are preferable to drugs for which resistance mutations may have already occurred. Toxicities should ideally be nonoverlapping. An individual's relative contraindications to a given drug or drugs should be considered. The regimen should not include agents that are either virologically antagonistic or incompatible in terms of drug-drug interactions. Compatible dosing schedules—prescribing medications that can be taken at the same time—improve adherence to treatment. Finally, highly complex therapeutic regimens should be reserved for individuals who are capable of adhering to the rigorous demands of taking multiple medications and having this therapy closely monitored. Conversely, simplified regimens that deliver the lowest number of pills given at the longest possible dosing intervals are desirable for patients who have difficulty taking multiple medications.

Possible ways of incorporating nonnucleoside agents and protease inhibitors into combinations are displayed in [Figure 31-2](#). A number of points about the "nucleoside backbone" of regimens have become clearer. First, the dual nucleoside combinations with most activity probably include zidovudine plus lamivudine, zidovudine plus didanosine, stavudine plus didanosine, and stavudine plus lamivudine. In these pairings, both agents are given in full doses. The combination of stavudine plus didanosine does not seem to lead to synergistic development of neuropathy despite both drugs' predilection to cause this side effect. However, the combination of stavudine and didanosine should be avoided in pregnant women because of the increased risk of lactic acidosis. Also notable is the fact that the addition of lamivudine to didanosine does not appear to result in the same level of viral suppression as when lamivudine is combined with zidovudine or stavudine. Finally, the nucleoside pair of zidovudine and stavudine are antagonistic and should never be used together. This results from stavudine inhibiting the phosphorylation of zidovudine to its active metabolite.

In choosing which third agent to include in an initial antiretroviral regimen, ease of administration, minimization of side effects, and future treatment options should all be considered. For this reason, most clinicians advocate starting patients on a protease-sparing regimen. This can be done using nevirapine, efavirenz, or abacavir along with two nucleoside analogs. For example, for patients for whom it is important to minimize the number of pills, a regimen of lamivudine/zidovudine (Combivir) and nevirapine offers a simple three-drug regimen (two pills twice a day). Another advantage of this regimen is that it reserves protease inhibitors for future use. Some persons who develop resistance to nelfinavir may still have sensitivity to indinavir and ritonavir. For this reason, many clinicians favor the use of nelfinavir as the initial protease inhibitor. Some clinicians advocate using two protease inhibitors simultaneously, particularly for patients with high viral loads (> 100,000/mL). The concern is that patients with particularly high viral loads are more likely to develop resistant virus on more conventional regimens. In addition to ritonavir-saquinavir, other combinations tried have included ritonavir-indinavir and indinavir-nelfinavir, with dosing of each agent reduced by roughly 50% of the usual recommended dose.

For some patients who have been heavily treated with antiretroviral agents it may be difficult to design second-line regimens when they are showing evidence of progression of disease on their existing regimen. In designing second-line regimens (sometimes called salvage regimens—a term that some patients may find offensive), the goal is to identify agents to which the patient is not resistant. This can be quite complicated because of cross resistance within types of agents. For example, the resistance patterns of ritonavir and indinavir are overlapping, and patients with virus resistant to these agents are unlikely to respond to nelfinavir or saquinavir even though they have never received treatment with these agents. Similarly, the resistance patterns of nevirapine and efavirenz are overlapping.

In addition to taking a careful history of what antiretroviral agents a patient has taken and for how long, genotypic and phenotypic resistance testing can provide useful information in designing second-line regimens. Interpretation of resistance testing often requires expert consultation.

Whatever regimen is chosen, patients should be coached in ways to improve adherence. This should include taking medicines on an established schedule (eg, first thing in the morning), keeping a medication diary, and keeping medications in a variety of places the patient is likely to be (eg, car, workplace). For certain populations (eg, unstably housed individuals), specially tailored programs that include drug dispensing are needed.

For some patients, it is impossible to construct a tolerable regimen that fully suppresses HIV. In such cases, clinicians and patients should consider their goals. Patients maintained on effective antiretroviral agents often benefit from these regimens (eg, higher CD4 counts, fewer opportunistic infections) even if their virus is detectable. In some cases, patients appear to benefit from a drug holiday during which patients are taken off all medications. Patients often immediately feel better because of the absence of drug side effects. Structured treatment interruptions are being studied with two major goals: (1) to lessen side effects through decreased cumulative exposure to the medications, and (2) to stimulate an immunologic response by allowing low levels of viral replication. There is hope that achieving the first goal will result in a decreased long-term complication rate from therapy, but at present treatment interruption should be viewed as an experimental strategy. Patients should be monitored very closely during drug holidays, since viral rebound and CD4 decline can occur rapidly.

C. Hematopoietic Stimulating Factors

Epoetin alfa (erythropoietin) is approved for use in HIV-infected patients with anemia, including those with anemia secondary to zidovudine use. It has been shown to decrease the need for blood transfusions. The drug is expensive, and an endogenous erythropoietin level < 500 mU/mL should be demonstrated before starting therapy. The starting dose is 8000 units subcutaneously three times a week. The target hematocrit is 35-40%. The dose may be increased by 12,000 units every 4-6 weeks as needed to a maximum dose of 48,000 units per week. Hypertension is the most common side effect.

Human granulocyte colony-stimulating factor (G-CSF [filgrastim]) and granulocyte-macrophage colony-stimulating factor (GM-CSF [sargramostim]) have been shown to increase the neutrophil counts of HIV-infected patients. G-CSF is preferred because of the theoretical concern of GM-CSF-stimulating HIV replication in infected monocytes. In patients receiving cytotoxic chemotherapy for lymphoma or Kaposi's sarcoma, daily subcutaneous doses of G-CSF at approximately 5 ug/kg (a 300 ug or 480 ug vial, depending upon weight) are given beginning 5-7 days after chemotherapy until the neutrophil count has rebounded to above 1000/uL. G-CSF may also have a role in ameliorating neutropenia caused by other drugs such as zidovudine or ganciclovir, when other therapeutic alternatives are not possible. Since the cost of this therapy is approximately \$150 per vial, dosage should be closely monitored and minimized, aiming for a neutrophil count of 1000/uL. When the drug is used for indications other than cytotoxic chemotherapy, one or two doses at 5 ug/kg per week is usually sufficient.

D. Prophylaxis of Opportunistic Infections

In general, decisions about prophylaxis of opportunistic infections are based on the CD4 count, other evidence of severe immune suppression (eg, oral candidiasis), and a history of having had the infection in the past. In the era prior to HAART, patients started on prophylactic regimens were maintained on them indefinitely. However, studies have shown that in patients with robust improvements in immune function—as measured by increases in CD4 counts above the levels that are used to initiate treatment—prophylactic regimens can safely be discontinued.

Primary prophylaxis for pneumocystis pneumonia should be offered to patients with CD4 counts below 200 cells/uL, a CD4 lymphocyte percentage below 14%, or weight loss or oral candidiasis. Patients with a history of pneumocystis pneumonia should receive secondary prophylaxis until they have had a durable virologic response to HAART for at least 3-6 months and maintain a CD4 count of > 250 cells/uL.

Regimens for prophylaxis are trimethoprim-sulfamethoxazole, dapsone, atovaquone, and aerosolized pentamidine (see [Table 31-6](#)). Trimethoprim-sulfamethoxazole is inexpensive, widely available, and the most effective agent for prophylaxis. In two studies comparing once-daily double-strength trimethoprim-sulfamethoxazole with aerosolized pentamidine for primary and secondary prophylaxis of pneumocystis pneumonia, patients randomized to trimethoprim-sulfamethoxazole were significantly less likely to develop pneumocystis pneumonia. Patients who receive trimethoprim-sulfamethoxazole are also less likely to develop bacterial infections (eg, pneumonia, sinusitis). Common side effects with trimethoprim-sulfamethoxazole are primarily fever, rash, and nausea and vomiting. Trimethoprim-sulfamethoxazole is dosed as one double-strength tablet three times a week to once daily. Patients who develop mild rashes on this regimen may be treated with diphenhydramine (25-50 mg every 4 hours). However, clinicians and patients must watch carefully for signs of Stevens-Johnson syndrome. Some clinicians are also using desensitization regimens to overcome allergic reactions. Reports suggest that desensitization may be successful in 40% of cases. Dapsone is a second-line prophylactic agent with minimal side effects. As is the case with trimethoprim-sulfamethoxazole, it is inexpensive and widely available. It may be used in patients with an allergic reaction to trimethoprim-sulfamethoxazole. Before prescribing dapsone, clinicians should make certain that the patient is not G6PD-deficient, since such patients are at high risk of developing hemolytic anemia with dapsone therapy. Patients taking dapsone concomitantly with didanosine should take the dapsone at least 2 hours prior to the didanosine since dapsone is not absorbed well in the neutral pH stomach environment created by the didanosine buffering agent. Finally, atovaquone may be an option

for individuals intolerant of other systemic therapies, but it appears to be less effective. It is available only as an oral suspension (1500 mg daily) and must be taken with food to promote absorption.

Finally, aerosolized pentamidine can be used if no systemic agents can be tolerated. Its disadvantages are expense (approximately \$160 for one treatment per month) and decreased effectiveness in the apical and peripheral areas of the lung. Cases of extrapulmonary pneumocystis infections in patients receiving aerosolized pentamidine have also been reported.

Aerosolized pentamidine may also increase the incidence of pneumothorax in patients with a history of pneumocystis infection.

Patients who develop pneumocystis infection on a particular prophylactic regimen should be switched to a different one.

Prophylaxis against *M avium* complex infection should be given to patients whose CD4 counts fall below 75-100 cells/uL. Clarithromycin (500 mg orally twice daily) and azithromycin (1200 mg orally weekly) have both been shown to decrease the incidence of disseminated disease by approximately 75%, with a low rate of breakthrough of resistant disease. The latter regimen is generally preferred on the basis of ease of compliance and cost. Adding rifabutin increases the toxicity of the regimen but does not significantly increase its efficacy and is therefore not recommended. As sole therapy, rifabutin (300 mg orally daily) is less effective and more toxic than clarithromycin or azithromycin. Clinicians should make certain that patients do not have active *M tuberculosis* infection by examination of a chest radiograph prior to starting rifabutin because of concern about the development of resistance to rifabutin with cross-resistance to rifampin. Similarly, before initiating prophylaxis, clinicians should establish with a blood culture that the patient does not have disseminated *M avium* complex infection. Common side effects of both azithromycin and clarithromycin are nausea and diarrhea. Two common side effects with rifabutin are rash and hepatic dysfunction. Rifabutin may induce hepatic enzymes, thereby decreasing the activity of some drugs metabolized by the liver.

Prophylaxis against *M avium* complex infection may be discontinued among patients whose CD4 counts go above 100 cells/uL in response to HAART.

Prophylaxis against *M tuberculosis* infection—isoniazid 300 mg daily plus pyridoxine 50 mg orally daily for 9 months to a year—should be given to all HIV-infected patients with positive PPD reactions (defined for HIV-infected patients as > 5 mm of induration).

Toxoplasmosis prophylaxis is desirable in patients with positive IgG toxoplasma serology. Trimethoprim-sulfamethoxazole (one double-strength tablet daily) offers good protection against toxoplasmosis, as does a combination of pyrimethamine, 25 mg orally once a week, plus dapsone, 100 mg orally daily.

Cytomegalovirus infection is also common in late HIV disease. Oral ganciclovir has been approved for CMV prophylaxis among HIV-infected persons with CD4 counts below 50 cells/uL. However, because the drug causes neutropenia, it is not widely used. Clinicians should consider performing serum CMV IgG antibody testing. Persons who are CMV IgG-negative are not at risk for development of CMV disease. Importantly, patients who are CMV IgG-negative should receive CMV-negative blood if they require a transfusion. Because over 99% of gay men are positive for CMV IgG, it is appropriate to reserve testing for heterosexuals with HIV.

Cryptococcosis, candidiasis, and endemic fungal diseases are also candidates for prophylaxis. One prophylactic trial showed a decreased incidence of cryptococcal disease with the use of fluconazole, 200 mg orally daily, but the treated group had no benefit in terms of mortality. Fluconazole (200 mg orally once a week) was found to prevent oral and vaginal candidiasis in women with CD4 counts below 300 cells/uL. In areas of the world where histoplasmosis and coccidioidomycosis are endemic and are frequent complications of HIV infection, prophylactic use of fluconazole or itraconazole may prove to be useful prophylactic strategies. However, the problem of identifying individuals at highest risk makes the targeting of prophylaxis difficult.

Since individuals with advanced HIV infection are susceptible to a number of opportunistic pathogens, the use of agents with activity against more than one pathogen is preferable. It has been shown, for example, that trimethoprim-sulfamethoxazole confers some protection against toxoplasmosis in individuals receiving this drug for pneumocystis prophylaxis.

Course & Prognosis

With improvements in therapy, patients are living longer after the diagnosis of AIDS. This has resulted in dramatic decreases in AIDS deaths nationally. In 1999 in the United States there were 16,273 deaths due to AIDS, compared with 50,610 deaths in 1995. It remains to be seen whether the decreases in number of deaths can be sustained over the long term. Maintaining access to quality care and treatment is one key element. Unfortunately, studies continue to show less access to treatment for some underserved groups, especially blacks, the homeless, and injecting drug users. Another key element in sustaining lower mortality is developing new treatments for patients who have been heavily treated with existing agents. Despite new therapeutic options, people continue to die from HIV infection. For patients whose disease progresses even though they are receiving appropriate treatment, meticulous palliative care must be provided (see Chapter 5), with attention to pain control, spiritual needs, and family (biologic and chosen) dynamics.

31. HIV Infection - *Mitchell H. Katz, MD, & Harry Hollander, MD*
General Considerations
 -

Table 31-1. CDC AIDS case definition for surveillance of adults and adolescents.

Definitive AIDS diagnoses (with or without laboratory evidence of HIV infection)

1. Candidiasis of the esophagus, trachea, bronchi, or lungs.
2. Cryptococcosis, extrapulmonary.
3. Cryptosporidiosis with diarrhea persisting > 1 month.
4. Cytomegalovirus disease of an organ other than liver, spleen, or lymph nodes.
5. Herpes simplex virus infection causing a mucocutaneous ulcer that persists longer than 1 month; or bronchitis, pneumonitis, or esophagitis of any duration.
6. Kaposi's sarcoma in a patient < 60 years of age.
7. Lymphoma of the brain (primary) in a patient < 60 years of age.
8. *Mycobacterium avium* complex or *Mycobacterium kansasii* disease, disseminated (at a site other than or in addition to lungs, skin, or cervical or hilar lymph nodes).
9. *Pneumocystis carinii* pneumonia.
10. Progressive multifocal leukoencephalopathy.
11. Toxoplasmosis of the brain.

Definitive AIDS diagnoses (with laboratory evidence of HIV infection)

1. Coccidioidomycosis, disseminated (at a site other than or in addition to lungs or cervical or hilar lymph nodes).
2. HIV encephalopathy.
3. Histoplasmosis, disseminated (at a site other than or in addition to lungs or cervical or hilar lymph nodes).
4. Isosporiasis with diarrhea persisting > 1 month.
5. Kaposi's sarcoma at any age.
6. Lymphoma of the brain (primary) at any age.
7. Other non-Hodgkin's lymphoma of B cell or unknown immunologic phenotype.
8. Any mycobacterial disease caused by mycobacteria other than *Mycobacterium tuberculosis*, disseminated (at a site other than or in addition to lungs, skin, or cervical or hilar lymph nodes).
9. Disease caused by extrapulmonary *M tuberculosis*.
10. Salmonella (nontyphoid) septicemia, recurrent.
11. HIV wasting syndrome.
12. CD4 lymphocyte count below 200 cells/μL or a CD4 lymphocyte percentage below 14%.
13. Pulmonary tuberculosis.
14. Recurrent pneumonia.
15. Invasive cervical cancer.

Presumptive AIDS diagnoses (with laboratory evidence of HIV infection)

1. Candidiasis of esophagus: (a) recent onset of retrosternal pain on swallowing; and (b) oral candidiasis.
2. Cytomegalovirus retinitis. A characteristic appearance on serial ophthalmoscopic examinations.
3. Mycobacteriosis. Specimen from stool or normally sterile body fluids or tissue from a site other than lungs, skin, or cervical or hilar lymph nodes, showing acid-fast bacilli of a species not identified by culture.
4. Kaposi's sarcoma. Erythematous or violaceous plaque-like lesion on skin or mucous membrane.
5. *Pneumocystis cariniip*pneumonia: (a) a history of dyspnea on exertion or nonproductive cough of recent onset (within the past 3 months); and (b) chest x-ray evidence of diffuse bilateral interstitial infiltrates or gallium scan evidence of diffuse bilateral pulmonary disease; and (c) arterial blood gas analysis showing an arterial oxygen partial pressure of < 70 mm Hg or a low respiratory diffusing capacity of < 80% of predicted values or an increase in the alveolar-arterial oxygen tension gradient; and (d) no evidence of a bacterial pneumonia.
6. Toxoplasmosis of the brain: (a) recent onset of a focal neurologic abnormality consistent with intracranial disease or a reduced level of consciousness; and (b) brain imaging evidence of a lesion having a mass effect or the radiographic appearance of which is enhanced by injection of contrast medium; and (c) serum antibody to toxoplasmosis or successful response to therapy for toxoplasmosis.
7. Recurrent pneumonia: (a) more than one episode in a 1-year period; and (b) acute pneumonia (new symptoms, signs, or radiologic evidence not present earlier) diagnosed on clinical or radiologic grounds by the patient's physician.
8. Pulmonary tuberculosis: (a) apical or miliary infiltrates and (b) radiographic and clinical response to antituberculous therapy.

 - TABLES
 - Table 31-1. CDC AIDS case definition for surveillance of adults and adolescents.
-

Table 31-2. Laboratory findings with HIV infection.

Test	Significance
HIV enzyme-linked immunosorbent assay (ELISA)	Screening test for HIV infection. 50% of ELISA tests are positive within 22 days after HIV transmission; 95% are positive within 6 weeks after transmission. Sensitivity > 99.9%; to avoid false-positive results, repeatedly reactive results must be confirmed with Western blot.
Western blot	Confirmatory test for HIV. Specificity when combined with ELISA > 99.99%. Indeterminate results with early HIV infection, HIV-2 infection, autoimmune disease, pregnancy, and recent tetanus toxoid administration.
CBC	Anemia, neutropenia, and thrombocytopenia common with advanced HIV infection.
Absolute CD4 lymphocyte count	Most widely used predictor of HIV progression. Risk of progression to an AIDS opportunistic infection or malignancy is high with CD4 < 200 cells/μL.
CD4 lymphocyte percentage	Percentage may be more reliable than the CD4 count. Risk of progression to an AIDS opportunistic infection or malignancy is high with percentage < 20%.
HIV viral load tests	These tests measure the amount of actively replicating HIV virus. Correlate with disease progression and response to antiretroviral drugs. Treatment is recommended for HIV-infected patients with > 30,000 viral copies by branched-chain DNA or > 55,000 viral copies by PCR testing. Best tests available for diagnosis of acute HIV infection, however, false positives are common, especially when the viral load is low.
β ₂ -Microglobulin	Cell surface protein indicative of macrophage-monocyte stimulation. Levels > 3.5 mg/dL associated with rapid progression of disease. Not useful with intravenous drug users.
p24 antigen	Indicates active HIV replication. Tends to be positive prior to seroconversion and with advanced disease.

-

Table 31-3. Health care maintenance of HIV-infected individuals.

For all HIV-infected individuals

- CD4 counts every 3-6 months
- Viral load tests every 3-6 months and 1 month following a change in therapy
- PPD
- INH for those with positive PPD and normal chest x-ray
- RPR or VDRL
- Toxoplasma IgG serology
- Cytomegalovirus IgG serology
- Pneumococcal vaccine
- Influenza vaccine in season
- Hepatitis B vaccine for those who are HBsAb-negative
- Haemophilus influenzae* b vaccination
- Papanicolaou smears every 6 months for women
- Consider anal swabs for cytologic evaluation yearly for men with history of receptive anal intercourse

For HIV-infected individuals with CD4 < 500 cells/μL

Antiretroviral therapy (see Figure 31-2)

For HIV-infected individuals with CD4 < 200 cells/μL

P carinii prophylaxis (see Table 31-6)

For HIV-infected individuals with CD4 < 100 cells/μL

- M avium* complex prophylaxis
- Consider CMV prophylaxis

Table 31-4. Treatment of AIDS-related opportunistic infections and malignancies.¹

Infection or Malignancy	Treatment	Complications
<i>P carinii</i> infection ²	Trimethoprim-sulfamethoxazole, 15 mg/kg/d (based on trimethoprim component) orally or IV for 14-21 days.	Nausea, neutropenia, anemia, hepatitis, drug rash, Stevens-Johnson syndrome.
	Pentamidine, 3-4 mg/kg/d IV for 14-21 days.	Hypotension, hypoglycemia, anemia, neutropenia, pancreatitis, hepatitis.
	Trimethoprim, 15 mg/kg/d orally, with dapsone, 100 mg/d orally, for 14-21 days. ³	Nausea, rash, hemolytic anemia in G6PD-deficient patients. Methemoglobinemia (weekly levels should be < 10% of total hemoglobin).
	Primaquine, 15-30 mg/d orally, and clindamycin, 600 mg every 8 hours orally, for 14-21 days.	Hemolytic anemia in G6PD-deficient patients. Methemoglobinemia, neutropenia, colitis.
	Atovaquone, 750 mg orally 3 times daily for 14-21 days.	Rash, elevated aminotransferases, anemia, neutropenia.
	Trimetrexate, 45 mg/m ² IV for 21 days (given with leucovorin calcium) if intolerant of all other regimens.	Leukopenia, rash, mucositis.
<i>M avium</i> complex infection	Clarithromycin, 500 mg orally twice daily with ethambutol, 15 mg/kg/d orally (maximum, 1 g). May also add:	Clarithromycin: hepatitis, nausea, diarrhea; ethambutol: hepatitis, optic neuritis.
Toxoplasmosis	Rifabutin, 300 mg orally daily.	Rash, hepatitis, uveitis.
	Pyrimethamine, 100-200 mg orally as loading dose, followed by 50-75 mg/d, combined with sulfadiazine, 4-6 g orally daily in 4 divided doses, and folinic acid, 10 mg daily for 4-8 weeks; then pyrimethamine, 25-50 mg/d, with clindamycin, 2 g/d, and folinic acid, 5 mg/d, until clinical and radiographic resolution is achieved.	Leukopenia, rash.
Lymphoma	Combination chemotherapy (eg, modified CHOP, M-BACOD, ⁴ with or without G-CSF or GM-CSF). ⁵ Central nervous system disease: radiation treatment with dexamethasone for edema.	Nausea, vomiting, anemia, leukopenia, cardiac toxicity (with doxorubicin).
Cryptococcal meningitis	Amphotericin B, 0.6 mg/kg/d IV, with or without flucytosine, 100 mg/kg/d orally in 4 divided doses for 2 weeks, followed by:	Fever, anemia, hypokalemia, and azotemia.
	Fluconazole, 400 mg orally daily for 6 weeks, then 200 mg orally daily.	Hepatitis.
Cytomegalovirus infection	Ganciclovir, 10 mg/kg/d IV in 2 divided doses for 10 days, followed by 6 mg/kg 5 days a week indefinitely. (Decrease dose for renal impairment.) May use ganciclovir as maintenance therapy (1 g orally with fatty foods 3 times a day).	Neutropenia (especially when used concurrently with zidovudine).
	Foscarnet, 60 mg/kg IV every 8 hours for 10-14 days (induction), followed by 90 mg/kg once daily. (Adjust for changes in renal function.)	Nausea, hypokalemia, hypocalcemia, hyperphosphatemia, azotemia.
Esophageal candidiasis or recurrent vaginal candidiasis	Fluconazole, 100-200 mg daily for 10-14 days.	Hepatitis, development of imidazole resistance.
	Ketoconazole, 200 mg orally twice daily for 10-14 days.	Hepatitis, adrenal insufficiency.
Herpes simplex infection	Acyclovir, 200 mg 5 times daily for 7-10 days; or acyclovir, 5 mg/kg IV every 8 hours for severe cases.	Resistant herpes simplex with chronic therapy.
	Famciclovir, 500 mg orally twice daily for 7 days.	Nausea
	Valacyclovir, 500 mg orally twice daily for 7 days	Nausea
	Foscarnet, 40 mg/kg IV every 8 hours, for acyclovir-resistant cases. (Adjust for changes in renal function.)	See above.
Herpes zoster	Acyclovir, 800 mg orally 4 or 5 times daily for 7 days. Intravenous therapy at 10 mg/kg every 8 hours for ocular involvement, disseminated disease.	See above.
	Famciclovir, 500 mg orally 3 times daily for 7 days.	Nausea.
	Valacyclovir, 500 mg orally 3 times daily for 7 days.	Nausea
	Foscarnet, 40 mg/kg IV every 8 hours for acyclovir-resistant cases. (Adjust for changes in renal function.)	See above.
Kaposi's sarcoma Limited cutaneous disease	Observation, intralesional vinblastine.	Inflammation, pain at site of injection.
Extensive or aggressive cutaneous disease	Systemic chemotherapy (eg, alternating weekly vinca alkaloids). Alpha interferon (for patients with CD4 > 200 cells/ μ L and no constitutional symptoms). Radiation (amelioration of edema).	Bone marrow suppression, peripheral neuritis, flu-like syndrome.
Visceral disease (eg, pulmonary)	Combination chemotherapy (eg, daunorubicin, bleomycin, vinblastine).	Bone marrow suppression, cardiac toxicity, fever.

¹For treatment of *Mycobacterium tuberculosis* infection, see Chapter 9.

²For moderate to severe *P carinii* infection (oxygen saturation < 90%), corticosteroids should be given with specific treatment. The dose of prednisone is 40 mg twice daily for 5 days, then 40 mg daily for 5 days, and then 20 mg daily until therapy is complete.

³When considering use of dapsone, check G6PD level in African-American patients and those of Mediterranean origin.

⁴CHOP = cyclophosphamide, doxorubicin, vincristine (Oncovin), and prednisone. Modified M-BACOD = methotrexate, bleomycin, doxorubicin, Adriamycin, cyclophosphamide, vincristine (Oncovin), and dexamethasone.

⁵G-CSF = granulocyte colony stimulating factor (filgrastim); GM-CSF = granulocyte-macrophage colony stimulating factor (sargramostim).

Drug	Dose	Common Side Effects	Monitoring	Cost ¹	Cost/Month
Nucleoside analogs					
Zidovudine (AZT) (Retrovir)	500-600 mg orally daily in two divided doses	Anemia, neutropenia, nausea, malaise, headache, insomnia, myopathy	Complete blood count and differential (every 3 months once stable)	\$5.90/300 mg	\$354.50
Didanosine (ddl) (Videx)	125-200 mg orally twice daily (for pill formulation) for persons = 60 kg	Peripheral neuropathy, pancreatitis, dry mouth, hepatitis	CBC and differential, aminotransferases, K ⁺ , amylase, triglycerides, bimonthly neurologic questionnaire for neuropathy	\$4.43/200 mg \$10.06/400 mg capsules	\$266.26 \$301.79
Zalcitabine (ddC) (Hivid)	0.375-0.75 mg orally 3 times daily	Peripheral neuropathy, aphthous ulcers, hepatitis	Monthly neurologic questionnaire for neuropathy, aminotransferases	\$2.73/0.75 mg	\$245.70
Stavudine (d4T) (Zerit)	40 mg orally twice daily	Peripheral neuropathy, hepatitis, pancreatitis	Monthly neurologic questionnaire for neuropathy, aminotransferases, amylase	\$5.58/40 mg	\$334.89
Lamivudine (3TC) (Epivir)	150 mg orally twice daily	Rash, peripheral neuropathy	No additional monitoring	\$5.06/150 mg	\$303.40
Abacavir (Ziagen)	300 mg orally twice daily	Rash, fever if occur, rechallenge may be fatal	No special monitoring	\$6.80/300 mg	\$407.70
Nucleotide analog					
Tenofovir	300 mg orally twice daily	Gastrointestinal distress	Renal function	\$13.60/300 mg	\$408.00
Protease inhibitors					
Saquinavir soft gel (Fortovase)	1200 mg three times daily	Gastrointestinal distress, headache	Bimonthly aminotransferases, cholesterol, triglycerides	\$1.34/200 mg	\$720.96
Ritonavir (Norvir)	600 mg orally twice daily or 100-400 mg orally twice daily in combination with other protease inhibitors	Gastrointestinal distress, peripheral paresthesias	Bimonthly aminotransferases, CK, uric acid, triglycerides	\$2.14/200 mg	\$771.54
Indinavir (Crixivan)	800 mg orally three times daily	Kidney stones	Bimonthly aminotransferases, bilirubin level, cholesterol, triglycerides	\$3.04/400 mg	\$546.38
Nelfinavir (Viracept)	750 mg orally three times daily	Diarrhea	Cholesterol, triglycerides	\$2.52/250 mg	\$680.99
Amprenavir (Invirase)	1200 mg orally twice daily	Gastrointestinal, rash	Cholesterol, triglycerides	\$1.47/150 mg	\$706.12
Lopinavir/ritonavir (Kaletra)	400 mg/100 mg orally twice daily	Diarrhea	Cholesterol, triglycerides, bimonthly aminotransferases	\$3.91/133 mg (lopinavir)	\$703.50
Nonnucleoside reverse transcriptase inhibitors (NNRTIs)					
Nevirapine (Viramune)	200 mg orally daily for 2 weeks, then 200 mg orally twice daily	Rash	No additional monitoring	\$6.12/200 mg	\$366.94
Delavirdine (Rescriptor)	400 mg orally three times daily	Rash	No additional monitoring	\$1.76/200 mg	\$316.35
Efavirenz (Sustiva)	600 mg orally daily	Neurologic disturbances	No additional monitoring	\$14.39/600 mg	\$431.65

Table 31-6. *Pneumocystis carinii* prophylaxis.

Drug	Dose	Side Effects	Limitations
Trimethoprim-sulfamethoxazole	One double-strength tablet 3 times a week to one tablet daily	Rash, neutropenia, hepatitis, Stevens-Johnson syndrome	Hypersensitivity reaction is common but, if mild, it may be possible to treat through.
Dapsone	50-100 mg daily or 100 mg 2 or 3 times per week	Anemia, nausea, methemoglobinemia, hemolytic anemia	Efficacy not established. G6PD level should be checked prior to therapy. Check methemoglobin level at 1 month.
Atovaquone	1500 mg daily with a meal	Rash, diarrhea, nausea	Less effective than suspension trimethoprim-sulfamethoxazole; equal efficacy to dapsone, but more expensive.
Aerosolized pentamidine	300 mg monthly	Bronchospasm (pretreat with bronchodilators); rare reports of pancreatitis	Apical <i>P carinii</i> pneumonia, extrapulmonary <i>P carinii</i> infections, pneumothorax.

■ VIRAL DISEASES

This section discusses viral diseases caused by herpesviruses, those preventable by vaccines, and others causing distinct syndromes. Rickettsial illnesses and Kawasaki syndrome are also included. Disorders caused by hepatotropic viruses ([Chapter 15](#)), papillomaviruses ([Chapter 6](#)), and human immunodeficiency virus ([Chapters 17](#) and [31](#)) are dealt with elsewhere.

Clinical Diagnosis

Some viral illnesses present with typical syndromes (measles, mumps, chickenpox). In others, the clinical picture suggests any of a number of viruses. For example, aseptic meningitis can be caused by the mumps virus, lymphocytic choriomeningitis virus, and several enteroviruses, among others. Symptoms of respiratory disease with many viruses are indistinguishable. Some viral diseases have a characteristic rash, though in most the rash associated with viral syndromes is not pathognomonic.

Identification of a virus is useful for confirmation of atypical cases, help with outbreak investigation, elucidation of confusing syndromes, and increasingly to support the need for specific antiviral therapy. The frequency with which certain pathogens cause certain diseases allows for educated guesses, eg, respiratory syncytial virus (RSV) for bronchiolitis or parainfluenza virus for croup. Instances where rapid diagnosis assists in patient management are noted.

Laboratory Diagnosis

Several techniques are used for diagnosis, including stain (the nonspecific Tzanck smear for herpesviruses), cell culture (coxsackievirus in suckling mice), immunologic detection (seroconversion with arboviruses, rabies virus on skin biopsy, detection of secretory IgA), or molecular techniques such as polymerase chain reaction (for herpes simplex virus) or antigen assays (for cytomegalovirus). Isolation of virus from a normally sterile site (cerebrospinal fluid, lung) or from a lesion (vesicles) in an immunocompetent individual is diagnostically significant. Isolation from nonsterile sites (nasopharynx, stool) may represent a carrier state, and seroconversion and pathologic change are needed to establish a diagnosis.

A. Microscopic Methods

Microscopic techniques are used to examine cells, body fluids, or biopsy material in search of virus or cytopathic changes specific for one virus or a group of viruses (eg, multinucleated giant cells at the base of herpes lesions, rotavirus structures on electron micrographs of diarrheal stools).

Immunofluorescent methods, often with monoclonal antibodies, can rapidly identify some antigens (rabies, varicella, herpes simplex, respiratory syncytial virus) in desquamated or scraped cells.

B. Immunologic Studies of Sera

Specific antibodies to viruses rise during the course of illness, though the rise and persistence of titer depend on both the virus and the host response. A fourfold or greater rise in antibody titer during illness is considered evidence of disease.

Single determinations are seldom helpful, and laboratories require paired sera (acute and convalescent, typically 2-3 weeks apart). Antigenic detection is used for certain viruses (HBsAg, CMV, HIV) and detects viral presence independently of disease duration or host response. Quantification of viral antigen titer is useful in the management of HIV disease and is becoming a standard of care for other chronic viral infections (eg, hepatitis C virus).

C. Molecular Techniques

Molecular technology has provided techniques such as PCR and nucleic acid probes that have proved useful in the identification of new pathogens (eg, HCV and Kaposi's sarcoma herpesvirus) as well as for the management of patients in whom quantification of viral activity, as with immunologic techniques, assists in following the course of clinical illness or the response to therapy. Results vary among laboratories.

Treatment

The armamentarium of antiviral therapy has expanded greatly with the advent of the HIV outbreak ([Table 31-5](#)), though for many viruses there remains no definitive antiviral therapy.

The mainstay of controlling viral diseases is vaccination. Currently available live vaccines include those against measles, mumps, rubella, poliovirus (Sabin vaccine), yellow fever, and varicella. The inactivated vaccines protect against the agents implicated in poliovirus (Salk vaccine), hepatitis A, hepatitis B, influenza A and B, rabies, respiratory syncytial virus (RSV), and Japanese B encephalitis. Passive immunoprophylaxis remains important in prevention of hepatitis A and B, RSV infection, and, among the immunosuppressed, varicella.

HUMAN HERPESVIRUSES

These viruses cause a wide spectrum of human disease. Eight identified human herpesviruses include herpes simplex virus (HSV) type 1, HSV type 2, varicella-zoster virus (type 3), Epstein-Barr (EB) infectious mononucleosis virus (type 4), and cytomegalovirus (CMV) (type 5). A sixth type (HHV-6) has been identified as a causative agent of roseola (exanthema subitum), and a seventh (HHV-7) is also serologically associated with roseola. Another herpesvirus (HHV-8) is linked with Kaposi's sarcoma (see [Chapter 31](#)).

Subclinical primary infection with the herpesviruses is more common than clinically manifest illness. Each persists in a latent state for the remainder of the host's life. With HSV and VZV, virus remains latent in sensory ganglia, and upon reactivation lesions appear in the distal sensory nerve distribution. As a result of disease-, drug-, or radiation-induced immunosuppression, virus reactivation may lead to widespread lesions in affected organs such as the viscera or the central nervous system. Severe or fatal illness may occur in infants and the immunodeficient. Herpesviruses can transform cells in tissue culture. Associations with malignancies include EBV with Burkitt's lymphoma and nasopharyngeal carcinoma and HHV-8 with primary effusion lymphoma and Kaposi's sarcoma.

1. Herpesviruses 1 & 2

Essentials of Diagnosis

- Spectrum of illness from stomatitis and urogenital lesions to facial nerve paralysis (Bell's palsy) and encephalitis.
- Variable intervals between exposure and clinical disease, since HSV causes both primary (which may be subclinical) and reactivation disease.
- Successful management with acyclovir or related acyclic compounds (valacyclovir, famciclovir).

General Considerations

Herpesviruses 1 and 2 affect primarily the oral and genital areas, respectively. Seroprevalence to both agents increases with age and, for HSV-2, with sexual activity. Disease is typically a manifestation of reactivation, and the triggers for clinical reactivation are not well understood.

Clinical Findings

A. Mucocutaneous Disease

Herpes simplex type 1 (HSV-1) mucocutaneous disease largely involves the mouth and oral cavity ("herpes labialis"), although HSV-1 is increasingly recognized to cause urogenital infections. HSV-2 is the most common cause of genital ulcers in the developing world.

Vesicles form moist ulcers after several days and if untreated epithelialize over 1-2 weeks. Primary infection may be asymptomatic. Recurrences are usually milder, involve fewer lesions, tend to be labial, heal faster, and are induced by stress, fever, infection, sunlight, chemotherapy (eg, fludarabine), or other undetermined factors.

Herpes simplex type 2 lesions largely involve the genital tract. Virus remains latent in presacral ganglia. Typical lesions are multiple, painful, small, grouped, and vesicular. A manifestation of primary infection, predominantly in women, may be aseptic meningitis. Urinary retention may occur. Asymptomatic shedding is common, especially following primary infection or symptomatic recurrences, and appears to be responsible for transmission.

Diagnosis is usually made clinically, but viral cultures of vesicular fluid or direct fluorescent antibody staining of scraped lesions may confirm the diagnosis. HSV can be identified in serum using PCR, and its presence correlates with clinical reactivation. The presence of intranuclear inclusions and multinucleated giant cells on a Tzanck preparation is supportive of a diagnosis of herpes viral infection.

Serologies are of epidemiologic benefit, and their use in STD, perinatal, and HIV clinic is controversial since many patients already show positive serologies.

B. Ocular Disease

HSV can cause keratitis, blepharitis, and keratoconjunctivitis. Keratitis is usually unilateral, is suggested by impaired visual acuity, and is diagnosed by branching (dendritic) ulcers that stain with fluorescein. It may be difficult to differentiate HSV conjunctivitis clinically from adenoviral conjunctivitis in the acute stage. Recurrences are frequent.

C. Neonatal and Congenital Infection

Both herpesviruses can infect the fetus and induce congenital malformations (organomegaly, bleeding, central nervous system abnormalities). Neonatal transmission at the time of delivery is a more common mode of vertical spread. Such transmission is most common during acute disease in the mother but also occurs with subclinical shedding at the time of delivery (even without a history of symptomatic genital herpes).

D. Encephalitis and Recurrent Meningitis

Herpes simplex encephalitis presents with nonspecific symptoms: a flu-like prodrome, followed by headache, fever, behavioral and speech disturbances, and seizures that may be focal or generalized. There is a propensity to involve the temporal lobe, with mass effect on imaging studies and temporal lobe seizure foci on EEGs. Cerebrospinal fluid white cell pleocytosis is common, with roughly equal numbers of red cells.

HSV DNA polymerase chain reaction (PCR) in the cerebrospinal fluid is a rapid and sensitive and specific tool for early diagnosis. Untreated disease and presentation with coma carry a high mortality rate, with many survivors suffering neurologic sequelae. HSV-2 has also been implicated as a major cause of benign recurrent lymphocytic (Mollaret's) meningitis.

E. Disseminated Infection

Disseminated HSV infection occurs in the setting of immunosuppression, either primary or iatrogenic, including corticosteroid usage, or rarely with pregnancy. Skin lesions are not always present.

F. Bell's Palsy

An association between HSV-1 and Bell's palsy has been established.

G. Esophagitis

Esophagitis from HSV-1 in AIDS and other immunocompromised patients is diagnosed by endoscopic biopsy and cultures. CMV esophagitis is distinguished by the size and depth of the lesion (smaller and deeper for HSV).

H. Erythema Multiforme

Herpes simplex viruses remain, with drugs, the leading association with erythema multiforme and with the more severe, mucosally involved Stevens-Johnson syndrome.

Treatment & Prevention

Drugs that inhibit replication of herpesvirus 1 and 2 include trifluridine (for keratitis), acyclovir and related compounds (for urogenital, encephalitic, or disseminated disease), and foscarnet (for resistant strains in the immunocompromised) ([Table 32-1](#)).

A. Mucocutaneous Disease

While treatment in immunocompetent patients is often not necessary, immunocompromised patients are treated with oral or topical acyclic derivatives, with intravenous acyclovir reserved for severe or recalcitrant disease. Lesions heal faster with topical penciclovir than with topical acyclovir. Oral agents are generally superior to topical ones and include (for primary infection) acyclovir, 200 mg five times a day, valacyclovir, 1000 mg twice daily, or famciclovir, 250 mg three times daily. Reactivation disease is treated with half the dose of the oral agents used against primary infection.

Acyclovir-resistant isolates associated with mucocutaneous lesions in the HIV-positive population are treated with foscarnet (phosphonoformic acid), 40-60 mg/kg intravenously every 8 hours, adjusting for renal function. The acyclic nucleoside analog cidofovir is used against HSV and CMV in rare cases of infection resistant to both acyclovir and foscarnet.

Acyclovir and related compounds are effective in secondary prevention. Patients with recurrent genital infections may be placed on maintenance acyclovir at a dosage of 400 mg twice a day. Prophylaxis for herpes labialis and mucocutaneous HSV infections may be especially useful for patients exposed to ultraviolet radiation such as during skiing or sailing trips when topical sun-blocking agents cannot be used or for wrestlers at risk for herpes gladiatorum. Famciclovir (250 mg twice daily or 500 mg once daily) and valacyclovir (500 mg twice daily or 1 g once daily) are more costly alternatives for preventing recurrent disease whose advantages include higher serum levels and less frequent administration. AIDS patients with a history of mucocutaneous disease should receive lifelong suppressive therapy. Acyclovir resistance occurs often among the immunodeficient.

B. Keratitis

Ophthalmic trifluridine, vidarabine, and acyclovir given as drops for 10 days (without corticosteroids) are the available alternatives. Acyclovir at a dosage of 800 mg/d orally decreases recurrence rates.

C. Neonatal Disease

Acyclovir intravenously is effective for disseminated lesions in neonatal disease. The dosage is 20 mg/kg intravenously every 8 hours for 14-21 days. The use of maternal antenatal suppressive therapy is not well established, but if undertaken it should be done with acyclovir or valacyclovir because of possible teratogenicity with famciclovir. The use of maternal antisympressive therapy with acyclovir at 800 mg/d orally decreases the need for cesarean section with recurrent genital herpes.

D. Encephalitis

Because of the need for rapid treatment and the difficulties associated with brain biopsy, patients with suspected HSV encephalitis are given intravenous acyclovir (10 mg/kg every 8 hours for 10 days or more, adjusting for renal impairment), starting upon suspicion of diagnosis, and stopping if another diagnosis is established. If the PCR is negative and clinical suspicion remains high in the absence of a biopsy, treatment should be continued for 10 days because of the relatively nontoxic nature of acyclovir. Long-term neurologic sequelae are common.

E. Disseminated Disease

Disseminated disease responds best to parenteral acyclovir (see the preceding paragraph for dosages) when treatment is initiated early.

F. Bell's Palsy

The efficacy of treating Bell's palsy with acyclovir or corticosteroids has not been established.

G. Esophagitis

Patients with esophagitis should receive either intravenous acyclovir at a dosage of 5-10 mg/kg every 8 hours or oral acyclovir, 400 mg five times daily. AIDS patients are maintained on acyclovir at a dosage of 400 mg three to five times daily.

H. Erythema Multiforme

Acyclovir may decrease the recurrence rate of HSV-associated erythema multiforme.

Prevention

Recurrent mucocutaneous disease is most effectively treated with acyclovir as outlined above; recurrent genital disease also requires use of barrier precautions during sexual activity. Preventing spread to hospital staff and other patients from cases with mucocutaneous, disseminated, or genital disease requires isolation and the use of hand washing and gloving-gowning precautions. Staff with active lesions (eg, whitlows) should not have contact with patients. Asymptomatic transmission occurs, especially with HSV-2.

2. Varicella (Chickenpox) & Herpes Zoster (Shingles)

Essentials of Diagnosis

- Exposure 14-21 days before onset.
- Fever and malaise just before or with eruption.
- Rash: pruritic, centrifugal, papular, changing to vesicular ("dewdrops on a rose petal"), pustular, and finally crusting.

General Considerations

Varicella-zoster virus is human herpesvirus 3. Disease manifestations are either chickenpox (varicella) or shingles (its reactivation). Chickenpox is highly contagious and is generally a disease of childhood, with spread by inhalation of infective droplets or contact with lesions after 10-20 days (average, 14-15 days).

Clinical Findings

A. Varicella

1. Symptoms and signs—(Table 32-2.) Fever and malaise are mild in children and more marked in adults. Vesicular lesions, quickly rupturing to form small ulcers, may appear first in the oropharynx. The pruritic rash evolves centrifugally, beginning prominently on the face, scalp, and trunk, but to a lesser extent involving the extremities. Maculopapules change in a few hours to vesicles that become pustular and eventually form crusts. New lesions may erupt for 1-5 days, so that all stages of the eruption are usually present simultaneously. The crusts slough in 7-14 days. The vesicles and pustules are superficial and elliptical, with slightly serrated borders.

After the primary infection, the virus remains dormant in nervous tissue. Reactivation later in life is typically manifested as herpes zoster (see below), although second varicella infections are more common than was formerly thought. Widespread dissemination can occur in the immunosuppressed, sometimes in the absence of cutaneous lesions.

2. Laboratory findings—Diagnosis is usually made clinically, with confirmation by direct immunofluorescent antibody (DFA) staining or PCR of scrapings from lesions. Multinucleated giant cells are usually apparent on a Tzanck smear of material from the vesicle bases. Leukopenia is often present.

B. Herpes Zoster

Pain is often severe and may precede the appearance of rash. Lesions follow any nerve root distribution, with thoracic and lumbar roots commonest, and cervical or trigeminal involvement is typical. In most cases a single unilateral dermatome is involved. The occurrence of zoster does not correlate with progression to AIDS in HIV-infected patients, but recurrent and in particular multidermatomal zoster indicates a poorer prognosis in established AIDS.

Skin lesions resemble those of chickenpox, developing as maculopapules and evolving into vesicles and pustules. Lesions on the tip of the nose indicate involvement of the nasociliary nerve, a branch of the ophthalmic division of the trigeminal nerve, which also serves the cornea. Facial palsy, lesions of the external ear with or without tympanic membrane involvement, vertigo and tinnitus, and deafness signify geniculate ganglion involvement (Ramsay Hunt syndrome). In either, treatment is indicated (see below).

Complications

A. Varicella

Interstitial pneumonia is more common in adults (especially the HIV-infected) than in children and may result in ARDS. After healing, numerous densely calcified lesions are seen throughout the lung fields on chest x-rays. Ischemic strokes have been recognized in the wake of acute varicella and may be due to an associated vasculitis. Hepatitis is suggested by aminotransferase elevations and occurs in a small percentage of varicella-zoster patients. Encephalitis is infrequent (1:1000) and is characterized by ataxia and nystagmus and may be life-threatening. Cerebellar ataxia occurs among younger people at a lower frequency than encephalitis (1:4000).

Secondary bacterial infections, particularly with group A beta-hemolytic streptococci, are common; cellulitis, erysipelas, epiglottitis, osteomyelitis, scarlet fever, and, rarely, meningitis are observed. Pitted scars are frequent sequelae.

Reye's syndrome (fatty liver with encephalopathy) also complicates varicella (and other viral infections, especially influenza B), usually in childhood, and is associated with aspirin therapy (see Influenza, below). The many manifestations of VZV infection that occur in HIV infection include multifocal encephalitis, ventriculitis, myeloradiculitis, and arteritis.

When contracted during the first or second trimesters of pregnancy, varicella carries a very small risk of congenital malformations, including cicatricial lesions of an extremity, growth retardation, microphthalmia, cataracts, chorioretinitis, deafness, and cerebrocortical atrophy. If a mother develops varicella within 5 days after delivery, the newborn is at risk for disseminated disease and should receive varicella-zoster immune globulin (VZIG). (See below for dosage.)

VZV is a major etiologic agent of Bell's palsy in patients lacking antibodies to HSV.

B. Herpes Zoster

In immunosuppressed and HIV-infected patients, herpes zoster may produce skin lesions beyond the dermatome, visceral lesions, and encephalitis. Postherpetic neuralgia occurs in 60-70% of zoster patients over age 60.

Prevention

Patients with active varicella or zoster are separated from seronegative patients. Respiratory isolation is needed in varicella pneumonia. Health care workers should be screened for varicella and vaccinated if seronegative. Health care workers should stay away from work when active vesicles are present, typically from the tenth day after onset through the twenty-first day. Varicella-zoster immune globulin (VZIG) is effective in preventing chickenpox in exposed susceptible—particularly immunosuppressed—individuals. These include (1) susceptible persons receiving immunosuppressive therapy; (2) persons with congenital cellular immunodeficiency; (3) persons with an acquired immunodeficiency, including AIDS; (4) some adults, in particular pregnant females, considering the exposure history and the likelihood of previous chickenpox; (5) newborns; and (6) premature infants of low birth weight.

A. Varicella

A live attenuated vaccine is recommended for administration to all children over 12-14 months of age who have not had chickenpox. Patients with impaired cellular immunity should not be immunized, although the vaccine appears to be safe and effective when given to asymptomatic or mildly symptomatic HIV-infected children. Susceptible, nonimmunocompromised household contacts with no prior history of varicella should also be vaccinated, assuming they are neither immunocompromised nor have had previous varicella. Under such conditions, the vaccine is 85% effective in preventing illness and 95% effective in preventing serious disease. Children receiving the vaccine should not take aspirin for at least 6 weeks, because of the possibility of Reye's syndrome. Adults should receive a second dose of the vaccine, typically 1-2 months after the first dose.

Varicella-zoster immune globulin (VZIG) is effective in preventing chickenpox in exposed susceptible—particularly immunosuppressed—individuals. It is given by intramuscular injection in a dosage of 12.5 units/kg up to a maximum of 625 units, with a repeat dose in 3 weeks if a high-risk patient remains exposed. VZIG has no place in therapy of established disease. Further information may be obtained by calling the Centers for Disease Control and Prevention's Immunization Information Hotline (800-232-2522). Because VZIG appears to bind the varicella vaccine, the two should not be given concomitantly.

B. Zoster

There is no effective prevention, though inactivated cell vaccine may protect against recurrence.

Treatment

A. General Measures

Patients should be isolated until primary crusts have disappeared and kept at bed rest until afebrile. Hospitalized patients with VZV infections should be isolated, and caregivers should wear gowns, gloves, and masks when in contact with them. The skin is kept clean. Pruritus can be relieved with antihistamines, calamine lotion, and colloidal oatmeal baths. As an antipyretic, acetaminophen is used.

B. Antiviral Therapy

For the infrequent varicella infection for which antiviral therapy is indicated, the mainstay of therapy is acyclovir; its derivatives (valacyclovir and famciclovir) are approved only for immunocompetent individuals. These agents reduce the severity and shorten the duration of chickenpox and zoster in adults and in children. Acyclovir, if given in the first 72 hours of zoster, may reduce postherpetic pain. Valacyclovir, 1000 mg three times daily, and famciclovir, 500 mg three times daily, reduce pain and heal lesions faster than acyclovir, 800 mg five times daily. Some authorities feel that otherwise healthy adults may benefit from a tapering course of prednisone over 21 days.

In immunocompromised patients, in pregnant women during the third trimester, and in patients with extracutaneous disease (encephalitis, pneumonitis), antiviral therapy with high-dose acyclovir (30 mg/kg/d in three divided doses intravenously for at least 7 days) should be started once the diagnosis is suspected. Acyclovir-resistant varicella has been observed in AIDS patients receiving chronic acyclovir therapy. Foscarnet may be used for acyclovir-resistant virus; however, resistance to foscarnet is also recognized.

C. Treatment of Complications

The most troublesome issue with VZV infection is postherpetic neuralgia, especially in older patients. Initial treatment with antivirals and possibly corticosteroids may reduce its incidence and severity. Once established, pain may respond to tricyclic antidepressants, lidocaine patches, gabapentin, or analgesics. Secondary bacterial infections of lesions are treated with antibiotics providing coverage for staphylococci.

Prognosis

The total duration of varicella from onset of symptoms to disappearance of crusts rarely exceeds 2 weeks. Fatalities are rare except in immunosuppressed patients.

Zoster resolves in 2-6 weeks. Antibodies persist longer and at higher levels than with primary varicella.

3. EBV & Infectious Mononucleosis

Essentials of Diagnosis

- Malaise, fever, and sore throat, sometimes with exudate.
- Lymphadenopathy, splenomegaly, and, occasionally, a maculopapular rash.
- Positive heterophil agglutination test (Monospot).
- Atypical large lymphocytes in blood smear; lymphocytosis.
- Possible complications: hepatitis, myocarditis, neuropathy, encephalitis, airway obstruction secondary to lymph node enlargement, anti-i hemolytic anemia, thrombocytopenia.

General Considerations

Infectious mononucleosis is usually due to the Epstein-Barr (EB) virus (human herpesvirus 4). It is universal in distribution and may be seen at any age but usually occurs in the United States in persons between the ages of 10 and 35, sporadically or in epidemic distribution. In the developing world, acute infections occur at much younger ages and tend to be less symptomatic. Rare cases have been reported in the elderly, usually without the full complex of symptoms. Its mode of transmission is probably by saliva. The incubation period is probably several weeks.

Clinical Findings

A. Symptoms and Signs

Symptoms vary but typically include fever, sore throat, and toxic symptoms (malaise, anorexia, and myalgia) in the early phase of the illness. Physical findings include lymphadenopathy (discrete, nonsuppurative, slightly painful, especially along the posterior cervical chain) and splenomegaly (in one-half). A maculopapular or occasionally petechial rash occurs in fewer than 15% unless ampicillin has been given (when rash is seen in > 90%). Exudative pharyngitis, tonsillitis, or gingivitis may occur and soft palatal petechiae may be noted.

Other manifestations include hepatitis, nervous system involvement with mononeuropathies and occasionally aseptic meningitis, encephalitis, or Guillain-Barre syndrome; hepatitis; renal failure from interstitial nephritis; pulmonary involvement with dyspnea and cough (in severe forms, "pseudocroup"); and myocarditis. Airway obstruction from lymph node enlargement is an indication for hospitalization or close observation.

B. Laboratory Findings

Initially, there is a granulocytopenia followed within 1 week by a lymphocytic leukocytosis. Many lymphocytes are larger than normal mature lymphocytes, stain more darkly, and frequently show vacuolated, foamy cytoplasm and dark chromatin in the nucleus. Hemolytic anemia, usually secondary to anti-i antibodies, is occasionally encountered, as is thrombocytopenia (at times marked).

Heterophil (sheep cell agglutination) antibody tests and the correlated mononucleosis spot (Monospot) test usually become positive within 4 weeks after onset of illness. Titer rises in antibodies directed at several EB virus antigens can be detected. During acute illness there is a rise and fall in IgM antibody to EB virus capsid antigen (VCA) and a rise in IgG antibody to VCA, which persists for life. Antibodies to EB virus nuclear antigen (EBNA) appear at 3-4 weeks after onset and also persist. A false-positive RPR occurs in 10%. PCR for EBV DNA is useful in immunocompromised patients in the differential diagnosis of central nervous system processes and perhaps in monitoring disease. Hepatic aminotransferases and bilirubin are commonly elevated. In aseptic meningitis, the cerebrospinal fluid may show increased opening pressure, lymphocytosis with abnormal morphology, and increased protein.

Differential Diagnosis

CMV infection, toxoplasmosis, acute HIV infection, and rubella may be indistinguishable from infectious mononucleosis due to EB virus, but exudative pharyngitis is usually absent and the heterophil antibody and Monospot tests are negative. With acute HIV infection, a rash is often seen. Mycoplasmal infection may also present primarily with pharyngitis, though lower respiratory symptoms usually predominate. A hypersensitivity syndrome induced by carbamazepine may mimic infectious mononucleosis.

The differential diagnosis of acute exudative pharyngitis includes diphtheria, gonococcal and streptococcal infections, and infections with adenovirus and herpes simplex. Head and neck soft tissue infections (pharyngeal and tonsillar abscesses) may occasionally be mistaken for the lymphadenopathy of mononucleosis.

Complications

Secondary bacterial throat infection can occur and is often streptococcal. Splenic rupture is a rare but dramatic complication, and a history of preceding trauma can be elicited in half of the cases. Pericarditis and myocarditis are also rare complications, although nonspecific electrocardiographic changes are seen in about 5% of all patients. Neurologic involvement—including transverse myelitis, encephalitis, and Guillain-Barre syndrome—is infrequent.

Treatment

A. General Measures

Given that over 95% of patients recover without specific antiviral therapy, treatment is largely symptomatic. Acyclovir decreases viral shedding but does not have verified clinical benefit. Efforts to sensitize the virus to nucleoside analogs have yet to be proved beneficial. Symptomatic relief can be achieved by the administration of acetaminophen or other nonsteroidal anti-inflammatory agents and warm saline throat irrigations or gargles three or four times daily. The use of corticosteroids, while widespread, is not recommended in uncomplicated cases. Their use is reserved for impending airway obstruction from enlarged lymph nodes, hemolytic anemia, and severe thrombocytopenia. Their value in impending splenic rupture, pericarditis, myocarditis, and nervous system involvement is less well defined. If a throat culture grows beta-hemolytic streptococci, a 10-day course of penicillin or erythromycin is indicated. Ampicillin and amoxicillin are avoided because of the frequent association with rash.

B. Treatment of Complications

Hepatitis, myocarditis, and encephalitis are treated symptomatically. Rupture of the spleen requires splenectomy and is most often caused by deep palpation of the spleen or vigorous activity.

Prognosis

In uncomplicated cases, fever disappears in 10 days and lymphadenopathy and splenomegaly in 4 weeks. The debility sometimes lingers for 2-3 months.

Death is uncommon and usually due to splenic rupture, hypersplenic phenomena (severe hemolytic anemia, thrombocytopenic purpura), or encephalitis.

See references at end of next section.

4. Other EBV Syndromes

EBV viral antigens have been found in over 90% of patients with African Burkitt's lymphoma or nasopharyngeal carcinoma. A causative role for EBV has been postulated with both neoplasms. Chronic EBV infection is associated with an X-linked lymphoproliferative syndrome (Duncan's disease). EBV-induced lymphoproliferation gives rise to B cell lymphomas among immunodeficient patients, such as the HIV-infected or after transplantation ("posttransplant lymphoproliferative disorder"). Immunologically privileged areas such as the central nervous system are particularly susceptible. The prophylactic use of EBV-specific cytotoxic T cell lymphocytes may prevent the development of EBV-associated lymphoproliferative disease.

EBV has also been associated with leiomyomas in children with AIDS and with nasal T cell lymphomas. There is no persuasive evidence that chronic fatigue syndrome is caused by EBV infection. Oral hairy leukoplakia is discussed in [Chapter 8](#). A fatal T cell lymphoproliferative disorder in children is serologically associated with EBV infection.

EBV has been tentatively implicated in the pathogenesis of Hodgkin's disease but also in the pathogenesis of a variety of solid neoplasms, including oral tumors, and with systemic lupus erythematosus, encephalitis, rheumatoid arthritis, and Sjogren's syndrome.

5. Cytomegalovirus Disease

Most cytomegalovirus (CMV) infections are asymptomatic, with the virus remaining latent. It can be isolated from a variety of tissues under nonpathogenic conditions including up to 25% of salivary glands and 10% of uterine cervixes. Nevertheless, the cells of latency are unknown. Seroprevalence increases with age and with the number of sexual partners. Detectable antibody is present in the serum of most homosexual men. Transmission is sexual, congenital, through blood products or transplantation, and person-to-person (eg, day care centers). Serious disease occurs primarily in the immunocompromised, especially AIDS and transplant patients.

Clinical Findings

A. Classification

There are three recognizable clinical syndromes.

1. Perinatal disease and CMV inclusion disease—This neonatal syndrome is acquired in utero and seen in 10% of newborns born to mothers with primary CMV infection during pregnancy. It is characterized by jaundice, hepatosplenomegaly, thrombocytopenia, periventricular central nervous system calcifications, mental retardation, motor disability, and purpura. Neonatally acquired disease is often asymptomatic, but neurologic deficits may ensue later in life.

2. Acute acquired CMV infection—Akin to EBV-associated infectious mononucleosis, this syndrome is characterized by fever, malaise, myalgias and arthralgias (but rarely exudative pharyngitis or cervical lymphadenopathy), splenomegaly, atypical lymphocytes, and abnormal liver function tests. Typically, leukopenia is followed by leukocytosis. Heterophil antibody is absent. Transmission occurs by sexual contact, in breast milk, via respiratory droplets among nursery or day care center attendants, and by transfusions of blood. Complications include mucosal gastrointestinal damage, encephalitis, Guillain-Barre syndrome, pericarditis, and myocarditis.

3. Disease in immunocompromised hosts—Tissue and bone marrow transplant patients are mainly at risk in the first 100 days after allograft transplantation. HIV-infected patients may show numerous manifestations. CMV is itself immunosuppressive and may worsen pneumocystis pneumonia. CMV may contribute to transplanted organ dysfunction.

a. CMV retinitis—Retinitis occurs in AIDS patients with CD4 counts less than 50 cells/uL. Ophthalmologic documentation of neovascular, proliferative lesions ("pizza-pie" retinopathy) is required for diagnosis. With HAART, the frequency of retinitis is reduced, CD4 counts are less predictive, and active disease may be reversible.

b. Gastrointestinal and hepatobiliary CMV—Serious gastrointestinal CMV disease occurs in AIDS and after organ transplantation, cancer chemotherapy, or steroid therapy. Esophagitis presents with odynophagia; small bowel disease may mimic inflammatory bowel disease or may present as ulceration or perforation. Colonic CMV disease causes diarrhea, hematochezia, abdominal pain, fever, and weight loss. CMV has been identified—often with other pathogens such as cryptosporidium—in up to 15% of patients with AIDS cholangiopathy. Diagnosis is made by mucosal biopsy showing characteristic CMV histopathologic findings of intranuclear ("owl's eye") and intracytoplasmic inclusions.

c. Pulmonary CMV—CMV pneumonitis—characterized by cough, dyspnea, and relatively little sputum production—occurs in transplant recipients and AIDS patients and is associated with a high mortality. In AIDS patients, the significant morbidity and mortality appear to be diminished by the use of antiretroviral therapy. CMV-seronegative blood products should be used in seronegative recipients of seronegative transplants. High-titer CMV immunoglobulins may be effective in preventing CMV pneumonia in seronegative recipients.

d. Neurologic CMV—Neurologic syndromes associated with CMV include polyradiculopathy, transverse myelitis, and encephalitis. The encephalitis has a subacute onset in patients with advanced AIDS and is usually associated with disseminated CMV infection. CMV can be isolated in the cerebrospinal fluid in cases of transverse myelitis or disseminated disease.

B. Laboratory Findings

Virus isolation is most useful when combined with the pathologic findings. Cultures alone are of little use in diagnosing AIDS-related CMV infections, but when positive have been associated with a risk of progressive retinitis. Tissue confirmation is especially useful in establishing a diagnosis of CMV pneumonitis and CMV gastrointestinal or neurologic disease.

The acute mononucleosis-like syndrome is associated with lymphocytosis, often 2 weeks after the fever, but absolute leukopenia may also be noted. Serologic tests are useful primarily in seroepidemiologic studies and occasionally in confirming acute infection (with IgM) in nonimmunosuppressed patients. Antigen detection in blood components, urine, or cerebrospinal fluid by virus technology (including the PCR technique) should be interpreted in the context of clinical and pathologic findings but is increasingly being used to guide both treatment and prevention.

Prevention

No vaccine is currently available. Strategies for prevention in transplant recipients include antiviral agents and CMV immune globulin. The risk for CMV disease is proportionate to the intensity of immunosuppression, which depends in part on the organ being transplanted. PCR and antigen assays increase the ability to detect CMV disease prior to clinical expression. Oral ganciclovir is being replaced by oral valganciclovir in prevention because of its greater bioavailability. The optimum system for monitoring and preventing CMV disease among transplant patients remains to be elucidated. HAART is effective in preventing CMV infections in HIV-infected patients.

Treatment

Four antiviral agents with efficacy against CMV infections are ganciclovir, 5 mg/kg intravenously every 12 hours for 14-21 days; valganciclovir, 900 mg/kg twice daily; foscarnet, loading with 20 mg/kg intravenously, followed by 60 mg/kg every 8 hours over weeks; and cidofovir, 5 mg/kg intravenously every week for 2 weeks. A daily maintenance regimen using both ganciclovir (3.75 mg/kg intravenously) and foscarnet (60 mg/kg intravenously), each over 1 hour, has been shown to be safe and effective in inhibiting CMV replication. Cidofovir is given only every 2 weeks, 375 mg intravenously, for maintenance. Oral valganciclovir (900 mg daily) is replacing oral ganciclovir for maintenance. Dosage adjustments of all medications are needed for renal impairment. In addition, a sustained-release ganciclovir implant controls disease in the implanted eye (but not elsewhere) more effectively than intravenous ganciclovir. Again, the role of HAART in reducing the need for CMV antivirals is primary. Fomivirsen is an intravitreal agent active against CMV strains that are resistant to ganciclovir, foscarnet, and cidofovir. Adjuvant filgrastim may be useful in AIDS-associated CMV retinitis.

6. Human Herpesviruses 6, 7, 8

Human herpesvirus 6 (HHV-6) is a B cell lymphotropic virus that is the principal cause of exanthema subitum (roseola infantum, sixth disease). Primary HHV-6 infection occurs most commonly in children under 2 years of age and is the most common cause of infantile febrile seizures. HHV-6 in adults is associated with immunocompromised states such as HIV and lymphoma. It is associated with graft rejection and bone marrow suppression in transplant patients and with encephalitis and pneumonitis in AIDS; it is mentioned as a factor in the etiology of multiple sclerosis.

Two variants (A and B) of HHV-6 have been identified. HHV6B is the predominant strain found in both normal and immunocompromised hosts. In vitro data suggest susceptibility to ganciclovir and foscarnet but not acyclovir. HHV-7 is a T cell lymphotropic virus that is serologically associated with roseola. Infection with HHV-7 appears to be synergistic with CMV in renal transplant recipients. The membrane glycoprotein CD4 is involved in HHV-7 recognition, and an antagonistic interaction between HHV-7 and HIV is established. HHV-7 may invade the central nervous system in children.

HHV-8 is associated with Kaposi's sarcoma in AIDS patients. It has also been implicated in multicentric Castleman's disease and primary effusion lymphoma (body cavity lymphoma). See [Chapter 31](#) for pathogenesis and management.

MAJOR VACCINE-PREVENTABLE VIRAL INFECTIONS

1. Measles

- Exposure 10-14 days before onset in an unvaccinated patient.
- Prodrome of fever, coryza, cough, conjunctivitis, malaise, irritability, photophobia, Koplik's spots.
- Rash: brick-red, irregular, maculopapular; onset 3-4 days after onset of prodrome; begins on the face and proceeds "downward and outward," affecting the palms and soles last.
- Leukopenia.

General Considerations

Measles is an acute systemic paramyxoviral infection transmitted by inhalation of infective droplets. This virus tropic for monocytes is a major worldwide cause of pediatric morbidity and mortality, with an estimated 1 million deaths annually. Illness confers permanent immunity. Communicability is greatest during the preeruptive and catarrhal stages but continues as long as the rash remains. The largest recent outbreak in the Americas was in Sao Paolo, Brazil, with over 42,000 cases among largely unvaccinated young adults. This and other sporadic recent outbreaks of the disease in adults, adolescents, and unvaccinated preschool children in dense urban areas emphasize the need for specific recommendations concerning prevention (see below).

In the United States, in view of the preponderance of imported cases and the low number of geographically dispersed cases whose isolates fail to show a recurrent strain, measles is no longer considered endemic.

Clinical Findings

A. Symptoms and Signs

([Table 32-2.](#)) Fever is often as high as 40-40.6°C. It persists through the prodrome and early rash (about 5-7 days). Malaise may be marked. Coryza (nasal obstruction, sneezing, and sore throat) resembles that seen with upper respiratory infections. Cough is persistent and nonproductive. Conjunctivitis manifests as redness, swelling, photophobia, and discharge.

Koplik's spots are pathognomonic of measles. They appear about 2 days before the rash and last 1-4 days as tiny "table salt crystals" on the dull red mucous membranes of the cheeks and often on inner conjunctival folds and vaginal mucous membranes. Other findings include pharyngeal erythema, a yellowish exudate on the tonsils, coating of the tongue in the center with a red tip and margins, moderate generalized lymphadenopathy, and, in occasional cases, splenomegaly.

The rash usually appears first on the face and behind the ears 4 days after the onset of symptoms. The initial lesions are pinhead-sized papules which coalesce to form a brick-red, irregular, blotchy maculopapular rash. In severe cases, the rash may coalesce to form a nearly uniform erythema on some body areas. The rash next

appears on the trunk, followed by the extremities, including the palms and soles. It fades in order of appearance. Hyperpigmentation remains in fair-skinned individuals and severe cases. Slight desquamation may follow.

Atypical measles is a syndrome occurring in adults who received inactivated measles vaccine (available 1963-1967) or who received live measles vaccine before age 12 months and as a result developed hypersensitivity rather than protective immunity. When infected later with wild measles virus, such individuals may develop a potentially fatal illness with high fever, unusual rashes (papular, hemorrhagic) without Koplik's spots, headache, arthralgias, hepatitis, and interstitial or nodular infiltrates, occasionally with pleural effusions.

Measles may occur in HIV-infected individuals in an uncharacteristic fashion, with higher rates of pneumonitis and higher mortality. Vaccine failure rates, both primary and secondary, are higher in HIV-infected children. The frequent difficulty in establishing a diagnosis suggests that measles may be more prevalent in epidemics than heretofore recognized.

B. Laboratory Findings

Leukopenia is usually present unless secondary bacterial complications exist. A lymphocyte count under 2000/uL is a poor prognostic sign. Proteinuria is often observed. Although technically difficult, virus can be cultured from nasopharyngeal washings and from blood. A fourfold rise in serum hemagglutination inhibition antibody supports the diagnosis. Fluorescent antibody staining of respiratory or urinary epithelial cells can also confirm the diagnosis.

Differential Diagnosis

Measles is usually diagnosed clinically but may be mistaken for other exanthematous infections (see [Table 32-2](#)).

Complications

A. Central Nervous System Complications

Encephalitis occurs in approximately 0.05-0.1% of cases. Its onset is usually 3-7 days after the rash. Vomiting, convulsions, coma, and a variety of severe neurologic symptoms and signs may develop. Treatment is symptomatic and supportive. Virus is usually not found in the central nervous system, though demyelination is prominent. There is an appreciable mortality rate (10-20%), and many patients are left with neurologic morbidity.

A similar form, "inclusion body encephalitis," is also reported to occur after measles vaccination but is associated with isolation of the measles virus.

Subacute sclerosing panencephalitis (SSPE) is a very late central nervous system complication, the measles virus acting as a "slow virus" to produce degenerative central nervous system disease years after the initial infection. SSPE is rare (1:100,000 cases of measles) and occurs more often when measles develops early in life, among males, and in persons living in rural environments.

An acute progressive encephalitis (subacute measles encephalitis), characterized by seizures, neurologic deficits, and often progressive stupor and death, can occur among immunosuppressed patients; measles virus opportunistically invades the central nervous system. Treatment is supportive, withholding immunosuppressive chemotherapy when feasible. Interferon and ribavirin have been variably successful.

B. Respiratory Tract Disease

Early in the course of the disease, bronchopneumonia or bronchiolitis due to the measles virus may occur in up to 5% and result in serious respiratory difficulties. Pneumonia occurring with or without an evanescent rash is seen in atypical measles.

C. Secondary Bacterial Infections

Immediately following measles, secondary bacterial infection, particularly cervical adenitis, otitis media, and pneumonia, occurs in about 15% of patients.

D. Immune Reactivity

Measles produces temporary anergy to the tuberculin skin test.

E. Gastroenteritis

Diarrhea and protein-losing enteropathy (prodromal rectal Koplik spots may be seen) are significant complications when measles affects malnourished children.

Prevention

In the United States, it is recommended that children receive their first vaccine dose at 12-15 months and a second at age 4-6 years prior to entry into school (see [Table 30-4](#)).

Students beyond high school and medical staff starting employment must have the above vaccination schedule documented or must have serologic evidence of immunity if they were born after 1956. For individuals born before 1957, herd immunity can be assumed. Health care workers should be screened and vaccinated if necessary regardless of date of birth.

Outbreak control in the United States is similar. If outbreaks are occurring in preschool children under 1 year of age, initial vaccination may be given at 6 months, with repeat at 15 months. When outbreaks take place in day care centers, K-12 institutions, or colleges and universities, revaccination is probably indicated for all, in particular for students and their siblings born after 1956 who do not have documentation of immunity as defined above. Susceptible personnel who have been exposed should be isolated from patient contact from the fifth to the 21st day after exposure regardless of whether they have been vaccinated or have received immune globulin. If they develop measles, they should be isolated from patient contact until 7 days after the rash develops.

Ancillary control measures used in the developing world include "catch-up days"—when all children regardless of immunization history are vaccinated—maintenance and follow-up of immunization histories ("catch-up, keep-up, and follow-up"), surveillance of acute cases, and confirmation of whether isolates from cases are imported or outbreak-associated.

When susceptible individuals are exposed to measles, the live virus vaccine can prevent disease if given within 5 days of exposure. This is rarely feasible in a household. Later, immune globulin (0.25 mL/kg [0.11 mL/lb] body weight) can be injected intramuscularly for prevention or modification of clinical illness if given within 6 days after exposure. This must be followed by active immunization with live measles vaccine 3 months later. Vaccination of all immunocompetent persons born after 1956 who travel to the developing world is important.

Pregnant women and the immunosuppressed should *not* receive this vaccine. There are two exceptions: asymptomatic HIV-infected patients, who have not shown adverse effects from measles vaccination, and HIV-infected children, in whom exposure to vaccines improves survival after measles. In the developing world, the use of "high-titer" vaccine is associated with a higher delayed mortality rate. Immune globulin should be considered for postexposure prophylaxis in any HIV-infected person exposed to measles.

Severe allergic reactions to the measles, mumps, and rubella (MMR) vaccine are rare, though fever and rash appear to occur slightly more often among female recipients.

Treatment

A. General Measures

The patient should be isolated for the week following onset of rash and kept at bed rest until afebrile. Treatment is symptomatic as needed. Vitamin A, 200,000 units/d orally (the beneficial effects of which include maintenance of gastrointestinal and respiratory epithelial mucosa and perhaps immune enhancement), reduces pediatric morbidity rates.

B. Treatment of Complications

Secondary bacterial infections are treated with appropriate antimicrobial drugs. Pneumonia is managed with antibacterial antibiotics when clinical signs suggest sepsis or significant pulmonary findings. Postmeasles encephalitis, including SSPE, can only be managed symptomatically.

Prognosis

The mortality rate of measles in infants was 0.6% in a recent outbreak in California; the mortality rate may be as high as 10% in developing nations. Deaths in the United States are due principally to encephalitis (15% mortality rate) and secondary bacterial pneumonia. Deaths in the developing world are mainly related to diarrhea and protein-losing enteropathy.

2. Mumps

Essentials of Diagnosis

- Exposure 14-21 days before onset.
- Painful, swollen salivary glands, usually parotid.
- Frequent involvement of other tissues, including testes, pancreas, and meninges, in unvaccinated individuals.

General Considerations

Mumps is a paramyxoviral disease spread by respiratory droplets that usually produces inflammation of the salivary glands and, less commonly, orchitis, aseptic meningitis, pancreatitis, and oophoritis. Most patients are children, and the incidence is highest in spring. The incubation period is 14-21 days (average, 18 days). Infectivity occurs via saliva and urine and precedes the symptoms by about 1 day and is maximal for 3 days but may last a week.

Clinical Findings

A. Symptoms and Signs

Parotid tenderness and overlying facial edema are the most common physical findings. Occasionally, swelling in one gland subsides completely before the other parotid or salivary glands become involved. Swelling and tenderness of the submaxillary and sublingual glands are variable. The orifice of Stensen's duct may be red and swollen.

Fever and malaise are variable and are often minimal in young children. High fever usually accompanies meningitis or orchitis. Neck stiffness, headache, and lethargy suggest meningitis. Testicular swelling and tenderness (unilateral in 75%) denote orchitis. Orchitis, which develops typically 7-10 days after the onset of parotitis, occurs in about 25-40% of postpubertal men, but sterility is rare. Upper abdominal pain, nausea, and vomiting suggest pancreatitis. Mumps is the leading cause of pancreatitis in children. Lower abdominal pain and ovarian enlargement suggest oophoritis, but the diagnosis may be difficult to make. Pain and swelling of one or both (75%) of the parotid or other salivary glands occur, usually in succession 1-3 days apart.

B. Laboratory Findings

Relative lymphocytosis may be present. Serum amylase is commonly elevated with or without pancreatitis because of salivary gland involvement. Lymphocytic pleocytosis (and normal to low glucose) of the cerebrospinal fluid is present in meningitis, which may be asymptomatic. The diagnosis of mumps is confirmed by isolating the virus from saliva or cerebrospinal fluid or demonstrating a fourfold rise in complement-fixing antibodies in paired sera.

Differential Diagnosis

Swelling of the parotid gland may be due to calculi in the parotid ducts or to a reaction to iodides. Other causes include starch ingestion, sarcoidosis, cirrhosis, diabetes, bulimia, pilocarpine use for dry mouth, and Sjogren's syndrome. Parotitis may also be produced by pyogenic organisms (eg, *Staphylococcus aureus*), particularly in debilitated individuals, drug reaction (phenothiazines, propylthiouracil), and other viruses (influenza A, parainfluenza, EBV infection, coxsackieviruses). Swelling of the parotid gland must be differentiated from inflammation of the lymph nodes located more posteriorly and inferiorly than the parotid gland.

Complications

Other manifestations of the disease are less common than inflammation of the salivary glands. These usually follow the parotitis but may precede it or occur without salivary gland involvement and include meningitis (30%), orchitis (on rare occasion leads to priapism or testicular infarction), pancreatitis, oophoritis, thyroiditis, neuritis, hepatitis, myocarditis, thrombocytopenia, migratory arthralgias, and nephritis. Mumps has also been associated with cases of endocardial fibroelastosis.

Rare neurologic complications include encephalitis, Guillain-Barre syndrome, cerebellar ataxia, and transverse myelitis. Encephalitis is associated with cerebral edema, serious neurologic manifestations, and sometimes death. Deafness develops rarely from eighth nerve neuritis.

Prevention

Mumps live virus vaccine is safe and highly effective. It is recommended for routine immunization for children over age 1 year, either alone or in combination with other virus vaccines (eg, with measles and rubella—in MMR vaccine). Reactions are reviewed in the measles section. It should not be given to pregnant women or to immunocompromised individuals, though the vaccine has been given to asymptomatic HIV-infected individuals without adverse sequelae. Its use has markedly decreased the incidence of mumps in the United States. The mumps skin test is less reliable in determining immunity than are serum neutralization titers.

Treatment

A. General Measures

The patient should be isolated until swelling subsides and kept at bed rest during the febrile period. Treatment is symptomatic as needed.

B. Management of Complications

1. Meningitis—The treatment of aseptic meningitis is purely symptomatic. The management of encephalitis requires attention to cerebral edema, the airway, and vital functions.

2. Orchitis—The scrotum should be suspended in a suspensory or toweling "bridge" and ice bags applied. Incision of the tunica may be necessary in severe cases. Codeine or meperidine may be given as necessary for pain. Pain can also be relieved by injection of the spermatic cord at the external inguinal ring with 10-20 mL of 1% procaine solution. The merit of hydrocortisone sodium succinate (100 mg intravenously, followed by 20 mg orally every 6 hours for 2 or 3 days) to reduce the inflammatory reaction is not firmly established.

3. Pancreatitis—Symptomatic treatment is provided by emphasis on parenteral hydration.

Prognosis

The entire course of mumps rarely exceeds 2 weeks. Fatalities (usually from encephalitis) are rare

Da Cunha SS et al: Outbreak of aseptic meningitis and mumps after mass vaccination with MMR vaccine using the Leningrad-Zagreb mumps strain. *Vaccine* 2002;20:1106. [\[PMID: 11803071\]](#)

Galazka AM et al: Mumps and mumps vaccine: a global review. *Bull WHO* 1999;77:3. [\[PMID: 10063655\]](#)

3. Poliomyelitis

Essentials of Diagnosis

- Muscle weakness, headache, stiff neck, fever, nausea and vomiting, sore throat.
- Lower motor neuron lesion (flaccid paralysis) with decreased deep tendon reflexes and muscle wasting.
- Cerebrospinal fluid shows excess leukocytes, with lymphocytic predominance; count is rarely more than 500/uL.

General Considerations

Poliomyelitis virus, an enterovirus, is present in throat washings and stools. Infection is most commonly acquired by the fecal-oral route. Since the introduction of an effective vaccine, poliomyelitis has become a rare disease in developed areas of the world, and globally, between 1988 and 2001, the number of cases decreased by 99%. The global poliomyelitis eradication initiative was launched in 1988 and has led to elimination of wild poliovirus from the Western hemisphere. The Pacific Rim, Europe, and Central Asia also appear to be polio-free. Polio remains endemic in Pakistan, India, and central and western Africa. Three antigenically distinct types of poliomyelitis virus are recognized, with no cross-immunity between them. The incubation period is 5-35 days (usually 7-14 days). Disease with type 2 (of the three types) in particular is on the verge of extinction. Infectivity is maximal during the first week, but virus is excreted in stools for several weeks.

Clinical Findings

A. Symptoms and Signs

At least 95% of infections are asymptomatic, but in those who become ill the following manifestations are seen.

1. Minor illness (abortive poliomyelitis)—The symptoms are fever, headache, vomiting, diarrhea, constipation, and sore throat.

2. Nonparalytic poliomyelitis—In addition to the above symptoms, signs of meningeal irritation and muscle spasm occur in the absence of frank paralysis.

3. Paralytic poliomyelitis—Paralytic poliomyelitis represents 0.1% of all poliomyelitis cases (the incidence is higher when infections are acquired later in life). Paralysis may occur at any time during the febrile period. Tremors, muscle weakness, constipation, and ileus may appear. Paralytic poliomyelitis is divided into two forms, which may coexist: **(1) spinal poliomyelitis**, with involvement of the muscles innervated by the spinal nerves, and **(2) bulbar poliomyelitis**, with weakness of the muscles supplied by the cranial nerves (especially nerves IX and X) and of the respiratory and vasomotor centers.

In spinal poliomyelitis, paralysis of the shoulder girdle often precedes intercostal and diaphragmatic paralysis, which leads to diminished chest expansion and decreased vital capacity.

In bulbar poliomyelitis, symptoms include diplopia (uncommonly), facial weakness, dysphagia, dysphonia, nasal voice, weakness of the sternocleidomastoid and trapezius muscles, difficulty in chewing, inability to swallow or expel saliva, and regurgitation of fluids through the nose. The most life-threatening aspect of bulbar poliomyelitis is respiratory paralysis. Lethargy or coma may be due to hypoxia, most often from hypoventilation. Alterations in blood pressure and heart rate may occur. Convulsions are rare.

B. Laboratory Findings

The peripheral white blood cell count may be normal or mildly elevated. Cerebrospinal fluid pressure and protein are normal or slightly increased. Glucose is not decreased. White blood cells usually number fewer than 500/uL and are principally lymphocytes after the first 24 hours. Cerebrospinal fluid is normal in 5% of patients. The virus may be recovered from throat washings (early) and stools (early and late). Neutralizing and complement-fixing antibodies appear during the first or second week of illness.

Differential Diagnosis

Nonparalytic poliomyelitis is similar to other forms of enteroviral meningitis; the distinction is made serologically. Acute inflammatory polyneuritis (Guillain-Barre) and tick paralysis may initially resemble poliomyelitis. In Guillain-Barre syndrome (see [Chapter 24](#)), the weakness is more symmetric and ascending in most cases, but the Miller-Fisher variant is quite similar to bulbar polio. The cerebrospinal fluid usually has a high protein content but normal cell count in Guillain-Barre syndrome.

Complications

Urinary tract infection, atelectasis, pneumonia, myocarditis, and pulmonary edema may occur. Respiratory failure may be a result of paralysis of respiratory muscles, airway obstruction from involvement of cranial nerve nuclei, or lesions of the respiratory center.

Prevention

Given the epidemiologic distribution of poliomyelitis and the continued concern about vaccine-associated disease with the oral live vaccine, recommendations for prevention have been modified. Currently in the United States, the inactive (Salk) parenteral vaccination is used for all four doses (at ages 2 months, 4 months, and 6-18 months and at 4-6 years). Oral vaccines are alternatively given for outbreak control, for travel to endemic areas within the ensuing month, and in protection of children whose parents do not comply with the recommended number of immunizations. Oral vaccines, however, are being completely replaced by inactivated poliovirus vaccine for routine use in the developed world. The limited advantages of oral vaccination are the ease of administration, the effective local gastrointestinal and circulating immunity, and herd immunity.

Routine immunization of adults in the United States is not recommended because of the low incidence of the disease. Exceptions include adults exposed to poliomyelitis or planning to travel to endemic areas who have not received polio immunization within the past decade. They should be given inactivated poliomyelitis vaccine (Salk). Immunodeficient or immunosuppressed individuals and members of their households should also be given inactivated vaccines.

In the developing world, the interval between OPV doses should probably be longer than 1 month (because of interference from enteric pathogens). Intramuscular injections should be routinely avoided during the month following oral poliomyelitis vaccination to prevent provocation paralysis. Ancillary useful control measures in polio-endemic countries include national immunization days (mass campaigns in which all children are vaccinated twice, 4-6 weeks apart, regardless of vaccine history); cross-border vaccination activities; surveillance for "acute flaccid paralysis," an indicator for poliomyelitis; and aggressive outbreak responses and intensified immunization activities in countries recently affected by armed conflicts.

In the summer of 2000, an outbreak of vaccine-derived poliomyelitis occurred in Hispaniola following the use of oral vaccine (Sabin). This serves as a reminder of the need to maintain high levels of immunization coverage even in the absence of overt disease. The risks associated with oral vaccination and the importance of continued surveillance for disease are continuing public health concerns.

Treatment

Strict bed rest in the first few days of illness reduces the rate of paralysis. Cranial nerve involvement must be vigilantly sought. Comfortable but rotating positions should be maintained in a "polio bed": firm mattress, footboard, sponge rubber pads or rolls, sandbags, and light splints. Fecal impaction and urinary retention (especially with paraplegia) are managed appropriately. In cases of respiratory weakness or paralysis, intensive care is needed.

Prognosis

During the febrile period, paralysis may develop or progress. Mild weakness of small muscles is more likely to regress than is severe weakness of large muscles. Bulbar poliomyelitis carries a mortality rate of up to 50%. New muscle weakness may develop and progress slowly years after recovery from acute paralytic poliomyelitis. This entity, postpoliomyelitis syndrome, presents with signs of chronic and new denervation, is not infectious in origin, and is associated with increasing dysfunction of surviving motor neurons. Series that report increased incidences of multiple sclerosis or other motor neuron diseases among poliomyelitis survivors need be evaluated in light of what is known about the postpoliomyelitis syndrome.

4. Rubella

Essentials of Diagnosis

- Exposure 14-21 days before onset.
- Arthralgia, particularly in young women.
- No prodrome in children, mild prodrome in adults; mild symptoms (fever, malaise, coryza) coinciding with eruption.
- Posterior cervical and postauricular lymphadenopathy 5-10 days before rash.
- Fine maculopapular rash of 3 days' duration; face to trunk to extremities.
- Leukopenia, thrombocytopenia.

General Considerations

Rubella is a systemic disease caused by a togavirus transmitted by inhalation of infective droplets. It is only moderately communicable. One attack usually confers permanent immunity. The incubation period is 14-21 days (average, 16 days). The disease is transmissible from 1 week before the rash appears until 15 days afterward.

The clinical picture of rubella is difficult to distinguish from other viral illnesses such as infectious mononucleosis, echovirus infections, and coxsackievirus infections, though arthritis is more prominent in rubella. Definitive diagnosis can be made only by isolating the virus or serologically.

In the United States, rubella and congenital rubella syndrome are on the verge of elimination, though an outbreak of 83 cases of rubella occurred in 1999 in Nebraska, largely among Latinos working in a meat-packing plant.

The principal importance of rubella lies in its devastating effects on the fetus in utero, producing teratogenic effects and a continuing congenital infection. Congenital rubella syndrome continues to occur in parts of the developing world at rates equivalent to those reported from the industrialized world during the prevaccine era. More than 100,000 cases occur annually in the developing world.

Clinical Findings (Table 32-2)

A. Symptoms and Signs

Fever and malaise, usually mild, accompanied by tender suboccipital adenitis, may precede the eruption by 1 week. Mild coryza may be present. Polyarthritis occurs in about 25% of adult cases. These symptoms usually subside within 7 days but may persist for weeks.

Early posterior cervical and postauricular lymphadenopathy is very common. Erythema of the palate and throat, sometimes patchy, may be noted. A fine, pink maculopapular rash appears on the face, trunk, and extremities in rapid progression (2-3 days) and fades quickly, usually lasting 1 day in each area. Rubella without rash may be at least as common as the exanthematous disease. Diagnosis, when suspected because of epidemiologic evidence of the disease in the community, requires serologic confirmation.

B. Laboratory Findings

Leukopenia may be present early and may be followed by an increase in plasma cells. Virus isolation and serologic tests of immunity (rubella virus hemagglutination inhibition and fluorescent antibody tests) are available. Definitive diagnosis is based on a fourfold or greater rise in antibody titers.

Complications

A. Exposure During Pregnancy

Rubella antibodies are sought at the beginning of pregnancy, since fetal infection during the first trimester leads to congenital rubella in at least 80% of fetuses.

When a pregnant woman is exposed to a possible case of rubella, an immediate hemagglutination-inhibiting rubella antibody level should be obtained; there is no reason for concern in positive tests. If no antibodies are found, clinical observation and serologic follow-up are essential although an isolated IgM-positive test needs to be interpreted with caution because it does not necessarily imply acute infection. Confirmation of rubella in the expectant mother raises the question of therapeutic abortion, an alternative to be considered in the light of personal, religious, legal, and other factors. The risk to the fetus is highest for maternal infection in the first trimester but continues into the second trimester.

B. Congenital Rubella

An infant acquiring the infection in utero may be normal at birth but probably—half in a series of nearly 70 pregnant women with rubella in Mexico—will manifest a wide variety of manifestations, including early-onset cataracts, microphthalmia, and glaucoma, hearing deficits, psychomotor retardation, congenital heart defects, organomegaly, and maculopapular rash. Viral excretion in the throat and urine persists for many months despite high antibody levels. The diagnosis is confirmed by isolation of the virus. A specific test for IgM rubella antibody is useful for diagnosis in the newborn. Treatment is directed toward the many anomalies.

C. Postinfectious Encephalopathy

In 1:6000 cases, postinfectious encephalopathy develops 1-6 days after the rash; the virus cannot always be isolated. The mortality rate is 20%, but residual deficits are rare among the recovered. The mechanism is unknown.

Prevention

Live attenuated rubella virus vaccine should be given to all infants and to susceptible girls before the menarche. When women are immunized, they should not be pregnant, and the absence of antibodies should be established. (In the United States, about 80% of 20-year-old women are immune to rubella.) Postpartum administration to susceptible female hospital employees is recommended, though many hospitals fail to comply. While it is recommended that birth control be practiced for at least 3 months after vaccine administration, there are no reports of congenital rubella syndrome after rubella immunization, and inadvertent immunization of a pregnant woman is not considered an indication for therapeutic abortion. Arthritis is more marked after rubella vaccination than in native disease and appears to be immunologically mediated. The association between chronic arthropathies and rubella vaccination is controversial. MMR may be given in conjunction with DPT boosters as adequate serologic responses are documented.

Treatment

Acetaminophen provides symptomatic relief. Encephalitis and non-life-threatening thrombocytopenia should be treated symptomatically.

Prognosis

Rubella is a mild illness and rarely lasts more than 3-4 days. Congenital rubella, on the other hand, has a high mortality rate, and the associated congenital defects are largely permanent.

OTHER NEUROTROPIC VIRUSES

1. Rabies

Essentials of Diagnosis

- History of animal bite.
- Paresthesia, hydrophobia, rage alternating with calm.
- Convulsions, paralysis, thick tenacious saliva.

General Considerations

Rabies is a viral (rhabdovirus) encephalitis transmitted by infected saliva that gains entry into the body by an animal bite or an open wound. Cases in the United States are rare but probably underreported. Raccoons, skunks, bats, and foxes are commonly infected. Biting species that cause rabies in the United States and are geographically determined include raccoons in the East, including New England; skunks in New England, in the Midwest and Southwest, and in California (skunk risk is high and increasing in many areas); coyotes in Texas; and foxes in the Southwest, in New England, and in Alaska. Dogs and cats are infected in developing countries (including the Mexican border). Ten out of 20 Americans with rabies acquired the disease abroad during the 1980s. Rodents and lagomorphs (eg, rabbits) are unlikely to have rabies. The virus gains entry into the salivary glands of dogs 5-7 days before their death from rabies, thus limiting their period of infectivity.

The incubation period may range from 10 days to many years but is usually 3-7 weeks. The interval is dependent in part on distance of the wound from the central nervous system. The virus travels in the nerves to the brain, multiplies there, and then migrates along the efferent nerves to the salivary glands.

Rabies is almost uniformly fatal, with four documented surviving cases; all received postexposure prophylaxis. The most common clinical problem confronting the physician is the management of a patient bitten by an animal (see Prevention).

Clinical Findings

A. Symptoms and Signs

There is usually a history of animal bite, though bat bites may not be remembered. The prodromal syndrome consists of pain at the site of the bite in association with fever, malaise, nausea, and vomiting. The skin is sensitive to changes of temperature, especially air currents. About 10 days later, the central nervous system stage begins, which may be either encephalitic ("furious") or paralytic ("dumb"). The encephalitic form produces the classic rabies manifestations of delirium alternating with periods of calm, when attempts at drinking cause extremely painful laryngeal spasms (hydrophobia). In the less common paralytic form, an acute ascending paralysis resembling Guillain-Barre syndrome, predominates with relative sparing of higher cortical functions initially. Both forms progress relentlessly to coma, autonomic nervous system dysfunction, and death despite intensive support.

B. Laboratory Findings

Biting animals who are apparently well should be kept under observation for 7-10 days. Sick or dead animals should be examined for rabies. A wild animal, if captured, should be sacrificed and the head shipped on ice to the nearest laboratory qualified to examine the brain for evidence of rabies virus; the diagnosis is made by the fluorescent antibody technique. When the animal cannot be examined, raccoons, skunks, bats, and foxes should be presumed to be rabid.

Fluorescent antibody testing of skin biopsy material from the posterior neck (where hair follicles are highly innervated) has a sensitivity of 60-80%.

Reverse transcriptase PCR and nucleic acid sequence-based amplification of the cerebrospinal fluid or saliva are being advocated as definitive diagnostic assays.

Prevention

Since rabies is almost always fatal, prevention is the only reasonable approach, and all exposures must be evaluated individually. Immunization of household dogs and cats and active immunization of persons with significant animal exposure (eg, veterinarians) are important. The most important common decisions, however, concern animal bites.

In the developing world, education, surveillance, and animal (particularly dog) vaccination programs are preferred over mass destruction of dogs, which is followed typically by invasion of susceptible feral animals into urban areas.

A. Local Treatment of Animal Bites and Scratches

Thorough cleansing, debridement, and repeated flushing of wounds with soap and water are important. If rabies immune globulin or antiserum is to be used, a portion should be infiltrated locally around the wound (see below) and the remainder given intramuscularly. Wounds caused by animal bites should not be sutured.

B. Postexposure Immunization

Therapy is indicated only when the disease is seriously under consideration. Medical decisions should be based on recommendations of the USPHS Advisory Committee but also on circumstances of the bite, including the extent and location of the wound, the biting animal, history of prior vaccination, and the local endemicity of rabies. Consultation is available from state and local health departments. Postexposure treatment includes both passive antibody and vaccination.

The optimal form of passive immunization is rabies immune globulin (20 IU/kg). As much as possible of the full dose should be infiltrated around the wound, with any remaining injected intramuscularly at a site distant from the wound. If immune globulin (human) is not available, equine rabies antiserum (20-40 IU/kg) can be used if available (last produced in 2001) after appropriate tests for horse serum sensitivity. An inactivated human diploid cell rabies vaccine (HDCV) is given as five injections of 1 mL intramuscularly (in the deltoid rather than the gluteal muscle) on days 0, 3, 7, 14, and 28 after exposure.

Several cell culture vaccines are available and are preferable to embryonated tissue vaccine (eg, duck embryo vaccine; DEV) because of better antigenic response and fewer systemic reactions. HDCV availability and cost limit its use in the developing world.

Rabies immune globulin and rabies vaccine (human diploid cell vaccine) should never be given in the same syringe or at the same site. Allergic reactions to the vaccine are rare, though local reactions (pruritus, erythema, tenderness) occur in about 25% and mild systemic reactions (headaches, myalgias, nausea) in about 20% of recipients. The vaccine is commercially available or can be obtained through health departments. For patients who previously received pre- or postexposure vaccine, rabies immune globulin should not be given; vaccine, 1 mL in the deltoid, should be given twice (on days 0 and 3).

In other countries, the less costly inactivated duck embryo vaccine or mouse brain vaccine may be available, but the method of administration is more complex, the rate of allergic reactions—including ascending paralysis—is higher, and the efficacy is less.

C. Preexposure Immunization

Preexposure prophylaxis with three injections of diploid cell vaccine intramuscularly (1 mL on days 0, 7, and 21 or 28) or intradermally (0.1 mL on days 0, 7, and 28, over the deltoid) is recommended for persons at high risk of exposure: veterinarians (who should have rabies antibody titers checked every 2 years and be boosted with 1 mL intramuscularly or 0.1 mL intradermally if seronegative), animal handlers, Peace Corps workers, and travelers to remote areas (rabies immune globulin is in short supply worldwide). An intradermal route is available for preexposure prophylaxis only. Immunosuppressive illness and agents including corticosteroids as well as antimalarials—in particular chloroquine—may diminish the antibody response.

Treatment

This very severe illness with an almost universally fatal outcome requires intensive care with attention to the airway, maintenance of oxygenation, and control of seizures. Universal precautions are essential.

Prognosis

Once the symptoms have appeared, death almost inevitably occurs after 7 days, usually from respiratory failure.

2. *Arbovirus Encephalitides*

Essentials of Diagnosis

- Fever, malaise, stiff neck, sore throat, and nausea and vomiting, progressing to stupor, coma, and convulsions.
- Signs of an upper motor neuron lesion (exaggerated deep tendon reflexes, absent superficial reflexes, pathologic reflexes, spastic paralysis).
- Cerebrospinal fluid protein and opening pressure often increased, with lymphocytic pleocytosis.

General Considerations

The arboviruses are arthropod-borne agents that produce clinical manifestations in humans. The mosquito-borne agents include three alphaviruses (causing Western, Eastern, and Venezuelan equine encephalitis), five flaviviruses (causing West Nile fever, St. Louis encephalitis, Japanese B encephalitis, dengue, and yellow fever), bunyaviruses (the California serogroup of viruses [in particular, California encephalitis caused by the Lacrosse agent]), and some causes of viral hemorrhagic fever (Rift Valley fever). The tick-borne causes of encephalitis include the flavivirus Powassan (northeastern United States and Canada) and tick-borne encephalitides of Europe. Agents associated with viral hemorrhagic fever are discussed below, and only those viruses causing primarily encephalitis in the United States will be discussed here.

Infection with West Nile virus was first identified in the United States in the New York City area in 1999. The virus has spread rapidly, with most cases occurring along the Atlantic seaboard and in the Midwest, but cases have been reported even in California. The summer and fall of 2002 saw the largest outbreak yet, with the highest concentration of cases in the upper Midwest, and current cases are reported throughout most of the United States. The disease caused outbreaks in France in the early 1960s and in Romania in 1996. Along with West Nile fever, the leading causes of arbovirus encephalitis in the United States are St. Louis encephalitis and California encephalitis. Agent-specific reservoirs (typically small mammals or birds) are responsible for maintaining the encephalitis-producing viruses in nature. Substantial avian mortality has accompanied West Nile fever outbreaks and is used to monitor disease patterns. Outbreaks tend to occur in late summer and early fall.

Clinical Findings

A. Symptoms and Signs

The symptoms of arboviral encephalitis include fever, malaise, sore throat, headache, gastrointestinal upset, lethargy, and stupor progressing to coma. Signs include stiff neck, tremors, convulsions, cranial nerve palsies, paralysis of extremities, and pathologic reflexes. About 50% of patients in the United States with West Nile virus infection who were admitted to hospital had significant muscle weakness during their illness to the point where the diagnosis has been confused with Guillain-Barre syndrome. Rash has been reported in fewer than one-third of cases.

The experience with West Nile fever in the United States has been that about one in five infected persons develops a mild febrile illness while one in 150 develops neurologic disease. When frank encephalitis develops, the outcome is age-dependent. St. Louis and West Nile encephalitides occur largely in adults, with residual damage principally in older patients. The other encephalitis-causing agents cause morbidity chiefly among children.

B. Laboratory Findings

The peripheral white blood cell count is variable. Cerebrospinal fluid protein is elevated; cerebrospinal fluid glucose is normal; there is usually a lymphocytic pleocytosis; and polymorphonuclear cells may predominate early. The diagnosis of arboviral encephalitides—including West Nile fever—depends on serologic tests. For West Nile virus, an IgM capture ELISA can be done on either serum or cerebrospinal fluid and is almost always positive by the time patients present clinically. There is cross-reaction among the different flaviviruses, so a plaque reduction assay may be necessary to definitively distinguish between West Nile fever and St. Louis encephalitis. Serum IgM may be positive for many months after acute infection, so an increase in antibody titer between acute and convalescent samples is necessary to confirm acute infection when cerebrospinal fluid samples are unavailable. CT of the brain usually shows no acute disease, but MRI may reveal leptomeningeal, basal ganglial, thalamic, or periventricular enhancement.

Differential Diagnosis

Mild forms of encephalitis must be differentiated from aseptic meningitis, lymphocytic choriomeningitis, and nonparalytic poliomyelitis.

Severe forms of arbovirus encephalitides ([Table 32-2](#)) are to be differentiated from other causes of viral encephalitis (herpes simplex virus, mumps virus, poliovirus or other enteroviruses, HIV), encephalitis accompanying exanthematous diseases of childhood (measles, varicella, infectious mononucleosis, rubella), encephalitis following vaccination (a demyelinating type following rabies, measles, pertussis), toxic encephalitis (from drugs, poisons, or bacterial toxins such as *Shigella dysenteriae* type 1), Reye's syndrome, and severe forms of stroke, brain tumors, brain abscess, autoimmune processes such as lupus cerebritis, and intoxications.

Complications

Bronchial pneumonia, urinary retention and infection, prolonged weakness, and decubitus ulcers may occur. Late sequelae are mental deterioration, parkinsonism, and epilepsy.

Prevention

No vaccine is currently available. Mosquito control (repellents, protective clothing, insecticides) is effective in prevention. The West Nile virus has been documented to be transmitted via both organ donation and blood transfusion. Testing all donated blood is currently under way. A vaccine against Japanese B encephalitis is recommended for travelers to rural areas of East Asia, though the risk of disease acquisition is estimated at only 1:1,000,000.

Treatment

Although specific antiviral therapy is not available for most causative entities, vigorous supportive measures can be helpful. Such measures include reduction of intracranial pressure (mannitol) and monitoring of intraventricular pressure. The efficacy of corticosteroids in these infections is not established. Preliminary evidence that ribavirin was useful in West Nile encephalitis has not been substantiated.

Prognosis

The prognosis is always guarded, especially at the extremes of age. Sequelae may become apparent late in the course of what appears to be a successful recovery. The prognosis is generally better for Western equine than for Eastern equine or St. Louis encephalitis. The case fatality rate for the original 78 patients with West Nile encephalitis from the New York City area was 12%.

3. Lymphocytic Choriomeningitis

Essentials of Diagnosis

- "Influenza-like" prodrome of fever, chills, malaise, and cough, followed by meningitis with associated stiff neck.
- Aseptic meningitis with positive Kernig's sign, headache, nausea, vomiting, and lethargy.
- Cerebrospinal fluid: slight increase of protein, lymphocytic pleocytosis (500-3000/uL); low glucose in 25% of patients.
- Complement-fixing antibodies within 2 weeks.

General Considerations

Lymphocytic choriomeningitis is an arenaviral infection of the central nervous system. The main reservoir of infection is the infected house mouse, though other reservoirs include guinea pigs, monkeys, dogs, swine, and even pet hamsters. The virus is shed by the infected animal via oronasal secretions, urine, and feces, with transmission to humans probably through exposure to animal droppings via contaminated food and dust. The virus is not spread person-to-person, though vertical transmission occurs and lymphocytic choriomeningitis is considered a fetal teratogen. The incubation period is 8-13 days to the appearance of systemic manifestations and 15-21 days to the appearance of meningeal symptoms. CD4 cells may be involved in pathogenesis. Lymphocytic choriomeningitis is considered a model of cell-mediated immunity in vaccine development.

Outbreaks have occurred among persons with rodent exposure. Complications of clinical disease are rare.

This disease is principally confined to the eastern seaboard and northeastern states of the United States, and serologic evidence of infection is increased among women, the elderly, and members of lower socioeconomic groups.

Clinical Findings

A. Symptoms and Signs

Symptoms are biphasic. The prodromal illness is characterized by fever, chills, headache, myalgia, cough, and vomiting; the meningeal phase by headache, nausea and vomiting, and lethargy. Signs of pneumonia are occasionally present during the prodromal phase. During the meningeal phase there may be neck and back stiffness with a positive Kernig sign. Obstructive hydrocephalus is a rare complication. Arthralgias can develop late.

The prodrome may terminate in complete recovery, or meningeal symptoms may appear after a few days of remission. Chorioretinitis also appears to be a sequela of lymphocytic choriomeningitis.

B. Laboratory Findings

Leukocytosis or leukopenia and thrombocytopenia may be present. Cerebrospinal fluid lymphocytic pleocytosis (total count is often 500-3000/uL) may occur, with slight increase in protein and normal to low glucose in at least 25%. Complement-fixing antibodies appear during or after the second week. The virus may be recovered from the blood and cerebrospinal fluid by mouse inoculation. A PCR technique for the detection of lymphocytic choriomeningitis virus in the cerebrospinal fluid has been described.

Differential Diagnosis

The influenza-like prodrome and latent period help distinguish this from other aseptic meningitides, and bacterial and granulomatous meningitis. A history of exposure to mice or other potential vectors is an important diagnostic clue.

Treatment

Treatment is supportive as for encephalitis or aseptic meningitis. The membrane protein alpha-dystroglycan interacts with lymphocytic choriomeningitis and Lassa fever virus (both arenaviruses), and this interaction provides a potential avenue for future interventions.

Prognosis

Fatalities are rare. The illness usually lasts 1-2 weeks, though convalescence may be prolonged.

Barton LL et al: Congenital lymphocytic choriomeningitis virus infection: decade of rediscovery. Clin Infect Dis 2001;33: 370. [\[PMID: 11438904\]](#)

4. Prion Disease

Several neurologic diseases can be caused by communicable agents with slow replication and long latent intervals in the host. Such agents have been called *proteinaceous infectious particles*, or "prions," and are resistant to most procedures that modify nucleic acid. The transmissible agents induce conversion of a normal brain protein (PrP^C) to an abnormal isoform (PrP^{Sc}), a process that appears to be both genetically determined and in need of the infectious agent. The accumulated abnormal isoform proteins are associated with disease, though the pathogenesis of spongiform changes and the accumulation in some cases of amyloid plaque are poorly understood. A variety of animal diseases exhibit these properties, including visna and scrapie in sheep and goats, chronic wasting disease of mule deer, and transmissible encephalopathy of mink. The agents or related agents that cause human disease are discussed here.

Kuru and Creutzfeldt-Jakob disease are transmissible in brain or eye tissue to primates, including humans. After an incubation period measured in years, disease ensues characterized by an inexorably progressive downhill course. Kuru—once prevalent in central New Guinea but no longer seen since abandonment of cannibalism—was characterized by cerebellar ataxia, tremors, dysarthria, and emotional lability.

The four forms of Creutzfeldt-Jakob disease are sporadic (classic, cCJD) (80-85%), familial (15%), iatrogenic (< 1%), and a new variant (vCJD), described below. There are no definitive risk factors for cCJD, which occurs worldwide with an incidence of 1 per million. Patients with cCJD usually present in the sixth or seventh decade with dementia progressive over several months, myoclonic fasciculations, ataxia, and somnolence. The characteristic electroencephalographic pattern shows paroxysms with high voltages and slow waves. MRI typically shows bilateral areas of increased signal intensity, predominantly in the caudate and putamen. Assays of the cerebrospinal fluid for 14-3-3 protein and neuron-specific enolase may help with the diagnosis. Familial cases are inherited in an autosomal dominant pattern with variable penetrance. Iatrogenic cases have occurred in patients who receive tissue such as cadaveric growth hormone and dural grafts from the central nervous systems of patients with Creutzfeldt-Jakob disease.

There is no specific treatment, and the only known means of prevention is avoidance of contamination by affected brain tissue, electrodes, or neurosurgical tools or by transplants of cornea, dura, or cadaveric growth hormone from infected donors. Disinfection of equipment requires autoclaving at 15 psi for 1 hour, and disinfection of contaminated surfaces requires 5% hypochlorite or 0.1-N sodium hydroxide solution.

New variant Creutzfeldt-Jakob disease (vCJD) was originally described in a small outbreak from Britain and since then increasingly from other countries in western Europe. The patients are younger, the duration is longer, the clinical symptomatology is unique (psychiatric symptoms and cerebellar signs are more common), and the electroencephalographic findings are not typical of cCJD. The disease probably results from ingestion of beefsteak from livestock infected with **bovine spongiform encephalopathy (BSE)** ("mad cow disease").

Other prion diseases include fatal familial insomnia (rarely sporadic) and Gerstmann-Straussler-Scheinker disease (with dementia and spastic paraparesis).

5. Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy is a demyelinating central nervous system disorder with a propensity for affliction of immunosuppressed adults, especially AIDS patients. The cause is JC virus (JCV), a papovavirus that targets myelinating oligodendrocytes of the central nervous system. PCR of the cerebrospinal fluid for JCV is used for diagnosis in patients with compatible clinical and radiologic findings. Highly active antiretroviral therapy (HAART) for HIV infection is effective in improving survival as well as the clinical and radiographic features associated with this disease. The use of cidofovir, while becoming more widespread, is not routinely recommended at present. This disorder should not be confused with Creutzfeldt-Jakob disease despite the similar initials of the causative agents.

Garcia De Viedma D et al: JC virus load in progressive multifocal leukoencephalopathy: analysis of the correlation between the viral burden in cerebrospinal fluid, patient survival, and the volume of neurological lesions. Clin Infect Dis 2002;34:1568. [\[PMID: 12032891\]](#)

6. Human T Cell Lymphotropic Virus (HTLV)

Retroviruses include both the lympholytic HIV agents and the lymphotropic oncoviruses, human T cell leukemia viruses types 1 and 2 (HTLV-1 and -2). The isolation of HTLV-1 from a young man with T cell lymphoma established an association of the virus with adult T cell lymphoma/leukemia (ATL)—an association that has been confirmed from endemic areas throughout the world, including the Caribbean, southern Japan, sub-Saharan Africa (where over 10% of the population of Gabon and Cameroon are seropositive), Latin America, and the southeastern United States (where seroprevalence is most common among intravenous drug users).

The lifetime risk of developing ATL among the seropositive is estimated to be 3% among women and 7% among men, with an incubation period of at least 15 years. HTLV-1 is oncogenic primarily through the simultaneous induction of both interleukin-2 and interleukin-2 receptor.

Common clinical features of ATL include diffuse lymphadenopathy, maculopapular skin lesions that may evolve into erythroderma, organomegaly, lytic bone lesions, and hypercalcemia.

There is a predisposition to opportunistic infections such as *Pneumocystis jiroveci* pneumonia and cryptococcal meningitis. A large percentage of patients are infected with *Strongyloides stercoralis*. Diagnosis requires identification of HTLV-1 antibodies. Confirmatory demonstration of monoclonal proviral DNA integration in tumor cells is helpful.

HTLV-1 also causes HTLV-associated myelopathy (HAM; tropical spastic paraparesis). It is characterized by progressive motor weakness, especially of the lower extremities, with spastic paraparesis or paraplegia with hyperreflexia. Sensory disturbances and urinary incontinence may also be seen. The disease may resemble multiple sclerosis but does not remit. Cranial nerve abnormalities are rare, and cognitive function is usually preserved. HAM develops in less than 1% of HTLV-1 seropositive individuals.

HTLV-2 was initially implicated in hairy cell leukemia, but this association has not been confirmed. HTLV-2 seropositivity is common in some American populations, especially intravenous drug users. It infects primarily CD8 cells, whereas HTLV-1 infects primarily CD4 cells. The role of HTLV-2 in disease is under investigation.

Management of ATL is similar to that for non-Hodgkin's lymphoma and includes combination chemotherapy and radiation of particular sites (weight-bearing bony lesions, paraspinal masses, intracerebral lesions). HTLV-associated myelopathy is treated with a variety of immune-modulating agents without consistent results. Antiretrovirals have not shown clear benefit for ATL- or HTLV-associated myelopathy.

Screening of the blood supply for HTLV-1 is required in the United States, since transfusion is a recognized mode of transmission along with sexual contact and vertical transfer. There is significant cross-reactivity between HTLV-1 and HTLV-2 on serologic studies, but PCR can differentiate the two.

OTHER SYSTEMIC VIRAL DISEASES

1. Hemorrhagic Fevers

This is a diverse group of illnesses resulting from several diverse viral families (Filoviridae, Arenaviridae, Bunyaviridae, and Flaviviridae) and immunologic responses to them. The common clinical features include high fever, leukopenia, and altered mental status combined with a hemorrhagic diathesis. Marked toxicity and death may occur. Modes of transmission are similarly diverse. Dengue and yellow fever are due to flaviviruses which are transmitted by mosquitoes, while Omsk hemorrhagic fever and Kyasanur Forest disease are due to tick-borne flaviviruses. Lassa fever is rodent-associated, as are Junin hemorrhagic fever and other diseases due to New World Arenaviridae. Ebola fever and Marburg fever are due to filoviruses with unknown vectors. The bunyaviruses include the tick-borne Crimean-Congo hemorrhagic fever and the mosquito-borne Rift Valley fever, while the infections due to hantaviruses are associated with rodent exposure.

The Nipah virus in Malaysia is a zoonotic paramyxovirus that does not cause hemorrhagic fever but instead causes a primarily encephalitic infection in most cases associated with a history of contact with pigs.

Persons who present with symptoms compatible with those of hemorrhagic fever and who have traveled from a possible endemic area should be isolated for diagnosis and symptomatic treatment. Diagnosis may be made by growing the virus from blood obtained early in the disease, by reverse transcriptase PCR, or by demonstration of a significant specific fourfold or greater rise in antibody titer. These tests are generally available only through the Centers for Disease Control and Prevention. Isolation is particularly important because diseases due to some of these agents, such as Ebola virus, are highly transmissible and carry a mortality rate of 50-90%.

For most of these entities, no specific treatment is available. Lassa fever and hemorrhagic fever with renal failure can be treated with intravenous ribavirin if started promptly: 30 mg/kg as loading dose, followed by 16 mg/kg every 6 hours for 4 days and then 8 mg/kg every 8 hours for 3 days (see [Chapter 37](#)). One must differentiate hemorrhagic fever from differently treated entities such as meningococcemia or other septicemias, Rocky Mountain spotted fever, dengue, and malaria. The likelihood of hemorrhagic fevers among travelers remains low.

2. Dengue

Essentials of Diagnosis

- Exposure 7-10 days before onset.
- Sudden onset of high fever, chills, severe aching, headache, sore throat, prostration, and depression.
- Biphasic fever curve: initial phase, 3-7 days; remission, few hours to 2 days; second phase, 1-2 days.
- The rash is biphasic: first evanescent, followed by maculopapular, scarlatiniform, morbilliform, or petechial changes from extremities to torso.
- Leukopenia and thrombocytopenia in the hemorrhagic form.

General Considerations

Dengue is due to a flavivirus transmitted by the bite of the aedes mosquito. It may be caused by one of four serotypes widely distributed between the tropics of Capricorn and Cancer. An estimated 50-100 million cases of dengue fever and several hundred thousand cases of dengue hemorrhagic fever occur each year. The incubation period is 3-15 days (usually 7-10 days). Transmission occurred in the United States in southern Texas and nearby Mexican border towns in 1986 and 1999.

Clinical Findings

A. Symptoms and Signs

Dengue is usually a nonspecific, self-limited febrile illness, but its presentation may range from asymptomatic to severe hemorrhagic fever and fatal shock (**dengue shock syndrome**). Severe dengue begins with a sudden onset of high fever, chills, and "breakbone" aching of the head, back, and extremities accompanied by sore throat, prostration, and malaise. There may be conjunctival redness and flushing or blotching of the skin. Rash is a feature in over half of cases—usually macular or maculopapular, with sparing of small areas of normal skin.

Dengue hemorrhagic fever usually affects children living in endemic areas and is most likely to occur in secondary infections with serotype 2. A few days into the illness, signs of hemorrhage such as ecchymoses, gastrointestinal bleeding, and epistaxis appear. Some dengue virus envelope glycoproteins are homologous with segments of clotting factors, including plasminogen, and thus the hemorrhagic fever may represent an autoimmune reaction. A subset of patients progress to dengue shock syndrome in which a capillary leak process is prominent, manifesting as pleural effusions and ascites.

Before the rash of dengue appears, the infection is difficult to distinguish from malaria, yellow fever, or influenza; the rash makes dengue far more likely. Continuous abdominal pain with vomiting, a decrease in the level of consciousness, and hypothermia should arouse concern about dengue shock syndrome.

B. Laboratory Findings

Leukopenia is characteristic. Thrombocytopenia and hemoconcentration occur in the hemorrhagic form of the disease. The nonspecific nature of the illness mandates laboratory verification for diagnosis, which is usually done with IgM and IgG ELISA tests. Virus may be recovered from the blood during the acute phase, and several PCR protocols are being developed. Immunohistochemistry for antigen detection in tissue samples can also be used.

Complications

Depression, pneumonia, bone marrow failure, iritis, orchitis, oophoritis, and a variety of neurologic complications such as encephalitis and transverse myelitis have been reported.

Prevention

Available prophylactic measures include control of mosquitoes by screening and insect repellents, particularly during early morning and late afternoon exposures. The increased severity of disease in secondary infections has caused concerns in the search for an effective vaccine.

Treatment

Treatment entails the appropriate use of volume support and pressor agents, acetaminophen rather than nonsteroidal anti-inflammatory agents for analgesia, and the gradual restoration of activity during prolonged convalescence. Monitoring patients with platelet counts and for hemoconcentration is useful in anticipating the complications of dengue hemorrhagic fever or shock syndrome.

Prognosis

Fatalities are rare but do occur, especially during epidemic outbreaks. Convalescence tends to be slow.

3. Hantaviruses

Hantaviruses are rodent-borne RNA bunyaviruses with several distinct serotypes. These differ in rodent hosts, geographic distribution, and degree of pathogenicity for humans. They cause two major clinical syndromes: hemorrhagic fever (discussed above) and the hantavirus pulmonary syndrome. The ubiquitousness of hantaviruses is becoming recognized, with descriptions of infections from North and South America and additional infections from Europe and Asia. The Hantaan serotype viruses cause severe hemorrhagic fever with renal syndrome and are found primarily in Korea, China, and eastern Russia. The Seoul viruses produce a less severe form and are found primarily in Korea and China. The Puumala and Dobrava viruses are found in Scandinavia and Europe and are associated with a milder form of the syndrome.

The Sin Nombre (Muerto Canyon, Four Corners) virus is one of the viruses responsible for the **hantavirus pulmonary syndrome**, most cases of which have been seen in the southwestern United States. Approximately 300 cases have been reported from 31 states since 1993. Outbreaks are currently being reported from Central and South America. Hantavirus pulmonary syndrome begins as a nonspecific febrile illness followed by rapid progression to a shock-like state, associated with increased pulmonary vascular permeability and ARDS. Hematologic features include thrombocytopenia, hemoconcentration, and leukocytosis. Recently, it is recognized that clinical similarities—namely, renal involvement—exist between the New World hantaviruses and Old World counterparts.

Diagnosis can be made serologically, with the vast majority having both IgM and IgG antibodies at the time of presentation; by immunohistochemical staining; or by PCR amplification of viral tissue DNA. Since infection is thought to occur by inhalation of rodent wastes, prevention is aimed toward eradication of rodents in houses and avoidance of exposure to rodent excreta in rural settings.

No treatment has been established as definitely effective for hantavirus pulmonary syndrome. Intravenous ribavirin has been used with some success in hemorrhagic fever with renal syndrome, and studies are currently ongoing for its use in hantavirus pulmonary syndrome.

Peters CJ et al: Hantavirus pulmonary syndrome: the new American hemorrhagic fever. *Clin Infect Dis* 2002;34:1224. [\[PMID: 11941549\]](#)

4. Yellow Fever

Essentials of Diagnosis

- Endemic area exposure (tropical South and Central America, Africa, but not Asia).
- Sudden onset of severe headache, aching in legs, and tachycardia.

- Brief (1 day) remission, followed by bradycardia, hypotension, jaundice, hemorrhagic tendency.
- Proteinuria, leukopenia, bilirubinemia, bilirubinuria.

General Considerations

Yellow fever is a zoonotic flavivirus infection transmitted by the aedes and jungle mosquitoes. It occurs in an urban and jungle cycle in Africa and in a jungle cycle in South America. Epidemics have extended far into the temperate zone during warm seasons. The role of yellow fever in preventing economic development in tropical areas is devastating.

The mosquito transmits the infection by first biting an individual having the disease and then biting a susceptible individual after the virus has multiplied within the mosquito's body. The incubation period in humans is 3-6 days. Adults and children are equally susceptible, though attack rates are highest among adult males because of their work habits.

Clinical Findings

A. Symptoms and Signs

1. Mild form—Symptoms are malaise, headache, fever, retro-orbital pain, nausea, vomiting, and photophobia. Bradycardia may be present.

2. Severe form—About 15% of those infected with yellow fever develop severe illness. Initial symptoms are similar to the mild form, but a brief remission after about 3-6 days of acute illness is followed by a "period of intoxication" manifested by fever and bradycardia (Faget's sign), hypotension, jaundice, hemorrhage (gastrointestinal, nasal, oral), and delirium that may progress to coma.

B. Laboratory Findings

Leukopenia occurs, although it may not be present at the onset. Proteinuria is present, sometimes as high as 5-6 g/L, and disappears completely with recovery. Abnormal liver function tests are seen, and prothrombin time may be elevated. Serologic diagnosis is chiefly by measurement of IgM by a capture ELISA. Other serologic tests include hemagglutination-inhibition and neutralization. PCR is becoming more widely available.

Differential Diagnosis

It may be difficult to distinguish yellow fever from hepatitis, malaria, leptospirosis, louse-borne relapsing fever, dengue, and other hemorrhagic fevers on clinical evidence alone. Serologic confirmation is often needed.

Prevention

Transmission is prevented through mosquito control. Live virus vaccine is highly effective and should be provided for immunocompetent persons over 9 months of age living in or traveling to endemic areas. There have been cases of vaccine-induced yellow fever among elderly patients. The safety of the vaccine in pregnant patients has not been verified, and pregnant women should if possible defer travel to endemic areas (see [Chapter 30](#)). Detailed recommendations are contained in the MMWR document referenced below. Eradication is difficult because of the sylvatic cycle, with forest rodents serving as a reservoir. (See [Chapter 30](#).)

Treatment

No specific antiviral therapy is available. Treatment is directed toward symptomatic relief and management of complications.

Prognosis

The mortality rate of the severe form is 20-50%, with death occurring most commonly between the sixth and the tenth days. In survivors, the temperature returns to normal by the seventh or eighth day. The prognosis in any individual case is guarded at the onset, since sudden changes for the worse are common. Intractable hiccups, copious black vomitus, melena, and anuria are unfavorable signs. Convalescence is prolonged, including 1-2 weeks of asthenia. Infection confers lifelong immunity.

5. Colorado Tick Fever

Essentials of Diagnosis

- Onset 1-19 days (average, 4 days) following tick bite.
- Fever, chills, myalgia, headache, prostration.
- Leukopenia.
- Second attack of fever after remission lasting 2-3 days.

General Considerations

Colorado tick fever is an acute coltivirus infection transmitted by *Dermacentor andersoni* bites. The disease is limited to the western United States and Canada and is most prevalent during the tick season (March to November). The incubation period is 3-6 days.

Clinical Findings

A. Symptoms and Signs

The onset of fever (to 38.9-40.6°C) is abrupt, sometimes with chills. Severe myalgia, headache, photophobia, anorexia, nausea and vomiting, and generalized weakness are prominent symptoms. Physical findings are limited to an occasional faint rash. Fever continues for 3 days, followed by a remission of 1-3 days and then by a full recrudescence lasting 2-4 days. In an occasional case there may be three bouts of fever.

The differential diagnosis includes influenza, Rocky Mountain spotted fever, numerous other viral infections, and, in the right setting, relapsing fevers.

B. Laboratory Findings

Leukopenia (2000-3000/uL) with a shift to the left occurs. Viremia may be demonstrated by inoculation of blood into mice or by fluorescent antibody staining of the patient's red cells (with adsorbed virus). Complement-fixing antibodies do not appear until the third week of disease but are the most frequently used tool to document an infection. A reverse transcriptase PCR assay may be used to detect viremia.

Complications

Aseptic meningitis, encephalitis, and hemorrhagic fever occur rarely. Malaise may ensue, but fatalities are very rare.

Treatment

No specific treatment is available. Ribavirin has shown efficacy in an animal model. Aspirin or another nonsteroidal anti-inflammatory agent, codeine or hydrocodone may be given for pain.

Prognosis

The disease is usually self-limited and benign.

COMMON VIRAL RESPIRATORY INFECTIONS

Infections of the respiratory tract are perhaps the most common human ailments. Specific associations of some groups of viruses with certain disease syndromes have been established. In young infants and in the elderly, or in persons with impaired respiratory tract reserve, bacterial superinfection increases morbidity and mortality. Croup, epiglottitis, and the common cold are discussed in [Chapter 8](#)

Muether PS: Variant effect of first- and second-generation antihistamines as clues to their mechanism of action on the sneeze reflex in the common cold. Clin Infect Dis 2001; 33:1483. [\[PMID: 11588693\]](#)

Seemungal T et al: Respiratory viruses, symptoms, and inflammatory markers in acute exacerbations and stable chronic obstructive pulmonary disease. Am J Respir Crit Care Med 2001;164:1618. [\[PMID: 11719299\]](#)

1. Respiratory Syncytial Virus

Respiratory syncytial virus (RSV) causes annual outbreaks of pneumonia, bronchiolitis, and tracheobronchitis, with the majority of cases occurring in the very young. Premature infants with bronchopulmonary dysplasia are at highest risk. Incomplete immunity commonly leads to reinfection manifested typically as an upper respiratory tract infection and tracheobronchitis in older children or adults. Serious pulmonary RSV infections have been described in elderly and immunocompromised adults. Outbreaks with a high mortality rate in bone marrow transplant and pediatric liver transplant patients are reported.

Annual epidemics occur in winter and spring. The average incubation period is 5 days. Inoculation may occur through the nose or the eyes.

In bronchiolitis, proliferation and necrosis of bronchiolar epithelium develop, producing obstruction from sloughed epithelium and increased mucus secretion. Signs include low-grade fever, tachypnea, and wheezes. Hyperinflated lungs, decreased gas exchange, and increased work of breathing are present. Otitis media is a frequent complication often with concomitant *S pneumoniae* infection.

RSV is the only respiratory pathogen that produces its most serious illness at a time when specific maternal antibody is invariably present. This—combined with the observation that infants who received a particular past live RSV vaccine had more severe disease—suggests an immune-mediated component to the disease.

Rapid diagnosis may be made by viral antigen identification of nasal washings using an ELISA or immunofluorescent assay. Culture of nasopharyngeal secretions remains the standard of diagnosis.

Treatment consists of hydration, humidification of inspired air, and ventilatory support as needed. While bronchodilating agents, ribavirin, and corticosteroids are widely used, evidence supporting their effectiveness in populations not at high risk is lacking. Pregnant women should avoid ribavirin exposure—and indeed, patients with upper respiratory RSV infections probably do not need ribavirin. Hyperimmune RSV immunoglobulin G (1500 mg/kg) is effective in combination with ribavirin in the management of RSV infections among immunocompromised adults; its role in the treatment of children with lower respiratory tract infections remains under study.

Given the high morbidity in certain infant subgroups, efforts have been made to develop preventive agents. RSV immune globulin is being replaced with palivizumab, a monoclonal RSV antibody. The FDA recommends the administration of palivizumab prophylactically to infants with high-risk factors such as prematurity, bronchopulmonary dysplasia, and congenital heart disease. The search for an effective vaccine is ongoing. Because nosocomial RSV infections disseminate rapidly, prevention in hospitals entails rapid diagnosis, hand washing, and perhaps passive immunization.

2. Influenza

Essentials of Diagnosis

- Cases usually in epidemic pattern, not sporadic.
- Abrupt onset with fever, chills, malaise, cough, coryza, and muscle aches.
- Aching, fever, and prostration out of proportion to catarrhal symptoms.
- Leukopenia.

General Considerations

Influenza (an orthomyxovirus) is transmitted by the respiratory route. In contrast to RSV and rhinoviruses, transmission occurs by droplet nuclei rather than fomites or large particle aerosols. Although sporadic cases occur, epidemics and pandemics appear at varying intervals, usually in the fall or winter. Antigenic types A and B produce clinically indistinguishable infections, whereas type C is usually a minor illness. New epidemic strains may evolve from reassortment, through pig vectors, between avian and human strains. Pandemics—associated with higher mortality—typically are associated with type A infections in which significant genetic recombination of the virus (antigenic shift) has taken place. The incubation period is 1-4 days.

A small number of human cases of a new strain of avian influenza A (H5N1) were reported from Hong Kong in December 1997. Surveillance suggested that the highest risk for disease occurred among those with poultry exposure, though person-to-person transmission was not fully excluded. A massive poultry slaughter ensued based on these findings. The continued surveillance for future potentially pandemic strains is an important aspect of influenza control.

It is difficult to diagnose influenza in the absence of an epidemic. The disease resembles many other mild febrile illnesses but is almost always accompanied by a cough.

Clinical Findings

A. Symptoms and Signs

The onset is usually abrupt, with fever, chills, malaise, muscular aching, substernal soreness, headache, nasal stuffiness, and occasionally nausea. Fever lasts 1-7 days (usually 3-5). Coryza, nonproductive cough, and sore throat are present. Signs include mild pharyngeal injection, flushed face, and conjunctival redness.

B. Laboratory Findings

Leukopenia is common. Proteinuria may be present. The virus may be isolated from throat washings by inoculation of embryonated eggs or cell cultures. Rapid laboratory tests for influenza antigens from nasal or throat swabs are becoming widely available. Complement-fixing and hemagglutination-inhibiting antibodies appear during the second week.

Complications

Influenza causes necrosis of the respiratory epithelium, which predisposes to secondary bacterial infections. The interactions between bacteria and influenza are bidirectional, with bacterial enzymes (eg, proteases, trypsin-like compounds, streptokinase, plasminogen) activating influenza viruses. Frequent complications are acute sinusitis, otitis media, purulent bronchitis, and pneumonia. The elderly and the chronically ill are at high risk for complications. Rhabdomyolysis is a rare late complication.

Pneumonia is commonly due to bacterial infection with pneumococci or, less often, staphylococci or haemophilus or, on occasion, the influenza virus itself. Pericarditis, myocarditis, and thrombophlebitis sometimes occur.

Reye's syndrome (fatty liver with encephalopathy) is a rare and severe complication of influenza and other viral diseases (eg, varicella), particularly in young children. It consists of rapidly progressive hepatic failure and encephalopathy, and there is a 30% fatality rate. The pathogenesis is unknown, but the syndrome is associated with aspirin use in such viral infections. Hypoglycemia, elevation of serum aminotransferases and blood ammonia, prolonged prothrombin time, and change in mental status all occur within 2-3 weeks after onset of the viral infection. Histologically, the periphery of liver lobules shows striking fatty infiltration and glycogen depletion. Treatment is supportive and directed toward the management of cerebral edema.

Prevention

Trivalent influenza virus vaccine provides partial immunity (about 85% efficacy) for a few months to 1 year. The vaccine's antigenic configuration changes yearly and is based on prevalent strains of the preceding year. Vaccination in October or November each year is recommended for persons over 50 (a substantial portion of the older population suffer from at least one chronic medical condition), children (over 6 months of age) and teenagers receiving chronic aspirin therapy, nursing home residents, patients with chronic lung or heart disease or other debilitating illnesses (including pregnant women during the second and third trimesters), and health care workers. The vaccine is contraindicated in persons with hypersensitivity to chicken eggs or other components of the vaccine, persons with an acute febrile illness, or thrombocytopenia. Concomitant warfarin or corticosteroid therapy is not a contraindication. Side effects are infrequent and include tenderness, redness, or induration at the site of the injection and, rarely, myalgias or fever.

Adequate immunity is achieved about 2 weeks after vaccination. In healthy subjects, the antibody level remains sufficiently high throughout the season. Levels wane quickly, however, in elderly nursing home patients. Therefore, the vaccine should not be administered too early in the influenza season. The vaccination effectively reduces both morbidity (preventing 35-60% of hospital admissions in the elderly) and mortality (preventing 35-80% of hospital deaths). A live attenuated vaccine has been widely used among Russian adults.

HIV-infected persons can be safely vaccinated, and concerns about activating replication of the HIV virus by the immunogen appear to be exaggerated and may be less severe than the increase in HIV viral load associated with a full influenza infection. Vaccination is less effective when CD4 counts are less than 100/uL. False-positive assays with HIV, HTLV-1, and HCV are reported in the wake of influenza vaccination. Chemoprophylaxis can be accomplished with either amantadine or rimantadine or the newer neuraminidase inhibitors, zanamivir and oseltamivir. Amantadine (200 mg/d orally in two divided doses—or 100 mg/d in the elderly, who are susceptible to central nervous system side effects) and rimantadine (200 mg/d in two divided doses) are effective only against influenza A. Oseltamivir (75 mg/d) and zanamivir (10 mg inhaled daily) are effective against influenza A and B. All the above medications will reduce the attack rate among unvaccinated individuals if begun shortly after exposure. Comparative trials among the agents have not been done.

Treatment

Many patients with influenza prefer to rest in bed. Analgesics and a cough mixture may be used. Amantadine or rimantadine, in the same doses as are used for prophylaxis, appreciably decrease the duration of symptoms and signs. Rimantadine is preferred in patients with renal failure. The clinical significance of resistance to antiviral agents is controversial. Ribavirin (1.1 g/d, diluted to 20 mg/mL and delivered as particulate aerosol with oxygen over 12-18 hours a day for 3-7 days [[Table 32-1](#)]) helps severely ill patients with influenza A or B. The new neuraminidase inhibitors, either inhaled zanamivir (two 5-mg inhalations twice daily for 5 days) or oral oseltamivir (75 mg twice daily for 5 days), are equally helpful in the treatment of influenza but are more costly. All agents are most effective when given within 48 hours after symptom onset and are shown to be effective mainly in patients over age 12.

Antibacterial antibiotics should be reserved for treatment of bacterial complications. Acetaminophen rather than aspirin should be used for fever in children.

Prognosis

The duration of the uncomplicated illness is 1-7 days, and the prognosis is excellent. Purulent bronchitis and bronchiectasis may result in chronic pulmonary disease and fibrosis that persist throughout life. Most fatalities are due to bacterial pneumonia. Influenza pneumonia has a high mortality rate among pregnant women and persons with a history of rheumatic heart disease. In recent epidemics, the mortality rate has been low except in debilitated individuals.

If the fever persists for more than 4 days with productive cough and white cell count over 10,000/uL, secondary bacterial infection should be suspected. Pneumococcal pneumonia is the most common such infection, and staphylococcal pneumonia is the most serious.

3. Severe Acute Respiratory Syndrome (SARS)

Essentials of Diagnosis

- Mild, moderate, or severe respiratory illness.
- Travel to endemic area within 10 days before symptom onset, including mainland China, Hong Kong, Singapore, Taiwan, Vietnam, and Toronto.
- Fever ubiquitous; cough, dyspnea in most, with respiratory embarrassment common.
- Diagnosis confirmed by antibody testing or isolation of virus.
- No specific treatment; mortality as high as 10% in clinically diagnosed cases.

General Considerations

Severe acute respiratory syndrome (SARS) is a newly recognized respiratory syndrome of varying severity but capable of causing death in as many as 10% of clinically established cases. It is caused by an apparently unique coronavirus, so named because of a crown-like morphologic appearance around the central core of the pathogen by electron microscopy. The earliest cases were traced to a health care worker in Guangdong Province in China in late 2002, with rapid spread thereafter to Hong Kong, Singapore, Vietnam, Taiwan, and Toronto. Transmission clearly takes place via the respiratory route, with droplets of several sizes capable of carrying the pathogen. It was speculated in May 2003 that the masked palm civet, a mongoose-like mammal considered a culinary delicacy in Guangdong Province from which a similar but not identical coronavirus was isolated, could have been the vector for the first cases, with transmission by droplets or fomites during the preparation of a meal. Further evidence is necessary to establish this theory. The variable distribution of cases throughout Asia and Canada is considered a consequence of spread through travel. The virus is sufficiently virulent that individual cases may be transmitted by patients during brief stops in airports. As a result, sporadic confirmed and suspected cases appear throughout the United States. As of early June 2003, about 8400 cases were reported to the World Health Organization from about 30 countries, with 745 fatalities reported to that date.

Clinical Findings

A. Symptoms and Signs

SARS is considered an atypical pneumonia, an infection not due to customary bacterial or viral pathogens. The CDC recognizes asymptomatic or mild cases, moderate disease, and severe respiratory illness. In all clinical cases, fever is present; cough, shortness of breath, rales, and rhonchi are the rule. Many patients report headache, myalgia, and sore throat as well. With an incubation period of 2-7 days, SARS can spread to contacts of affected patients for 10 days. No single symptom or sign is diagnostic or highly suggestive, and the history and physical examination of a suspected patient are to be interpreted in this context.

B. Laboratory Findings and Imaging

Leukopenia and especially lymphopenia are observed commonly. Thrombocytopenia is present in many patients, and abnormal chemistries include modest elevations of alanine aminotransferase and creatine kinase. Arterial oxygen saturation is less than 95% in 80% of affected individuals, and pulmonary infiltrates are noted in all. The roentgenographic pattern is not specific, and severe cases may progress to adult respiratory distress syndrome (ARDS), with extensive bilateral consolidation. Serum studies, including enzyme immunoassay and fluorescent antibody testing, are available through public health departments at the state level, although seroconversion may not occur until 3 weeks after the onset of symptoms. Polymerase chain reaction assays are also available, and viral RNA is retrievable from serum, nasal secretions, and stool specimens. Although viral isolation is also possible, it is a more technically laborious and time-consuming procedure.

Complications

To date, the principal complications are confined to the lung. As with any viral pneumonia, physiologic pulmonary decompensation is the most feared problem. Refractory hypoxia requiring intubation and mechanical ventilation may be required. Sequelae of intensive care include infection with nosocomial pathogens, tension pneumothorax from ventilation at high peak pressures, and noncardiogenic pulmonary edema.

Treatment

There is no specific treatment for SARS as of mid-2003. Empiric ribavirin to date is not effective, and about 20% of patients receiving the drug develop side effects. Corticosteroids are also not successful. Recovery in severe cases requires intensive care support.

Prognosis

The overall mortality rate of identified cases is 9%, and probably higher in Asia than in North America. Many subclinical cases probably go undiagnosed. At the extremes of age, outcomes are poorer. Seasonality, as with influenza, is not established. Coronaviruses show relative genetic stability compared with influenza. Although the overall case incidence diminishes in areas where appropriate preventive measures are taken, sporadic outbreaks, including one near Toronto, were reported through mid-June 2003.

Prevention

Considerable worldwide interest in SARS prevention is evidenced by the early appearance of numerous articles in the lay and scientific press and other media. The similarity of SARS to any atypical pneumonia requires meticulous attention to case definition. The CDC website provides specific criteria for diagnosis, treatment, and prevention and is updated weekly. Because aerosol-producing procedures such as intubation, suctioning, and nebulization are implicated as effective methods of transmission, health care workers involved in these procedures are at high risk in endemic areas or when caring for travelers returning from those places. Transmission may occur shortly after the development of symptoms and perhaps before the appearance of fever, cough, and dyspnea. Thus, an increased level of suspicion is critical, and isolation of high-risk patients is essential.

Measures enacted for air travelers have included screening for fever and compatible symptoms and quarantine in the home for high-risk exposed persons. Persistence in reporting suspected cases is likewise important, as is awareness of recommendations for international travel. The most cautious modalities include monitoring for 10 days after the last potential exposure and confinement of recovering patients for a similar interval. The use of face masks, as instituted by many in endemic areas, is not harmful. Health care workers should use universal precautions, including handwashing, gowning, gloving, and eye protection in the care of patients.

SARS shows the importance of integrated public health measures. Despite the uncertainty of the future course of SARS globally, conditions such as HIV infection, tuberculosis, and malaria are far more common and cause greater morbidity than SARS.

ADENOVIRUS INFECTIONS

Adenoviruses (there are over 40 antigenic types) produce a variety of clinical syndromes. These infections are usually self-limited or clinically inapparent and most common among infants, young children, and military recruits. Outbreaks in liver, bone marrow, and renal transplant recipients have been reported, and dissemination may occur. The incubation period is 4-9 days. Adenoviruses, although a common cause of human disease, have also received particular recognition through their role in gene therapy.

Clinical syndromes of adenovirus infection, often overlapping, include the following: The **common cold** (see [Chapter 8](#)) is characterized by rhinitis, pharyngitis, and mild malaise without fever. **Nonstreptococcal exudative pharyngitis** is characterized by fever lasting 2-12 days and accompanied by malaise and myalgia. Sore throat is often manifested by diffuse injection, a patchy exudate, and cervical lymphadenopathy. Cough is sometimes accompanied by rales and x-ray evidence of pneumonitis. Conjunctivitis is often present. **Lower respiratory tract infection** may occur, including bronchiolitis, suggested by cough and rales, or pneumonia (type 3 and type 7 commonly cause acute respiratory disease and pneumonia). **Pharyngoconjunctival fever** is manifested by fever and malaise, conjunctivitis (often unilateral), and mild pharyngitis. **Epidemic keratoconjunctivitis** (transmissible person-to-person) occurs in adults and is manifested by unilateral conjunctival redness, pain, tearing, and an enlarged preauricular lymph node. Keratitis may lead to subepithelial opacities (especially with types 8, 19, or 37). **Acute hemorrhagic cystitis** is a disorder of children often associated with adenovirus type 11. **Sexually transmitted genitourinary ulcers and urethritis** may be caused by types 2, 8, and 37 in particular. Adenoviruses also cause **acute gastroenteritis** (types 40, 41), leading to intussusception, and are rarely associated with encephalitis and pericarditis.

Infected liver transplant recipients tend to develop hepatitis (type 5 adenovirus), whereas bone marrow and renal transplant recipients tend to develop pneumonia or hemorrhagic cystitis. Ribavirin and cidofovir are used in immunocompromised individuals with anecdotal success.

Vaccines are not available for general use. Live oral vaccines containing attenuated type 4 and type 7 are used in military personnel.

Treatment is symptomatic, though there is increasing interest in the use of cidofovir, especially in the immunocompromised.

OTHER EXANTHEMATOUS VIRAL INFECTIONS

1. Parvovirus Infections

Parvovirus B19 is quite widespread and causes several syndromes. In children, an exanthematous illness ("fifth disease," erythema infectiosum) is characterized by a fiery red "slapped cheek" appearance, circumoral pallor, and a subsequent lacy, maculopapular, evanescent truncal rash. Malaise, headache, and pruritus occur, but little fever. In immunosuppressed patients, including those with HIV infection, or post transplantation, or with hematologic conditions such as sickle cell disease, a severe hypoproliferative anemia due to red cell hypoplasia occurs as a consequence of binding to erythrocyte P antigen (globoside). Middle-aged persons (especially women) develop a limited symmetric polyarthritis that mimics lupus erythematosus and rheumatoid arthritis, preferentially involving the proximal interphalangeal joints of the hands and the wrists and knees. Arthralgias are uncommon in children. Rashes, especially facial, are uncommon in adults. Hepatitis may occur. In pregnancy, fetal loss and hydrops fetalis have been reported. An association with Henoch-Schonlein purpura has also been noted.

The diagnosis is clinical ([Table 32-2](#)) but may be confirmed by an elevated titer of IgM anti-parvovirus antibodies in serum or with PCR. Scarlet fever is the most similar disorder. Arthritis with hypocomplementemia is a common complication in some outbreaks. Uncommon complications of infection include encephalitis, chronic hemolytic anemia, thrombotic thrombocytopenic purpuric syndrome, acute postinfectious glomerulonephritis, and hepatitis.

Treatment in healthy persons is symptomatic. NSAIDs can be used to treat arthralgias and transfusions to treat transient aplastic crises. In immunosuppressed patients, intravenous immunoglobulin aids in reduction of anemia.

Screening of donated blood could potentially prevent transfusion-related infection. Several nosocomial outbreaks have been documented, and hospital infection control personnel should administer standard containment guidelines, including hand washing after patient exposure and avoiding contact with pregnant women.

The prognosis is generally excellent in immunocompetent individuals. In immunosuppressed patients, persistent anemia may require prolonged transfusion dependence. Remission of parvovirus infection in AIDS patients may occur with HAART.

2. Poxvirus Infections

Among the nine poxviruses causing disease in humans, the following are clinically important.

(1) **Variola:** Smallpox was a highly contagious disease characterized by severe headache, fever, and prostration and accompanied by a centrifugal rash developing in order of progression from macules to papules to vesicles to pustules. An international consensus among the scientific community in the 1990s resulted in a recommendation to destroy the virus since elimination of the disease had been achieved. As long as this recommendation is not implemented, there remains a risk of unauthorized access to the remaining samples and potential misuse for military or terrorist purposes, resulting in exposure of a large unvaccinated civilian population.

In the wake of the September 11, 2001, terrorism incidents, there exists concern about the potential use of smallpox and other agents as biologic weapons. Most physicians in practice today have never seen a case of smallpox. The disseminated lesions of smallpox in the past were often confused with those of varicella, though the synchronous progression in smallpox readily distinguishes these lesions from those of varicella, wherein lesions of several stages are usually present simultaneously. (See also [Chapter 37](#).)

(2) **Molluscum contagiosum** may be transmitted sexually or by other close contact. It is manifested by pearly, raised, umbilicated skin nodules sparing the palms and soles. Marked and persistent lesions in AIDS patients appear to respond readily to combination antiretroviral therapy. The many anecdotal agents reported to hasten resolution include cimetidine and CO₂ laser therapy combined with natural interferon-beta gel. 5% imiquimod cream appears to be effective in curing molluscum lesions.

(3) **Vaccinia:** Vaccination with vaccinia was crucial for smallpox eradication. Civilian vaccination is now indicated only for laboratory workers who must handle virus. The smallpox and monkeypox vaccines, while generally safe, are associated with significant side effects, and death occurs in 1:1,000,000 vaccinated individuals. This has led to considerable debate regarding the risk-benefit ratio of widespread vaccination for a disease that has officially been eradicated for 30 years. Vaccination has been reinstated in the United States military but is not required for any international travel; it is effective in prevention of monkeypox (see below). Any form of immunosuppression is an absolute contraindication to smallpox vaccination. Eczema (or a history of it) in a patient or family member, other forms of dermatitis, and burns also contraindicate vaccination. Currently, there is a voluntary campaign for vaccination among health care personnel who are likely to be the first responders in case of intentional release of smallpox virus. Dilution of existing stores of smallpox vaccine by fivefold to tenfold does not significantly reduce its effectiveness in stimulating an immune response and of course greatly increases availability.

(4) **Orf** (contagious pustular dermatitis, or ecthyma contagiosa) and **paravaccinia** (milker's nodules) are occupational diseases acquired by contact with sheep and cattle, respectively.

(5) **Monkeypox**, first identified in 1970, is enzootic in the rain forests of equatorial Africa and presents in humans as a syndrome similar to smallpox. The incubation period is about 12 days, and limited person-to-person spread occurs. African mortality rates vary from 3% to 11% depending upon the immune status of the patient. Secondary attack rates, which are hard to determine because of diagnostic confusion with varicella in older series, appear to be about 10%. Primary prevention entails the use of vaccinia immunization, a procedure accompanied by a risk of dissemination in HIV-infected persons—a real concern considering the coincident areas of endemicity of HIV-1 and monkeypox. The first community-acquired outbreak in the United States of monkeypox is occurring as of this writing in 2003 in Wisconsin and other states of the upper Midwest. The source appears to be imported Gambian giant rats via consequent exposure of prairie dogs. Clinical findings include a prodrome of fever and chills, headaches, myalgias, and sweats. About one-third of patients report a nonproductive cough. After 1-10 days, a papular rash appears that progresses through stages of vesiculation, pustulation, umbilication, and crusting—and in some cases ulceration. The rash starts on the head, trunk, and extremities, with occasional satellite lesions on the palms, soles, and extremities, and in some cases becomes generalized. Susceptible animals include nonhuman primates, rabbits, and rodents. Contact with these species is the primary means of transmission to humans. General precautions that should be taken are avoidance of contact with prairie dogs and Gambian giant rats (whose illness is manifested by alopecia, rash, and ocular or nasal discharge), appropriate care and isolation of those who are ill and also exposed within 3 prior weeks to such animals, and veterinary examination and investigation of suspect animals through health departments. CDC recommends smallpox vaccination to individuals if their exposure to infected animals is sufficient and if the candidate vaccinee has no contraindications (outlined above). Cidofovir is under current study. Submission of specimens and case reporting can be conducted using the Web site first listed below.

VIRUSES & GASTROENTERITIS

Viruses are responsible for at least 30-40% of cases of infectious diarrhea in the United States, and rotaviruses are a leading worldwide cause of dehydrating

gastroenteritis in young children. The agents that can cause disease include group B rotaviruses, caliciviruses such as Norwalk and Norwalk-like viruses (which cause epidemics of vomiting and diarrhea in contained environments), and other caliciviruses, astroviruses, and enteric adenoviruses.

Rotaviruses (G1-G4 and G9 are the most common serotypes) are a major cause of diarrheal morbidity worldwide (due to dehydration), can also cause infections in adults exposed to infected infants, and are ubiquitous in the environment of an outbreak. (Secondary rates are between 16% and 30%.) The disease is usually mild, and cases also occur among travelers, in epidemic fashion, and after waterborne exposure. Sensitive and specific immunoassays to detect viral RNA in fecal specimens are available. Treatment is symptomatic, with fluid and electrolyte replacement. Vaccine administration was discontinued because of a putative association with intussusception. The **Norwalk virus** was first identified using electron microscopy on infectious stool infiltrate derived from an outbreak of gastroenteritis at a school in Norwalk, Ohio. This virus and the related **Norwalk-like viruses** are responsible for over 40% of cases of group-related and institutional outbreaks of diarrhea. There have been several recent reports of gastroenteritis outbreaks induced by Norwalk-like viruses on cruise ships.

Norwalk virus is also often responsible for military outbreaks. While transmission is usually fecal-oral, airborne transmission is also documented. Infections appear to be more common during cold weather intervals. Reverse transcriptase PCR of stool samples is used for epidemiologic purposes. Treatment is largely symptomatic. The presence of antibodies is not associated with protection against reinfection.

ENTEROVIRUSES THAT PRODUCE SEVERAL SYNDROMES

1. *Coxsackievirus Infections*

Coxsackievirus infections cause several clinical syndromes. As with other enteroviruses, infections are most common during the summer. Two groups, A and B, are defined either serologically or by mouse bioassay. There are more than 50 serotypes.

Clinical Findings

A. Symptoms and Signs

The clinical syndromes associated with coxsackievirus infection may be described briefly as follows.

1. Summer gripe (A and B)—A febrile illness, principally of children, lasting 1-4 days. Minor symptoms and respiratory tract infection are often present.

2. Herpangina (A2-6, 10)—Sudden onset of fever, which may be as high as 40.6°C, sometimes with febrile convulsions; headache, myalgia, and vomiting; and sore throat, characterized early by petechiae or papules on the soft palate that become shallow ulcers in about 3 days and then heal.

3. Epidemic pleurodynia (Bornholm disease) (B1-5)—Pleuritic pain is prominent, and tenderness, hyperesthesia, and muscle swelling are present over the area of diaphragmatic attachment. Other findings include headache, sore throat, malaise, and nausea. Orchitis and aseptic meningitis are uncommon manifestations.

4. Aseptic meningitis (A and B) and other neurologic syndromes—Fever, headache, nausea, vomiting, stiff neck, drowsiness, and cerebrospinal fluid lymphocytosis without chemical abnormalities may occur, and pediatric clusters of group B meningitis are reported. Focal encephalitis, transverse myelitis, and acute flaccid paralysis are reported with coxsackievirus group A and a disseminated encephalitis after group B infection.

5. Acute nonspecific pericarditis (B types)—Sudden onset of anterior chest pain, often worse with inspiration and in the supine position, is typical. Fever, myalgia, headache, and pericardial friction rub appear early; evidence for pericardial effusion on imaging studies is often present, and the occasional patient has a paradoxical pulse. Electrocardiographic evidence of pericarditis is often present. Relapses may occur.

6. Myocarditis (B1-5)—Heart failure in the neonatal period secondary to in utero myocarditis and over 20% of adult cases of myocarditis and dilated cardiomyopathy are possibly associated with group B infections.

7. Hand, foot, and mouth disease (A5, 10, 16)—Sometimes epidemic and characterized by stomatitis and a vesicular rash on hands and feet. Enterovirus 71 is also a causative agent.

8. Hepatitis (B1)—Fulminant neonatal hepatitis with thrombocytopenia and coagulopathy occurs rarely.

9. Type 1 diabetes mellitus (B types)—An association purportedly exists between coxsackievirus B infections and subsequent development of type 1 diabetes mellitus.

10. Glomerulopathy and tubular injury—Renal damage has been reported with several group B infections.

B. Laboratory Findings

Routine laboratory studies show no characteristic abnormalities. Neutralizing antibodies appear during convalescence. The virus may be isolated from throat washings or stools inoculated into suckling mice.

Treatment & Prognosis

Treatment is symptomatic. With the exception of myocarditis, pericarditis, perhaps diabetes, and rare illnesses such as pancreatitis or polio-like syndrome, the syndromes caused by coxsackieviruses are benign and self-limited. There are anecdotal reports of success with pleconaril as well as with intravenous immunoglobulin in severe disease.

Peigue-Lafeuille H et al: Enterovirus meningitis in adults in 1999-2000 and evaluation of clinical management. J Med Virol 2002;67:47. [\[PMID: 11920817\]](#)

Sawyer MH: Enterovirus infections: diagnosis and treatment. Semin Pediatr Infect Dis 2002;13:40. [\[PMID: 12118843\]](#)

2. *Echovirus Infections*

Echoviruses are enteroviruses that produce several clinical syndromes, particularly in children. Infection is most common during summer.

Over 30 serotypes have been demonstrated. Most cause aseptic meningitis, which may be associated with a rubelliform rash. Type 30 outbreaks have been reported from Japan, France, Germany, Turkey, and Canada (Saskatchewan) while an increased number of type 13 cases occurred in the United States recently. Diseases associated with echoviruses range from common respiratory diseases and epidemic diarrhea (including type 22) to myocarditis, a hemorrhagic obstetric syndrome, keratoconjunctivitis, leukocytoclastic vasculitis, and neonatal as well as adult cases of encephalitis and sepsis to myocarditis, encephalitis, uveitis, and septic shock.

As with other enterovirus infections, diagnosis is best established by correlation of clinical, epidemiologic, and laboratory evidence. Cytopathic effects are produced in tissue culture after recovery of virus from throat washings, blood, or cerebrospinal fluid. PCR of the cerebrospinal fluid may be diagnostic. Fourfold or greater rises in antibody titer signify systemic infection.

Treatment is usually symptomatic, and the prognosis is excellent, though there are reports of mild paralysis after central nervous system infection. Hand washing is an effective control measure in outbreaks of aseptic meningitis.

Viskari HR et al: Maternal first-trimester enterovirus infection and future risk of type 1 diabetes in the exposed fetus. Diabetes 2002;51:2568. [\[PMID: 12145172\]](#)

3. *Enteroviruses 70 & 71*

Several clinical syndromes are being described in association with newer enteroviruses. The most common of these are **enterovirus 70**, associated with **acute**

hemorrhagic conjunctivitis, a ubiquitous agent first identified in 1969 and responsible for abrupt bilateral eye discharge and occasional systemic symptoms, but in most cases subconjunctival hemorrhage, and **enterovirus 71**, associated with **hand, foot, and mouth disease** as well as a form of **epidemic encephalitis**, most recently in children from East and Southeast Asia. Diagnosis of both entities is facilitated by the clinical and epidemiologic findings with the isolation of the suspect agent from either conjunctival scraping for enterovirus 70 or vesicle swabs, body secretions, or cerebrospinal fluid for enterovirus 71.

Treatment of both entities remains largely symptomatic, though there are increasing reports of the successful use of pleconaril, an agent available in some countries but not the United States. The major complication associated with enterovirus 70 is the development in a small percentage of cases of an acute neurologic illness with motor paralysis akin to poliomyelitis.

Enterovirus 72 is another term for hepatitis A virus (see [Chapter 15](#)).

■ **RICKETTSIAL DISEASES**

The rickettsioses are febrile exanthematous diseases caused by rickettsiae, small gram-negative obligate intracellular bacteria. In arthropods, rickettsiae grow in the gut lining, often without harming the host. Human infection results from either an arthropod bite or contamination with its feces. In humans, rickettsiae grow principally in endothelial cells of small blood vessels, producing vasculitis, cell necrosis, thrombosis of vessels, skin rashes, and organ dysfunctions.

Different rickettsiae and their vectors are endemic in different parts of the world, but two or more types may coexist in the same geographic area. New organisms are identified regularly. A summary of epidemiologic features is given in [Table 32-3](#). The clinical picture is variable but usually includes a prodromal stage followed by fever, rash, and prostration. Isolation of rickettsiae from the patient is difficult and potentially hazardous to laboratory workers. Diagnosis is usually based on clinical examination and epidemiologic evidence. Laboratory diagnosis relies on the development of specific antibodies detected by complement fixation (for diagnosis), immunofluorescence, or hemagglutination (for species identification) tests. Other newer means of isolation are the centrifugation shell-vial technique and PCR.

Prevention & Treatment

Preventive measures are directed at control of the vector, and avoidance of exposure by use of repellents and protective clothing. A search of body surfaces should be conducted after potential exposure and the vector (louse, tick, or mite) gently removed. Many patients do not recall exposure to a vector.

Rickettsiae can be inhibited by tetracyclines or chloramphenicol. All early infections respond to treatment with these drugs. Dosage schedules are listed below.

Parola P et al: Ticks and tickborne bacterial diseases in humans: an emerging infectious threat. Clin Infect Dis 2001;32:897. [\[PMID: 11247714\]](#)

TYPHUS GROUP

1. Epidemic Louse-Borne Typhus

- Prodrome of headache, then chills and fever.
- Severe, intractable headaches, prostration, persisting high fever.
- Macular rash appearing on the fourth to seventh days on the trunk and in the axillae, spreading to the rest of the body but sparing the face, palms, and soles.
- Diagnosis confirmed by specific antibodies using complement fixation, microagglutination, or immunofluorescence.

General Considerations

Epidemic louse-borne typhus is due to infection with *Rickettsia prowazekii*, a parasite of the body louse that ultimately kills the louse. Transmission is favored by crowded living conditions, famine, war, or any circumstances that predispose to heavy infestation with lice. When the louse sucks the blood of a person infected with *R. prowazekii*, the organism becomes established in the gut of the louse and grows there. When the louse is transmitted to another person (through contact or clothing) and has a blood meal, it defecates simultaneously, and the infected feces are rubbed into the itching bite wound. Dry, infectious louse feces may also enter the respiratory tract.

In a person who recovers from clinical or subclinical typhus infection, *R. prowazekii* may survive in lymphoid tissues. Years later, there may be a recrudescence of disease (Brill's disease) without exposure to infected lice.

Mild and atypical cases of *R. prowazekii* have rarely occurred in the United States after contact with flying squirrels or their ectoparasites or decades following exposure (eg, among concentration camp victims of World War II). Cases can be acquired by travel to pockets of infection (eg, central and northeastern Africa).

Clinical Findings

A. Symptoms and Signs

([Table 32-3](#).) Prodromal malaise, cough, headache, backache, arthralgia, and chest pain begin after an incubation period of 10-14 days, followed by an abrupt onset of chills, high fever, and prostration, with flu-like symptoms progressing to delirium and stupor. The headache is severe, and the fever prolonged.

Other findings consist of conjunctivitis, hearing loss from neuropathy of the eighth cranial nerve, flushed facies, rales at the lung bases, and often splenomegaly. A macular rash (that may become confluent) appears first in the axillas and then over the trunk, spreading to the extremities but rarely involving the face, palms, or soles. In severely ill patients, the rash becomes hemorrhagic, and hypotension becomes marked. There may be renal insufficiency, stupor, and delirium. In spontaneous recovery, improvement begins 13-16 days after onset with rapid drop of fever.

B. Laboratory Findings

The white blood cell count is variable. Proteinuria and hematuria commonly occur. Serum obtained 5-12 days after onset of symptoms usually shows specific antibodies for *R. prowazekii* antigens as demonstrated by complement fixation, microagglutination, or immunofluorescence. In primary rickettsial infection, early antibodies are IgM; in recrudescence (Brill's disease), early antibodies are predominantly IgG.

C. Imaging

Radiographs of the chest may show patchy consolidation.

Differential Diagnosis

The prodromal symptoms and the early febrile stage are not specific enough to permit diagnosis in nonepidemic situations. The rash is usually sufficiently distinctive for diagnosis, but it may be absent in up to 10% of cases or may be difficult to observe in dark-skinned persons. A variety of other acute febrile diseases should be considered, including typhoid fever, meningococcemia, and measles.

Brill's disease (recrudescent epidemic typhus) has a more gradual onset than primary *R. prowazekii* infection, fever and rash are of shorter duration, and the disease is milder and rarely fatal.

Complications

Pneumonia, thromboses, vasculitis with major vessel obstruction and gangrene, circulatory collapse, myocarditis, and uremia may occur.

Prevention

Prevention consists of louse control with insecticides, particularly by applying chemicals to clothing or treating it with heat, and frequent bathing. A deloused and bathed typhus patient is not infectious. The disease is not transmitted from person to person. Patients are infective for the lice during the febrile period and perhaps 2-3 days after the fever returns to normal. Infected lice pass rickettsiae in their feces within 2-6 days after the blood meal and can be infective earlier if crushed. Rickettsiae remain viable in a dead louse for weeks.

Immunization with vaccines consisting of inactivated egg-grown *R prowazekii* gives some protection to laboratory personnel, physicians, or field workers who are exposed to the parasite. This vaccine is not currently commercially available in the United States or Canada. An improved cell culture vaccine is being developed.

Treatment

Treatment consists of either tetracycline (25 mg/kg/d in four divided doses) or chloramphenicol (50-100 mg/kg/d in four divided doses) for 4-10 days.

Prognosis

The prognosis depends greatly upon age and immunization status. In children under age 10, the disease is usually mild. The mortality rate is 10% in the second and third decades but in the past reached 60% in the sixth decade. Effective vaccination can convert a potentially serious disease into a mild one.

2. Endemic Flea-Borne Typhus (Murine Typhus)

Rickettsia typhi, a ubiquitous pathogen, is transmitted from rat to rat through the rat flea. Humans usually acquire the infection in an urban or suburban setting when bitten by an infected flea, which releases infected feces while sucking blood. Rare cases in the developed world follow travel, usually to Southeast Asia. A second causative agent, *R felis*, has been linked to the cat flea and opossum exposures. Most cases in the United States are reported from southern Texas and California.

Endemic typhus resembles recrudescent epidemic typhus in that it has a gradual onset, less severe symptoms, and a shorter duration of illness than epidemic typhus (7-10 days versus 14-21 days). The presentation is nonspecific, including fever, headache, and chills. The rash is maculopapular and concentrated on the trunk and fades fairly rapidly. Fatalities are rare (less than 1%) and limited to the elderly.

The most common entity in the differential diagnosis is Rocky Mountain spotted fever, usually occurring after a rural exposure and with a different rash (centrifugal, versus centripetal for endemic typhus). Serologic confirmation may be necessary for differentiation, with complement-fixing or immunofluorescent antibodies detectable within 15 days after onset, with specific *R typhi* antigens.

Preventive measures are directed at control of rats and ectoparasites (rat fleas) with insecticides, rat poisons, and rat-proofing of buildings. Antibiotic treatment with tetracycline (25-50 mg/kg/d in four divided doses) or chloramphenicol (50-75 mg/kg/d in four divided doses) is indicated through 3 full days of defervescence.

Gikas A et al: Murine typhus in Greece: epidemiological, clinical, and therapeutic data from 83 cases. Trans R Soc Trop Med Hyg 2002;96:250. [PMID: 12174771]

3. Scrub Typhus (Tsutsugamushi Fever)

Essentials of Diagnosis

- Exposure to mites in endemic area of Southeast Asia, the western Pacific (including Korea), and Australia.
- Black eschar at site of bite, with regional and generalized lymphadenopathy.
- Conjunctivitis and a short-lived macular rash.
- Frequent pneumonitis, encephalitis, and cardiac failure.

General Considerations

Scrub typhus is caused by *Orientia tsutsugamushi*, which is principally a parasite of rodents transmitted by mites in the endemic areas listed above. The mites live on vegetation but complete their maturation cycle by biting humans who come in contact with infested vegetation. Vertical transmission occurs, and blood transfusions may transmit the pathogen. Serosurveys from Bangkok show prevalences over 20% for blood donors and nearly 60% for febrile malaria clinic patients. Rare occupational transmission via inhalation is documented among laboratory workers.

Clinical Findings

A. Symptoms and Signs

After a 1- to 3-week incubation period, malaise, chills, severe headache, and backache develop. At the site of the bite, a papule evolves into a flat black eschar. The regional lymph nodes are enlarged and tender, and there may be generalized adenopathy. Fever rises gradually, and a macular rash appears primarily on the trunk after a week of fever and may be fleeting or may last a week. The patient may become obtunded. During the second or third week, pneumonitis, myocarditis and cardiac failure, and encephalitis or meningitis, acute abdominal pain, granulomatous hepatitis, disseminated intravascular coagulation, or acute renal failure may develop. In the gastrointestinal tract, there may appear superficial mucosal hemorrhage, multiple erosions, or ulcers. An attack confers prolonged immunity against homologous strains and transient immunity against heterologous strains. Heterologous strains produce mild disease if infection occurs within a year after the first episode.

B. Laboratory Findings

Blood obtained during the first few days of illness may permit isolation of the rickettsial organism by mouse inoculation. Fluorescein-labeled antirickettsial assays or commercial dot-blot ELISA dipstick assays are convenient means of establishing the diagnosis, though PCR may be the most sensitive test. A reticulonodular infiltrate is the most common radiologic finding on chest x-ray.

Differential Diagnosis

Leptospirosis, typhoid, dengue, malaria, and other rickettsial infections should be considered. Scrub typhus is a recognized cause of obscure tropical fevers, especially in children. When the rash is fleeting and the eschar not evident, laboratory results are required for diagnosis, including a conventional indirect fluorescent assay or a more sensitive rapid immunochromatographic flow assay that is under development. Upper tract endoscopy may help with gastrointestinal lesions.

Prevention

Repeated application of long-acting miticides can make endemic areas safe. Insect repellents on clothing and skin provide some protection. For short exposure, chemoprophylaxis with doxycycline (200 mg weekly) can prevent the disease but permits infection. No effective vaccines are available.

Treatment & Prognosis

Without treatment, fever subsides spontaneously after 2 weeks, but the mortality rate may be 10-30%. Treatment for 3 days with doxycycline, 100 mg twice daily, or for 7 days with chloramphenicol, 25 mg/kg/d in four divided doses, virtually eliminates deaths and relapses, though chloramphenicol- and tetracycline-resistant strains have been reported from Southeast Asia, and azithromycin may become the drug of choice for children, pregnant women, and patients with refractory disease. Rifampin also appears to be effective. HIV infection does not appear to influence the severity of scrub typhus.

SPOTTED FEVERS

1. Rocky Mountain Spotted Fever

Essentials of Diagnosis

- Exposure to tick bite in endemic area.
- An influenza-like prodrome followed by chills, fever, severe headache, myalgias, restlessness, and prostration; occasionally, delirium and coma.
- Red macular rash appears between the second and sixth days of fever, first on the wrists and ankles and then spreading centrally; it may become petechial.
- Serial serologic examinations by indirect fluorescent antibody (IFA) confirm the diagnosis retrospectively.

General Considerations

Despite its name, most cases occur outside the Rocky Mountain area, with cases in the United States concentrated along the Middle and Southern Atlantic seaboard and in the central Mississippi valley. The causative agent, *Rickettsia*, is transmitted to humans by the bite of ticks, including the wood tick, *Dermacentor andersoni*, in the western United States and by the bite of the dog tick, *Dermacentor variabilis*, in the eastern United States. Other hard ticks transmit the organism in the southern United States and in Central and South America and are responsible for transmitting it among rodents, dogs, porcupines, and other animals. Most human cases occur in late spring and summer. In the United States, most cases occur in the eastern third of the country, with about 1000 reported per year, primarily from April through September, and with a higher incidence among children and men.

Clinical Findings

A. Symptoms and Signs

Two to 14 days (mean, 7 days) after the bite of an infectious tick, symptoms begin with fever, chills, headache, nausea and vomiting, myalgias, restlessness, insomnia, and irritability. Cough and pneumonitis may develop. Delirium, lethargy, seizures, stupor, and coma may appear. The face is flushed and the conjunctiva injected. The rash (faint macules that progress to maculopapules and then petechiae) appears between days 2 and 6 of fever, first on the wrists and ankles, spreading centrally to the arms, legs, and trunk for 2-3 days; involvement of the palms and soles is characteristic. About 10% of cases occur without rash or with minimal rash. In some cases there is splenomegaly, hepatomegaly, jaundice, myocarditis, or uremia; acute respiratory distress syndrome (ARDS) is of greatest concern. About 3-5 % of reported cases in the United States during recent years have been fatal.

B. Laboratory Findings

Thrombocytopenia, hyponatremia, elevated aminotransferases, and hyperbilirubinemia are common. Cerebrospinal fluid may show hypoglycorrachia and mild pleocytosis. Disseminated intravascular coagulation is observed in severe cases. Diagnosis during the acute phase of the illness can be made by immunohistologic demonstration of *Rickettsia* in skin biopsy specimens, but this must be performed as soon as skin lesions become apparent to achieve maximum sensitivity. Isolation of the organism using the shell vial technique is available in some laboratories but is hazardous.

Serologic studies confirm the diagnosis, but the majority of patients do not mount an antibody response until the second week of illness. Indirect fluorescent antibody (IFA) is most commonly used. There is no longer any role for the Weil-Felix test.

Differential Diagnosis

The early symptoms and signs of Rocky Mountain spotted fever resemble those of many other infections. The rash may be confused with that of measles, typhoid, and ehrlichiosis, or—most importantly—meningococcemia. Blood cultures and cerebrospinal fluid examination establish the latter.

Prevention

Protective clothing, tick-repellent chemicals, and the removal of ticks at frequent intervals are helpful measures. Prophylactic therapy after a tick bite is not currently recommended.

Treatment & Prognosis

Doxycycline (200 mg/d) either orally or intravenously is the drug of choice. Chloramphenicol (50 mg/kg/d in four divided doses) is reserved for pregnant women. Patients usually defervesce within 48-72 hours. Mild cases in low-risk individuals may be observed without treatment.

The mortality rate for Rocky Mountain spotted fever varies strikingly with age. In the untreated elderly, it may be 70%, but it is usually less than 20% in children. Other risk factors for a fatal outcome include advanced age, atypical clinical features (absence of headache, no history of tick attachment, gastrointestinal symptoms), and a delay in initiation of appropriate antibiotic therapy. The usual cause of death is pneumonitis with respiratory or cardiac failure. Sequelae, more common than formerly recognized, may include seizures, encephalopathy, peripheral neuropathy, paraparesis, bowel and bladder incontinence, cerebellar and vestibular dysfunction, hearing loss, and motor deficits.

Sexton DJ et al: Rocky mountain spotted fever. Med Clin North Am 2002;86:351 [\[PMID: 11982306\]](#)

2. Rickettsialpox

Rickettsia akari is a parasite of mice, transmitted by mites (*Allodermanyssus sanguineus*). Rickettsialpox occurs in humans where crowded conditions and mouse-infested housing allow transmission of the pathogen to humans. Pathologic findings include dermal edema, subepidermal vesicles, and at times a lymphocytic vasculitis. The incubation period is 7-12 days. Onset is sudden, with chills, fever, headache, photophobia, and disseminated aches and pains. The primary lesion is a painless red papule that vesiculates and forms a black eschar. Two to 4 days after onset of symptoms, a widespread papular eruption appears that becomes vesicular and forms crusts that are shed in about 10 days. Early lesions may resemble those of chickenpox (typically vesicular versus papulovesicular in rickettsialpox).

Leukopenia and a rise in antibody titer to rickettsial antigen with complement fixation or indirect fluorescent assays using a conjugated antirickettsial globulin can identify antigen in punch biopsies of skin lesions.

Treatment includes tetracycline, 15 mg/kg/d orally in four divided doses for 3-5 days.

Even without treatment, the disease is fairly mild and self-limited, treatment only hastening resolution. Control requires the elimination of mice from human habitations and insecticide applications to suppress the mite vectors.

Comer JA et al: Serologic evidence of rickettsialpox infection among intravenous drug users in inner-city Baltimore, Maryland. Am J Trop Med Hyg 1999;60:894. [\[PMID: 10403316\]](#)

3. Tick Typhus (Rickettsial Fever)

The term "tick typhus" denotes a variety of spotted rickettsial fevers. They are often named by geography, eg, Israel tick fever, Kenya tick fever, Mediterranean spotted fever, Queensland tick typhus, Flinders Island spotted fever; or morphology, eg, boutonneuse fever. These illnesses are transmitted by tick vectors of the rickettsial agents *R. conorii*, *R. australis*, *R. japonica*, *R. africae*, and *R. sibirica*. Dogs and wild animals may serve as reservoirs. The pathogens usually produce a black spot (tache noire) at the site of the tick bite that may be useful in diagnosis, though spotless boutonneuse fever occurs. Rarely, papulovesicular lesions may resemble rickettsialpox. Endothelial injury produces perivascular edema and dermal necrosis. Regional adenopathy, disseminated lesions, and focal hepatic necrosis may occur. The disease occurs among travelers, with occasional cases recorded among returnees from Africa in particular. Diagnosis is clinical, with serologic or PCR confirmation. Prevention entails protective clothing, repellents, and inspection for and removal of ticks. Treatment is with the following drugs given for 7-10 days: tetracycline (25-50 mg/kg/d in four divided doses), chloramphenicol (50-75 mg/kg/d in four divided doses), or ciprofloxacin (500 mg twice daily). The combination of erythromycin and rifampin is effective and safe in pregnancy.

OTHER RICKETTSIAL & RICKETTSIAL- LIKE DISEASES

1. Ehrlichiosis

Ehrlichiosis presents two clinical entities: human monocytic ehrlichiosis and human granulocytic ehrlichiosis. Human monocytic ehrlichiosis is caused by *Ehrlichia chaffeensis* and by the closely related agents *E equi* and *E canis*. Human granulocytic ehrlichiosis is caused by *E phagocytophila*. *E sennetsu* is the etiologic agent of sennetsu fever, which appears to be confined to western Japan. *E ewingii* causes a form of human granulocytic ehrlichiosis but is biologically more akin to *E chaffeensis*.

Ehrlichiae are small tick-borne gram-negative obligate intracellular bacteria. The major nonhuman hosts include mice, dogs, and horses. Ehrlichiae grow as microcolonies in phagosomes of hematopoietic cells and form characteristic inclusions seen with Giemsa's stain. Human monocytic ehrlichiosis is seen primarily in the Southeast, mid-Atlantic, and South Central states of the United States, though serologic evidence now documents a much more global endemicity (Israel, Japan, Mexico). Its major vector is the Lone Star tick (*Amblyomma americanus*). Clinical disease ranges from mild to life-threatening. Typically, after about a 9-day incubation period and a prodrome consisting of malaise, rigors, and nausea, patients develop worsening fever and headache; a pleomorphic rash may occur. Leukopenia and absolute lymphopenia as well as thrombocytopenia occur often. Serious sequelae include acute respiratory failure and ARDS, encephalopathy, and acute renal failure, which may mimic thrombotic thrombocytopenic purpura. An indirect fluorescent antibody assay is available through CDC and requires acute and convalescent sera. A PCR assay applied to whole blood samples is a rapid diagnostic tool, if available.

Human granulocytic ehrlichiosis has a geographic area of distribution similar to that for Lyme disease, though the geographic boundaries are as yet not fully determined and seroconversion with clinically consistent cases is now reported from Israel and northern Europe. The vectors are ticks of the ixodes genus, and the reservoirs include woodrats, deer mice, chipmunks, deer, and perhaps horses. The incidence peaks in summer, but cases are seen year-round in warmer areas where ticks remain viable. The symptoms are similar to those seen with human monocytic ehrlichiosis. Persistent fever and malaise are reported to occur for 2 or more years. Coinfection with Lyme disease may occur, though patients with granulocytic ehrlichiosis appear to be older and sicker than those with acute Lyme disease.

Diagnosis is made by the history of tick exposure followed by a clinical illness with the characteristic symptoms and signs. Further laboratory evaluation is similar to that described for human monocytic ehrlichiosis.

Treatment for both forms of ehrlichiosis is with doxycycline, 200 mg orally or intravenously for at least 7 days or until 3 days of defervescence. Treatment should not be withheld while awaiting confirmatory serology when suspicion is high.

2. Q Fever

Essentials of Diagnosis

- Exposure to sheep, goats, cattle, or their products is common; some infections are laboratory-acquired.
- An acute or chronic febrile illness with severe headache, cough, prostration, and abdominal pain.
- Extensive pneumonitis, hepatitis, or encephalopathy; rarely endocarditis.

General Considerations

Coxiella burnetii is unique among rickettsiae in that it is usually transmitted to humans not by arthropods but by inhalation or ingestion. It is distributed worldwide with few exceptions. Coxiella infections occur mostly in cattle, sheep, and goats, in which they cause mild or subclinical disease. Transmission by cows and goats is principally through the milk and placenta and by sheep through feces, placenta, and milk. Dry feces and milk, dust contaminated with them, and the tissues of these animals contain large numbers of infectious organisms that are spread by the airborne route. Inhalation of contaminated dust and of droplets from infected animal tissues is the main source of human infection. Outbreaks have been described in association with parturient cats. There is an occupational risk for animal handlers, slaughterhouse workers, veterinarians, and laboratory workers.

The route of acquisition appears to determine the main clinical syndrome. Endocarditis is an uncommon but serious form of coxiella infection and has been linked with preexisting valvular conditions, immunocompromise, urban residence, and raw milk ingestion. Coxiella is resistant to heat and drying, perhaps because the organism forms endospore-like structures. Thus, it survives in dust, on the fleece of infected animals, or in inadequately pasteurized milk. Spread from one human to another does not seem to occur even in the presence of florid pneumonitis, but maternal-fetal infection can occur.

Clinical Findings

A. Symptoms and Signs

After an incubation period of 1-3 weeks, a febrile illness develops with headache, prostration, and muscle pains, often with a nonproductive cough. Pneumonia is the predominant manifestation of acute Q fever, although granulomatous hepatitis and central nervous system manifestations may occur. The most common manifestation of chronic Q fever is culture-negative endocarditis, which occurs in less than 1% of infected individuals. It is found mainly in the setting of preexisting valve disease. Uncommon manifestations of coxiella infection include myocarditis, encephalitis, hemolytic anemia, orchitis, acute renal failure, and mediastinal lymphadenopathy. The clinical course may be acute or may be chronic and relapsing.

B. Laboratory Findings

Laboratory examination during the acute phase may show elevated liver function tests and occasionally leukocytosis. Patients with acute Q fever usually produce antibodies to *C burnetii* phase II antigen. A fourfold rise between acute and convalescent sera is diagnostic.

The diagnosis of Q fever endocarditis is made serologically. The IgG titer is usually 1:200 or greater and is directed against phase I antigen. Sometimes the diagnosis is not made until the time of valve replacement. Isolation of *C burnetii* from affected valves is possible using the shell-vial technique, but the organism is highly transmissible to laboratory workers.

C. Imaging

Radiographs of the chest show patchy pulmonary infiltrates, often more prominent than the physical signs would suggest.

Differential Diagnosis

Viral, mycoplasmal, and bacterial pneumonias, viral hepatitis, brucellosis, tuberculosis, psittacosis, and other animal-borne diseases must be considered. The history of exposure to animals or animal dusts or tissues (eg, in slaughterhouses) should lead to appropriate specific serologic tests. Unexplained fevers with negative blood cultures in association with embolic or cardiac disease should make one consider Q fever.

Prevention

Prevention is based on detection of the infection in livestock, reduction of contact with infected animals or dusts contaminated by them, special care when working with animal tissues, and effective pasteurization of milk. A vaccine of formalin-inactivated phase 1 coxiella is being developed for persons at high risk of infection and appears to be protective. A vaccine is available in some countries for persons with high-risk exposures.

Treatment & Prognosis

For acute infection, treatment with tetracycline (25 mg/kg/d in four divided doses) or doxycycline (100 mg twice daily) can suppress symptoms and shorten the clinical course but does not always eradicate the infection. The newer macrolides are an alternative. Treatment should continue through 3 full days of defervescence, which usually occurs within 72 hours. Even in untreated patients, the mortality rate is usually low, except when endocarditis develops (see below).

Although the optimal regimen for the treatment of endocarditis is not known, most experts recommend a combination of doxycycline (200 mg/d) plus hydroxychloroquine (600 mg/d), usually for at least 2 years. Serologic responses can be followed to determine cessation of therapy. Heart valve replacement may be necessary in refractory disease. Given the difficulty in treating endocarditis, the same combination therapy for 1 year is recommended for patients with acute disease and underlying valvular heart disease.

KAWASAKI SYNDROME

Kawasaki syndrome is a worldwide multisystemic disease initially described by Tomisaku Kawasaki in 1967. It is also known as the "mucocutaneous lymph node syndrome." It occurs mainly in children under age 5 but occasionally in adults, at times in epidemic fashion. Asian children are at higher risk. The epidemiology suggests an infectious origin, though no agent has been identified. While disease is probably not mediated by a bacterial toxin, a staphylococcal toxin may serve as a "superantigen" that interacts with T cells. IgA plasma cell infiltration is noted in the visceral organs, lungs, and coronary arteries of Kawasaki syndrome patients.

The disease is characterized by fever and four of the following for at least 5 days: bilateral nonexudative conjunctivitis, mucous membrane changes of at least one type (injected pharynx, cracked lips, strawberry tongue), extremity changes of at least one type (edema, desquamation, erythema), a polymorphous rash, and cervical lymphadenopathy greater than 1.5 cm.

A major complication is arteritis of the coronary vessels, occurring in about 25% of untreated cases and on occasion causing myocardial infarction. Noninvasive diagnosis can be made with magnetic resonance angiography or transthoracic ultrasound. Factors associated with the development of coronary artery aneurysms are leukocytosis and elevated C-reactive protein. Arteritis of extremity vessels and peripheral gangrene are also reported. Cerebrospinal fluid pleocytosis is reported in one-third of cases. The cause of these complications is also unknown. Differentiation from disseminated adenovirus infection is important and may be facilitated in the future with rapid adenovirus assays.

Management is with aspirin (80-100 mg/kg/d in divided doses with subsequent tapering) and intravenous immune globulin, 2 g/kg over 10 hours. Plasmapheresis may be useful in the up to 10% of cases that are unresponsive to immune globulin. Corticosteroids are used by some in refractory disease. Their role in increasing the likelihood of the development of coronary aneurysms is controversial. Aspirin is used for patients with persisting coronary artery aneurysms, while warfarin is indicated for aneurysms larger than 8 mm in diameter. Regular follow-up by a cardiologist is recommended for patients with coronary artery disease or aneurysms. Success is reported with interventional catheter treatment, including stent implantation in patients with long-term cardiac complications.

Table 32-1. Agents for viral infections.¹

Drug	Dosing	Spectrum	Renal Clearance/ Hemodialysis		CNS/CSF Penetration	Toxicities
Acyclovir	200-800 mg orally five times daily; 250-500 mg/m ² IV every 8 hours for 7 days	HSV	Yes/Yes		Yes	Neurotoxic reactions, reversible renal dysfunction, local reactions
Amantadine	100 mg orally twice daily (100 mg/d in elderly) for 10 days	Influenza A	Yes/No		Yes	Confusion, gastrointestinal symptoms
Cidofovir	5 mg/kg IV weekly for 2 weeks, then every other week	CMV	Yes/NA		NA	Neutropenia, renal failure, ocular hypotonia
Famciclovir	500 mg orally 3 times daily	VZV, ?HSV	Yes/NA		NA	NA
Foscarnet	20 mg/kg IV bolus, then 120 mg/kg IV every 8 hours for 2 weeks; maintain with 60 mg/kg/d IV for 5 days each week	CMV, HSV resistant to acyclovir, VZV, HIV-1	Yes/Yes		Variable	Nephrotoxicity, genital ulcerations, calcium disturbances
Ganciclovir	5 mg/kg IV bolus every 12 hours for 14-21 days; maintain with 3.75 mg/kg/d IV for 5 days each week	CMV	Yes/Yes		Yes	Neutropenia, thrombocytopenia, CNS side effects
Idoxuridine	Topical, 0.1% every 1-2 hours for 3-5 days	HSV keratitis	—		—	Local reactions
Interferon alfa-2b	3-5 million IU SC 3 times weekly to daily Intralesionally: 1 million IU per 0.1 mL in up to 5 warts 3 times weekly for 3 weeks	HBV, HCV, papillomavirus	Yes/Yes			Influenza-like syndrome, myelosuppression, neurotoxicity
Interferon alfa-n3	0.05 mL/wart biweekly up to 8 weeks 3 mU IV 3 times per week	HPV ?HCV	NA/NA NA/NA		NA NA	Local reactions Influenza-like syndrome, myelosuppression, neurotoxicity
Lamivudine (3TC)	12 mg/kg/d	HIV-1, ?HIV-2, HBV	Yes/NA		Yes	Skin rash, headache, insomnia
Oseltamivir	Influenza A and B	Yes/NA	NA	Few		
Ribavirin	Aerosol: 1.1 g/d as 20 mg/mL dilution over 12-18 hours for 3-7 days (See text for Lassa fever doses.)	RSV, severe influenza A or B, Lassa fever	Yes/No		Yes	Wheezing
Rimantadine	100 mg orally twice daily	Influenza A	Yes/No		Yes	Same as amantadine, but less severe
Trifluridine	Topical, 1% drops every 2 hours to 9 drops/d	HSV keratitis	—		—	Local reactions
Valacyclovir	1 g orally 3 times daily for 7 days for VZV; 500 mg twice daily for HSV	VZV, ?HSV	Yes/Poorly		NA	Thrombotic thrombocytopenic purpura or hemolytic uremic syndrome in AIDS
Vidarabine	15 mg/kg/d IV for 10 days	HSV, VZV	Yes/Yes		Yes	Teratogenic, megaloblastosis, neurotoxicity
Zanamivir	2-5 mg inhalations twice daily for 5 days	Influenza A and B	Yes/NA		NA	Few

Table 32-2. Diagnostic features of some acute exanthems.

Disease	Prodromal Signs and Symptoms	Nature of Eruption	Other Diagnostic Features	Laboratory Tests
Eczema herpeticum	None.	Vesiculopustular lesions in area of eczema.		Herpes simplex virus isolated in cell culture. Multinucleate giant cells in smear of lesion.
Varicella (chickenpox)	0-1 day of fever, anorexia, headache.	Rapid evolution of macules to papules, vesicles, crusts; all stages simultaneously present; lesions superficial, distribution centripetal.	Lesions on scalp and mucous membranes.	Specialized complement fixation and virus neutralization in cell culture. Fluorescent antibody test of smear of lesions.
Infectious mononucleosis (EBV)	Fever, adenopathy, sore throat.	Maculopapular rash resembling rubella, rarely papulovesicular.	Splenomegaly, tonsillar exudate.	Atypical lymphocytes in blood smears; heterophil agglutination. Monospot test.
Exanthema subitum (HHV-6, 7; roseola)	3-4 days of high fever.	As fever falls by crisis, pink maculopapules appear on chest and trunk; fade in 1-3 days.		White blood count low.
Measles (rubeola)	3-4 days of fever, coryza, conjunctivitis, and cough.	Maculopapular, brick-red; begins on head and neck; spreads downward and outward, in 5-6 days rash brownish, desquamating. See atypical measles.	Koplik's spots on buccal mucosa.	White blood count low. Virus isolation in cell culture. Antibody tests by hemagglutination inhibition or neutralization.
Atypical measles	Same as measles.	Maculopapular centripetal rash, becoming confluent.	History of measles vaccination.	Measles antibody present in past, with titer rise during illness.
Rubella	Little or no prodrome.	Maculopapular, pink; begins on head and neck, spreads downward, fades in 3 days. No desquamation.	Lymphadenopathy, postauricular or occipital.	White blood count normal or low. Serologic tests for immunity and definitive diagnosis (hemagglutination inhibition).
Erythema infectiosum (parvo-virus B19)	None. Usually in epidemics.	Red, flushed cheeks; circumoral pallor; maculopapules on extremities.	"Slapped face" appearance.	White blood count normal.
Enterovirus infections	1-2 days of fever, malaise.	Maculopapular rash resembling rubella, rarely papulovesicular or petechial.	Aseptic meningitis.	Virus isolation from stool or cerebrospinal fluid; complement fixation titer rise.
Typhus	3-4 days of fever, chills, severe headaches.	Maculopapules, petechiae, initial distribution centrifugal (trunk to extremities).	Endemic area, lice.	Complement fixation.
Rocky Mountain spotted fever	3-4 days of fever, vomiting.	Maculopapules, petechiae, initial distribution centripetal (extremities to trunk, including palms).	History of tick bite.	Complement fixation.
Ehrlichiosis	Headache, malaise.	Rash in one-third, similiar to Rocky Mountain spotted fever.	Pancytopenia, elevated liver function tests.	Polymerase chain reaction, immunofluorescent antibody.
Scarlet fever	One-half to 2 days of malaise, sore throat, fever, vomiting.	Generalized, punctate, red; prominent on neck, in axillae, groin, skinfolds; circumoral pallor; fine desquamation involves hands and feet.	Strawberry tongue, exudative tonsillitis.	Group A beta-hemolytic streptococci in cultures from throat; anti-streptolysin O titer rise.
Meningococcemia	Hours of fever, vomiting.	Maculopapules, petechiae, purpura.	Meningeal signs, toxicity, shock.	Cultures of blood, cerebrospinal fluid. High white blood count.
Kawasaki disease	Fever, adenopathy, conjunctivitis.	Cracked lips, strawberry tongue, maculopapular polymorphous rash, peeling skin on fingers and toes.	Edema of extremities. Angiitis of coronary arteries.	Thrombocytosis, electrocardiographic changes.

■ INFECTIONS CAUSED BY GRAM-POSITIVE BACTERIA

STREPTOCOCCAL INFECTIONS

1. *Pharyngitis*

Essentials of Diagnosis

- Abrupt onset of sore throat, fever, malaise, nausea, and headache.
- Throat red and edematous, with or without exudate; cervical nodes tender.
- Diagnosis confirmed by culture of throat.

General Considerations

Group A beta-hemolytic streptococci (*Streptococcus pyogenes*) are the most common bacterial cause of pharyngitis. Transmission occurs by droplets of infected secretions. Group A streptococci producing erythrogenic toxin may cause scarlet fever in susceptible persons.

Clinical Findings

A. Symptoms and Signs

"Strep throat" is characterized by a sudden onset of fever, sore throat, pain on swallowing, tender cervical adenopathy, malaise, and nausea. The pharynx, soft palate, and tonsils are red and edematous. There may be a purulent exudate. The rash of scarlet fever is diffusely erythematous, resembling a sunburn, with superimposed fine red papules, and is most intense in the groin and axillas. It blanches on pressure, may become petechial, and fades in 2-5 days, leaving a fine desquamation. The face is flushed, with circumoral pallor, and the tongue is coated with enlarged red papillae (strawberry tongue).

B. Laboratory Findings

Leukocytosis with neutrophil predominance is common. Throat culture onto a single blood agar plate has a sensitivity of 80-90%. Rapid diagnostic tests based on detection of streptococcal antigen are slightly less sensitive than culture.

Complications

Suppurative complications include sinusitis, otitis media, mastoiditis, peritonsillar abscess, and suppuration of cervical lymph nodes.

Nonsuppurative complications are rheumatic fever and glomerulonephritis. Rheumatic fever may follow recurrent episodes of pharyngitis beginning 1-4 weeks after the onset of symptoms. Glomerulonephritis follows a single infection with a nephritogenic strain of streptococcus group A (eg, types 4, 12, 2, 49, and 60), more commonly on the skin than in the throat, and begins 1-3 weeks after the onset of the infection.

Differential Diagnosis

Streptococcal sore throat resembles (and cannot be reliably distinguished clinically from) pharyngitis caused by adenoviruses, Epstein-Barr virus, *Arcanobacterium haemolyticus* (which also may cause a rash), and other agents. Pharyngitis and lymphadenopathy are common findings in primary HIV infection. Generalized lymphadenopathy, splenomegaly, atypical lymphocytosis, and a positive serologic test distinguish mononucleosis from streptococcal pharyngitis. Diphtheria is characterized by a pseudomembrane; candidiasis shows white patches of exudate and less erythema; and necrotizing ulcerative gingivostomatitis (Vincent's fusospirochetal disease) presents with shallow ulcers in the mouth. Retropharyngeal abscess or bacterial epiglottitis should be considered when odynophagia and difficulty in handling secretions are present and when the severity of symptoms is disproportionate to findings on examination of the pharynx.

Treatment

Antimicrobial therapy has a minimal effect on resolution of symptoms. Because its main purpose is prevention of complications, therapy may be withheld pending results of culture. Because throat culture (especially if a single plate is used) and rapid detection methods may be falsely negative in 30% or more of cases, if clinical suspicion is high and the risk of therapy is low (eg, no drug allergy), antimicrobial therapy may be given without laboratory evaluation.

A. Benzathine Penicillin G

Benzathine penicillin G, 1.2 million units intramuscularly as a single dose, is optimal therapy.

B. Penicillin VK

Penicillin VK, 500 mg orally four times a day (or amoxicillin, 750 mg orally twice daily), is effective, but compliance may be poor after the patient becomes asymptomatic in 2-4 days.

C. Macrolides

Erythromycin, 500 mg orally four times a day, or azithromycin, 500 mg once daily for 3 days, are alternatives for the penicillin-allergic patient. Macrolides are less effective than penicillins. Depending on the location, the prevalence of macrolide resistance among strains of group A streptococci is up to 40%. Therefore, macrolides are considered second-line agents because of the risk of treatment failure. Macrolide-resistant strains almost always are susceptible to clindamycin, an alternative for serious infections. A 10-day course of 300 mg three times a day orally should be effective.

Prevention of Recurrent Rheumatic Fever

Effectively controlling rheumatic fever depends upon identification and treatment of primary streptococcal infection and secondary prevention of recurrences. Patients who have had rheumatic fever should be treated with a continuous course of antimicrobial prophylaxis for at least 5 years. Effective regimens are erythromycin, 250 mg orally twice daily, or penicillin G, 500 mg orally daily.

Kurtz B et al: Importance of inoculum size and sampling effect in rapid antigen detection for diagnosis of *Streptococcus pyogenes* pharyngitis. J Clin Microbiol 2000;38:279. [PMID: 10618101]

2. *Streptococcal Skin Infections*

Beta-hemolytic streptococci are not normal skin flora. Streptococcal skin infections result from colonization of normal skin by contact with other infected individuals or by preceding streptococcal respiratory infection.

Clinical Findings

A. Symptoms and Signs

Impetigo is a focal, vesicular, pustular lesion with a thick, amber-colored crust with a "stuck-on" appearance.

Erysipelas is a painful superficial cellulitis that frequently involves the face. It is well demarcated from the surrounding normal skin. It affects skin with impaired lymphatic drainage, such as edematous lower extremities or wounds.

B. Laboratory Findings

Cultures obtained from a wound or pustule are likely to grow group A streptococci. Blood cultures are occasionally positive.

Treatment

Parenteral antibiotics are indicated for patients with facial erysipelas or evidence of systemic infection. Penicillin, 2 million units intravenously every 4 hours, is the drug of choice.

Cutaneous infections caused by staphylococci may at times be difficult to differentiate from streptococcal infections. Coinfection also occurs. Therefore, initial therapy for patients who have risk factors for staphylococcal infection (eg, intravenous drug use, wound infection, diabetes) should include an agent—such as nafcillin, 1.5 g intravenously every 6 hours—that also is active against *Staphylococcus aureus*. In the patient with minor penicillin allergy, cefazolin, 500 mg intravenously or intramuscularly every 8 hours, may be used. In the patient with a serious penicillin allergy (ie, anaphylaxis), vancomycin, 1000 mg intravenously every 12 hours, should be used.

Patients who do not require parenteral therapy may be treated with amoxicillin, 750 mg twice daily for 7-10 days. For pharyngitis, high prevalence of resistance among strains makes macrolides a less attractive alternative for penicillin-allergic patients. A first-generation oral cephalosporin, eg, cephalexin, 500 mg four times daily, or clindamycin, 300 mg orally three times daily, is an alternative to amoxicillin.

Carapetis JR et al: Epidemiology and prevention of group A streptococcal infections: acute respiratory tract infections, skin infections, and their sequelae at the close of the twentieth century. Clin Infect Dis 1999;28:205. [\[PMID: 10064227\]](#)

3. Other Group A Streptococcal Infections

Arthritis, pneumonia, empyema, endocarditis, and necrotizing fasciitis are relatively uncommon infections that may be caused by group A streptococci. Toxic shock-like syndrome also occurs.

Arthritis generally occurs in association with cellulitis. In addition to intravenous therapy with penicillin G, 2 million units every 4 hours (or cefazolin or vancomycin in doses recommended above for penicillin-allergic patients), frequent percutaneous needle aspiration should be performed to remove joint effusions. Open surgical drainage may be necessary when the hip or shoulder is infected.

Pneumonia and **empyema** often are characterized by extensive tissue destruction and an aggressive, rapidly progressive clinical course associated with significant morbidity and mortality rates. High-dose penicillin and chest tube drainage are indicated for treatment of empyema. Vancomycin is an acceptable substitute in penicillin-allergic patients.

Group A streptococci can cause **endocarditis**. This complication should be suspected when bacteremia accompanies pneumonia, particularly if the patient abuses parenteral drugs. The tricuspid valve is most commonly involved. Endocarditis should be treated with 4 million units of penicillin G every 4 hours for 4 weeks. Vancomycin, 1000 mg every 12 hours, is recommended for persons allergic to penicillin.

Necrotizing fasciitis is a rapidly spreading infection involving the fascia of deep muscle. The clinical findings at presentation may be those of severe cellulitis, but the presence of systemic toxicity and severe pain, which may be followed by anesthesia of the involved area due to destruction of nerves as infection advances through the fascial planes, is a to the diagnosis. Surgical exploration is mandatory when the diagnosis is suspected. Early and extensive debridement is essential for survival.

Any streptococcal infection—and necrotizing fasciitis in particular—can be associated with **streptococcal toxic shock syndrome**, typified by invasion of skin or soft tissues, acute respiratory distress syndrome, and renal failure. The very young, the elderly, and those with underlying medical conditions are at particularly high risk for invasive disease. Bacteremia, uncommon in staphylococcal toxic shock syndrome, occurs in the majority. Skin rash and desquamation may not be present. Mortality rates up to 80% have been reported for patients with the full-blown syndrome. The syndrome is due to elaboration of pyrogenic erythrogenic toxin (which also causes **scarlet fever**), a superantigen that stimulates massive release of inflammatory cytokines felt to mediate the shock. Clindamycin—but not penicillin—inhibits toxin production.

Penicillin remains the drug of choice for treatment of serious streptococcal infections. Some recommend adding clindamycin (600 mg every 8 hours intravenously) for invasive disease, especially in the presence of shock. It has been suggested that a possible survival benefit accrues from administration of intravenous immune globulin for streptococcal toxic shock syndrome. Two dosage regimens show no differences in outcome: 450 mg/kg once daily for 5 days or a single dose of 2 g/kg with a repeat dose at 48 hours if the patient remains unstable. The presumed therapeutic benefit—yet to be proved—may be due to specific antibody to streptococcal exotoxins in immune globulin preparations.

Outbreaks of invasive disease have been associated with colonization by invasive clones that can be transmitted to close contacts who, though asymptomatic, may be a reservoir for disease. Tracing contacts of patients with invasive disease is controversial.

Stevens DL: Streptococcal toxic shock syndrome associated with necrotizing fasciitis. Annu Rev Med 2000;51:271. [\[PMID: 10774464\]](#)

4. Non-Group A Streptococcal Infections

Non-group A streptococci produce a spectrum of disease similar to that of group A streptococci. Some non-group A streptococci are β -hemolytic (eg, groups B, C, and G). The treatment of infections caused by these strains is the same as for group A streptococci.

Group B streptococci are an important cause of sepsis, bacteremia, and meningitis in the neonate. This organism, part of the normal vaginal flora, may cause septic abortion, endometritis, or peripartum infections and, less commonly, cellulitis, bacteremia, and endocarditis in adults. Treatment of infections caused by group B streptococci is with either penicillin or vancomycin in doses recommended for group A streptococci. Because of in vitro synergism, some recommend the addition of low-dose gentamicin, 1 mg/kg every 8 hours.

Viridans streptococci, which are nonhemolytic or α -hemolytic (ie, producing a green zone of hemolysis on blood agar), are part of the normal oral flora. Although these strains may produce focal pyogenic infection, they are most notable as the leading cause of native valve endocarditis (see below).

Group D streptococci include *Streptococcus bovis* and the enterococci. *S bovis* is a cause of endocarditis in association with bowel neoplasia or cirrhosis and is treated like viridans streptococci.

Perovic O et al: Invasive group B streptococcal disease in nonpregnant adults. Eur J Clin Microbiol Infect Dis 1999; 18:362. [\[PMID: 10421045\]](#)

ENTEROCOCCAL INFECTIONS

Two species, *Enterococcus faecalis* and *Enterococcus faecium*, are responsible for most human enterococcal infections. Enterococci cause wound infections, urinary tract infections, and endocarditis. Except for meningitis, endocarditis, bacteremia in the immunocompromised host, and osteomyelitis, enterococcal infections can still be treated with penicillin, 3 million units every 4 hours, ampicillin (which is slightly more active than penicillin in vitro), 2 g every 6 hours, or vancomycin, 1 g every 12 hours. Because these antibiotics are not bactericidal for enterococci, gentamicin in a dose of 1 mg/kg every 8 hours is added for treatment of endocarditis or other serious infection.

Resistance to vancomycin, penicillin, and gentamicin is common among enterococcal isolates, especially *E faecium*; it is essential to determine antimicrobial susceptibility of isolates. Infection control measures that may be indicated to limit their spread include isolation, strict adherence to barrier precautions, and avoidance of overuse of vancomycin and gentamicin. Optimal therapy for infection caused by vancomycin- and gentamicin-resistant strains is not known. Quinupristin/dalfopristin and linezolid are FDA-approved for treatment of infections caused by vancomycin-resistant strains of enterococci. Quinupristin/dalfopristin is not active against strains of *Enterococcus faecalis* and should be used only for infections caused by *E faecium*. The dose is 7.5 mg/kg intravenously every 8-12 hours. Phlebitis and irritation at the infusion site (often requiring a central line) and an arthralgia-myalgia syndrome are relatively common side effects. Quinupristin/dalfopristin has important drug interactions with midazolam, nifedipine, and cyclosporine because it is an inhibitor of cytochrome P450 enzyme 3A4, which metabolizes these drugs. The reported microbiologic success rate is approximately 70% overall. Linezolid, an oxazolidinone, is active against both *E faecalis* and *E faecium*. The dose is 600 mg twice daily, and both intravenous and oral preparations are available. The overall microbiologic cure rate is approximately 85%, though emergence of resistance has occurred during therapy for nosocomial infections. The drug is well tolerated, with hematologic abnormalities as the principal toxicity.

PNEUMOCOCCAL INFECTIONS

1. *Pneumococcal Pneumonia*

Essentials of Diagnosis

- Productive cough, fever, rigors, dyspnea, early pleuritic chest pain.
- Consolidating lobar pneumonia on chest x-ray.
- Gram-positive small diplococci on Gram stain of sputum.

General Considerations

The pneumococcus is the most common cause of community-acquired pyogenic bacterial pneumonia. Alcoholism, HIV infection, sickle cell disease, splenectomy, and hematologic disorders are predisposing factors. The mortality rate remains high in the setting of advanced age, multilobar disease, severe hypoxemia, extrapulmonary complications, and bacteremia.

Clinical Findings

A. Symptoms and Signs

The patient presents with high fever, productive cough, occasionally hemoptysis, and pleuritic chest pain. Rigors occur within the first few hours of infection but are uncommon thereafter. Bronchial breath sounds are an early sign.

B. Laboratory Findings

Pneumococcal pneumonia classically is a lobar pneumonia with radiographic findings of consolidation and occasionally effusion. However, differentiating it from other pneumonias is not possible radiographically or clinically because of significant overlap in presentations. Diagnosis requires isolation of the organism in culture, occurring in only 60% of cases, although the Gram stain appearance of sputum can be suggestive. Sputum and blood cultures should be obtained prior to initiation of antimicrobial therapy in particularly ill patients. A good-quality sputum sample (less than 10 epithelial cells and more than 25 polymorphonuclear leukocytes per high-power field) shows gram-positive diplococci in 80-90% of cases. Sputum culture alone is less sensitive than Gram's stain, and carrier states are common, especially in patients who have contact with children. Blood cultures are positive in up to 25% of cases, and much more commonly so in HIV-positive patients.

Complications

Parapneumonic (sympathetic) effusion is common and may cause recurrence or persistence of fever. These sterile fluid accumulations need no specific therapy. Empyema occurs in 5% or less of cases and is differentiated from sympathetic effusion by the presence of organisms on Gram-stained fluid or positive pleural fluid cultures.

Pneumococcal pericarditis is a rare complication that can cause tamponade. Pneumococcal arthritis also is uncommon. Pneumococcal endocarditis usually involves the aortic valve and often occurs in association with meningitis and pneumonia. Early heart failure and multiple embolic events are typical.

Treatment

A. Specific Measures

Initial antimicrobial therapy of pneumonia is empirical (see [Chapter 9](#) for specific recommendations) pending isolation and identification of the causative agent. Once the pneumonia is determined to be caused by *S pneumoniae*, any of several antimicrobial agents may be used depending on the clinical setting, community patterns of penicillin resistance, and susceptibility of the particular isolate. Uncomplicated pneumococcal pneumonia (ie, arterial PO₂ > 60 mm Hg, no coexisting medical problems, and single-lobe disease without signs of extrapulmonary infection) caused by penicillin-susceptible strains of pneumococcus may be treated on an outpatient basis with amoxicillin, 750 mg twice daily for 7-10 days. For penicillin-allergic patients, alternatives are azithromycin, one 500-mg dose on the first day and 250 mg for the next 4 days, clarithromycin, 500 mg twice daily for 10 days, or doxycycline, 200 mg twice daily for 10 days. Patients should be followed for clinical response (eg, less cough, defervescence within 2-3 days) because pneumococci have become increasingly resistant to penicillin and the second-line agents.

Parenteral therapy is generally recommended for the hospitalized patient at least until there has been clinical improvement. Aqueous penicillin G, 2 million units intravenously every 4 hours, is effective for strains that are not highly penicillin-resistant (ie, MIC > 1 ug/mL). A low-dose regimen of procaine penicillin, 600,000 units intramuscularly every 12 hours, can be used for pneumonia caused by penicillin-sensitive strains (MIC < 0.1 ug/mL). For penicillin-allergic patients without a history of immediate hypersensitivity reaction, ceftriaxone, 1 g intravenously every 24 hours, may be used. For serious penicillin allergy of infection caused by a highly penicillin-resistant strain, vancomycin, 1 g every 12 hours, is effective. Alternatively, a fluoroquinolone (eg, levofloxacin, 500 mg, or a comparable dose of any one of several newer fluoroquinolones now on the market, orally or intravenously) can be used. The total duration of therapy is not well defined, though a duration of 10-14 days is standard. Although uncommon, primary and acquired resistance to fluoroquinolones may eventually limit the utility of this drug class.

B. Treatment of Complications

Pleural effusions developing after initiation of antimicrobial therapy usually are sterile, and thoracentesis need not be performed if the patient is otherwise improving. Thoracentesis is indicated for an effusion present prior to initiation of therapy and in the patient who has not responded to antibiotics after 3-4 days. Chest tube drainage may be required if pneumococci are identified by culture or Gram stain, especially if aspiration of the fluid is difficult.

Echocardiography should be done if pericardial effusion is suspected. Patients with pericardial effusion who are responding to therapy and have no signs of tamponade may be followed and treated with indomethacin, 50 mg three times daily, for pain. In patients with increasing effusion, unsatisfactory clinical response, or evidence of tamponade, pericardiocentesis will determine if the pericardial space is infected. Infected fluid must be drained either percutaneously (by tube placement or needle aspiration), by placement of a pericardial window, or by pericardiectomy. Pericardiectomy eventually may be required to prevent or treat constrictive pericarditis, a common sequela of bacterial pericarditis.

Endocarditis should be treated with 24 million units of penicillin G intravenously (or vancomycin, 30 mg/kg/d, for penicillin-allergic patients or for infections caused by penicillin-resistant strains) daily for 3-4 weeks. Mild heart failure may respond to medical therapy, but moderate to severe heart failure is an indication for prosthetic valve implantation, as are systemic emboli or large friable vegetations as determined by echocardiography.

C. Penicillin-Resistant Pneumococci

The prevalence of penicillin-resistant pneumococci (MIC > 0.1 ug/mL) in the United States is increasing, accounting for 10-15% of bloodstream isolates in some regions. All blood and cerebrospinal fluid isolates should now be tested for resistance to penicillin. Pneumonia caused by intermediately resistant strains (penicillin MIC > 0.1 ug/mL but = 1 ug/mL) generally will respond to high-dose penicillin therapy. High-dose penicillin is likely to be effective for infections other than meningitis caused by highly penicillin-resistant strains (MIC > 1 ug/mL). However, ceftriaxone, 1 g once daily, or vancomycin, 1 g every 12 hours, results in a more favorable ratio between serum drug concentration and MIC and may be preferred, especially for immunocompromised patients. Fluoroquinolones with enhanced gram-positive activity (eg, levofloxacin 500 mg once daily, moxifloxacin 400 mg once daily, or gatifloxacin 400 mg once daily) are effective oral alternatives. Penicillin-resistant strains of pneumococci often are resistant to multiple antibiotics, including macrolides, trimethoprim-sulfamethoxazole, and chloramphenicol, and susceptibility must be documented prior to their use.

Pallares R: Treatment of pneumococcal pneumonia. Semin Respir Infect 1999;14:276. [\[PMID: 10501315\]](#)

2. *Pneumococcal Meningitis*

Essentials of Diagnosis

- Fever, headache, altered mental status.
- Meningismus.
- Gram-positive diplococci on Gram stain of cerebrospinal fluid; counterimmunoelectrophoresis may be positive in partially treated cases.

General Considerations

Streptococcus pneumoniae is the most common cause of meningitis in adults and the second most common cause of meningitis in children over the age of 6 years. Head trauma, with cerebrospinal fluid leaks, sinusitis, and pneumonia may precede it.

Clinical Findings

A. Symptoms and Signs

The onset is rapid, with fever, headache, and altered mentation. Pneumonia may be present. Compared with meningitis caused by the meningococcus, pneumococcal meningitis lacks a rash, and focal neurologic deficits, cranial nerve palsies, and obtundation are more prominent features.

B. Laboratory Findings

The cerebrospinal fluid typically has more than 1000 white blood cells per microliter, over 60% of which are polymorphonuclear leukocytes; the glucose concentration is less than 40 mg/dL, or less than 50% of the simultaneous serum concentration; and the protein usually exceeds 150 mg/dL. Not all cases of meningitis will have these typical findings, and alterations in cerebrospinal fluid cell counts and chemistries may be surprisingly minimal, overlapping with those of aseptic meningitis.

Gram stain of cerebrospinal fluid shows gram-positive cocci in 80-90% of cases, and in untreated cases blood or cerebrospinal fluid cultures are almost always positive. Tests such as counterimmunoelectrophoresis or latex agglutination to detect pneumococcal antigens in cerebrospinal fluid are less sensitive than culture and Gram stain but may be helpful in establishing the diagnosis in patients who have been partially treated and in whom cultures and stains are negative.

Treatment

Antibiotics are given as soon as the diagnosis is suspected. If lumbar puncture must be delayed (eg, while awaiting results of an imaging study to exclude a mass lesion), ceftriaxone, 4 g, is given intravenously after blood cultures (positive in 50% of cases) have been obtained. If gram-positive diplococci are present on the Gram stain, then vancomycin, 45 mg/kg/d intravenously in three divided doses, should be administered in addition to ceftriaxone until the isolate is confirmed not to be penicillin-resistant. Once susceptibility to penicillin has been confirmed, penicillin, 24 million units daily in six divided doses, ceftriaxone, 4 g/d, or chloramphenicol, 6 g/d in four divided doses, is continued for 10-14 days in documented cases.

The best therapy for penicillin-resistant strains is not known. Penicillin-resistant strains often are cross-resistant to the third-generation cephalosporins as well as other antibiotics. Susceptibility testing is essential to proper management of this infection. Treatment failures have been reported with ceftriaxone or cefotaxime for meningitis caused by strains with penicillin MICs = 2 ug/mL. If the MIC of ceftriaxone or cefotaxime is = 0.5 ug/mL, single-drug therapy with either of these cephalosporins is likely to be effective; when the MIC is = 1 ug/mL, treatment with a combination of ceftriaxone, 2 g every 12 hours, plus vancomycin, 45 mg/kg/d in three divided doses, is recommended. If a patient with a penicillin-resistant organism has not responded to a third-generation cephalosporin, repeat lumbar puncture is indicated to assess the bacteriologic response.

Dexamethasone administered with antibiotic to adults has been associated with a 60% reduction in mortality and a 50% reduction in unfavorable outcomes. It is recommended that adults with acute bacterial meningitis be given 10 mg of dexamethasone intravenously immediately prior to or concomitantly with the first dose of appropriate antibiotic and every 6 hours thereafter for a total of 4 days. Because anti-inflammatory activity could impair penetration of some drugs into the cerebrospinal fluid, patients infected with penicillin-resistant organisms—particularly if vancomycin is being used—are potential treatment failures.

STAPHYLOCOCCUS AUREUS INFECTIONS

1. Skin & Soft Tissue Infections

Essentials of Diagnosis

- Localized erythema with induration.
- Tendency toward abscess formation.
- Folliculitis commonly observed.
- Gram stain of pus with gram-positive cocci in clusters; cultures usually positive.

General Considerations

Most staphylococci found on cultures of normal skin belong to the *Staphylococcus epidermidis* group. *Staphylococcus aureus* is not normal skin flora. *S aureus* tends to cause more localized skin infections than streptococci, and abscess formation is common.

Clinical Findings

A. Symptoms and Signs

S aureus skin infections may begin around one or more hair follicles, causing folliculitis. These infections may localize to form boils (or furuncles) or spread to adjacent skin and deeper subcutaneous tissue (ie, a carbuncle). Myositis or fasciitis may occur, often in association with a deep wound or other inoculation or injection.

B. Laboratory Findings

Cultures of the wound or abscess material will almost always yield the organism. In patients with other systemic signs of infection, blood cultures should be obtained because of potential endocarditis, osteomyelitis, or metastatic seeding of other sites.

Treatment

Proper drainage of abscess fluid or other focal infections is the mainstay of therapy. Drainage may be all that is needed for cutaneous abscess. Antibiotic therapy alone is unlikely to be effective if collections of infected material are undrained.

For uncomplicated skin infections, oral therapy is satisfactory. An oral penicillinase-resistant penicillin or cephalosporin, such as dicloxacillin or cephalexin, 500 mg four times a day for 7-10 days, is the drug of choice. Erythromycin, 500 mg four times a day, may be used in the penicillin-allergic patient, although the prevalence of erythromycin-resistant strains (40-60%) makes this regimen less attractive.

For more complicated infections with extensive cutaneous or deep tissue involvement or fever, parenteral therapy is indicated initially. A penicillinase-resistant penicillin such as nafcillin or oxacillin in a dosage of 1.5 g every 6 hours intravenously is preferred. In allergic patients without a serious reaction, cefazolin, 0.5-1 g intravenously or intramuscularly every 8 hours, can be used. In patients with a serious allergy to β -lactam antibiotics or if the strain is methicillin-resistant, vancomycin, 1000 mg intravenously every 12 hours, is the drug of choice.

2. Osteomyelitis

S aureus is the cause of approximately 60% of all cases of osteomyelitis. Osteomyelitis may be caused by direct inoculation, eg, from an open fracture or as a result of surgery; by extension from a contiguous focus of infection or open wound; or, more commonly, by hematogenous spread. Long bones and vertebrae are the usual sites. Epidural abscess is a common complication of vertebral osteomyelitis and should be suspected if fever and severe back or neck pain are accompanied by radicular pain or symptoms or signs indicative of spinal cord compression (eg, incontinence, extremity weakness, pathologic reflexes).

Clinical Findings

A. Symptoms and Signs

The infection may be acute, with abrupt development of local symptoms and systemic toxicity, or indolent, with insidious onset of vague pain over the site of infection, progressing to local tenderness. Fever is absent in one-third or more of cases. Abscess formation is a late and unusual manifestation. Draining sinus tracts occur in chronic infections or infections of foreign body implants.

B. Laboratory Findings

The diagnosis is established by isolation of *S aureus* from the blood, bone, or a contiguous focus of a patient with signs and symptoms of focal bone infection. Blood culture will be positive in approximately 60% of untreated cases. Bone biopsy and culture are considered if blood cultures are sterile.

C. Imaging

Bone scan and gallium scan, each with a sensitivity of approximately 95% and a specificity of 60-70%, are useful in identifying or confirming the site of bone infection. Plain bone films early in the course of infection are often normal but will become abnormal in most cases even with effective therapy. Spinal infection (unlike malignancy) traverses the disk space to involve the contiguous vertebral body. CT is more sensitive than plain films and helps localize associated abscesses. MRI is somewhat less sensitive than bone scan but has a specificity of 90%. It is indicated when epidural abscess is suspected in association with vertebral osteomyelitis.

Treatment

Prolonged therapy is required to cure staphylococcal osteomyelitis. Durations of 4-6 weeks or longer are recommended. Although oral regimens can be effective, parenteral regimens are advised during the acute phase of the infection for patients with systemic toxicity. Nafcillin or oxacillin, 9-12 g/d in six divided doses, is the drug of choice. Cefazolin, 1 g every 6-8 hours, also is effective. Vancomycin, 1 g every 12 hours, may be used for the penicillin-allergic patient.

Oral regimens are dicloxacillin or cephalexin, 1 g every 6 hours. Addition to the regimen of rifampin, 300 mg twice daily, probably prevents late relapse and should be strongly considered. For example, an oral regimen of ciprofloxacin, 750 mg, plus rifampin, 300 mg twice daily, improved outcome in implant-related staphylococcal infections, which are very prone to relapse.

Zimmerli W et al: Role of rifampin for treatment of orthopedic implant-related staphylococcal infections: a randomized controlled trial. Foreign-Body Infection Study Group. JAMA 1998;279:1537. [\[PMID: 9605897\]](#)

3. Staphylococcal Bacteremia

S aureus readily invades the bloodstream and infects sites distant from the primary site of infection, which may be relatively minor or even inapparent. Though commonly arising from skin lesions or intravenous lines, whenever *S aureus* is recovered from blood cultures, the possibility of endocarditis, osteomyelitis, or other metastatic deep infection must be considered. The appropriate duration of therapy for uncomplicated bacteremia arising from a removable source (eg, intravenous device) or drainable focus (eg, skin abscess) has not been well defined, but a 10- to 14-day course of therapy appears to be the minimum. However, 5% or more of patients relapse, usually with endocarditis or osteomyelitis, even if treated for 2 weeks.

Nafcillin or oxacillin, 1.5 g intravenously every 4-6 hours, cefazolin, 500-1000 mg every 8 hours, or vancomycin, 1000 mg every 12 hours, is recommended for uncomplicated staphylococcal bacteremia. Vancomycin should be reserved for patients with serious penicillin allergy or with infections caused by methicillin-resistant strains because it is less active than β -lactam antibiotics. Longer courses of either parenteral or oral therapy may be considered for patients (eg, those with diabetes, immunocompromised persons) at risk for late complications from bacteremia and for those in whom endocarditis is suspected. Transesophageal echocardiography (TEE) is a sensitive and cost-effective method for excluding underlying endocarditis. It is considered for patients for whom the pretest probability of endocarditis is 5% or higher—and perhaps for all patients with unexplained *S aureus* bacteremia.

Treatment failures occur with intermediate-resistant strains in foreign body infections, in association with prolonged or repeated courses of vancomycin therapy, and in patients with chronic renal failure. These strains have also been resistant to methicillin and numerous other antibiotics, severely limiting therapeutic options. An antistaphylococcal penicillin in combination with vancomycin may be synergistic in vitro against vancomycin-resistant strains and is an option for infections that do not respond to vancomycin alone.

Empirical therapy of suspected staphylococcal infection, whether of community or hospital onset, depends on the severity of the infection and the likelihood that it is caused by methicillin-resistant strains. If the prevalence exceeds 5-10% for more seriously ill patients, initial therapy should include vancomycin, 1 g every 12 hours (for patients with normal renal function), until results of susceptibility tests are known. Resistance to vancomycin remains rare and should not affect the choice of empirical therapy, though with continuing use emergence of staphylococci resistant to this drug merits concern. Cases of vancomycin treatment failures in which the staphylococcal isolate exhibits a vancomycin MIC = 4 ug/mL should be reported to CDC to help track this potentially serious and emerging problem.

4. Toxic Shock Syndrome

Strains of staphylococci may produce toxins that can cause three important entities: "scalded skin syndrome" in children, toxic shock syndrome in adults, and enterotoxin food poisoning. Toxic shock syndrome is characterized by abrupt onset of high fever, vomiting, and watery diarrhea. Sore throat, myalgias, and headache are common. Hypotension with renal and cardiac failure is associated with a poor outcome. A diffuse macular erythematous rash and nonpurulent conjunctivitis are common, and desquamation, especially of palms and soles, is typical during recovery. Fatality rates may be as high as 15%. Although toxic shock syndrome has occurred in men, most cases (90% or more) have been reported in women of childbearing age. Of these, symptoms begin in nearly all patients within 5 days of the onset of a menstrual period in women who have used tampons. The syndrome is possible in any patient with a focus of toxin-producing *S aureus*. Nonmenstrual cases of toxic shock syndrome are now about as common as menstrual cases. Organisms from various sites, including the nasopharynx, bones, vagina, or rectum, or from wounds have all been associated with the illness. Toxic shock syndrome toxin-1 (TSST-1) is the most common cause. Nonmenstrual cases of toxic shock syndrome are frequently caused by strains that do not produce TSST-1. Blood cultures are negative, because symptoms are due to the effects of the toxin and not to the invasive properties of the organism.

Important aspects of treatment include rapid rehydration, antistaphylococcal drugs, management of renal or cardiac failure, and addressing sources of toxin, eg, removal of tampon or drainage of abscess. Intravenous immune globulin may be effective in ameliorating toxicity.

5. Infections Caused by Coagulase-Negative Staphylococci

Coagulase-negative staphylococci are an important cause of infections of intravascular and prosthetic devices and of wound infection following cardiothoracic surgery. Rarely, these organisms cause infections such as osteomyelitis and endocarditis in the absence of a prosthesis. Most human infections are caused by *Staphylococcus epidermidis*, *S haemolyticus*, *S hominis*, *S warnerii*, *S saprophyticus*, *S saccharolyticus*, and *S cohnii*. These common nosocomial pathogens are less virulent than *S aureus*, and infections caused by them tend to be more indolent.

Because coagulase-negative staphylococci are normal inhabitants of human skin, it is difficult to distinguish infection from contamination, the latter perhaps accounting for three-fourths of blood culture isolates. Infection is more likely if the patient has a foreign body (eg, sternal wires, prosthetic joint, prosthetic cardiac valve, pacemaker, intracranial pressure monitor, cerebrospinal fluid shunt, peritoneal dialysis catheter) or an intravascular device in place. Purulent or serosanguineous drainage, erythema, pain, or tenderness at the site of the foreign body or device suggests infection. Instability and pain are signs of prosthetic joint infection. Fever, a new murmur, instability of the prosthesis, or signs of systemic embolization are evidence of prosthetic valve endocarditis. Immunosuppression and recent antimicrobial therapy also are risk factors.

Infection is also more likely if the same strain is consistently isolated from two or more blood cultures (particularly if samples were obtained at different times) and from the foreign body site. Contamination is more likely when a single blood culture is positive or if more than one strain is isolated from blood cultures. The antimicrobial susceptibility pattern and speciation are used to determine whether one or more strains have been isolated. More sophisticated typing methods, eg, pulse-field gel electrophoresis of restriction enzyme digested chromosomal DNA, may be required to identify distinct strains.

Whenever possible, the intravascular device or foreign body suspected of being infected by coagulase-negative staphylococci should be removed. However, removal and replacement of some devices (eg, prosthetic joint, prosthetic valve, cerebrospinal fluid shunt) can be a difficult or risky procedure, and it may sometimes be preferable to treat with antibiotics alone with the understanding that the probability of cure is reduced and that surgical management may eventually be necessary.

Coagulase-negative staphylococci are commonly resistant to methicillin and multiple other antibiotics. For patients with normal renal function, vancomycin, 1 g intravenously every 12 hours, is the treatment of choice for suspected or confirmed infection caused by these organisms until susceptibility to penicillinase-resistant penicillins or other agents has been confirmed. Duration of therapy has not been established for relatively uncomplicated infections, such as those secondary to intravenous devices, which may be eliminated by simply removing the infected device. Infection involving bone or a prosthetic valve should be treated for 6 weeks. A combination regimen of vancomycin plus rifampin, 300 mg orally twice daily, and gentamicin, 1 mg/kg intravenously every 8 hours, is recommended for treatment of prosthetic valve endocarditis caused by methicillin-resistant strains.

CLOSTRIDIAL DISEASES

1. Clostridial Myonecrosis (Gas Gangrene)

Essentials of Diagnosis

- Sudden onset of pain and edema in an area of wound contamination.
- Prostration and systemic toxicity.
- Brown to blood-tinged watery exudate, with skin discoloration of surrounding area.
- Gas in the tissue by palpation or x-ray.
- Gram-positive rods in culture or smear of exudate.

General Considerations

Gas gangrene or clostridial myonecrosis is produced by entry of one of several clostridia (*Clostridium perfringens*, *Clostridium ramosum*, *Clostridium bifermentans*, *Clostridium histolyticum*, *Clostridium novyi*, etc) into devitalized tissues. Toxins produced under anaerobic conditions result in shock, hemolysis, and myonecrosis.

Clinical Findings

A. Symptoms and Signs

The onset is usually sudden, with rapidly increasing pain in the affected area, hypotension, and tachycardia. Fever is present but is not proportionate to the severity of the infection. In the last stages of the disease, severe prostration, stupor, delirium, and coma occur.

The wound becomes swollen, and the surrounding skin is pale. There is a foul-smelling brown, blood-tinged serous discharge. As the disease advances, the surrounding tissue changes from pale to dusky and finally becomes deeply discolored, with coalescent, red, fluid-filled vesicles. Gas may be palpable in the tissues.

B. Laboratory Findings

Gas gangrene is a clinical diagnosis, and empirical therapy is indicated if the diagnosis is suspected. Radiographic studies may show gas within the soft tissues, but this finding is not specific. The smear shows a remarkable absence of neutrophils and the presence of gram-positive rods. Anaerobic culture confirms the diagnosis.

Differential Diagnosis

Other types of infection can cause gas formation in the tissue, eg, enterobacter, escherichia, and mixed anaerobic infections including bacteroides and peptostreptococci. Clostridia may produce serious puerperal infection with hemolysis due to a lecithinase elaborated by the organism.

Treatment

Penicillin, 2 million units every 3 hours intravenously, is effective. Other agents (eg, tetracycline, clindamycin, metronidazole, chloramphenicol, cefoxitin) are active against clostridium species in vitro and probably in vivo as well. Adequate surgical debridement and exposure of infected areas are essential, with radical surgical excision often necessary. Hyperbaric oxygen therapy has been used empirically but must be used in conjunction with administration of an appropriate antibiotic and surgical debridement.

Petit L et al: *Clostridium perfringens*: toxinotype and genotype. Trends Microbiol 1999;7:104. [PMID: 10203838]

2. Tetanus

Essentials of Diagnosis

- History of wound and possible contamination.
- Jaw stiffness followed by spasms of jaw muscles (trismus).
- Stiffness of the neck and other muscles, dysphagia, irritability, hyperreflexia.
- Finally, painful convulsions precipitated by minimal stimuli.

General Considerations

Tetanus is caused by the neurotoxin tetanospasmin, elaborated by *Clostridium tetani*. Spores of this organism are ubiquitous in soil. When introduced into a wound, spores may germinate. The vegetative bacteria produce tetanospasmin, a zinc metalloprotease that cleaves synaptobrevin, a protein essential for neurotransmitter release. Tetanospasmin interferes with neurotransmission at spinal synapses of inhibitory neurons. As a result, minor stimuli result in uncontrolled spasms, and reflexes are exaggerated. The incubation period is 5 days to 15 weeks, with the average being 8-12 days.

Most cases occur in unvaccinated individuals. Persons at risk are the elderly, migrant workers, newborns, and injection drug users, who may acquire the disease through subcutaneous injections. While puncture wounds are recognized as particularly prone to causing tetanus, any wound, including decubiti, where dead tissue and anaerobic conditions are present may become colonized and infected by *C tetani*.

Clinical Findings

A. Symptoms and Signs

The first symptom may be pain and tingling at the site of inoculation, followed by spasticity of the muscles nearby. Stiffness of the jaw, neck stiffness, dysphagia, and irritability are other early signs. Hyperreflexia develops later, with spasms of the jaw muscles (trismus) or facial muscles and rigidity and spasm of the muscles of the abdomen, neck, and back. Painful tonic convulsions precipitated by minor stimuli are common. Spasms of the glottis and respiratory muscles may cause acute asphyxia. The patient is awake and alert throughout the illness. The sensory examination is normal. The temperature is normal or only slightly elevated.

B. Laboratory Findings

The diagnosis of tetanus is made clinically.

Differential Diagnosis

Tetanus must be differentiated from various acute central nervous system infections such as meningitis. Trismus may occasionally develop with the use of phenothiazines. Strychnine poisoning should also be considered.

Complications

Airway obstruction is common. Urinary retention and constipation may result from spasm of the sphincters. Respiratory arrest and cardiac failure are late, life-threatening events.

Prevention

Tetanus is completely preventable by active immunization. Immunizations for children include tetanus toxoid, usually as DTP (see [Table 30-4](#) for schedule). For primary immunization of adults, tetanus toxoid is administered as two doses 4-6 weeks apart, with a third dose 6-12 months later. Booster doses are given every 10 years or at the time of major injury if it occurs more than 5 years after a dose.

Passive immunization should be used in nonimmunized individuals and those whose immunization status is uncertain whenever a wound is contaminated or likely to have devitalized tissue. Tetanus immune globulin, 250 units, is given intramuscularly. Active immunization with tetanus toxoid is started concurrently. [Table 33-1](#) provides a guide to prophylactic management.

Treatment

A. Specific Measures

Tetanus immune globulin, 5000 units, is administered intramuscularly. Tetanus does not produce natural immunity, and a full course of immunization with tetanus toxoid should be administered once the patient has recovered.

B. General Measures

Minimal stimuli can provoke spasms, so the patient should be placed at bed rest and monitored under the quietest conditions possible. Sedation, paralysis with curare-like agents, and mechanical ventilation are often necessary to control tetanic spasms. Penicillin, 20 million units daily, is given to all patients—even those with mild illness—to eradicate toxin-producing organisms.

Prognosis

High mortality rates are associated with a short incubation period, early onset of convulsions, and delay in treatment. Contaminated lesions about the head and face are more dangerous than wounds on other parts of the body. The overall mortality rate historically is about 40%, but this can be considerably reduced with ventilator management as described.

Hsu SS et al: Tetanus in the emergency department: a current review. J Emerg Med 2001;20:357. [\[PMID: 11348815\]](#)

3. Botulism

Essentials of Diagnosis

- History of recent ingestion of home-canned or smoked foods or of injection drug use and demonstration of toxin in serum or food.
- Sudden onset of diplopia, dry mouth, dysphagia, dysphonia, and muscle weakness progressing to respiratory paralysis.
- Pupils are fixed and dilated in most cases.

General Considerations

Botulism is a paralytic disease caused by botulinum toxin, which is produced by *Clostridium botulinum*, a ubiquitous, strictly anaerobic, spore-forming bacillus found in soil. Four toxin types—A, B, E, and F—cause human disease. Botulinum toxin is a zinc metalloprotease that inhibits release of acetylcholine at the neuromuscular junction by cleaving a specific component of the synaptic vesicle membrane docking and fusion complex. Early nervous system involvement leads to respiratory paralysis and death in untreated cases. Botulinum toxin is extremely potent and is classified by the Centers for Disease Control and Prevention as a high-priority agent because of its potential for use as an agent of bioterrorism. Naturally occurring botulism occurs in one of three forms: food-borne botulism, infant botulism, or wound botulism. Food-borne botulism is caused by ingestion of preformed toxin present in canned, smoked, or vacuum-packed foods such as home-canned vegetables, smoked meats, and vacuum-packed fish. Commercial foods have also been associated with outbreaks of botulism. Infant botulism (associated with ingestion of honey) and wound botulism (which typically occurs in association with injection drug use) result from organisms present in the gut or wound that elaborate toxin in vivo.

Clinical Findings

A. Symptoms and Signs

Twelve to 36 hours after ingestion of the toxin, visual disturbances appear, particularly diplopia and loss of accommodation. Ptosis, cranial nerve palsies with impairment of extraocular muscles, and fixed dilated pupils are characteristic signs. The sensory examination is normal. Other symptoms are dry mouth, dysphagia, and dysphonia. Nausea and vomiting may be present, particularly with type E toxin. The sensorium remains clear and the temperature normal. Respiratory paralysis may lead to death unless mechanical assistance is provided.

B. Laboratory Findings

Toxin in patients' serum and in suspected foods may be shown by mouse inoculation and identified with specific antiserum.

Differential Diagnosis

Cranial nerve involvement suggests vertebrobasilar insufficiency, the C. Miller Fisher variant of Guillain-Barre syndrome, myasthenia gravis, or any basilar meningitis, infectious or carcinomatous. Intestinal obstruction or other types of food poisoning are considered when nausea and vomiting are present.

Treatment

If botulism is suspected, the physician should contact the state health authorities or the Centers for Disease Control and Prevention for advice and help with procurement of botulinus antitoxin and for assistance in obtaining assays for toxin in serum, stool, or food. During off hours, the CDC provides assistance via a recorded message at 404-639-2206.

Respiratory failure is managed with intubation and mechanical ventilation. Parenteral fluids or alimentation should be given while swallowing difficulty persists.

The removal of unabsorbed toxin from the gut may be attempted. Any remnants of suspected foods should be assayed for toxin. Persons who might have eaten the suspected food must be located and observed.

ANTHRAX

Essentials of Diagnosis

- Appropriate epidemiologic setting, eg, exposure to animals or animal hides, or potential exposure resulting from an act of bioterrorism.

- A cutaneous black eschar, typically painless and on exposed areas of the skin, with marked surrounding edema and vesicles.
- Nonspecific flu-like symptoms that rapidly progress to extreme dyspnea and shock in association with mediastinal widening and pleural effusions on chest x-ray.

General Considerations

The death of a Florida photo editor from inhalational anthrax acquired from a letter deliberately contaminated with spores of *Bacillus anthracis* thrust this extremely rare infection into the public awareness. Between September 18 and November 21 of 2001, there were 13 cases of cutaneous anthrax and 11 cases of inhalational anthrax in association with known or presumed exposure to anthrax spores in contaminated mail.

Naturally occurring anthrax is a disease of sheep, cattle, horses, goats, and swine. *B. anthracis* is a gram-positive spore-forming aerobic rod. Spores—not vegetative bacteria—are the infectious form of the organism. These are transmitted to humans from contaminated animals, animal products, or soil by inoculation of broken skin or mucous membranes; by inhalation of aerosolized spores; or, rarely, by ingestion resulting in cutaneous, inhalational, or gastrointestinal forms of anthrax, respectively. The spores germinate into vegetative bacteria that multiply locally in cutaneous and gastrointestinal anthrax but may also disseminate to cause systemic infection. Spores entering the lungs are ingested by macrophages and carried via lymphatics to regional lymph nodes, where they germinate. The bacteria rapidly multiply within the lymphatics, causing a hemorrhagic lymphadenitis. Invasion of the bloodstream leads to overwhelming sepsis, killing the host. Virulence is determined by two plasmids, pXO1 and pXO2, which carry, respectively, genes for two toxins, lethal toxin and edema toxin, and genes for capsule production. Loss of either plasmid attenuates strain virulence. Edema toxin impairs neutrophil function and probably is responsible for the striking edema present in cutaneous anthrax. Lethal factor is thought to mediate the shock syndrome. The capsule allows the bacteria to evade host immune defenses.

Clinical Findings

A. Symptoms and Signs

1. Cutaneous anthrax—This occurs within 2 weeks after exposure to spores; there is no latency period for cutaneous disease. The initial lesion is an erythematous papule, often on an exposed area of skin, that vesiculates and then ulcerates and undergoes necrosis, ultimately progressing to a purple to black eschar. The eschar typically is painless; pain indicates secondary staphylococcal or streptococcal infection. The surrounding area is edematous and vesicular but not purulent. Regional adenopathy, fever, malaise, headache, and nausea and vomiting may be present. The infection is self-limited in most cases, but hematogenous spread with sepsis or meningitis may occur.

2. Inhalational anthrax—Onset of illness, which occurs in two stages, begins on average 10 days after exposure, although a longer incubation period of up to 6 weeks can occur. Nonspecific viral-like symptoms such as fever, malaise, headache, dyspnea, cough, and congestion of the nose, throat, and larynx are characteristic of the initial stage. Anterior chest pain is an early symptom of mediastinitis. Within hours to a few days, progression to the fulminant stage of infection occurs in which signs and symptoms of overwhelming sepsis predominate. Delirium, obtundation, or findings of meningeal irritation suggest an accompanying hemorrhagic meningitis.

3. Gastrointestinal anthrax—This form has not been reported in the United States. Symptoms begin 2-5 days after ingestion of meat contaminated with anthrax spores. Fever, diffuse abdominal pain, rebound abdominal tenderness, vomiting, constipation, and diarrhea occur. Because the primary lesion is ulcerative, emesis is blood-tinged or coffee-grounds and stool may be blood-tinged or melenic. Bowel perforation can occur. The oropharyngeal form of the disease is characterized by local lymphadenopathy, cervical edema, dysphagia, and upper respiratory tract obstruction.

B. Laboratory Findings

Laboratory findings are nonspecific. The white blood cell count initially may be normal or modestly elevated, with polymorphonuclear predominance and an increase in early forms. Pleural fluid from patients with inhalational anthrax is typically hemorrhagic with a relative paucity of white cells. Cerebrospinal fluid from meningitis cases is also hemorrhagic. Gram stain of fluid from a cutaneous lesion, pleural fluid, cerebrospinal fluid, unspun blood, or blood culture may show the characteristic boxcar-shaped encapsulated rods in chains.

The diagnosis is established by isolation of the organism from culture of the skin lesion (or fluid expressed from it), blood, or pleural fluid—or cerebrospinal fluid in cases of meningitis. In the absence of prior antimicrobial therapy, cultures are invariably positive. Cultures obtained after initiation of antimicrobial therapy may be negative. If anthrax is suspected on clinical or epidemiologic grounds, immunohistochemical tests (eg, to detect capsular antigen), polymerase chain reaction assays, and serologic tests (useful for documenting past cutaneous infection) are available through the CDC and should be utilized to establish the diagnosis. Any suspected case of anthrax should be immediately reported to CDC so that a complete investigation can be conducted.

C. Imaging Studies

The chest x-ray is the most sensitive test for inhalational disease, being abnormal (though the findings can be subtle) initially in every case of bioterrorism-associated disease. Mediastinal widening due to hemorrhagic lymphadenitis, a hallmark feature of the disease, has been present in 70% of the bioterrorism-related cases. Pleural effusions were present initially or occurred over the course of illness in all cases, and approximately three-fourths had pulmonary infiltrates or signs of consolidation.

Differential Diagnosis

Cutaneous anthrax, despite its characteristic appearance, can be confused with a variety of other also uncommon or rare conditions such as ecthyma gangrenosum, rat-bite fever, ulceroglandular tularemia, plague, glanders, rickettsialpox, orf (parapoxvirus infection), or cutaneous mycobacterial infection. Inhalational anthrax must be differentiated from mediastinitis due to other bacterial causes, fibrous mediastinitis due to histoplasmosis, coccidioidomycosis, atypical or viral pneumonia, silicosis, sarcoidosis, and other causes of mediastinal widening (eg, superior vena cava syndrome or aortic aneurysm or dissection). Gastrointestinal anthrax shares clinical features with a variety of common intra-abdominal disorders, including bowel obstruction, perforated viscus, peritonitis, gastroenteritis, and peptic ulcer disease.

Treatment

Strains of *B. anthracis* (including the strain isolated in the bioterrorism cases) are susceptible in vitro to penicillin, amoxicillin, chloramphenicol, clindamycin, imipenem, doxycycline, ciprofloxacin (as well as other fluoroquinolones), macrolides, rifampin, and vancomycin. Susceptibility to cephalosporins is variable. *B. anthracis* may express beta-lactamases that confer resistance to cephalosporins and penicillins. For this reason, penicillin or amoxicillin is no longer recommended for use as a single agent in treatment of disseminated disease. Based on results of animal experiments and because of concern for engineered drug resistance in strains of *B. anthracis* used in bioterrorism or weaponized, ciprofloxacin is considered the drug of choice ([Table 33-2](#)) for treatment and for prophylaxis following exposure to anthrax spores. Other fluoroquinolones with activity against gram-positive bacteria (eg, levofloxacin, gatifloxacin, moxifloxacin), though they have not been formally tested, are likely to be just as effective. Doxycycline is an alternative first-line agent. Combination therapy with at least one additional agent is recommended for inhalational or disseminated disease and in cutaneous infection involving the face, head, and neck or associated with extensive local edema or systemic signs of infection, eg, fever, tachycardia, and elevated white blood cell count. Anecdotally, four of the six survivors of the recent inhalational cases were treated with combinations that included both a fluoroquinolone and rifampin. Single-drug therapy is recommended for prophylaxis following exposure to spores.

The required duration of therapy is poorly defined. In naturally occurring disease, treatment for 7-10 days for cutaneous disease and for at least 2 weeks following clinical response for disseminated, inhalational, or gastrointestinal infection have been standard recommendations. Because of concern about relapse from latent spores acquired by inhalation of aerosol in bioterrorism-associated cases, the initial recommendation was treatment for 60 days. For postal workers receiving prophylaxis for exposure to contaminated mail, CDC has since set forth two new options: (1) antibiotics for 100 days (fearing that even with 60 days of treatment late relapses might occur) or (2) vaccination with an investigational agent (three doses administered over a 1-month period) in conjunction with 40 days of antibiotic administration to cover the time required for a protective antibody response to develop. There is at present not enough information on which to base a recommendation for any one over another.

There is also an FDA-approved vaccine for persons at high risk of exposure to anthrax spores. The vaccine is cell-free antigen prepared from an attenuated strain of *B. anthracis*. Multiple injections over 18 months and an annual booster dose are required to achieve and maintain protection. Existing supplies have been reserved for vaccination of military personnel.

The prognosis in cutaneous infection is excellent. Death is unlikely if the infection has remained localized, and lesions heal without complications in most cases. The reported mortality rate for gastrointestinal and inhalational infections is up to 85%. The experience with bioterrorism-associated inhalational cases in which six of eleven victims survived suggests a somewhat better outcome with modern supportive care and antibiotics provided that treatment is initiated before the patient has progressed to the fulminant stage of disease. No cases of anthrax have occurred among the several thousand individuals receiving antimicrobial prophylaxis following exposure to spores.

DIPHTHERIA

Essentials of Diagnosis

- Tenacious gray membrane at portal of entry in pharynx.
- Sore throat, nasal discharge, hoarseness, malaise, fever.
- Myocarditis, neuropathy.
- Culture confirms the diagnosis.

General Considerations

Diphtheria is an acute infection, caused by *Corynebacterium diphtheriae*, that usually attacks the respiratory tract but may involve any mucous membrane or skin wound. The organism is spread chiefly by respiratory secretions. Exotoxin produced by the organism is responsible for myocarditis and neuropathy. This exotoxin inhibits elongation factor, which is required for protein synthesis.

Clinical Findings

A. Symptoms and Signs

Nasal, laryngeal, pharyngeal, and cutaneous forms of diphtheria occur. Nasal infection produces few symptoms other than a nasal discharge. Laryngeal infection may lead to upper airway and bronchial obstruction. In pharyngeal diphtheria, the most common form, a tenacious gray membrane covers the tonsils and pharynx. Mild sore throat, fever, and malaise are followed by toxemia and prostration.

Myocarditis and neuropathy are the most common and most serious complications. Myocarditis causes cardiac arrhythmias, heart block, and heart failure. The neuropathy usually involves the cranial nerves first, producing diplopia, slurred speech, and difficulty in swallowing.

B. Laboratory Findings

The diagnosis is made clinically but can be confirmed by culture of the organism.

Differential Diagnosis

Diphtheria must be differentiated from streptococcal pharyngitis, infectious mononucleosis, adenovirus or herpes simplex infection, Vincent's angina, pharyngitis due to *Arcanobacterium haemolyticum*, and candidiasis. A presumptive diagnosis of diphtheria should be made on clinical grounds without waiting for laboratory verification, since emergency treatment is needed.

Prevention

Active immunization with diphtheria toxoid is part of routine childhood immunization (usually as DTP) with appropriate booster injections. The immunization schedule for adults is the same as for tetanus. In order to avoid major allergic reactions, only the "adult type" toxoid (Td) should be used.

Susceptible persons exposed to diphtheria should receive a booster dose of diphtheria toxoid plus active immunization if not previously immunized, as well as a course of penicillin or erythromycin.

Treatment

Antitoxin, which is prepared from horse serum, must be given in all cases when diphtheria is suspected. For mild early pharyngeal or laryngeal disease, the dose is 20,000-40,000 units; for moderate nasopharyngeal disease, 40,000-60,000 units; for severe, extensive, or late (3 days or more) disease, 80,000-100,000 units. Diphtheria equine antitoxin can be obtained from the Centers for Disease Control and Prevention.

Removal of membrane by direct laryngoscopy or bronchoscopy may be necessary to prevent or alleviate airway obstruction.

Either penicillin, 250 mg orally four times daily, or erythromycin, 500 mg orally four times daily, for 14 days is effective therapy, though erythromycin is slightly more effective in eliminating the carrier state. Azithromycin or clarithromycin is quite likely to be as effective as erythromycin. The patient should be isolated until three consecutive cultures at the completion of therapy have documented elimination of the organism from the oropharynx. Contacts to a case should receive erythromycin, 500 mg four times daily for 7 days, to eradicate carriage.

LISTERIOSIS

Listeria monocytogenes is a motile, gram-positive rod that is a facultative intracellular organism capable of invading several cell types. Most cases of infection caused by *L. monocytogenes* are sporadic, but outbreaks have been traced to eating contaminated food, including unpasteurized dairy products, hot dogs, and delicatessen meats. Five types of infection are recognized:

(1) Infection during pregnancy, usually in the last trimester, is a mild febrile illness without an apparent primary focus. This is a relatively benign disease for both mother and fetus that may resolve without specific therapy.

(2) Granulomatosis infantisepticum is a neonatal infection acquired in utero, characterized by disseminated abscesses, granulomas, and a high mortality rate.

(3) Bacteremia with or without sepsis syndrome is an infection of neonates or immunocompromised adults. The presentation is of a febrile illness without a recognized source.

(4) Meningitis caused by *L. monocytogenes* affects infants under 2 months of age and adults, ranking third and fourth, respectively, among the common causes of bacterial meningitis. Adults with meningitis are often immunocompromised, and cases have been associated with HIV infection. Cerebrospinal fluid shows a *neutrophilic* pleocytosis.

(5) Finally, focal infections, including adenitis, brain abscess, endocarditis, osteomyelitis, and arthritis, occur rarely.

Therapy of infections caused by listeria is controversial. The drug of choice is probably ampicillin, 8-12 g/d intravenously in four to six divided doses (the higher dose for meningitis). It has relatively good penetration into cerebrospinal fluid, and the response seems better than that to penicillin, erythromycin, or chloramphenicol. Gentamicin is synergistic with ampicillin against listeria in vitro and in animal models, and the use of combination therapy may be considered during the first few days of treatment to enhance eradication of organisms. Mortality and morbidity rates still are high, and relapses occur, perhaps related to poor penetration of ampicillin into cells where organisms reside. Clinical observations indicating efficacy of trimethoprim-sulfamethoxazole and its excellent cellular and cerebrospinal fluid penetration support its use for therapy of listeriosis. The dose is 10-20 mg/kg/d of the trimethoprim component. Therapy should be administered for at least 2-3 weeks. Longer durations—between 3 and 6 weeks—have been recommended for treatment of meningitis, especially in the immunocompromised.

■ INFECTIVE ENDOCARDITIS

Essentials of Diagnosis

- Preexisting organic heart lesion.
- Fever.
- New or changing heart murmur.
- Evidence of systemic emboli.
- Positive blood culture.
- Evidence of vegetation on echocardiography.

General Considerations

Important factors that determine the clinical presentation are (1) the nature of the infecting organism, (2) which valve or valves are infected, and (3) the route of infection, since endocarditis in intravenous drug users and infections acquired during open heart surgery have special features.

More virulent organisms—*Staphylococcus aureus* in particular—tend to produce a more rapidly progressive and destructive infection. Patients are more likely to present with acute febrile illnesses, early embolization, and acute valvular regurgitation and myocardial abscess formation. Conversely, these organisms can produce a more gradual illness, and more indolent organisms can occasionally cause the acute presentation. Viridans strains of streptococci, enterococci, and a variety of other gram-positive and gram-negative bacilli, yeasts, and fungi tend to cause a more subacute picture. Systemic and peripheral manifestations may predominate. Acute deterioration due to valve perforations or large emboli may occur at any time.

Most patients who develop infective endocarditis have underlying cardiac disease, though this is not the case with intravenous drug users and hospital-acquired infections. Abnormal valves or endocardial changes due to jet flow effects in congenital lesions (most commonly ventricular septal defect, tetralogy of Fallot, coarctation of the aorta, or patent ductus arteriosus) provide a nidus for infection during bacteremic episodes. Predisposing valvular abnormalities include rheumatic involvement of any valve, bicuspid aortic valves, calcific or sclerotic aortic valves, hypertrophic subaortic stenosis, and mitral valve prolapse. Rheumatic disease is no longer the major predisposing factor in developed countries. Regurgitation lesions are more susceptible than stenotic ones.

The initiating event in infective endocarditis is colonization of the valve by bacteria during bacteremia. Transient bacteremia is common during dental, upper respiratory, urologic, and lower gastrointestinal diagnostic and surgical procedures. It is less common during upper gastrointestinal and gynecologic procedures, though a high incidence has been reported during suction abortion.

Nearly all native valve endocarditis is due to viridans streptococci (60%), *S aureus* (20%), and enterococci (5-10%). Gram-negative organisms and fungi account for a small percentage.

The microbiology of native valve endocarditis in intravenous drug users differs from that of other patients. *S aureus* accounts for over 60% of these cases and for 80-90% of cases in which the tricuspid valve is infected. Enterococci and streptococci comprise the balance in about equal proportions. Gram-negative aerobic bacilli, fungi, and unusual organisms that rarely infect others may cause endocarditis in intravenous drug users.

The microbiology of prosthetic valve endocarditis also is distinctive. Early infections (ie, those occurring within 2 months after valve implantation) are commonly caused by staphylococci—both coagulase-positive and coagulase-negative—gram-negative organisms, and fungi. In late prosthetic valve endocarditis, infections are caused by streptococci, though coagulase-negative staphylococci still cause many cases.

Clinical Findings

A. Symptoms and Signs

Most patients present with a febrile illness that has lasted several days to 2 weeks. Nonspecific symptoms are common. Cough, dyspnea, arthralgias or arthritis, diarrhea, and abdominal, back, or flank pain may occur as a result of embolization or immunologically mediated phenomena. The initial symptoms or signs of endocarditis may be caused by arterial emboli or cardiac damage.

Most patients are febrile, though older individuals may be euthermic. In the majority, heart murmurs are stable, and although a changing murmur is significant diagnostically, it is the exception rather than the rule. The characteristic peripheral lesions—petechiae (on the palate or conjunctiva or beneath the fingernails), subungual ("splinter") hemorrhages, Osler nodes (painful, violaceous raised lesions of the fingers, toes, or feet), Janeway lesions (painless erythematous lesions of the palms or soles), and Roth spots (exudative lesions in the retina)—occur in 20-25% of patients, if that. Pallor and splenomegaly are other helpful signs.

In acute endocarditis, leukocytosis is common; in subacute cases, anemia of chronic disease and a normal white count are the rule. Hematuria and proteinuria as well as renal dysfunction may result from emboli or immunologically mediated glomerulonephritis.

B. Diagnostic Studies

Blood cultures establish the diagnosis; the current recommendation for maximizing the yield is to obtain three sets of blood cultures at least 1 hour apart before starting antibiotics. Up to 5% will be culture-negative, usually attributable to administration of antimicrobials prior to obtaining cultures. These cases may also be due to a fungus (50% of patients with fungal endocarditis have negative blood cultures), organisms that require special media for growth (eg, legionella, bartonella, nutritionally deficient streptococci), organisms that do not grow on artificial media (agents of Q fever, psittacosis), or those that are slow-growing and may require several weeks of incubation (eg, brucella, anaerobes, certain *Haemophilus* species, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and kingella). If antimicrobial therapy has been administered prior to cultures and the patient is clinically stable, it is reasonable to withhold further antimicrobial therapy for 2-3 days so that appropriate cultures can be obtained.

The chest x-ray may show evidence for the underlying cardiac abnormality and, in right-sided endocarditis, pulmonary infiltrates. The ECG is nondiagnostic. New conduction abnormalities suggest myocardial abscess formation.

Echocardiography is useful in diagnosis and may provide adjunctive information about the specific valve or valves that are infected. The sensitivity of transthoracic echocardiography is between 55% and 65%, and it cannot reliably rule out endocarditis but may confirm a clinical suspicion. Transesophageal echocardiography is 90% sensitive in detecting vegetations and is particularly useful for identifying valve ring abscesses as well as pulmonary and prosthetic valve endocarditis.

Clinical events (referred to as the Duke criteria) for the diagnosis of endocarditis have been proposed. Major abnormalities include (1) two positive blood cultures for a microorganism that typically causes infective endocarditis, and (2) evidence of endocardial involvement documented by echocardiography (definite vegetation, myocardial abscess, or new partial dehiscence of a prosthetic valve) or development of a new regurgitant murmur. Minor criteria include (1) the presence of a predisposing condition, (2) fever = 38°C, (3) embolic disease, (4) immunologic phenomena (glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor), (5) positive blood cultures not meeting the major criteria, and (6) a positive echocardiogram not meeting the major findings. A definite diagnosis can be made with 80% accuracy if two major criteria, one major criterion and three minor criteria, or five minor criteria are fulfilled. If none are found and either an alternative explanation for illness is identified or the patient has defervesced within 4 days, endocarditis is unlikely.

Complications

The course of infective endocarditis is determined by the degree of damage to the heart, by the site of infection (right- versus left-sided, aortic versus mitral valve), by the presence of metastatic foci of infection, by whether embolization occurs, and by immunologically mediated processes. Destruction of infected heart valves is especially common and precipitous with *S aureus* and often enterococci but can occur with any organism. The resulting regurgitation can be mild or severe and can progress even after bacteriologic cure. The infection can also extend into the myocardium, resulting in abscesses leading to conduction disturbances, and involving the wall of the aorta, creating sinus of Valsalva aneurysms.

Peripheral embolization can occur with any organism. The most important are cerebral and myocardial embolizations, with resulting infarctions. The spleen and kidneys are also common sites. Peripheral emboli may initiate metastatic infections or may become established in vessel walls, leading to mycotic aneurysms. Right-sided endocarditis, which usually involves the tricuspid valve, causes septic pulmonary emboli, occasionally with infarction and lung abscesses.

Prevention

Some cases of endocarditis occur after dental procedures or operations involving the upper respiratory, genitourinary, or intestinal tract. Prophylactic antibiotics are

given to patients with predisposing congenital or valvular anomalies who are to have any of these procedures ([Tables 33-3](#) and [33-4](#)). Current recommendations are given in [Table 33-5](#).

Treatment

Empirical regimens for endocarditis while culture results are pending should include agents active against staphylococci, streptococci, and enterococci. Nafcillin or oxacillin, 1.5 g every 4 hours, plus penicillin, 2-3 million units every 4 hours (or ampicillin, 1.5 g every 4 hours), plus gentamicin, 1 mg/kg every 8 hours, is such a regimen. Vancomycin, 15 mg/kg every 12 hours, may be used instead of the penicillins in the penicillin-allergic patient or if infection by methicillin-resistant staphylococci is suspected.

A. Viridans Streptococci

For penicillin-susceptible viridans streptococcal endocarditis (ie, MIC = 0.1 ug/mL), penicillin G, 2-3 million units intravenously every 4 hours for 4 weeks, is recommended. The duration of therapy can be shortened to 2 weeks if gentamicin, 1 mg/kg every 8 hours, is used with penicillin. Ceftriaxone, 2 g once daily intravenously or intramuscularly for 4 weeks, is also effective therapy for penicillin-susceptible strains and is a convenient regimen for home therapy. For the penicillin-allergic patient, vancomycin, 15 mg/kg every 12 hours for 4 weeks, is given. The 2-week regimen is not recommended for patients with symptoms of more than 3 months' duration or with complications such as myocardial abscess or extracardiac infection. Prosthetic valve endocarditis is treated with a 6-week course of penicillin with at least 2 weeks of gentamicin.

Viridans streptococci relatively resistant to penicillin (ie, MIC > 0.1 ug/mL but = 0.5 ug/mL) should be treated for 4 weeks. Penicillin G, 3 million units intravenously every 4 hours, is combined with gentamicin, 1 mg/kg every 8 hours for the first 2 weeks. In the patient with IgE-mediated allergy to penicillin, vancomycin alone, 15 mg/kg every 12 hours for 4 weeks, should be administered.

Viridans streptococci with an MIC > 0.5 ug/mL and nutritionally deficient streptococci should be treated like enterococci (see below).

B. Other Streptococci

Endocarditis caused by *Streptococcus pneumoniae*, *Streptococcus pyogenes* (group A streptococcus), or groups B, C, and G streptococci is unusual. Antibiotic regimens have not been determined. *S pneumoniae* sensitive to penicillin (MIC < 0.1 ug/mL) can be treated with penicillin alone, 2-3 million units every 4 hours for 4-6 weeks. Strains resistant to penicillin (MIC > 0.1 ug/mL) occur with increasing frequency; vancomycin should be effective based on in vitro data. Group A streptococcal infection can be treated with penicillin, ceftriaxone, or vancomycin for 4-6 weeks. Groups B, C, and G streptococci tend to be more resistant to penicillin than group A streptococci, and some have recommended adding gentamicin, 1 mg/kg every 8 hours, to penicillin for the first 2 weeks of a 4- to 6-week course.

C. Enterococci

For enterococcal endocarditis, penicillin used alone is inadequate; either streptomycin or gentamicin must be included in the regimen. Because aminoglycoside resistance occurs in enterococci, susceptibility should be documented. Gentamicin is the aminoglycoside of choice, because streptomycin resistance is more common and the nephrotoxicity of gentamicin is generally more easily managed than the vestibular toxicity of streptomycin. Ampicillin, 2 g intravenously every 4 hours, or penicillin G, 3-4 million units every 4 hours (or, in the penicillin-allergic patient, vancomycin, 15 mg/kg every 12 hours), plus gentamicin, 1 mg/kg every 8 hours, are recommended. Standard practice is to continue this regimen for 4-6 weeks (the longer duration for patients with symptoms for more than 3 months, relapse, or prosthetic valve endocarditis), though it has been suggested that for native valve enterococcal endocarditis less than 4 weeks of aminoglycoside may be sufficient. Experience is more extensive with penicillin and ampicillin than with vancomycin for therapy of enterococcal endocarditis, and penicillin and ampicillin are superior to vancomycin in vitro. Thus, whenever possible, either ampicillin or penicillin should be used. If endocarditis is caused by an organism that demonstrates high-level resistance to aminoglycosides (ie, not inhibited by 500 ug/mL of gentamicin), then their addition will not be beneficial. Therapy with high doses of penicillin (eg, 6 g/d administered as a continuous infusion) is recommended for 8-12 weeks, but the relapse rate may be as high as 50%. Surgery may be the only option in such situations.

D. Staphylococci

For methicillin-susceptible *S aureus*, nafcillin or oxacillin, 1.5 g every 4 hours for 4-6 weeks, is the preferred therapy. For penicillin-allergic patients, cefazolin, 2 g intravenously every 8 hours, or vancomycin, 15 mg/kg every 12 hours, may be used. For methicillin-resistant strains, vancomycin is the only agent of proved effectiveness. Aminoglycoside combination regimens may be useful in shortening the duration of bacteremia. Their maximum benefit is achieved at low doses (1 mg/kg every 8 hours) and in the first 3-5 days of therapy, and they should not be continued beyond the early phase of therapy. For treatment of tricuspid valve endocarditis (with or without pulmonary involvement) in the injection drug user who does not have serious extrapulmonary sites of infection, the total duration of therapy can be shortened from 4 weeks to 2 weeks if an aminoglycoside is added to an antistaphylococcal drug for the entire 2 weeks of therapy. The effect of rifampin with antistaphylococcal drugs is variable, and its routine use is not recommended.

Because coagulase-negative staphylococci—a common cause of prosthetic valve endocarditis—are routinely resistant to methicillin, β -lactam antibiotics should not be used for this infection until the isolate is known to be susceptible. A combination of vancomycin for 6 weeks, rifampin, 300 mg every 8 hours for 6 weeks, and gentamicin, 1 mg/kg every 8 hours for the first 2 weeks, is the regimen of choice. If the organism is sensitive to methicillin, either nafcillin or oxacillin or cefazolin can be used in combination with rifampin and gentamicin. Combination therapy with nafcillin or oxacillin (vancomycin for methicillin-resistant strains or patients allergic to β -lactams), rifampin, and gentamicin is also recommended for treatment of *S aureus* prosthetic valve infection.

E. HACEK Organisms

HACEK organisms (*Haemophilus aphrophilus*, *Haemophilus parainfluenzae*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*) are slow-growing, fastidious gram-negative coccobacilli or bacilli that are normal oral flora and cause less than 10% of all cases of endocarditis. They may elaborate β -lactamase, and thus the treatment of choice is ceftriaxone (or some other third-generation cephalosporin), 2 g once daily for 4 weeks. Prosthetic valve endocarditis should be treated for 6 weeks. In the penicillin-allergic patient, experience is limited, but trimethoprim-sulfamethoxazole, quinolones, and aztreonam have in vitro activity and should be considered; desensitization may be preferable.

F. Role of Surgery

While most cases can be successfully treated medically, operative management is sometimes required. Valvular regurgitation resulting in acute heart failure unresponsive to medical therapy is an indication for valve replacement even if active infection is present, especially in the aortic position. Infections unresponsive to appropriate antimicrobial therapy after 7-10 days (ie, persistent fevers, positive blood cultures despite therapy) are more likely to be eradicated if the valve is replaced. Surgery is nearly always required for fungal endocarditis and is more often necessary with gram-negative bacilli. It is also indicated when the infection involves the sinus of Valsalva or produces septal abscesses. Recurrent infection with the same organism prompts an operative approach, especially with infected prosthetic valves. Continuing embolization presents a difficult problem when the infection is otherwise responding; surgery may be the proper approach. Particularly challenging is a large and fragile vegetation demonstrated by echo in the absence of embolization. Most clinicians favor an operative approach if the patient is a good candidate. Embolization after bacteriologic cure, however, does not necessarily imply recurrence of endocarditis.

G. Role of Anticoagulation

Anticoagulation is contraindicated in native valve endocarditis because of an increased risk of intracerebral hemorrhage. The role of anticoagulant therapy during active prosthetic valve endocarditis is more controversial. Reversal of anticoagulation may result in thrombosis of the mechanical prosthesis, particularly in the mitral position. On the other hand, anticoagulation during active prosthetic valve endocarditis caused by *S aureus* has been associated with fatal intracerebral hemorrhage. One approach is to discontinue anticoagulation during the septic phase of *S aureus* prosthetic valve endocarditis. Indications for anticoagulation following prosthetic valve implantation for endocarditis are the same as for patients with prosthetic valves without endocarditis (eg, nonporcine mechanical valves and valves in the mitral position).

Response to Therapy

If infection is caused by viridans streptococci, enterococci, or coagulase-negative staphylococci, defervescence occurs in 3-4 days on average; with *Staphylococcus aureus* or *Pseudomonas aeruginosa*, fever commonly persists for 9-12 days. If so, blood cultures are obtained to ensure adequacy of therapy. Other causes of persistent fever are myocardial or metastatic abscess, sterile embolization, superimposed nosocomial infection, and drug reaction. Most relapses occur within 1-2 months after completion of therapy. Obtaining one or two blood cultures during this period is prudent.

■ INFECTIONS CAUSED BY GRAM-NEGATIVE BACTERIA

BORDETELLA PERTUSSIS INFECTION (WHOOPING COUGH)

Essentials of Diagnosis

- Predominantly in infants under age 2 years. Adults are an important reservoir of infection.
- Two-week prodromal catarrhal stage of malaise, cough, coryza, and anorexia.
- Paroxysmal cough ending in a high-pitched inspiratory "whoop."
- Absolute lymphocytosis, often striking; culture confirms diagnosis.

General Considerations

Pertussis is an acute infection of the respiratory tract caused by *Bordetella pertussis* that is transmitted by respiratory droplets. The incubation period is 7-17 days. Half of all cases occur before age 2 years. Neither immunization nor disease confers lasting immunity to pertussis. Consequently, adults are an important reservoir of the disease.

Clinical Findings

The symptoms of classic pertussis last about 6 weeks and are divided into three consecutive stages. The catarrhal stage is characterized by its insidious onset, with lacrimation, sneezing, and coryza, anorexia and malaise, and a hacking night cough that becomes diurnal. The paroxysmal stage is characterized by bursts of rapid, consecutive coughs followed by a deep, high-pitched inspiration (whoop). The convalescent stage begins 4 weeks after onset of the illness with a decrease in the frequency and severity of paroxysms of cough. The diagnosis often is not considered in adults, who may not have a typical presentation. Cough persisting more than 2 weeks is suggestive. Infection may also be asymptomatic.

The white blood cell count is usually 15,000- 20,000/uL (rarely, as high as 50,000/uL or more), 60-80% of which are lymphocytes. The diagnosis is established by isolating the organism from nasopharyngeal culture. A special medium (eg, Bordet-Gengou agar) must be requested.

Prevention

Pertussis vaccine is recommended for all infants, combined with diphtheria and tetanus toxoids (DTP). Infants and susceptible adults with significant exposure should receive prophylaxis with erythromycin (40 mg/kg/d, up to 2 g/d, for 10 days). Booster doses of pertussis vaccine have not been recommended after age 6 except in outbreaks. Recognition of adults as an important reservoir of infection and development of an effective acellular vaccine with fewer side effects than whole cell vaccine call for reevaluation of the current recommendations for vaccination of adults.

Treatment

Erythromycin, 500 mg four times a day orally for 10 days, shortens the duration of carriage. It also may diminish the severity of coughing paroxysms. Azithromycin, 500 mg orally for 3 days, or clarithromycin, 500 mg orally twice daily for 7 days, is probably as effective as erythromycin and likely to be better tolerated.

Hewlett EL: A commentary on the pathogenesis of pertussis. Clin Infect Dis 1999;28(Suppl 2):S94. [\[PMID: 10447025\]](#)

OTHER BORDETELLA INFECTIONS

Bordetella bronchiseptica is a pleomorphic gram-negative coccobacillus causing kennel cough in dogs. On occasion it causes upper and lower respiratory infection in humans, principally HIV-infected patients. Infection has been associated with contact with dogs and cats, suggesting animal-to-human transmission. Treatment of *B bronchiseptica* infection is guided by results of in vitro susceptibility tests.

Dworkin MS et al: *Bordetella bronchiseptica* infection in human immunodeficiency virus-infected patients. Clin Infect Dis 1999;28:1095. [\[PMID: 10452641\]](#)

MENINGOCOCCAL MENINGITIS

Essentials of Diagnosis

- Fever, headache, vomiting, confusion, delirium, convulsions.
- Petechial rash of skin and mucous membranes in many.
- Neck and back stiffness with positive Kernig and Brudzinski signs is characteristic.
- Purulent spinal fluid with gram-negative intracellular and extracellular diplococci.
- Culture of cerebrospinal fluid, blood, or petechial aspiration confirms the diagnosis.

General Considerations

Meningococcal meningitis is caused by *Neisseria meningitidis* of groups A, B, C, Y, and W-135, among others. Meningitis due to serogroup A is uncommon in the United States. Serogroup B generally causes sporadic cases. The frequency of outbreaks of meningitis caused by group C meningococcus has increased, and this serotype is the most common cause of epidemic disease in the United States. Up to 40% of persons are nasopharyngeal carriers of meningococci, but relatively few develop disease. Infection is transmitted by droplets. The clinical illness may take the form of meningococcemia (a fulminant form of septicemia without meningitis), meningococcemia with meningitis, or meningitis. Recurrent meningococcemia with fever, rash, and arthritis is seen rarely in patients with certain terminal complement deficiencies.

Clinical Findings

A. Symptoms and Signs

High fever, chills, and headache; back, abdominal, and extremity pains; and nausea and vomiting are typical. Rapidly developing confusion, delirium, seizures, and coma occur in some.

On examination, nuchal and back rigidity are typical, with positive Kernig and Brudzinski signs. (Kernig's sign is pain in the hamstrings upon extension of the knee with the hip at 90-degree flexion; Brudzinski's sign is flexion of the knee in response to flexion of the neck.) A petechial rash appearing in the lower extremities and at pressure points is found in most cases. Petechiae may vary in size from pinpoint lesions to large ecchymoses or even skin gangrene that may later slough if the patient survives.

B. Laboratory Findings

Lumbar puncture typically reveals a cloudy or purulent cerebrospinal fluid, with elevated pressure, increased protein, and decreased glucose content. The fluid usually contains more than 1000 cells/uL, with polymorphonuclear cells predominating and containing gram-negative intracellular diplococci. The absence of organisms in a Gram-stained smear of the cerebrospinal fluid sediment does not rule out the diagnosis. The capsular polysaccharide can be demonstrated in cerebrospinal fluid or urine by latex agglutination; this is useful in partially treated patients, though sensitivity is 60-80%. The organism is usually demonstrated by smear and culture of the cerebrospinal fluid, oropharynx, blood, or aspirated petechiae.

Disseminated intravascular coagulation is an important complication of meningococcal infection and is typically present in toxic patients with ecchymotic skin lesions.

Differential Diagnosis

Meningococcal meningitis must be differentiated from other meningitides. In small infants and in the elderly, fever or stiff neck is often missing, and altered mental status may dominate the picture.

Rickettsial, echovirus, and, rarely, other bacterial infections (eg, staphylococcal infections, scarlet fever) also cause petechial rash.

Prevention

There are no effective polysaccharide vaccines for groups A, C, Y, and W-135. A and C vaccines have reduced the incidence of these infections in military recruits. The vaccines are advised for control of epidemics in civilian populations. The Advisory Committee on Immunization Practices now recommends immunization with a single dose of polyvalent vaccine (active against groups A, C, Y, and W-135) for college freshmen—particularly those living in dormitories, who have a modestly increased risk of invasive meningococcal disease.

Outbreaks in closed populations are best controlled by eliminating nasopharyngeal carriage of meningococci. Rifampin is the drug of choice in a dosage of 600 mg twice a day for 2 days. A single 500-mg oral dose of ciprofloxacin or one intramuscular 250-mg dose of ceftriaxone in adults is also effective.

Household members exposed to a person with meningococcal meningitis are at increased risk and should be given rifampin prophylaxis as outlined above, as are day care center contacts. School and work contacts need not be treated. Hospital contacts receive therapy only if intense exposure has occurred (eg, mouth-to-mouth resuscitation).

Accidentally discovered carriers without known close contact with meningococcal disease do not require prophylactic antimicrobials.

Treatment

Blood cultures must be obtained and intravenous antimicrobial therapy started immediately. This may be done prior to lumbar puncture in patients in whom the diagnosis is not straightforward and for those in whom MR or CT imaging is indicated to exclude mass lesions. Aqueous penicillin G is the antibiotic of choice (24 million units/24 h in divided doses every 4 hours). In penicillin-allergic patients or those in whom *Haemophilus influenzae* or gram-negative meningitis is a consideration, ceftriaxone, 4 g intravenously once a day, should be used. Chloramphenicol, 1 g every 6 hours, is an alternative in the severely penicillin- or cephalosporin-allergic patient.

Treatment should be continued in full doses by the intravenous route until the patient is afebrile for 5 days. Shorter courses—as few as 4 days if ceftriaxone is used—are also effective.

Obtundation or deterioration in mental status may result from cerebral edema and increased intracranial pressure.

Heparinization in patients with disseminated intravascular coagulation and bleeding reverses clotting factor abnormalities but does not influence prognosis. As with pneumococcal meningitis (see above), administration of dexamethasone may improve outcome.

Peltola H: Prophylaxis of bacterial meningitis. Infect Dis Clin North Am 1999;13:685. [\[PMID: 10470562\]](#)

INFECTIONS CAUSED BY HAEMOPHILUS SPECIES

Haemophilus influenzae and other haemophilus species may cause sinusitis, otitis, bronchitis, epiglottitis, pneumonitis, cellulitis, arthritis, meningitis, and endocarditis. **Pneumonia** is one of the more common infections of adults caused by *H influenzae* type b. Nontypeable strains are responsible for most disease in adults. The presentation is of a typical bacterial pneumonia, with purulent sputum containing a predominance of gram-negative, pleomorphic rods. Alcoholism, smoking, chronic lung disease, advanced age, and HIV infection are risk factors. Haemophilus species frequently cause purulent bronchitis and also colonize the upper respiratory tract in COPD patients. Positive pleural fluid or blood cultures are required to establish pneumonia.

Beta-lactamase-producing strains are less common in adults than in children. For adults with sinusitis, otitis, or respiratory tract infection, oral amoxicillin, 750 mg twice daily for 10-14 days, is adequate. For beta-lactamase-producing strains, use of the fixed drug combination of amoxicillin, 875 mg, with clavulanate, 125 mg, is indicated. For the penicillin-allergic patient, cefuroxime axetil, 250 mg twice daily, or trimethoprim-sulfamethoxazole, 800/160 mg orally twice daily, for 10 days is effective. Azithromycin and clarithromycin are less effective.

In the more seriously ill patient (eg, the toxic patient with multilobar pneumonia), use of a second- or third-generation cephalosporin—cefuroxime, 750 mg every 8 hours, or ceftriaxone, 1 g/d—is advisable pending determination of whether the infecting strain is a β -lactamase producer. Trimethoprim-sulfamethoxazole, administered based on a dose of 10 mg/kg/d of trimethoprim, can be used for the penicillin-allergic patient. A 10- to 14-day course of therapy is adequate for most cases.

Epiglottitis, which occasionally occurs in adults, is characterized by an abrupt onset of high fever, drooling, and inability to handle secretions. The patient often has a severe sore throat despite an unimpressive examination of the pharynx. This is a clue to the diagnosis. Stridor and respiratory distress result from laryngeal obstruction. The diagnosis is best made by direct visualization of the cherry-red, swollen epiglottis at laryngoscopy. Because laryngoscopy may provoke laryngospasm and obstruction, especially in children, it should be performed in an intensive care unit or similar setting, and only at a time when intubation can be performed promptly. Cefuroxime, 1.5 g every 8 hours for 7-10 days, or ceftriaxone, 1 g every 24 hours for 7-10 days, is the drug of choice. Trimethoprim-sulfamethoxazole (see above for dosage) or chloramphenicol, 4 g/d, may be used in the patient with serious penicillin allergy.

Meningitis, rare in adults, becomes a consideration in the patient who has meningitis associated with sinusitis or otitis. Initial therapy of suspected *H influenzae* meningitis should be with ceftriaxone, 4 g/d in one or two divided doses, until the strain is proved not to produce β -lactamase. Chloramphenicol, 100 mg/kg/d in four divided doses, can be used if the patient has a serious, life-threatening allergy to β -lactam antibiotics. Traditionally, meningitis has been treated for 10-14 days. Dexamethasone, 0.15 mg/kg intravenously every 6 hours, is a valuable adjunctive agent in treatment of meningitis in infants and children, resulting in reduction in long-term sequelae, principally hearing loss.

INFECTIONS CAUSED BY MORAXELLA CATARRHALIS

Moraxella catarrhalis is a gram-negative aerobic coccus morphologically and biochemically similar to neisseria. It causes sinusitis, bronchitis, and pneumonia. Bacteremia and meningitis have also been reported in immunocompromised patients. The organism frequently colonizes the respiratory tract, making differentiation of colonization from infection difficult. If *M catarrhalis* is the predominant isolate, therapy is directed against it. *M catarrhalis* typically produces β -lactamase and therefore is usually resistant to ampicillin and amoxicillin. It is susceptible to amoxicillin-clavulanate, ampicillin-sulbactam, trimethoprim-sulfamethoxazole, ciprofloxacin, and second- and third-generation cephalosporins.

LEGIONNAIRE'S DISEASE

Essentials of Diagnosis

- Patients are often immunocompromised, smokers, or have chronic lung disease.
- Scant sputum production, pleuritic chest pain, toxic appearance.
- Chest x-ray shows focal patchy infiltrates or consolidation.
- Gram's stain of sputum shows polymorphonuclear leukocytes and no organisms.

General Considerations

Legionella infection ranks among the three or four most common causes of community-acquired pneumonia and is considered whenever the etiology of a pneumonia is in question. Legionnaire's disease is more common in immunocompromised persons, in smokers, and in those with chronic lung disease. Outbreaks have been associated with contaminated water sources, such as shower heads and faucets in patient rooms and air conditioning cooling towers.

Clinical Findings

A. Symptoms and Signs

Legionnaire's disease is one of the atypical pneumonias, so called because a Gram-stained smear of sputum does not show organisms. However, many features of Legionnaire's disease are more like typical pneumonia, with high fevers, a toxic patient, pleurisy, and grossly purulent sputum. Classically, this pneumonia is caused by *Legionella pneumophila*, though other species can cause identical disease.

B. Laboratory Findings

Culture onto charcoal-yeast extract agar or similar enriched medium is the most sensitive method (80-90% sensitivity) for diagnosis and permits identification of infections caused by species and serotypes other than *L pneumophila* serotype 1. Dieterle's silver staining of tissue, pleural fluid, or other infected material is also a reliable method for detecting legionella species. Direct fluorescent antibody stains and serologic testing are less sensitive because these will detect only *L pneumophila* serotype 1. In addition, making a serologic diagnosis requires that the host respond with sufficient specific antibody production. Urinary antigen tests, which are targeted for detection of *L pneumophila* serotype 1, are also less sensitive than culture.

Treatment

Erythromycin, 1 g every 6 hours intravenously, followed by 500 mg orally four times daily for 14-21 days, has been the preferred regimen for treatment of legionellosis. Alternative agents with excellent in vitro activity against legionella and more easily administered and better tolerated are levofloxacin (500 mg once daily orally or intravenously), azithromycin (500 mg then 250 mg once daily, orally or intravenously), and clarithromycin (500 mg orally twice daily)—all administered for 10-14 days. Azithromycin may be effective as a 5-day regimen. These agents are just as effective as erythromycin and are now preferred to erythromycin. A 21-day course of treatment and combination therapy (eg, addition of rifampin 300 mg twice daily or macrolide-fluoroquinolone) has been recommended for legionellosis in the immunocompromised patient, but improved outcomes for combination regimens have not been consistently observed. Tetracyclines and trimethoprim-sulfamethoxazole also appear to be effective. Their use for documented infection has been limited, however, and they are reserved for the patient who cannot be treated with either a macrolide or a fluoroquinolone.

Waterer GW et al: Legionella and community-acquired pneumonia: a review of current diagnostic tests from a clinician's viewpoint. Am J Med 2001;110:41. [PMID: 11152864]

GRAM-NEGATIVE BACTEREMIA & SEPSIS

There are numerous episodes of gram-negative sepsis in hospitals every year. Patients with potentially fatal underlying conditions in the short term such as neutropenia or immunoparesis have a mortality rate of 40-60%; those with serious underlying diseases likely to be fatal in 5 years, such as solid tumors, cirrhosis, and aplastic anemia, die in 15-20% of cases; and individuals with no underlying diseases have a mortality rate of 5% or less. Gram-negative bacteremia can originate in a number of sites, the most common being the genitourinary system, hepatobiliary tract, gastrointestinal tract, and lungs. Less common sources include intravenous lines, infusion fluids, surgical wounds, drains, and decubitus ulcers.

Clinical Findings

A. Symptoms and Signs

Most patients have fevers and chills, often with abrupt onset. However, 15% of patients are hypothermic (temperature = 36.4°C) at presentation, and 5% never develop a temperature above 37.5°C. Hyperventilation with respiratory alkalosis and changes in mental status are important early manifestations. Hypotension and shock, which occur in 20-50% of patients, are unfavorable prognostic signs.

B. Laboratory Findings

Neutropenia or neutrophilia, often with increased numbers of immature forms of polymorphonuclear leukocytes, is the most common laboratory abnormality in septic patients. Thrombocytopenia occurs in 50% of patients, laboratory evidence of coagulation abnormalities in 10%, and overt DIC in 2-3%. Both clinical manifestations and the laboratory abnormalities are nonspecific and insensitive, which accounts for the relatively low rate of blood culture positivity (approximately 20-40%). If possible, three blood cultures from separate sites should be obtained in rapid succession before starting antimicrobial therapy. The chance of recovering the organism in at least one of the three blood cultures is greater than 95%. The false-negative rate for a single culture of 5-10 mL of blood is 30%. This may be reduced to 5-10% (albeit with a slight false-positive rate due to isolation of contaminants) if a single volume of 30 mL is inoculated into several blood culture bottles. Because blood cultures may be falsely negative, when a patient with presumed septic shock, negative blood cultures, and inadequate explanation for the clinical course responds to antimicrobials, therapy should be continued for 10-14 days.

Treatment

Several factors are important in the management of patients with sepsis.

A. Removal of Predisposing Factors

This usually means decreasing or stopping immunosuppressive medications and in certain circumstances (eg, positive blood cultures) giving granulocyte colony-stimulating factor (filgrastim; G-CSF) to the neutropenic patient.

B. Identifying the Source of Bacteremia

By simply finding the source of bacteremia and removing it (intravenous line) or draining it (abscess), a fatal disease becomes easily treatable.

C. Supportive Measures

The use of fluids and pressors for maintaining blood pressure is discussed in [Chapter 11](#); management of disseminated intravascular coagulation is discussed in [Chapter 13](#).

D. Antibiotics

Antibiotics are given as soon as the diagnosis is suspected, since delays in therapy have been associated with increased mortality rates. In general, bactericidal antibiotics should be used and given intravenously to ensure therapeutic serum levels. Penetration of antibiotics into the site of primary infection is critical for successful therapy—ie, if the infection originates in the central nervous system, antibiotics that penetrate the blood-brain barrier should be used—eg, penicillin, ampicillin, chloramphenicol, and third-generation cephalosporins—but not first-generation cephalosporins or aminoglycosides, which penetrate poorly. Sepsis caused by gram-positive organisms cannot be differentiated on clinical grounds from that due to gram-negative bacteria. Therefore, initial therapy should include antibiotics active against both types of organisms.

The number of antibiotics necessary remains controversial and depends upon the cause. [Table 37-2](#) provides a guide for empirical therapy. Most authorities believe that for patients with rapidly fatal underlying diseases, a synergistic combination of antibiotics, including an aminoglycoside, should be used. For patients with nonfatal or ultimately fatal diseases and who are not in shock, a single-drug regimen with any of several broad-spectrum antibiotics (eg, a third-generation cephalosporin, ticarcillin-clavulanate, imipenem) is adequate. Therapy can be altered once results of culture and sensitivity are known.

E. Corticosteroids

There is no role for corticosteroids in the therapy of sepsis or septic shock.

F. Adjunctive Therapy

Expanded knowledge of the pathophysiology of sepsis and septic shock and recognition that cytokines play a critical role have led to novel approaches to therapy. Strategies include blocking the effects of endotoxin with anti-endotoxin monoclonal antibodies; blockade of TNF α , a potent cytokine mediator of septic shock, with anti-TNF monoclonal antibody or soluble TNF receptor; use of IL-1 receptor antagonists to inhibit the proinflammatory effects of IL-1 binding to its receptor; and blocking platelet or thrombin activation. These strategies have not been met with improved survival. However, recombinant human activated protein C (drotrecogin alfa) shows a significant mortality reduction in certain septic patients. This drug should be used cautiously because of the risk of bleeding. Patients considered to have an infectious cause of severe sepsis (defined as three or more signs of systemic inflammation—eg, fever or hypothermia, tachycardia, tachypnea—plus sepsis-induced dysfunction of at least one organ system) of less than 24 hours' duration are the best candidates. Platelet counts less than 30,000/ uL, conditions associated with an increased risk of bleeding (eg, recent trauma, surgery, or bleeding episode; anticoagulation), or hypercoagulable states have not been investigated. These criteria should be followed when selecting candidates for treatment with drotrecogin alfa (activated). The agent is administered intravenously by constant infusion at a dosage of 24 ug/kg/h for 96 hours.

Bernard GR et al: Efficacy and safety of recombinant human activated protein C for severe sepsis. N Engl J Med 2001;344: 699. [PMID: 11236773]

Wheeler AW et al: Current concepts: Treating patients with severe sepsis. N Engl J Med 1999;340:207. [PMID: 9895401]

SALMONELLOSIS

Salmonellosis includes infection by any of approximately 2000 serotypes of salmonellae. The taxonomy of salmonella species has been confusing. All salmonella serotypes are members of a single species, *S enterica*. Human infections are caused almost exclusively by *S enterica* subsp *enterica*, of which three serotypes—typhi, typhimurium, and choleraesuis—are predominantly isolated. Three clinical patterns of infection are recognized: (1) enteric fever, the best example of which is typhoid fever, due to serotype typhi; (2) acute enterocolitis, caused by serotype typhimurium, among others; and (3) the "septicemic" type, characterized by bacteremia and focal lesions, exemplified by infection with serotype choleraesuis. All types are transmitted by ingestion of the organism, usually from contaminated food or drink.

1. Enteric Fever (Typhoid Fever)

Essentials of Diagnosis

- Gradual onset of malaise, headache, sore throat, cough, and either diarrhea or constipation.
- Rose spots, relative bradycardia, splenomegaly, and abdominal distention and tenderness.
- Slow (stepladder) rise of fever to maximum and then slow return to normal.
- Leukopenia; blood, stool, and urine culture positive for salmonella.

General Considerations

Enteric fever is a clinical syndrome characterized by constitutional and gastrointestinal symptoms and by headache. It can be caused by any salmonella species. The term "typhoid fever" applies when serotype typhi is the cause. Infection is transmitted by consumption of contaminated food or drink. The incubation period is 5-14 days. Salmonella is an intracellular pathogen. Infection begins when organisms breach the mucosal epithelium of the intestines by transcytosis, an organism-mediated transport process through the cell via an endocytic vesicle. Having crossed the epithelial barrier, organisms invade and replicate in macrophages in Peyer's patches, mesenteric lymph nodes, and the spleen. Serotypes other than typhi usually do not cause invasive disease, presumably because they lack the necessary human-specific virulence factors. Bacteremia occurs, and the infection then localizes principally in the lymphoid tissue of the small intestine (particularly within 60 cm of the ileocecal valve). Peyer's patches become inflamed and may ulcerate, with involvement greatest during the third week of disease. The organism may disseminate to the lungs, gallbladder, kidneys, or central nervous system.

Clinical Findings

A. Symptoms and Signs

During the prodromal stage, there is increasing malaise, headache, cough, and sore throat, often with abdominal pain and constipation, while the fever ascends in a stepwise fashion. After about 7-10 days, it reaches a plateau and the patient is much more ill, appearing exhausted and often prostrated. There may be marked constipation, especially early, or "pea soup" diarrhea; marked abdominal distention occurs as well. If there are no complications, the patient's condition will gradually improve over 7-10 days. However, relapse may occur for up to 2 weeks after defervescence.

During the early prodrome, physical findings are few. Later, splenomegaly, abdominal distention and tenderness, relative bradycardia, and occasionally meningismus appear. The rash (rose spots) commonly appears during the second week of disease. The individual spot, found principally on the trunk, is a pink papule 2-3 mm in diameter that fades on pressure. It disappears in 3-4 days.

B. Laboratory Findings

Typhoid fever is best diagnosed by blood culture, which is positive in the first week of illness in 80% of patients who have not taken antimicrobials. The rate of positivity declines thereafter, but one-fourth or more of patients still have positive blood cultures in the third week. Cultures of bone marrow occasionally are positive when blood cultures are not. Stool culture is unreliable because it may be positive in gastroenteritis without typhoid fever. Relative bradycardia and leukopenia are typical.

Differential Diagnosis

Enteric fever must be distinguished from other gastrointestinal illnesses and from other infections that have few localizing findings. Examples include tuberculosis, infective endocarditis, brucellosis, lymphoma, and Q fever. Often there is a history of recent travel to endemic areas, and viral hepatitis, malaria, or amebiasis may be in the differential as well.

Complications

Complications occur in about 30% of untreated cases and account for 75% of deaths. Intestinal hemorrhage, manifested by a sudden drop in temperature and signs of shock followed by dark or fresh blood in the stool, or intestinal perforation, accompanied by abdominal pain and tenderness, is most likely to occur during the third week. Appearance of leukocytosis and tachycardia should suggest these complications. Urinary retention, pneumonia, thrombophlebitis, myocarditis, psychosis, cholecystitis, nephritis, osteomyelitis, and meningitis are less often observed.

Prevention

Immunization is not always effective but should be considered for household contacts of a typhoid carrier, for travelers to endemic areas, and during epidemic outbreaks. A multiple-dose oral vaccine and a single-dose parenteral vaccine are available. Their efficacies are similar, but oral vaccine causes fewer side effects. Boosters, when indicated, should be given every 5 years and 3 years for oral and parenteral preparations, respectively.

Adequate waste disposal and protection of food and water supplies from contamination are important public health measures to prevent salmonellosis. Carriers cannot work as food handlers.

Treatment

A. Specific Measures

Ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole may be effective. All can be given orally or intravenously depending on the patient's condition. Because many salmonella strains are resistant to ampicillin and chloramphenicol, trimethoprim-sulfamethoxazole is the agent of choice for treatment of salmonella infections. Resistance to trimethoprim-sulfamethoxazole now appears to be on the rise. Salmonellae remain susceptible to ceftriaxone and fluoroquinolones, though resistance to the latter is now also appearing. The dose of ceftriaxone is 2 g orally once daily; ciprofloxacin is given in a dosage of 750 mg orally twice daily. Fluoroquinolones are contraindicated in children and pregnant women. The recommended duration of therapy traditionally has been 2 weeks, but 5-10 days may be sufficient.

B. Treatment of Carriers

Chemotherapy often is unsuccessful in eradicating the carrier state. While treatment of carriage with ampicillin, trimethoprim-sulfamethoxazole, or chloramphenicol may be successful, ciprofloxacin, 750 mg twice a day for 4 weeks, has proved to be highly effective. Cholecystectomy may also achieve this goal.

Prognosis

The mortality rate of typhoid fever is about 2% in treated cases. Elderly or debilitated persons are likely to do poorly. With complications, the prognosis is poor. Relapses occur in up to 15% of cases. A residual carrier state frequently persists in spite of chemotherapy.

Akalin HE: Quinolones in the treatment of typhoid fever. *Drugs* 1999;58(Suppl 2):52. [PMID: 10553706]

2. Salmonella Gastroenteritis

By far the most common form of salmonellosis is acute enterocolitis caused by numerous salmonella serotypes. The incubation period is 8-48 hours after ingestion of contaminated food or liquid.

Symptoms and signs consist of fever (often with chills), nausea and vomiting, cramping abdominal pain, and diarrhea, which may be grossly bloody, lasting 3-5 days. Differentiation must be made from viral gastroenteritis, food poisoning, shigellosis, amebic dysentery, and acute ulcerative colitis. The diagnosis is made by culturing the organism from the stool.

The disease is usually self-limited, but bacteremia with localization in joints or bones may occur, especially in patients with sickle cell disease.

Treatment of uncomplicated enterocolitis is symptomatic only. Malnourished or severely ill patients, those with sickle cell disease, and those with suspected bacteremia

should be treated for 3-5 days with trimethoprim-sulfamethoxazole (one double-strength tablet twice a day), ampicillin (100 mg/kg intravenously or orally), or ciprofloxacin (750 mg twice a day).

3. *Salmonella Bacteremia*

Salmonella infection may be manifested by prolonged or recurrent fevers accompanied by bacteremia and local infection in bone, joints, pleura, pericardium, lungs, or other sites. Mycotic abdominal aortic aneurysms may also occur. Serotypes other than typhi usually are isolated. This complication tends to occur in immunocompromised persons and is seen in HIV-infected individuals, who typically have bacteremia without an obvious source. Treatment is the same as for typhoid fever, plus drainage of any abscesses. In HIV-infected patients, relapse is common, and lifelong suppressive therapy may be needed. Ciprofloxacin, 750 mg twice a day, is effective both for therapy of acute infection and for suppression of recurrence.

SHIGELLOSIS

Essentials of Diagnosis

- Diarrhea, often with blood and mucus.
- Crampy abdominal pain and systemic toxicity.
- White blood cells in stools; organism isolated on stool culture.

General Considerations

Shigella dysentery is a common disease, often self-limited and mild but occasionally serious. *Shigella sonnei* is the leading cause in the United States, followed by *Shigella flexneri*. *Shigella dysenteriae* causes the most serious form of the illness. Shigellae are invasive organisms. The infective dose is 10^2 - 10^3 organisms. There has been a rise in strains resistant to multiple antibiotics.

Clinical Findings

A. Symptoms and Signs

The illness usually starts abruptly, with diarrhea, lower abdominal cramps, and tenesmus. The diarrheal stool often is mixed with blood and mucus. Systemic symptoms are fever, chills, anorexia and malaise, and headache. The abdomen is tender. Sigmoidoscopic examination reveals an inflamed, engorged mucosa with punctate and sometimes large areas of ulceration.

B. Laboratory Findings

The stool shows many leukocytes and red cells. Stool culture is positive for shigellae in most cases, but blood cultures grow the organism in less than 5% of cases.

Differential Diagnosis

Bacillary dysentery must be distinguished from salmonella enterocolitis and from disease due to enterotoxigenic *E coli*, campylobacter, and *Y enterocolitica*. Amebic dysentery may be similar clinically and is diagnosed by finding amebas in the fresh stool specimen. Ulcerative colitis in the adolescent and adult is also an important cause of bloody diarrhea.

Complications

Temporary disaccharidase deficiency may follow the diarrhea. Reactive arthritis is an uncommon complication, usually occurring in HLA-B27 individuals infected by shigella.

Treatment

Treatment of dehydration and hypotension is lifesaving in severe cases. The current antimicrobial treatment of choice is trimethoprim-sulfamethoxazole, one double-strength tablet twice a day for 7-10 days, or ciprofloxacin (contraindicated in pregnancy), 750 mg twice daily for 7-10 days, or fluoroquinolone (ciprofloxacin, 750 mg twice daily, or levofloxacin, 500 mg once daily) for 3 days. Fluoroquinolones are also contraindicated in pregnancy. Shigellae resistant to ampicillin are common, but if the isolate is susceptible, a dose of 500 mg four times a day is also effective. Amoxicillin, which is less effective, should not be used.

GASTROENTERITIS CAUSED BY *ESCHERICHIA COLI*

Escherichia coli causes gastroenteritis by a variety of mechanisms. Enterotoxigenic *E coli* (ETEC) elaborates either a heat-stable or heat-labile toxin that mediates the disease. ETEC is an important cause of traveler's diarrhea. Enteroinvasive *E coli* (EIEC) differs from other *E coli* bowel pathogens in that these strains invade cells, causing bloody diarrhea and dysentery similar to infection with shigella species. EIEC is uncommon in the United States. Neither ETEC nor EIEC strains are routinely isolated and identified from stool cultures because there is no selective medium. Antimicrobial therapy directed against salmonella and shigella shortens the clinical course, but the disease is self-limited.

Enterohemorrhagic *E coli* (EHEC) produces two shiga-like toxins that mediate the clinical manifestations, which include an asymptomatic carriage stage, nonbloody diarrhea, hemorrhagic colitis, hemolytic-uremic syndrome, and thrombotic thrombocytopenic purpura. Although there are several serotypes of EHEC, O157:H7 is responsible for most cases in the United States. *E coli* O157:H7 has caused several outbreaks of diarrhea and hemolytic-uremic syndrome related to consumption of undercooked hamburger and unpasteurized apple juice. Older individuals and young children are most affected, with hemolytic-uremic syndrome being more common in the latter group. *E coli* O157:H7 is not identified by routine stool cultures. Isolation requires identification of sorbitol-negative colonies of *E coli* on sorbitol-MacConkey agar followed by serologic testing to confirm the serotype. Antimicrobial therapy does not alter the course of the disease, and may increase the risk of hemolytic-uremic syndrome. Treatment is primarily supportive. Hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura occurring in association with a diarrheal illness suggests the diagnosis and should prompt evaluation for EHEC. Confirmed infections should be reported to public health officials.

Wong CS et al: The risk of the hemolytic-uremic syndrome after antibiotic treatment of *Escherichia coli* O157:H7 infections. N Engl J Med 2000;342:1930. [\[PMID: 10874060\]](#)

CHOLERA

Essentials of Diagnosis

- History of travel in endemic area or contact with infected person.
- Voluminous diarrhea.
- Stool is liquid, gray, turbid, and without fecal odor, blood, or pus ("rice water stool").
- Rapid development of marked dehydration.
- Positive stool cultures and agglutination of vibrios with specific sera.

General Considerations

Cholera is an acute diarrheal illness caused by certain serotypes of *Vibrio cholerae*. The disease is toxin-mediated, and fever is unusual. The toxin activates adenyl cyclase in intestinal epithelial cells of the small intestines, producing hypersecretion of water and chloride ion and a massive diarrhea of up to 15 L/d. Death results from profound hypovolemia.

Cholera occurs in epidemics under conditions of crowding, war, and famine (eg, in refugee camps) and where sanitation is inadequate. Infection is acquired by ingestion of contaminated food or water. Cholera was rarely seen in the United States until 1991, when epidemic cholera returned to the Western Hemisphere, originating as an outbreak in coastal cities of Peru. The epidemic spread to involve several countries in South and Central America as well as Mexico, and cases have been imported into the United States. Cholera should be considered in the differential diagnosis of severe watery diarrhea, especially in those who have traveled to affected countries.

Clinical Findings

Cholera is characterized by a sudden onset of severe, frequent watery diarrhea (up to 1 L/h). The liquid stool is gray, turbid, and without fecal odor, blood, or pus ("rice water stool"). Dehydration and hypotension develop rapidly. Stool cultures are positive, and agglutination of vibrios with specific sera can be demonstrated.

Prevention

A vaccine is available that confers short-lived, limited protection and may be required for entry into or reentry after travel to some countries. It is administered in two doses 1-4 weeks apart. A booster dose every 6 months is recommended for persons remaining in areas where cholera is a hazard.

Vaccination programs are expensive and not particularly effective in managing outbreaks of cholera. When outbreaks occur, efforts should be directed toward establishing clean water and food sources and proper waste disposal.

Treatment

Treatment is by replacement of fluids. In mild or moderate illness, oral rehydration usually is adequate. A simple oral replacement fluid can be made from 1 teaspoon of table salt and 4 heaping teaspoons of sugar added to 1 L of water. Intravenous fluids are indicated for persons in with signs of severe hypovolemia and those who cannot take adequate fluids orally. Lactated Ringer's infusion is satisfactory.

Antimicrobial therapy will shorten the course of illness. Several antimicrobials are active against *V cholerae*, including tetracycline, ampicillin, chloramphenicol, trimethoprim-sulfamethoxazole, and fluoroquinolones. Multiple antibiotic resistance does occur, so susceptibility testing, if available, is advisable.

Guerrant RL et al: How intestinal bacteria cause disease. J Infect Dis 1999;179(Suppl 2):S331. [PMID: 10081504]

INFECTIONS CAUSED BY OTHER VIBRIO SPECIES

Vibrios other than *Vibrio cholerae* that cause human disease are *Vibrio parahaemolyticus*, *Vibrio vulnificus*, and *Vibrio alginolyticus*. All are halophilic marine organisms. Infection is acquired by exposure to organisms in contaminated, undercooked, or raw crustaceans or shellfish and warm (> 20°C) ocean waters and estuaries. Infections are more common during the summer months from regions along the Atlantic coast and the Gulf of Mexico in the United States and from tropical waters around the world. Oysters are implicated in up to 90% of food-related cases. *V parahaemolyticus* causes an acute watery diarrhea with crampy abdominal pain and fever, typically occurring within 24 hours after ingestion of contaminated shellfish. The disease is self-limited, and antimicrobial therapy is usually not necessary. *V parahaemolyticus* may also cause cellulitis and sepsis, though these findings are more characteristic of *V vulnificus* infection.

V vulnificus and *V alginolyticus*—neither of which is associated with diarrheal illness—are important causes of cellulitis and primary bacteremia, which may follow ingestion of contaminated shellfish or exposure to sea water. Cellulitis with or without sepsis may be accompanied by bulla formation and necrosis with extensive soft tissue destruction, at times requiring debridement and amputation. The infection can be rapidly progressive and is particularly severe in immunocompromised individuals—especially those with cirrhosis—with death rates as high as 50%. Patients with chronic liver disease and those who are immunocompromised should be cautioned to avoid eating raw oysters.

Tetracycline at a dose of 500 mg four times a day for 7-10 days is the drug of choice for treatment of suspected or documented primary bacteremia or cellulitis caused by *Vibrio* species. *V vulnificus* is susceptible in vitro to penicillin, ampicillin, cephalosporins, chloramphenicol, aminoglycosides, and fluoroquinolones, and these agents may also be effective. *V parahaemolyticus* and *V alginolyticus* produce β-lactamase and therefore are resistant to penicillin and ampicillin, but susceptibilities otherwise are similar to those listed for *V vulnificus*.

INFECTIONS CAUSED BY CAMPYLOBACTER SPECIES

Campylobacters are microaerophilic, motile, gram-negative rods. Two species infect humans: *Campylobacter jejuni*, an important cause of diarrheal disease, and *Campylobacter fetus* subsp *fetus*, which typically causes systemic infection and not diarrhea. Dairy cattle and poultry are an important reservoir for campylobacters. Outbreaks of enteritis have been associated with consumption of raw milk. Campylobacter gastroenteritis is associated with fever, abdominal pain, and diarrhea characterized by loose, watery, or bloody stools. The differential diagnosis includes shigellosis, salmonella gastroenteritis, and enteritis caused by *Yersinia enterocolitica* or invasive *Escherichia coli*. The disease is self-limited, but its duration can be shortened with antimicrobial therapy. Both erythromycin, 250-500 mg four times daily for 5-7 days, and ciprofloxacin, 500 mg twice daily for 3-5 days, are effective regimens. Pending identification of the causative agent of suspected bacterial gastroenteritis, ciprofloxacin is a rational choice for empirical therapy because all of the common bacterial pathogens are susceptible.

C fetus causes systemic infections that can be fatal, including primary bacteremia, endocarditis, meningitis, and focal abscesses. It infrequently causes gastroenteritis. Patients infected with *C fetus* are often older, debilitated, or immunocompromised. Closely related species, collectively termed campylobacter-like organisms, cause bacteremia in HIV-infected individuals. Systemic infections respond to therapy with gentamicin, chloramphenicol, ceftriaxone, or ciprofloxacin. Ceftriaxone or chloramphenicol should be used to treat infections of the central nervous system because of their ability to penetrate the blood-brain barrier.

BRUCELLOSIS

- History of animal exposure, ingestion of unpasteurized milk or cheese.
- Insidious onset: easy fatigability, headache, arthralgia, anorexia, sweating, irritability.
- Intermittent fever, especially at night, which may become chronic and undulant.
- Cervical and axillary lymphadenopathy; hepatosplenomegaly.
- Lymphocytosis, positive blood culture, elevated agglutination titer.

General Considerations

The infection is transmitted from animals to humans. *Brucella abortus* (cattle), *Brucella suis* (hogs), and *Brucella melitensis* (goats) are the main agents. Transmission to humans occurs by contact with infected meat (slaughterhouse workers), placentae of infected animals (farmers, veterinarians), or ingestion of infected unpasteurized milk or cheese. The incubation period varies from a few days to several weeks. The disorder may become chronic. In the United States, brucellosis is very rare except in the midwestern states (*B suis*) and in visitors or immigrants from countries where brucellosis is endemic (eg, Mexico, Spain, South American countries).

Clinical Findings

A. Symptoms and Signs

The onset may be acute, with fever, chills, and sweats, but more often is insidious. It may be weeks before the patient seeks medical care for weakness, weight loss, low-grade fevers, sweats, and exhaustion upon minimal activity. Symptoms also include headache, abdominal or back pain with anorexia and constipation, and arthralgias. Epididymitis occurs in 10% of cases in men. The chronic form may assume an undulant nature, with periods of normal temperature between acute attacks; symptoms may persist for years, either continuously or intermittently.

Physical findings are minimal. Half of cases have peripheral lymph node enlargement and splenomegaly; hepatomegaly is less common.

B. Laboratory Findings

Early in the course, the organism can be recovered from the blood, cerebrospinal fluid, urine, and bone marrow. Because the organism is slow-growing, cultures should be incubated for 21 days before being read as negative. Cultures are more likely to be negative in chronic cases. The diagnosis often is made by serologic testing. Rising serologic titers or an absolute agglutination titer of greater than 1:100 supports the diagnosis.

Differential Diagnosis

Brucellosis must be differentiated from any other acute febrile disease, especially influenza, tularemia, Q fever, mononucleosis, and enteric fever. In its chronic form it resembles Hodgkin's disease, tuberculosis, HIV infection, malaria, and disseminated fungal infections such as histoplasmosis and coccidioidomycosis.

Complications

The most frequent complications are bone and joint lesions such as spondylitis and suppurative arthritis (usually of a single joint), endocarditis, and meningoencephalitis. Less common complications are pneumonitis with pleural effusion, hepatitis, and cholecystitis.

Treatment

Single-drug regimens are not recommended because the relapse rate may be as high as 50%. Combination regimens of two or three drugs are more effective. Either (1) doxycycline plus rifampin or streptomycin (or both) *or* (2) trimethoprim-sulfamethoxazole plus rifampin or streptomycin (or both) is effective in doses as follows for 21 days: doxycycline, 100-200 mg/d in divided doses; trimethoprim, 320 mg/d, plus sulfamethoxazole, 1600 mg/d, in divided doses; rifampin, 600-1200 mg/d; and streptomycin, 500 mg intramuscularly twice a day. Longer courses of therapy (eg, several months) may be required to cure relapses, osteomyelitis, or meningitis.

Yagupsky P: Detection of brucellae in blood cultures. J Clin Microbiol 1999;37:3437. [\[PMID: 10523530\]](#)

TULAREMIA

Essentials of Diagnosis

- History of contact with rabbits, other rodents, and biting arthropods (eg, ticks in summer) in endemic area.
- Fever, headache, nausea, and prostration.
- Papule progressing to ulcer at site of inoculation.
- Enlarged regional lymph nodes.
- Serologic tests or culture of ulcer, lymph node aspirate, or blood confirm the diagnosis.

General Considerations

Tularemia is an infection of wild rodents—particularly rabbits and muskrats—with *Francisella (Pasteurella) tularensis*. Humans usually acquire the infection by contact with animal tissues (eg, trapping muskrats, skinning rabbits) or from ticks. Investigation of an outbreak of pneumonic tularemia on Martha's Vineyard in Massachusetts implicated lawn-mowing and brush-cutting as risk factors for infection, underscoring the potential for probable aerosol transmission of the organism. *F tularensis* has been classified as a high-priority agent for potential bioterrorism use because of its virulence and relative ease of dissemination. Infection in humans often produces a local lesion and widespread organ involvement but may be entirely asymptomatic. The incubation period is 2-10 days.

Clinical Findings

A. Symptoms and Signs

Fever, headache, and nausea begin suddenly, and a local lesion—a papule at the site of inoculation—develops and soon ulcerates. Regional lymph nodes may become enlarged and tender and may suppurate. The local lesion may be on the skin of an extremity or in the eye. Pneumonia may develop from hematogenous spread of the organism or may be primary after inhalation of infected aerosols, which are responsible for human-to-human transmission. Following ingestion of infected meat or water, an enteric form may be manifested by gastrointestinal symptoms, stupor, and delirium. In any type of involvement, the spleen may be enlarged and tender and there may be nonspecific rashes, myalgias, and prostration.

B. Laboratory Findings

Culturing the organism from blood or infected tissue requires special media. For this reason and because cultures of *F tularensis* may be hazardous to laboratory personnel, the diagnosis is usually made serologically. A positive agglutination test (> 1:80) develops in the second week after infection and may persist for several years.

Differential Diagnosis

Tularemia must be differentiated from rickettsial and meningococcal infections, cat-scratch disease, infectious mononucleosis, and various bacterial and fungal diseases.

Complications

Hematogenous spread may produce meningitis, perisplenitis, pericarditis, pneumonia, and osteomyelitis.

Treatment

Streptomycin, 0.5 g intramuscularly every 6-8 hours, together with tetracycline, 0.5 g orally every 6 hours, is administered until 4-5 days after the patient becomes afebrile. Chloramphenicol may be substituted for tetracycline in the same dosage.

Feldman KA et al: An outbreak of primary pneumonic tularemia on Martha's Vineyard. N Engl J Med 2001;345:1601. [\[PMID: 11757506\]](#)

PLAGUE

Essentials of Diagnosis

- History of exposure to rodents in endemic area.
- Sudden onset of high fever, malaise, muscular pains, and prostration.
- Axillary or inguinal lymphadenitis (bubo).
- Bacteremia, pneumonitis, and meningitis may occur.
- Positive smear and culture from bubo and positive blood culture.

General Considerations

Plague is an infection of wild rodents with *Yersinia pestis*, a small bipolar-staining gram-negative rod. It is endemic in California, Arizona, Nevada, and New Mexico. It is transmitted among rodents and to humans by the bites of fleas or from contact with infected animals. If a plague victim develops pneumonia, the infection can be transmitted by droplets to other individuals. The incubation period is 2-10 days.

Because of its extreme virulence, its potential for dissemination and person-to-person transmission, and efforts to develop the organism as an agent of biowarfare, plague bacillus is considered a high-priority agent for bioterrorism.

Following the flea bite, the organisms spread through the lymphatics to the lymph nodes, which become greatly enlarged (bubo). They may then reach the bloodstream to involve all organs. When pneumonia or meningitis develops, the outcome is often fatal.

Clinical Findings

A. Symptoms and Signs

The onset is sudden, with high fever, malaise, tachycardia, intense headache, and severe myalgias. The patient appears profoundly ill. Delirium may ensue. If pneumonia develops, tachypnea, productive cough, blood-tinged sputum, and cyanosis also occur. Signs of meningitis may develop. A pustule or ulcer at the site of inoculation and lymphangitis may be observed. Axillary, inguinal, or cervical lymph nodes become enlarged and tender and may suppurate and drain. With hematogenous spread, the patient may rapidly become toxic and comatose, with purpuric spots (black plague) appearing on the skin.

Primary plague pneumonia is a fulminant pneumonitis with bloody, frothy sputum and sepsis. It is usually fatal unless treatment is started within a few hours after onset.

B. Laboratory Findings

The plague bacillus may be found in smears from aspirates of buboes examined with Gram's stain. Cultures from bubo aspirate or pus and blood are positive but may

grow slowly. In convalescing patients, an antibody titer rise may be demonstrated by agglutination tests.

Differential Diagnosis

The lymphadenitis of plague is most commonly mistaken for the lymphadenitis accompanying staphylococcal or streptococcal infections of an extremity, sexually transmitted diseases such as lymphogranuloma venereum or syphilis, and tularemia. The systemic manifestations resemble those of enteric or rickettsial fevers, malaria, or influenza. The pneumonia resembles other bacterial pneumonias, and the meningitis is similar to those caused by other bacteria.

Prevention

Drug prophylaxis may provide temporary protection for persons exposed to the risk of plague infection, particularly by the respiratory route. Tetracycline hydrochloride, 500 mg orally once or twice daily for 5 days, is effective.

Plague vaccines—both live and killed—have been used for many years, but their efficacy is not clearly established.

Treatment

Therapy should be started immediately once plague is suspected. Either streptomycin (the agent with which there is greatest experience), 1 g every 12 hours intravenously, or gentamicin, administered as a 2-mg/kg loading dose, then 1.7 mg/kg every 8 hours intravenously, is effective. Alternatively, doxycycline, 100 mg orally or intravenously, may be used. The duration of therapy is 10 days. Patients with plague pneumonia are placed in strict respiratory isolation.

Koornhof HJ et al: Yersiniosis. II: The pathogenesis of *Yersinia* infections. Eur J Clin Microbiol Infect Dis 1999;18:87. [\[PMID: 10219573\]](#)

GNOCOCCAL INFECTIONS

Essentials of Diagnosis

- Purulent and profuse urethral discharge, especially in men, with dysuria, yielding positive smear.
- Epididymitis, prostatitis, periurethral inflammation, proctitis in men.
- Cervicitis in women with purulent discharge, or asymptomatic, yielding positive culture; vaginitis, salpingitis, proctitis also occur.
- Fever, rash, tenosynovitis, and arthritis with disseminated disease.
- Gram-negative intracellular diplococci seen in a smear or cultured from any site, particularly the urethra, cervix, pharynx, and rectum.

General Considerations

Gonorrhea is caused by *Neisseria gonorrhoeae*, a gram-negative diplococcus typically found inside polymorphonuclear cells. It is transmitted during sexual activity and has its greatest incidence in the 15- to 29-year-old age group. The incubation period is usually 2-8 days.

Anatomic Classification

A. Urethritis and Cervicitis

In men, there is initially burning on urination and a serous or milky discharge. One to 3 days later, the urethral pain is more pronounced and the discharge becomes yellow, creamy, and profuse, sometimes blood-tinged. The disorder may regress and become chronic or progress to involve the prostate, epididymis, and periurethral glands with painful inflammation. Chronic infection leads to prostatitis and urethral strictures. Rectal infection is common in homosexual men. Atypical sites of primary infection (eg, the pharynx) must always be considered. Asymptomatic infection is common and occurs in both sexes.

Gonococcal infection in women often becomes symptomatic during menses. Women may have dysuria, urinary frequency, and urgency, with a purulent urethral discharge. Vaginitis and cervicitis with inflammation of Bartholin's glands are common. Infection may be asymptomatic, with only slightly increased vaginal discharge and moderate cervicitis on examination. Infection may remain as a chronic cervicitis—an important reservoir of gonococci. It can progress to involve the uterus and tubes with acute and chronic salpingitis, with scarring of tubes and sterility. In pelvic inflammatory disease, anaerobes and chlamydiae often accompany gonococci. Rectal infection may result from spread of the organism from the genital tract or from anal coitus.

Gram stain of urethral discharge in men, especially during the first week after onset, shows gram-negative diplococci in polymorphonuclear leukocytes. Gram stain is less often positive in women. Culture has been the gold standard for diagnosis, particularly when the Gram stain is negative. A ligase chain reaction (LCR) assay that detects both *N gonorrhoeae* and *Chlamydia trachomatis* in cervical and urethral swab specimens and urine permits more rapid diagnosis of gonococcal infection. LCR also has improved sensitivity (approximately 90-95% for urine and > 95% for swab) and high specificity (= 99%) compared with culture of swab specimens (overall sensitivity of approximately 80%). This test is likely to replace culture, particularly for screening, given the convenience of obtaining a urine sample and because it detects *C trachomatis* coinfection. Identification of *N gonorrhoeae* from rectal or pharyngeal sites and in joint fluid still requires culture.

B. Disseminated Disease

Systemic complications follow the dissemination of gonococci from the primary site via the bloodstream. Gonococcal bacteremia is associated with intermittent fever, arthralgia, and skin lesions ranging from maculopapular to pustular or hemorrhagic, which tend to be few in number and peripherally located. Rarely, gonococcal endocarditis or meningitis develops. Arthritis and tenosynovitis are common complications, particularly involving the knees, ankles, and wrists. One or occasionally a few joints usually are involved. Gonococci are isolated by culture from less than half of patients with gonococcal arthritis.

C. Conjunctivitis

The most common form of eye involvement is direct inoculation of gonococci into the conjunctival sac. In adults, this occurs by autoinoculation of a person with genital infection. The purulent conjunctivitis may rapidly progress to panophthalmitis and loss of the eye unless treated promptly. A single 1-g dose of ceftriaxone is effective.

Differential Diagnosis

Gonococcal urethritis or cervicitis must be differentiated from nongonococcal urethritis; cervicitis or vaginitis due to *Chlamydia trachomatis*, *Gardnerella vaginalis*, trichomonas, candida, and many other agents associated with sexually transmitted diseases; and pelvic inflammatory disease, arthritis, proctitis, and skin lesions. Often, several such agents coexist in a patient. Reactive arthritis (urethritis, conjunctivitis, arthritis) may mimic gonorrhea or coexist with it.

Prevention

Prevention is based on education and mechanical or chemical prophylaxis. The condom, if properly used, can reduce the risk of infection. Effective drugs taken in therapeutic doses within 24 hours of exposure can abort an infection.

Treatment

Therapy typically is administered before antimicrobial susceptibilities are known. The choice of which regimen to use should be based on the prevalence of penicillin-resistant organisms. Nationwide, penicillin- and tetracycline-resistant gonococci have been increasingly observed. Consequently, penicillin should no longer be considered first-line therapy. All sexual partners should be treated and tested for HIV infection and syphilis, as should the patient as well.

A. Uncomplicated Gonorrhea

For urethritis or cervicitis, either ceftriaxone, 125 mg intramuscularly, or cefixime, 400 mg orally as a single dose, is the treatment of choice. Fluoroquinolones are no longer recommended as first-line agents because of emerging resistance; the same is true for amoxicillin. A single oral dose of ciprofloxacin 500 mg, ofloxacin 400 mg, or levofloxacin 250 mg is also effective. Spectinomycin, 1 g intramuscularly once, may be used for the penicillin-allergic patient. Anal gonorrhea in women responds to the same drugs, but in males ceftriaxone is most effective. Pharyngeal gonorrhea is treated by ceftriaxone in the same dosage and by trimethoprim-sulfamethoxazole, nine regular-strength tablets orally daily for 5 days. Since coexistent chlamydial infection is common, one should give doxycycline, 100 mg twice daily orally for 7 days, or a single 1 g oral dose of azithromycin, concurrently; women should be tested for pregnancy before any tetracycline is prescribed (see also below).

B. Treatment of Other Infections

Salpingitis, prostatitis, bacteremia, arthritis, and other complications due to susceptible strains in adults should be treated with penicillin G, 10 million units intravenously daily, for 5 days. Ceftriaxone, 1 g intravenously daily for 5 days, or an oral fluoroquinolone (ciprofloxacin, 500 mg twice daily, or levofloxacin, 500 mg once daily) for 5

days also is effective. Endocarditis should be treated with ceftriaxone, 1 g every 12 hours intravenously, for at least 3 weeks. Postgonococcal urethritis and cervicitis, which are usually caused by chlamydia, are treated with a regimen of erythromycin, doxycycline, or azithromycin as described above.

Pelvic inflammatory disease requires cefoxitin, 2 g parenterally every 6 hours, or cefotetan, 2 g intravenously every 12 hours. Clindamycin, 900 mg intravenously every 8 hours, plus gentamicin, administered as a 2-mg/kg loading dose followed by 1.5 mg/kg every 8 hours, is also effective. Cefoxitin, 2 g intramuscularly, plus probenecid, 1 g orally as a single dose, followed by a 14-day oral regimen of doxycycline, 100 mg twice a day, is an effective outpatient regimen. Concurrent treatment for chlamydial infection also is indicated.

Woodward C et al: Drug treatment of common STDs: Part I. Herpes, syphilis, urethritis, chlamydia and gonorrhea. Am Fam Physician 1999;60:1387. [\[PMID: 10537386\]](#)

CHANCROID

Chancroid is a sexually transmitted disease caused by the short gram-negative bacillus *Haemophilus ducreyi*. The incubation period is 3-5 days. The initial lesion at the site of inoculation is a vesicopustule that breaks down to form a painful, soft ulcer with a necrotic base, surrounding erythema, and undermined edges. Multiple lesions—started by autoinoculation—and inguinal adenitis often develop. The adenitis is usually unilateral and consists of tender, matted nodes of moderate size with overlying erythema. These may become fluctuant and rupture spontaneously. With lymph node involvement, fever, chills, and malaise may develop. Balanitis and phimosis are frequent complications in men. Women may have no external signs of infection. The diagnosis is established by culturing a swab of the lesion onto a special medium.

Chancroid must be differentiated from other genital ulcers. The chancre of syphilis is clean and painless, with a hard base. Mixed sexually transmitted disease is very common (including syphilis, herpes simplex, and HIV infection), as is infection of the ulcer with fusiforms, spirochetes, and other organisms.

A single dose of either azithromycin, 1 g orally, or ceftriaxone, 250 mg intramuscularly, is effective treatment. Effective multiple-dose regimens are amoxicillin-potassium clavulanate (500/125 mg) three times a day orally for 7 days, erythromycin, 500 mg orally four times a day for 7 days, or ciprofloxacin, 500 mg orally twice a day for 3 days.

GRANULOMA INGUINALE

Granuloma inguinale is a chronic, relapsing granulomatous anogenital infection due to *Calymmatobacterium (Donovania) granulomatis*. The pathognomonic cell, found in tissue scrapings or secretions, is large (25-90 um) and contains intracytoplasmic cysts filled with bodies (Donovan bodies) that stain deeply with Wright's stain.

The incubation period is 8 days to 12 weeks. The onset is insidious. The lesions occur on the skin or mucous membranes of the genitalia or perineal area. They are relatively painless infiltrated nodules that soon slough. A shallow, sharply demarcated ulcer forms, with a beefy-red friable base of granulation tissue. The lesion spreads by contiguity. The advancing border has a characteristic rolled edge of granulation tissue. Large ulcerations may advance onto the lower abdomen and thighs. Scar formation and healing occur along one border while the opposite border advances.

Superinfection with spirochete-fusiform organisms is common. The ulcer then becomes purulent, painful, foul-smelling, and extremely difficult to treat.

Several therapies are available. Because of the indolent nature of the disease, duration of therapy is relatively long. Erythromycin or tetracycline, 500 mg four times a day for 21 days, is effective. Ampicillin, 500 mg four times a day, is an alternative, but up to 12 weeks of therapy may be necessary.

BARTONELLA SPECIES

A revised classification of the a₂ subdivision of proteobacteria has grouped the species previously known as rochalimaea as members of the bartonellae based on ribosomal RNA. These organisms (which include *B quintana*, *B henselae*, *B vinsonii*, and *B elizabethae*) are responsible for a wide variety of clinical syndromes.

Bacillary angiomatosis, an important manifestation of bartonellosis, is discussed in [Chapter 31](#).

Trench fever is a self-limited, louse-borne relapsing febrile disease caused by *B quintana*. The disease has occurred epidemically in louse-infested troops and civilians during wars and endemically in residents of scattered geographic areas (eg, Central America). An urban equivalent of trench fever has been described among the homeless. Humans acquire infection when infected lice feces enter sites of skin breakdown. Onset of symptoms is abrupt and fever lasts 3-5 days, with relapses. The patient complains of weakness and severe pain behind the eyes and typically in the back and legs. Lymphadenopathy, splenomegaly, and a transient maculopapular rash may appear. Subclinical infection is frequent, and a carrier state is recognized. The differential diagnosis includes other febrile, self-limited states such as dengue, leptospirosis, malaria, relapsing fever, and typhus. Recovery occurs regularly even in the absence of treatment.

Cat-scratch disease is an acute infection of children and young adults caused by *Bartonella henselae*. It is transmitted from cats to humans as the result of a scratch or bite. Within a few days, one-third of patients will develop a papule or ulcer at the inoculation site. One to 3 weeks later, fever, headache, and malaise occur. Regional lymph nodes become enlarged, often tender, and may suppurate. Lymphadenopathy from cat scratches resembles that due to neoplasm, tuberculosis, lymphogranuloma venereum, and bacterial lymphadenitis. The diagnosis is usually made clinically. Special cultures for bartonellae, serology, or excisional biopsy, though rarely necessary, confirm the diagnosis. The biopsy reveals necrotizing lymphadenitis and is itself not specific for cat-scratch disease. Cat-scratch disease is usually self-limited, requiring no specific therapy. Encephalitis occurs rarely.

Disseminated forms of the disease—bacillary angiomatosis and peliosis hepatis—occur in HIV-infected persons. The lesions are vasculoproliferative and histopathologically distinct from those of cat-scratch disease. *Bartonella quintana*, the agent of trench fever, can also cause bacillary angiomatosis as well as culture-negative endocarditis. Bacillary angiomatosis and endocarditis respond to treatment with a macrolide or tetracycline administered in standard doses for 4-8 weeks. Relapse may occur.

ANAEROBIC INFECTIONS

Anaerobic bacteria comprise the majority of normal human flora. Normal microbial flora of the mouth (anaerobic spirochetes, prevotella, fusobacteria), the skin (anaerobic diphtheroids), the large bowel (bacteroides, anaerobic streptococci, clostridia), and the female tract (bacteroides, anaerobic streptococci, fusobacteria) produce disease when displaced from their normal sites into tissues or closed body spaces.

Certain characteristics are suggestive of anaerobic infections: (1) They are polymicrobial. (2) Abscess formation is the rule. (3) Pus and infected tissue often are malodorous. (4) Septic thrombophlebitis and metastatic infection are frequent and may require incision and drainage. (5) Many important anaerobes except *Bacteroides fragilis* are highly sensitive to penicillin G. (6) Diminished blood supply that favors proliferation of anaerobes because of reduced tissue oxygenation interferes with the delivery of antimicrobials to the site of anaerobic infection. (7) Bacteriologic examination may yield negative results or only inconsequential aerobes unless rigorous culture conditions are used.

Important types of infections that are most commonly caused by anaerobic organisms are listed below. Treatment of all these infections consists of surgical exploration and judicious excision in conjunction with administration of antimicrobial drugs.

Upper Respiratory Tract

Prevotella melaninogenica (formerly *Bacteroides melaninogenicus*) and anaerobic spirochetes are commonly involved in periodontal infections. These organisms, fusobacteria, and peptostreptococci may cause chronic sinusitis, peritonsillar abscess, chronic otitis media, and mastoiditis. Hygiene, drainage, and surgical debridement are as important in treatment as antimicrobials. Oral anaerobic organisms have been uniformly susceptible to penicillin, but there has been a recent trend of increasing penicillin resistance, usually due to β-lactamase production. Penicillin, 1-2 million units intravenously every 4 hours (if parenteral therapy is required) or 0.5 g orally four times daily for less severe infections, or clindamycin can be used (600 mg intravenously every 8 hours or 300 mg orally every 6 hours). Antimicrobial treatment is continued for a few days after signs and symptoms of infection have resolved. Indolent, established infections (eg, mastoiditis or osteomyelitis) may require prolonged courses of therapy, eg, 4-6 weeks or longer.

Chest Infections

Usually in the setting of poor oral hygiene and periodontal disease, aspiration of saliva (which contains 10⁸ anaerobic organisms per milliliter in addition to aerobes) may lead to necrotizing pneumonia, lung abscess, and empyema. While polymicrobial infection is the rule, anaerobes—particularly *P melaninogenica*, fusobacteria, and peptostreptococci—are common etiologic agents. Most pulmonary infections respond to antimicrobial therapy alone. Percutaneous chest tube or surgical drainage is indicated for empyema.

Penicillin has long been considered the drug of choice for treatment of anaerobic lung infections, but penicillin-resistant *B fragilis* and *P melaninogenica* are isolated in up to 25% of cases and have been associated with clinical failures. Clindamycin, 600 mg intravenously once, followed by 300 mg orally every 6-8 hours, is the treatment of choice for these infections. Penicillin, 2 million units intravenously every 4 hours, followed by amoxicillin, 500 mg every 8 hours orally, is a reasonable alternative. These infections respond slowly. A duration of 3-4 weeks or more of antimicrobial therapy is typical. The second-generation cephalosporins cefoxitin, cefotetan, and cefmetazole are active in vitro against anaerobes, including those that are penicillin-resistant.

Central Nervous System

Anaerobes are a common cause of brain abscess, subdural empyema, or septic central nervous system thrombophlebitis. The organisms reach the central nervous system by direct extension from sinusitis, otitis, or mastoiditis or by hematogenous spread from chronic lung infections. Antimicrobial therapy—eg, penicillin, 20 million units intravenously, in combination with metronidazole, 750 mg intravenously, every 8 hours—is an important adjunct to surgical drainage. Duration of therapy is 6-8 weeks. Some small multiple brain abscesses can be treated with antibiotics alone without surgical drainage. Alternatively, septic internal jugular thrombophlebitis (Lemierre's syndrome) originates from mouth anaerobes and may cause septic pulmonary embolization. Severe sore throat is a concomitant.

Intra-abdominal Infections

In the colon there are up to 10¹¹ anaerobes per gram of content—predominantly *B fragilis*, clostridia, and peptostreptococci. These organisms play a central role in most intra-abdominal abscesses following trauma to the colon, diverticulitis, appendicitis, or perirectal abscess and may also participate in hepatic abscess and cholecystitis, often in association with aerobic coliform bacteria. The gallbladder wall can be infected with clostridia as well. The bacteriology includes anaerobes as well as enteric gram-negative rods and on occasion enterococci. Therapy should be directed both against anaerobes and gram-negative aerobes. Multiple antibiotics may be required. Those reliably active against *B fragilis* include metronidazole, chloramphenicol, imipenem, ampicillin-sulbactam, and ticarcillin-clavulanic acid. Cefoxitin, cefotetan, and clindamycin are useful against 80-90% of strains, but most third-generation cephalosporins have poor efficacy, inhibiting only 50% of isolates. Non-fragilis species of bacteroides may be less susceptible to the cephalosporins.

Table 33-6 summarizes the antibiotic regimens for management of moderate to moderately severe infections (eg, patient hemodynamically stable, good surgical drainage possible or established, low APACHE score, no multiple organ failure) and severe infections (eg, major peritoneal soilage, large or multiple abscesses, patient hemodynamically unstable), particularly if drug-resistant organisms are suspected. An effective oral regimen for patients able to take it is presented also.

Female Genital Tract & Pelvic Infections

The normal flora of the vagina and cervix includes several species of bacteroides, peptostreptococci, group B streptococci, lactobacilli, coliform bacteria, and, occasionally, spirochetes and clostridia. These organisms commonly cause genital tract infections and may disseminate from there.

While salpingitis is often caused by gonococci and chlamydiae, tubo-ovarian and pelvic abscesses are associated with anaerobes in most cases. Postpartum infections may be caused by aerobic streptococci or staphylococci, but anaerobes are often found, and the worst cases of postpartum or postabortion sepsis are associated with clostridia and bacteroides. These have a high mortality rate, and treatment requires both antimicrobials directed against anaerobes and coliforms (see above) and abscess drainage or early hysterectomy.

Bacteremia & Endocarditis

Anaerobic bacteremia usually originates from the gastrointestinal tract, the oropharynx, decubitus ulcers, or the female genital tract. Endocarditis due to anaerobic and microaerophilic streptococci and bacteroides originates from the same sites. Most cases of anaerobic or microaerophilic streptococcal endocarditis can be effectively treated with 12-20 million units of penicillin G daily for 4-6 weeks, but optimal therapy of other types of anaerobic bacterial endocarditis must rely on laboratory guidance. Anaerobic corynebacteria (propionibacteria), clostridia, and bacteroides occasionally cause endocarditis.

Skin & Soft Tissue Infections

Anaerobic infections in the skin and soft tissue usually follow trauma, inadequate blood supply, or surgery and are commonest in areas that are contaminated by oral or fecal flora. There may be progressive tissue necrosis and a putrid odor.

Several terms, such as bacterial synergistic gangrene, synergistic necrotizing cellulitis, necrotizing fasciitis, and nonclostridial crepitant cellulitis, have been used to classify these infections. Although there are some differences in microbiology among them, their differentiation on clinical grounds alone is difficult. All are mixed infections caused by aerobic and anaerobic organisms and require aggressive surgical debridement of necrotic tissue for cure. Surgical consultation is obligatory to assist in diagnosis and treatment.

Broad-spectrum antibiotics active against both anaerobes and gram-positive and gram-negative aerobes (eg, vancomycin plus metronidazole and gentamicin or tobramycin) should be instituted empirically and modified by culture results (Table 37-2). They are given for about a week after progressive tissue destruction has been controlled and the margins of the wound remain free of inflammation.

■ ACTINOMYCOSIS

Essentials of Diagnosis

- History of recent dental infection or abdominal trauma.
- Chronic pneumonia or indolent intra-abdominal or cervicofacial abscess.
- Sinus tract formation.

General Considerations

Actinomyces israelii and other species of actinomyces occur in the normal flora of the mouth and tonsillar crypts. They are anaerobic, gram-positive, branching filamentous bacteria (1 um in diameter) that may fragment into bacillary forms. When introduced into traumatized tissue and associated with other anaerobic bacteria, these actinomycetes become pathogens.

The most common site of infection is the cervicofacial area (about 60% of cases). Infection typically follows extraction of a tooth or other trauma. Lesions may develop in the gastrointestinal tract or lungs following ingestion or aspiration of the organism from its endogenous source in the mouth.

Clinical Findings

A. Symptoms and Signs

1. Cervicofacial actinomycosis—Cervicofacial actinomycosis develops slowly. The area becomes markedly indurated, and the overlying skin becomes reddish or cyanotic. Abscesses eventually draining to the surface persist for long periods. Sulfur granules—masses of filamentous organisms—may be found in the pus. There is usually little pain unless there is secondary infection. Trismus indicates that the muscles of mastication are involved. Radiography may reveal bony involvement.

2. Thoracic actinomycosis—Thoracic involvement begins with fever, cough, and sputum production with night sweats and weight loss. Pleuritic pain may be present. Multiple sinuses may extend through the chest wall, to the heart, or into the abdominal cavity. Ribs may be involved. Radiography shows areas of consolidation and in many cases pleural effusion. Cervicofacial or thoracic disease may occasionally involve the central nervous system, most commonly brain abscess or meningitis.

3. Abdominal actinomycosis—Abdominal actinomycosis usually causes pain in the ileocecal region, spiking fever and chills, vomiting, and weight loss; it may be confused with Crohn's disease. Irregular abdominal masses may be palpated. Pelvic inflammatory disease caused by actinomycetes has been associated with prolonged use of an intrauterine contraceptive device. Sinuses draining to the exterior may develop. CT scanning reveals an inflammatory mass extended to involve

bone.

B. Laboratory Findings

The anaerobic, gram-positive organism may be demonstrated as a granule or as scattered branching gram-positive filaments in the pus. Anaerobic culture is necessary to distinguish actinomycetes from nocardiae because specific therapy differs for the two infections.

Treatment

Penicillin G is the drug of choice. Ten to 20 million units are given via a parenteral route for 2-4 weeks, followed by oral penicillin V, 500 mg four times daily.

Sulfonamides such as sulfamethoxazole may be an alternative regimen at a total daily dosage of 2-4 g. Response to therapy is slow. Therapy should be continued for weeks to months after clinical manifestations have disappeared in order to ensure cure. Surgical procedures such as drainage and resection may be beneficial.

With penicillin and surgery, the prognosis is good. The difficulties of diagnosis, however, may permit extensive destruction of tissue before the diagnosis is identified and therapy is started.

■ NOCARDIOSIS

Nocardia asteroides, an aerobic filamentous soil bacterium, causes pulmonary and systemic nocardiosis. Bronchopulmonary abnormalities (eg, alveolar proteinosis) predispose to colonization, but infection is unusual unless the patient is also receiving systemic corticosteroids or is otherwise immunosuppressed.

Pulmonary involvement usually begins with malaise, loss of weight, fever, and night sweats. Cough and production of purulent sputum are the chief complaints. Radiography may show infiltrates accompanied by pleural effusion. The lesions may penetrate to the exterior through the chest wall, invading the ribs.

Dissemination involves any organ. Brain abscesses and subcutaneous nodules are most frequent. This is seen exclusively in immunocompromised patients.

N asteroides is usually found as delicate, branching, gram-positive filaments. It may be weakly acid-fast, occasionally causing diagnostic confusion with tuberculosis. Identification is made by culture.

Therapy is initiated with intravenous trimethoprim-sulfamethoxazole administered at a dosage of 5-10 mg/kg/d (trimethoprim) and continued with oral trimethoprim-sulfamethoxazole, one double-strength tablet twice a day. Surgical procedures such as drainage and resection may be needed as adjunctive therapy.

Response may be slow, and therapy must be continued for at least 6 months. The prognosis in systemic nocardiosis is poor when diagnosis and therapy are delayed.

Nocardia brasiliensis typically causes a digital lesion—resembling herpetic whitlow—and ascending lymphangitis in normal hosts. Antimicrobial treatment is as for *N asteroides* infection, and the prognosis is excellent.

■ INFECTIONS CAUSED BY MYCOBACTERIA

NONTUBERCULOUS ATYPICAL MYCOBACTERIAL DISEASES

About 10% of mycobacterial infections are caused by atypical mycobacteria. Atypical mycobacterial infections are among the most common opportunistic infections in advanced HIV disease. These organisms have distinctive laboratory characteristics, occur ubiquitously in the environment, are not communicable from person to person, and are often strikingly resistant to antituberculous drugs.

Disseminated *Mycobacterium avium* Infection

Mycobacterium avium complex (MAC) produces asymptomatic colonization or a wide spectrum of diseases, including coin lesions, bronchitis in patients with chronic lung disease, and invasive pulmonary disease that is often cavitary and occurs in patients with underlying lung disease. MAC is a common cause of widespread disease in the late stages of HIV infection, when the CD4 cell count is less than 50/uL. Persistent fever and weight loss are the most common symptoms. The organism can usually be cultured from multiple sites, including blood, liver, lymph node, or bone marrow. Blood culture is the preferred means of establishing the diagnosis and has a sensitivity of 98%.

Agents with proved activity against MAC are rifabutin, azithromycin, clarithromycin, and ethambutol. Amikacin and ciprofloxacin work in vitro, but clinical results are inconsistent. Single-agent therapy should not be used because of rapid emergence of secondary resistance. Clarithromycin, 500 mg orally twice daily, plus ethambutol, 15 mg/kg/d as a single dose, with or without rifabutin, 300 mg/d, is the treatment of choice. Azithromycin, 500 mg once daily, may be used instead of clarithromycin. Too few data are available to permit specific recommendations about second-line regimens for patients intolerant of macrolides or those with macrolide-resistant organisms. A combination of two or more active agents should be used. The recommendation has been lifelong therapy for disseminated infection for patients with AIDS. It is not known whether immune reconstitution in patients receiving highly active antiretroviral therapy (HAART) whose CD4 counts exceed 100-200/uL is sufficient to permit discontinuation of therapy without relapse. This decision should be made on an individual basis.

Antimicrobial prophylaxis of MAC prevents disseminated disease and prolongs survival. It is the standard of care to offer it to all HIV-infected patients with CD4 counts = 50/uL. Primary prophylaxis for MAC infection can be stopped in patients who have responded to HIV protease inhibitor antiretroviral combination therapy with elevation of CD4 counts above 100 cells/uL for 3-6 months. Single-drug regimens of clarithromycin, 500 mg twice daily, azithromycin, 1200 mg once weekly, or rifabutin, 300 mg once daily, are effective. Clarithromycin and azithromycin are more effective and better tolerated than rifabutin, and for that reason a macrolide is preferred over rifabutin. Patients who develop disseminated disease while receiving macrolide prophylaxis may have macrolide-resistant organisms. Which regimen to use is not established, but most authorities recommend addition of rifabutin and ethambutol. Whether to continue the macrolide if the isolate is resistant in vitro is controversial.

Pulmonary Infections

MAC causes a chronic, slowly progressive pulmonary infection resembling tuberculosis in immunocompetent patients, who typically have underlying pulmonary disease.

Treatment of immunocompetent patients with pulmonary infection is empirical and based entirely on anecdotal data. A combination of agents is probably best. Rifampin, 600 mg once daily, plus ethambutol, 15-25 mg/kg/d, plus streptomycin, 1 g intramuscularly three to five times a week for the first 4-6 months, have been used. The role of rifabutin, fluoroquinolones, and the macrolides is not known, but based upon their excellent efficacy in immunocompromised AIDS patients, they may actually be more effective than the relatively weak agents traditionally used in immunocompetent patients. Clarithromycin is a very potent drug in the treatment of MAC in AIDS patients. Based on this, inclusion of clarithromycin in the initial treatment regimen of immunocompetent patients is prudent. Therapy is continued for a total of 18-24 months.

Mycobacterium kansasii can produce clinical disease resembling tuberculosis, but the illness progresses more slowly. Most such infections occur in patients with preexisting lung disease, though 40% of patients have no known pulmonary disease. Microbiologically, *M kansasii* is similar to *M tuberculosis* and is sensitive to the same drugs except pyrazinamide, to which it is resistant. Therapy with isoniazid, ethambutol, and rifampin for 2 years (or 1 year after sputum conversion) has been successful.

Less common causes of pulmonary disease include *Mycobacterium xenopi*, *Mycobacterium szulgai*, and *Mycobacterium gordonae*. These organisms have variable sensitivities, and treatment is based on results of sensitivity tests. *Mycobacterium fortuitum* and *Mycobacterium chelonae* also can cause pneumonia in the occasional patient.

Lymphadenitis

Most cases of lymphadenitis (scrofula) in adults are caused by *Mycobacterium tuberculosis* and can be a manifestation of disseminated disease. In children, the

majority of cases are due to nontuberculous mycobacterial species, with *Mycobacterium scrofulaceum* and MAC being the most common. *Mycobacterium kansasii*, *Mycobacterium bovis*, *Mycobacterium chelonae*, and *Mycobacterium fortuitum* are less commonly observed. Unlike disease caused by *M tuberculosis*, which requires systemic therapy for 6 months, infection with nontuberculous mycobacteria can be successfully treated by surgical excision without antituberculous therapy.

Skin & Soft Tissue Infections

Skin and soft tissue infections such as abscesses, septic arthritis, and osteomyelitis can result from direct inoculation or hematogenous dissemination or may occur as a complication of surgery.

M chelonae and *M fortuitum* are frequent causes of this type of infection. Most cases occur in the extremities and initially present as nodules. Ulceration with abscess formation often follows. The organisms are resistant to the usual antituberculous drugs but may be sensitive to a variety of antibiotics, including erythromycin, doxycycline, amikacin, cefoxitin, sulfonamides, imipenem, and ciprofloxacin. Therapy includes surgical debridement along with drug therapy. Initially, parenteral drugs are given for several weeks, and this is followed by an oral regimen to which the organism is sensitive. The duration of therapy is variable but usually continues for several months after the soft tissue lesions have healed.

Mycobacterium marinum infection ("swimming pool granuloma") presents as a nodular skin lesion following exposure to nonchlorinated water. The lesions respond to therapy with doxycycline, minocycline, or trimethoprim-sulfamethoxazole.

Mycobacterium ulcerans infection (Buruli ulcer) is seen mainly in Africa and Australia and produces a large ulcerative lesion. Therapy consists of surgical excision and skin grafting.

Diagnosis and treatment of disease caused by nontuberculous mycobacteria. Medical Section of the American Lung Association. Am J Respir Crit Care Med 1997;156(2 Part 2):S1. [PMID: 9279284]

MYCOBACTERIUM TUBERCULOSIS INFECTIONS

Tuberculosis is discussed in [Chapter 9](#). Further information and expert consultation can be obtained from the Francis J. Curry National Tuberculosis Center at the Web site <http://www.nationaltbcenter.edu> or, by phone, 415-502-4600, or fax, 415-502-4620.

TUBERCULOUS MENINGITIS

Essentials of Diagnosis

- Gradual onset of listlessness, irritability, and anorexia.
- Headache, vomiting, and seizures common.
- Cranial nerve abnormalities typical.
- Tuberculosis focus may be evident elsewhere.
- Cerebrospinal fluid shows several hundred lymphocytes, low glucose, and high protein.

General Considerations

Tuberculous meningitis is caused by rupture of a meningeal tuberculoma resulting from earlier hematogenous seeding of tubercle bacilli from a pulmonary focus, or it may be a consequence of miliary spread.

Clinical Findings

A. Symptoms and Signs

The onset is usually gradual, with listlessness, irritability, anorexia, and fever, followed by headache, vomiting, convulsions, and coma. In older patients, headache and behavioral changes are prominent early symptoms. Nuchal rigidity and cranial nerve palsies occur as the meningitis progresses. Evidence of active tuberculosis elsewhere or a history of prior tuberculosis is present in up to 75% of patients.

B. Laboratory Findings

The spinal fluid is frequently yellowish, with increased pressure, 100-500 cells/uL (predominantly lymphocytes, though neutrophils may be present early during infection), increased protein, and decreased glucose. Acid-fast stains of cerebrospinal fluid usually are negative, and cultures also may be negative in 15-25% of cases. Chest x-ray often reveals abnormalities compatible with tuberculosis but may be normal.

Differential Diagnosis

Tuberculous meningitis may be confused with any other type of meningitis, but the gradual onset, the predominantly lymphocytic pleocytosis of the spinal fluid, and evidence of tuberculosis elsewhere often point to the diagnosis. The tuberculin skin test is usually (not always) positive. Fungal and other granulomatous meningitides, syphilis, and carcinomatous meningitis are in the differential diagnosis.

Complications

Complications of tuberculous meningitis include seizure disorders, cranial nerve palsies, stroke, and obstructive hydrocephalus with impaired cognitive function. These result from inflammatory exudate primarily involving the basilar meninges and arteries.

Treatment

Presumptive diagnosis followed by early, empirical antituberculous therapy is essential for survival and to minimize sequelae. Even if cultures are not positive, a full course of therapy is warranted if the clinical setting is suggestive of tuberculous meningitis.

Regimens that are effective for pulmonary tuberculosis are effective also for tuberculous meningitis ([Table 9-14](#)). Rifampin, isoniazid, and pyrazinamide all penetrate into cerebrospinal fluid well. The penetration of ethambutol is more variable, but therapeutic concentrations can be achieved, and the drug has been successfully used for meningitis. Aminoglycosides penetrate less well. Regimens that do not include both isoniazid and rifampin may be effective but are less reliable and generally must be given for longer periods.

Some authorities recommend the addition of corticosteroids for patients with focal deficits or altered mental status. Dexamethasone, 0.15 mg/kg four times daily for 1-2 weeks, then discontinued in a tapering regimen over 4 weeks, may be used.

LEPROSY

Essentials of Diagnosis

- Pale, anesthetic macular—or nodular and erythematous—skin lesions.
- Superficial nerve thickening with associated anesthesia.
- History of residence in endemic area in childhood.
- Acid-fast bacilli in skin lesions or nasal scrapings, or characteristic histologic nerve changes.

General Considerations

Leprosy is a chronic infectious disease caused by the acid-fast rod *Mycobacterium leprae*. The mode of transmission probably is respiratory and involves prolonged exposure in childhood. The disease is endemic in tropical and subtropical Asia, Africa, Central and South America, and the Pacific regions, and rarely seen sporadically in the southern United States.

Clinical Findings

BR>**A. Symptoms and Signs**

The onset is insidious. The lesions involve the cooler body tissues: skin, superficial nerves, nose, pharynx, larynx, eyes, and testicles. Skin lesions may occur as pale, anesthetic macular lesions 1-10 cm in diameter; discrete erythematous, infiltrated nodules 1-5 cm in diameter; or diffuse skin infiltration. Neurologic disturbances are caused by nerve infiltration and thickening, with resultant anesthesia, and motor abnormalities. Bilateral ulnar neuropathy is highly suggestive. In untreated cases, disfigurement due to the skin infiltration and nerve involvement may be extreme, leading to trophic ulcers, bone resorption, and loss of digits.

The disease is divided clinically and by laboratory tests into two distinct types: lepromatous and tuberculoid. The lepromatous type occurs in persons with defective cellular immunity. The course is progressive and malignant, with nodular skin lesions; slow, symmetric nerve involvement; abundant acid-fast bacilli in the skin lesions; and a negative lepromin skin test. In the tuberculoid type, cellular immunity is intact and the course is more benign and less progressive, with macular skin lesions, severe asymmetric nerve involvement of sudden onset with few bacilli present in the lesions, and a positive lepromin skin test. Intermediate ("borderline") cases are frequent. Eye involvement (keratitis and iridocyclitis), nasal ulcers, epistaxis, anemia, and lymphadenopathy may occur.

B. Laboratory Findings

Laboratory confirmation of leprosy requires the demonstration of acid-fast bacilli in a skin biopsy. Biopsy of skin or of a thickened involved nerve also gives a typical histologic picture. *M leprae* does not grow in artificial media but does grow in the foot pads of armadillos.

Differential Diagnosis

The skin lesions of leprosy often resemble those of lupus erythematosus, sarcoidosis, syphilis, erythema nodosum, erythema multiforme, cutaneous tuberculosis, and vitiligo.

Complications

Renal failure and hepatomegaly from secondary amyloidosis may occur with long-standing disease.

Treatment

Combination therapy is recommended for treatment of all types of leprosy. Single-drug treatment is accompanied by emergence of resistance, and primary resistance to dapsone also occurs. For borderline and lepromatous cases, a three-drug regimen such as dapsone, 50-100 mg/d, clofazimine, 50 mg/d, and rifampin, 10 mg/kg/d (up to 600 mg/d), all given orally, should be used. The triple-drug combination should be administered for a minimum of 2-3 years and, ideally, until all biopsies are negative for acid-fast bacilli. For indeterminate and tuberculoid leprosy, the dapsone-rifampin combination is recommended for 6-12 months, often followed by a course of dapsone alone for 2 or more years.

Two reactional states—erythema nodosum leprosum and reversal reactions—may occur as a consequence of therapy. The reversal reaction, typical of borderline lepromatous leprosy, probably results from enhanced host immunity. Skin lesions and nerves become swollen and tender, but systemic manifestations are not seen. Erythema nodosum leprosum, typical of lepromatous leprosy, is a consequence of immune injury from antigen-antibody complex deposition in skin and other tissues; in addition to skin and nerve manifestations, fever and systemic involvement may be seen. Prednisone, 60 mg/d, or thalidomide, 300 mg/d (in the nonpregnant patient only), is effective for erythema nodosum leprosum. Improvement is expected within a few days after initiating prednisone, and thereafter the dose may be tapered over several weeks to avoid recurrence. Thalidomide is also tapered over several weeks to a 100-mg bedtime dose. Erythema nodosum leprosum is usually confined to the first year of therapy, and prednisone or thalidomide can be discontinued. Thalidomide is ineffective for reversal reactions, and prednisone, 60 mg/d, is indicated. Reversal reactions tend to recur, and the dose of prednisone should be slowly tapered over weeks to months. Therapy for leprosy should not be discontinued during treatment of reactional states.

Jacobson RR et al: Leprosy. Lancet 1999;353:655. [\[PMID: 10030346\]](#)

■ INFECTIONS CAUSED BY CHLAMYDIAE

Chlamydiae are a large group of obligate intracellular parasites closely related to gram-negative bacteria. They are assigned to three species—*Chlamydia trachomatis*, *Chlamydia psittaci*, and *Chlamydia pneumoniae*—on the basis of intracellular inclusions, sulfonamide susceptibility, antigenic composition, and disease production. *C trachomatis* causes many different human infections involving the eye (trachoma, inclusion conjunctivitis), the genital tract (lymphogranuloma venereum, nongonococcal urethritis, cervicitis, salpingitis), or the respiratory tract (pneumonitis). *C psittaci* causes psittacosis in humans and many animal diseases. *Chlamydia pneumoniae* has recently been recognized as a cause of respiratory tract infections.

CHLAMYDIA TRACHOMATIS INFECTIONS

1. Lymphogranuloma Venereum

Essentials of Diagnosis

- Evanescent primary genital lesion.
- Lymph node enlargement, softening, and suppuration, with draining sinuses.
- Proctitis and rectal stricture in women or homosexual men.
- Positive complement fixation test.

General Considerations

Lymphogranuloma venereum is an acute and chronic sexually transmitted disease caused by *Chlamydia trachomatis* types L1-L3. After the genital lesion disappears, the infection spreads to lymph channels and lymph nodes of the genital and rectal areas. The disease is acquired during intercourse or through contact with contaminated exudate from active lesions. The incubation period is 5-21 days. Inapparent infections and latent disease are not uncommon.

Clinical Findings

A. Symptoms and Signs

In men, the initial vesicular or ulcerative lesion (on the external genitalia) is evanescent and often goes unnoticed. Inguinal buboes appear 1-4 weeks after exposure, are often bilateral, and have a tendency to fuse, soften, and break down to form multiple draining sinuses, with extensive scarring. In women, the genital lymph drainage is to the perirectal glands. Early anorectal manifestations are proctitis with tenesmus and bloody purulent discharge; late manifestations are chronic cicatrizing inflammation of the rectal and perirectal tissue. These changes lead to obstipation and rectal stricture and, occasionally, rectovaginal and perianal fistulas. They are also seen in homosexual men.

B. Laboratory Findings

The complement fixation test may be positive, but cross-reaction with other chlamydiae occurs. Although a positive reaction may reflect remote infection, high titers usually indicate active disease. Specific immunofluorescence tests for IgM are more specific for acute infection.

Differential Diagnosis

The early lesion of lymphogranuloma venereum must be differentiated from the lesions of syphilis, genital herpes, and chancroid; lymph node involvement must be distinguished from that due to tularemia, tuberculosis, plague, neoplasm, or pyogenic infection; and rectal stricture must be distinguished from that due to neoplasm and ulcerative colitis.

Treatment

The antibiotic of choice is tetracycline (contraindicated in pregnancy), 0.25-0.5 g orally four times daily, or doxycycline, 0.1 g twice daily for 21 days. Erythromycin, 500 mg four times a day, or trimethoprim-sulfamethoxazole, 160/800 mg twice a day for 21 days, also is effective.

2. Chlamydial Urethritis & Cervicitis

Chlamydia trachomatis immunotypes D-K are isolated in about 50% of cases of nongonococcal urethritis and cervicitis by appropriate techniques. In other cases, *Ureaplasma urealyticum* can be grown as a possible etiologic agent. *C trachomatis* is an important cause of postgonococcal urethritis. Co-infection with gonococci and chlamydiae is common, and postgonococcal (ie, chlamydial) urethritis may persist after successful treatment of the gonococcal component. Occasionally, epididymitis, prostatitis, or proctitis is caused by chlamydial infection.

Females infected with chlamydiae may be asymptomatic or may have signs and symptoms of cervicitis, salpingitis, or pelvic inflammatory disease. Chlamydiae are a leading cause of infertility in females in the United States.

The diagnosis of chlamydial infection has been clinical because *C trachomatis* is difficult and expensive to culture. The urethral or cervical discharge tends to be less painful, less purulent, and watery in chlamydial versus gonococcal infection. A patient with urethritis or cervicitis and absence of gram-negative diplococci on Gram stain and of *N gonorrhoeae* on culture is assumed to have chlamydial infection. Direct immunofluorescence assay, enzyme-linked immunoassay, and a DNA probe test, although less sensitive than culture, are sometimes used to confirm the diagnosis and for screening. The ligase chain reaction (LCR) test for *C trachomatis* has superior sensitivity compared with all other methods (eg, sensitivity of 60-70% for DNA probe versus 90-95% for LCR). LCR also has excellent specificity, approaching 100%, and it can be performed on urine. For these reasons, it will probably replace all other methods for diagnosis of chlamydial urethritis and cervicitis.

Therapy often must be given presumptively. Sexual partners of infected patients should also be treated. Effective treatment regimens are tetracycline or erythromycin, 500 mg four times a day, or doxycycline, 100 mg twice daily for 7 days. Trimethoprim-sulfamethoxazole, 160/800 mg twice a day, is acceptable but may be less effective than tetracyclines or erythromycin. Erythromycin is the drug of choice in the pregnant patient. A single 1-g dose of azithromycin is effective for uncomplicated urethritis and cervicitis and has the advantage of improved patient compliance and minimal toxicity. As for all sexually transmitted diseases, studies for HIV and syphilis should be performed.

Cohen CR et al: Pathogenesis of *Chlamydia* induced pelvic inflammatory disease. Sex Transm Infect 1999;75:21. [\[PMID: 10448337\]](#)

CHLAMYDIA PSITTACI & PSITTACOSIS (ORNITHOSIS)

Essentials of Diagnosis

- Fever, chills, and cough; headache common.
- Atypical pneumonia with slightly delayed appearance of signs of pneumonitis.
- Contact with infected bird (psittacine, pigeons, many others) 7-15 days previously.
- Isolation of chlamydiae or rising titer of complement-fixing antibodies.

General Considerations

Psittacosis is acquired from contact with birds (parrots, parakeets, pigeons, chickens, ducks, and many others), which may or may not be ill. The history may be difficult to obtain if the patient acquired infection from an illegally imported bird.

Clinical Findings

The onset is usually rapid, with fever, chills, myalgia, dry cough, and headache. Signs include temperature-pulse dissociation, dullness to percussion, and rales. Pulmonary findings may be absent early. Dyspnea and cyanosis may occur later. Endocarditis, which is culture-negative, may occur. The radiographic findings in typical psittacosis are those of atypical pneumonia, which tends to be interstitial and diffuse in appearance, though consolidation can occur. Psittacosis is indistinguishable from other bacterial or viral pneumonias by radiography.

The organism is rarely isolated from cultures. The diagnosis is usually made serologically; antibodies appear during the second week and can be demonstrated by complement fixation or immunofluorescence. Antibody response may be suppressed by early chemotherapy.

Differential Diagnosis

The illness is indistinguishable from viral, mycoplasmal, or other atypical pneumonias except for the history of contact with birds. Psittacosis is in the differential diagnosis of culture-negative endocarditis.

Treatment

Treatment consists of giving tetracycline, 0.5 g orally every 6 hours or 0.5 g intravenously every 12 hours, for 14-21 days. Erythromycin may be effective as well.

CHLAMYDIA PNEUMONIAE INFECTION

Chlamydia pneumoniae causes pneumonia and bronchitis and has been associated seroepidemiologically with coronary artery disease. The clinical presentation of pneumonia is that of an atypical pneumonia. The organism accounts for approximately 10% of community-acquired pneumonias, ranking second to mycoplasma as an agent of atypical pneumonia. Its role in coronary artery disease remains to be defined, but *C pneumoniae* has been detected in up to 50% of coronary atheromatous lesions.

Like *C psittaci*, strains of *C pneumoniae* are resistant to sulfonamides. Erythromycin or tetracycline, 500 mg four times a day for 10-14 days, appears to be effective therapy. Fluoroquinolones such as levofloxacin or trovafloxacin are active in vitro against *C pneumoniae* and probably are effective clinically. The oral dose of levofloxacin is 500 mg once a day for 10-14 days.

Table 33-3. Cardiac lesions for which bacterial endocarditis prophylaxis is or is not recommended.^{1,2}

Endocarditis prophylaxis recommended

1. High-risk category
Prosthetic cardiac valves, including bioprosthetic and homograft valves
Previous bacterial endocarditis, even in the absence of heart disease
Complex cyanotic congenital heart disease (eg, single ventricle states, transposition of the great arteries, tetralogy of Fallot)
Surgically constructed systemic pulmonary shunts or conduits
2. Moderate-risk category
Most congenital cardiac malformations (other than those listed above and below)
Rheumatic and other acquired valvular dysfunction, even after valvular surgery
Hypertrophic cardiomyopathy
Mitral valve prolapse with valvular regurgitation^{3,4}

Endocarditis prophylaxis not recommended⁵

- Isolated secundum septal defect
Surgical repair of atrial septal defect, ventricular septal defect, or patent ductus arteriosus (without residua beyond 6 months)
Previous coronary artery bypass graft surgery
Mitral valve prolapse without valvular regurgitation⁶
Physiologic, functional, or innocent heart murmurs
Previous Kawasaki disease without valvular dysfunction
Previous rheumatic fever without valvular dysfunction
Cardiac pacemakers (intravascular and epicardial) and implanted defibrillators

34. Infectious Diseases: Spirochetal - *Richard A. Jacobs, MD, PhD*

■ SYPHILIS

NATURAL HISTORY & PRINCIPLES OF DIAGNOSIS & TREATMENT

Syphilis is a complex infectious disease caused by *Treponema pallidum*, a spirochete capable of infecting almost any organ or tissue in the body and causing protean clinical manifestations ([Table 34-1](#)). Transmission occurs most frequently during sexual contact, through minor skin or mucosal lesions; sites of inoculation are usually genital but may be extragenital. The risk of developing syphilis after unprotected sex with an individual with early syphilis is approximately 30-50%. The organism is extremely sensitive to heat and drying but can survive for days in fluids; therefore, it can be transmitted in blood from infected persons. Syphilis can be transferred via the placenta from mother to fetus after the tenth week of pregnancy (congenital syphilis).

The immunologic response to infection is complex, but it provides the basis for most clinical diagnoses. The infection induces the synthesis of a number of antibodies, some of which react specifically with pathogenic treponemes and some with components of normal tissues (see below). If the disease is untreated, sufficient defenses develop to produce a relative resistance to reinfection; however, in most cases these immune reactions fail to eradicate existing infection and may contribute to tissue destruction in the late stages. Patients treated early in the disease are fully susceptible to reinfection.

The natural history of acquired syphilis is generally divided into two major clinical stages: early (infectious) syphilis and late syphilis. The two stages are separated by a symptom-free latent phase during the first part of which (early latency) the infectious stage is liable to recur. Infectious syphilis includes the primary lesions (chancre and regional lymphadenopathy), the secondary lesions (commonly involving skin and mucous membranes, occasionally bone, central nervous system, or liver), relapsing lesions during early latency, and congenital lesions. The hallmark of these lesions is an abundance of spirochetes; tissue reaction is usually minimal. Late syphilis consists of so-called benign (gummatous) lesions involving skin, bones, and viscera; cardiovascular disease (principally aortitis); and a variety of central nervous system and ocular syndromes. These forms of syphilis are not contagious. The lesions contain few demonstrable spirochetes, but tissue reactivity (vasculitis, necrosis) is severe and suggestive of hypersensitivity phenomena.

As a result of intensive public health efforts during and after World War II, there was a reduction in the incidence of infectious syphilis. With the marked increase in all sexually transmitted diseases since the 1970s, there has been a rise in the number of reported cases of syphilis. In the early 1980s, the incidence of infectious syphilis increased, with a particularly high rate among homosexual men. In the mid-1980s, there was a slight decrease, chiefly as a result of changes in sexual practices in response to the AIDS epidemic. Between 1985 and 1990, there was again a dramatic increase in infectious syphilis, with 50,223 cases of primary and secondary syphilis reported in 1990. This increase was broad-based, affecting both men and women in inner city, urban, and rural areas, particularly in the southern regions of the United States. Although adolescent and young adult blacks were primarily affected, increases were seen in other ethnic groups also, as well as adults over 60. Limited access to health care, decreases in health department clinical services, increased use of illicit drugs (especially "crack cocaine"), the exchange of sex for drugs or money to buy drugs, and the difficulty of contact tracing when multiple sexual partners are involved all contributed to the dramatic increase. Concomitantly with the increase in acquired syphilis, there has also been an increase in congenital syphilis, particularly in urban areas. In response to this increase in infectious syphilis in 1998, the United States Congress allocated funds for a syphilis elimination program. This included intensive syphilis control programs targeting high-risk populations—women of childbearing age, sexually active teens, drug users, inmates of penal institutions, persons with multiple sexual partners or those who have sex with prostitutes—and emphasizing screening, early treatment, contact tracing, and condom use. This effort has mostly been successful, as evidenced by a decrease in the number of primary and secondary cases reported in 2001 (6103 cases) compared with 1998 (7035 cases). However, for the first time since 1990, the number of cases increased between 2000 (5979) and 2001. The increase occurred only among men having sex with men, while the number of cases actually declined among women and non-Hispanic blacks. Most cases are still reported from the South, but urban outbreaks (New York City, San Francisco) are being reported with increasing frequency, chiefly among men having sex with men.

Laboratory Diagnosis

Since the infectious agent of syphilis cannot be cultured in vitro, diagnostic measures must rely mainly on serologic testing, microscopic detection of *T pallidum* in lesions, and other examinations (biopsies, lumbar puncture, x-rays) for evidence of tissue damage.

A. Serologic Tests for Syphilis

([Table 34-2](#).) There are two general categories of serologic tests for syphilis: (1) Nontreponemal tests detect antibodies to lipoidal antigens present in either the host or in *T pallidum*. The original antigens employed to measure these nonspecific antibodies (reagin) were crude extracts of beef heart or liver and resulted in significant numbers of false-positive reactions. The cardiolipin-cholesterol-lecithin preparation presently used is much purer and gives fewer false-positive reactions. (2) Treponemal tests employ live or killed *T pallidum* as antigen to detect antibodies specific for pathogenic treponemes.

1. Nontreponemal antigen tests—The most commonly used nontreponemal antigen tests are the VDRL (Venereal Disease Research Laboratory) and RPR (rapid plasma reagin), which measure the ability of heated serum to flocculate a suspension of cardiolipin-cholesterol-lecithin. The flocculation tests are inexpensive, rapid, and easy to perform and are therefore used primarily for routine screening. Quantitative expression of the reactivity of the serum, based upon titration of dilutions of serum, is valuable in establishing the diagnosis and in evaluating the efficacy of treatment, since titers usually correlate with disease activity.

Nontreponemal tests generally become positive 4-6 weeks after infection, or 1-3 weeks after the appearance of a primary lesion; they are almost invariably positive in the secondary stage, with titers = 1:32. In the late stages, titers tend to be lower (< 1:4). These serologic tests are not highly specific and must be closely correlated with other clinical and laboratory findings. The tests are positive in patients with non-sexually transmitted treponematoses (see below). More importantly, "false-positive" serologic reactions are frequently encountered in a wide variety of nontreponemal states, including connective tissue diseases, infectious mononucleosis, malaria, febrile diseases, leprosy, intravenous drug use, infective endocarditis, old age, hepatitis C viral infection, and pregnancy. False-positive tests also occur more commonly in HIV-seropositive patients (4%) than in HIV-seronegative patients (0.8%). False-positive reactions are usually of low titer and transient and may be distinguished from true positives by specific treponemal antibody tests. False-negative results can be seen when very high antibody titers are present (the prozone phenomenon). If syphilis is strongly suspected and the nontreponemal test is negative, the laboratory should be instructed to dilute the specimen to detect a positive reaction. The RPR and VDRL tests are equally reliable, but titers of RPR tend to be higher than the VDRL. Thus, when these tests are used to follow disease activity, the same testing method should be used and preferably should be performed at the same laboratory.

Nontreponemal antibody titers are used to assess adequacy of therapy. The time required for the VDRL or RPR to become negative depends on the stage of the disease, the height of the initial titer, and whether the infection is an initial or repeat episode. In general, individuals with repeat infections, higher initial titers, and more advanced stages of disease at the time of treatment have a slower seroconversion rate and are more likely to remain serofast (ie, titers do not become negative). Older data derived from more intensive treatment regimens than are presently used indicate that in primary and secondary syphilis, the VDRL usually decreases fourfold by 3 months and eightfold by 6 months. Furthermore, seronegativity was seen in 97% of those with primary syphilis and 76% of those with secondary syphilis at 2 years. More recent data based on currently recommended treatment regimens (see below) suggest that decreases in titer may be slower—ie, in primary and secondary syphilis it may take 6 months to see a fourfold decrease in titer and 12 months to see an eightfold drop. In patients with early latent syphilis, response is even slower, with a fourfold drop in titer taking 12-24 months. Seronegativity was seen in 72% of patients with primary syphilis and only 56% of those with secondary syphilis after 3 years. Additional studies support a slower decline in titers with currently recommended treatment regimens.

2. Treponemal antibody tests—The fluorescent treponemal antibody absorption (FTA-ABS) test measures antibodies capable of reacting with killed *T pallidum* after absorption of the patient's serum with extracts of nonpathogenic treponemes. The FTA-ABS test is of value principally in determining whether a positive nontreponemal antigen test is "false-positive" or is indicative of syphilis. Because of its great sensitivity, particularly in the late stages of the disease, the FTA-ABS test is also of value when there is clinical evidence of syphilis but the nontreponemal serologic test for syphilis is negative. The test is positive in most patients with primary syphilis and in virtually all with secondary syphilis. Like nontreponemal antigen tests, the specific treponemal antibody test may revert to negative with adequate therapy. This is seen almost exclusively in initial infections in individuals with primary syphilis. In one study, 11% of individuals with a first episode of primary syphilis were seronegative by the FTA-ABS test at 1 year posttreatment, and 24% were negative by 3 years. Immunologic status may also affect antibody titers. Seven percent of asymptomatic HIV-infected patients became seronegative after treatment, as opposed to 38% of symptomatic HIV-infected individuals. The long-held belief that a positive FTA-ABS persists indefinitely is clearly not valid, and this test therefore cannot be used as a reliable marker of previous infection. False-positive FTA-ABS tests occur rarely in systemic lupus erythematosus and in other disorders associated with increased levels of gamma globulins. It is noteworthy that Lyme disease may cause a false-positive FTA-ABS test but rarely causes a false-positive reaginic test. The *T pallidum* hemagglutination (TPHA) test and the particle agglutination test (TPPA) are comparable in specificity and sensitivity to the FTA-ABS. The TPPA test, because of ease of performance, has supplanted the FTA-ABS test as the means of confirming the diagnosis of syphilis.

Investigational tests such as direct antigen detection, Western immunoblot, ELISA (CAPTIA Syph G, CAPTIA Syph M), latex agglutination (Syphilis Fast), and PCR are under study as diagnostic tools. They have shown promise in clinical trials, and the increased sensitivity (ELISA) and specificity (Western blot) of these tests make them attractive. However, because of limited clinical evaluation in field trials they have not yet supplanted the more traditional methods of diagnosis.

Final decisions about the significance of the results of serologic tests for syphilis must be based upon a total clinical appraisal.

B. Microscopic Examination

In infectious syphilis, *T pallidum* may be shown by darkfield microscopic examination of fresh exudate from lesions or material aspirated from regional lymph nodes. The darkfield examination requires considerable experience and care in the proper collection of specimens and in the identification of pathogenic spirochetes by observing characteristic features of morphology and motility. Repeated examinations may be necessary. Spirochetes usually are not found in late syphilitic lesions by this technique.

An immunofluorescent staining technique for demonstrating *T pallidum* in dried smears of fluid taken from early syphilitic lesions is available. Slides are fixed and treated with fluorescein-labeled antitreponemal antibody that has been preabsorbed with nonpathogenic treponemes. The slides are then examined for fluorescing spirochetes in an ultraviolet microscope. Because of its simplicity and convenience to clinicians (slides can be mailed), this technique has replaced darkfield microscopy in most health departments and medical center laboratories.

C. Spinal Fluid Examination

Cerebrospinal fluid findings in neurosyphilis are variable. In "classic" cases there is an elevation of total protein, lymphocytic pleocytosis, and a positive cerebrospinal fluid reagin test (VDRL). However, cerebrospinal fluid may be completely normal in neurosyphilis, and the VDRL may be negative. In one study, 25% of patients with primary or secondary syphilis in whom *T pallidum* was isolated from cerebrospinal fluid had a normal cerebrospinal fluid examination. In later stages of syphilis, normal cerebrospinal fluid analysis in the presence of infection can occur, but it is unusual. Because false-positive reagin tests rarely occur in the cerebrospinal fluid, a positive test confirms the presence of neurosyphilis. Because the cerebrospinal fluid VDRL may be negative in 30-70% of cases of neurosyphilis, *a negative test does not exclude neurosyphilis*. The use of cerebrospinal fluid FTA-ABS in the diagnosis of neurosyphilis is controversial. Some feel that it is more sensitive than the VDRL, but this is not accepted uniformly, and a high serum titer of FTA-ABS may result in a positive cerebrospinal fluid titer in the absence of neurosyphilis. However, the test is believed to be highly sensitive, and a negative cerebrospinal fluid FTA-ABS is strong evidence against the diagnosis of neurosyphilis. Other treponemal antibody tests likewise are not reliable in making the diagnosis of neurosyphilis, although a negative test is helpful in excluding the diagnosis.

Cerebrospinal fluid examination is recommended depending on the clinical manifestations and the stage of disease, as discussed below. Asymptomatic neurosyphilis (ie, positive cerebrospinal fluid findings without symptoms) requires prolonged penicillin treatment as given for symptomatic neurosyphilis. Adequate treatment is indicated by gradual decrease in cerebrospinal fluid cell count, protein concentration, and VDRL titer. Rarely, serologic tests of cerebrospinal fluid may remain positive for years after adequate treatment of neurosyphilis even though all other parameters have returned to normal.

Treatment

A. Specific Measures

1. Penicillin—Penicillin, as benzathine penicillin G or aqueous procaine penicillin G, is the drug of choice for all forms of syphilis and other spirochetal infections.

Effective tissue levels must be maintained for several days or weeks because of the spirochete's long generation time (about 30 hours). Penicillin is highly effective in early infections and variably effective in the late stages. The principal contraindication is hypersensitivity to the penicillins. The recommended treatment schedules are included below in the discussion of the various forms of syphilis.

2. Other antibiotic therapy—Oral tetracyclines are effective in the treatment of syphilis for patients who are allergic to penicillin. Tetracycline, 500 mg orally four times daily for 14 days, or doxycycline, 100 mg orally twice daily for 14 days, is given for infectious syphilis. In syphilis of more than 1 year's duration or of unknown duration, treatment is continued for 28 days in the same doses.

Preliminary data suggest that both ceftriaxone and azithromycin are effective for the therapy of early syphilis and are now accepted alternative regimens to penicillin after doxycycline and tetracycline. The recommended dose of ceftriaxone is 1 g daily either intramuscularly or intravenously for 8-10 days. Azithromycin can be administered as a single oral dose of 2 g. Because of the limited clinical experience with these regimens, close clinical and serologic follow-up is essential. Neither of these regimens has been studied in HIV-positive patients. Ceftriaxone at a higher dose of 2 g daily intramuscularly or intravenously for 10-14 days can also be used as alternative therapy for neurosyphilis in patients with non-IgE-mediated hypersensitivity to penicillin.

B. Local Measures (Mucocutaneous Lesions)

Local treatment is usually not necessary. No local antiseptics or other chemicals should be applied to a suspected syphilitic lesion until specimens for microscopy have been obtained.

C. Public Health Measures

Patients with infectious syphilis must abstain from sexual activity until rendered noninfectious by antibiotic therapy. All cases of syphilis must be reported to the appropriate public health agency for assistance in identifying and treating contacts. In addition, all patients with syphilis should have an HIV test at the time of diagnosis. In areas of high HIV prevalence, a repeat HIV test should be performed in 3 months if the initial test was negative.

D. Empirical Postexposure Treatment

Patients who have been exposed to infectious syphilis within the preceding 3 months may be infected but seronegative and thus should be treated as for early syphilis. Persons exposed more than 90 days previously should be treated based on serologic results. If their partners are unavailable for testing or unreliable for follow-up, empirical therapy is indicated. Others at high risk either for infection (ie, those with other sexually transmitted diseases and those infected with HIV) or its consequences (ie, pregnant women) should undergo serologic tests for syphilis. The present recommended therapy for gonorrhea (single-dose ceftriaxone or cefixime) may not be effective in treating incubating syphilis. Therefore, patients with gonorrhea and a known exposure to syphilis should be treated with separate regimens effective against both diseases.

Complications of Specific Therapy

The Jarisch-Herxheimer reaction is ascribed to the sudden massive destruction of spirochetes by drugs and release of toxic products and is manifested by fever and aggravation of the existing clinical picture. It is most likely to occur in early syphilis. It usually begins within the first 24 hours and subsides spontaneously within the next 24 hours of penicillin treatment. Treatment should not be discontinued unless the symptoms become severe or threaten to be fatal or unless syphilitic laryngitis, auditory neuritis, or labyrinthitis is present, where the reaction may cause irreversible damage.

The reaction may be prevented or modified by simultaneous administration of antipyretics or corticosteroids, though no proved method of prevention exists.

Follow-Up Care

Because treatment failures can occur and reinfection is always a possibility, patients treated for syphilis should be followed clinically and serologically. Response to therapy is difficult to assess, and no definite criteria exist for cure in patients with primary or secondary syphilis. In primary and secondary syphilis, failure of nontreponemal antibody titers to decrease fourfold by 6 months may identify a group at high risk of treatment failure. Optimal management of these patients is unclear, but at a minimum close clinical and serologic follow-up is indicated. If titers fail to decrease fourfold by 6 months, an HIV test should be repeated (all patients with syphilis should have an HIV test at the time of diagnosis); a lumbar puncture should be considered since unrecognized neurosyphilis can be a cause of treatment failure; and, if careful follow-up cannot be ensured (3-month intervals for HIV-positive individuals and 6-month intervals for HIV-negative patients), treatment should be repeated with 2.4 million units of benzathine penicillin intramuscularly weekly for 3 weeks. If symptoms or signs persist or recur after initial therapy or there is a fourfold or greater increase in nontreponemal titers, the patient has either failed therapy or has been reinfectd. In those individuals, an HIV test should be performed, a lumbar puncture done (unless reinfection is a certainty), and re-treatment given as indicated above. In patients with latent syphilis, nontreponemal serologic tests should be repeated at 6, 12, and 24 months. If titers increase fourfold or if initially high titers (= 1:32) fail to decrease fourfold by 12-24 months—or if symptoms or signs consistent with syphilis develop—an HIV test and lumbar puncture should be performed and re-treatment given according to the stage of the disease.

Prevention

Avoidance of sexual contact is the only completely reliable method of prophylaxis but is an impractical public health measure for obvious reasons. Annual screening for syphilis among men who have sex with men has been recommended based on preliminary data suggesting that this may decrease the rate of transmission. High-risk individuals (those who have multiple encounters with anonymous partners or who have sex in conjunction with the use of drugs) should be screened every 3-6 months.

A. Mechanical

The standard latex condom is effective but protects covered parts only. The exposed parts should be washed with soap and water as soon after contact as possible. This applies to both sexes.

B. Antibiotic

If there is known exposure to infectious syphilis, abortive penicillin therapy may be used. Give 2.4 million units of procaine penicillin G intramuscularly. Treatment of gonococcal (and chlamydial) infection with tetracyclines and ceftriaxone is probably effective against incubating syphilis in most cases. However, other antimicrobial

agents (eg, spectinomycin, quinolones) may be ineffective in aborting preclinical syphilis. Azithromycin administered as a single 1-g dose is also effective as preventive therapy in individuals exposed to infected partners. Because of concerns about treating incubating syphilis with nonpenicillin regimens, patients treated for gonorrhea should have a serologic test for syphilis 3-6 months after treatment.

Course & Prognosis (See [Table 34-3](#).)

The lesions associated with primary and secondary syphilis are self-limiting and resolve with few or no residua. Late syphilis may be highly destructive and permanently disabling and may lead to death. In broad terms, if no treatment is given, about one-third of people infected with syphilis will undergo spontaneous cure, about one-third will remain in the latent phase throughout life, and about one-third will develop serious late lesions. (See [Table 34-3](#))

CLINICAL STAGES OF SYPHILIS

1. Primary Syphilis

Essentials of Diagnosis

- History of sexual contact (often unreliable).
- Painless ulcer on genitalia, perianal area, rectum, pharynx, tongue, lip, or elsewhere 2-6 weeks after exposure.
- Nontender enlargement of regional lymph nodes.
- Fluid expressed from lesion contains *T pallidum* by immunofluorescence or darkfield microscopy.
- Serologic test for syphilis often positive.

General Considerations

This is the stage of invasion and may pass unrecognized. The typical lesion is the chancre at the site or sites of inoculation, most frequently located on the penis, labia, cervix, or anorectal region. Anorectal lesions are especially common among men who have sex with men. The primary lesion occurs occasionally in the oropharynx (lip, tongue, or tonsil) and rarely on the breast or finger. The chancre starts as a small erosion 10-90 days (average, 3-4 weeks) after inoculation that rapidly develops into a painless superficial ulcer with a clean base and firm, indurated margins, associated with enlargement of regional lymph nodes, which are rubbery, discrete, and nontender. Bacterial infection of the chancre may occur and may lead to pain. Healing occurs without treatment, but a scar may form, especially with secondary bacterial infection.

Laboratory Findings

The serologic test for syphilis is usually positive 1-2 weeks after the primary lesion is noted; rising titers are especially significant when there is a history of previous infection. Immunofluorescence or darkfield microscopy shows treponemes in at least 95% of chancres. Cerebrospinal fluid pleocytosis has been reported in 10-20% of patients with primary syphilis.

Differential Diagnosis

The syphilitic chancre may be confused with chancroid, lymphogranuloma venereum, genital herpes, or neoplasm. Any lesion on the genitalia should be considered a possible primary syphilitic lesion.

Treatment

Benzathine penicillin G, 2.4 million units intramuscularly in the gluteal area, is given once. For the nonpregnant penicillin-allergic patient, doxycycline, 100 mg orally twice daily for 2 weeks, or tetracycline, 500 mg orally four times a day for 2 weeks, can be used. There is more clinical experience with tetracycline, but compliance is probably better with doxycycline. As noted above, ceftriaxone and azithromycin can be used in the penicillin-allergic patient.

2. Secondary Syphilis

Essentials of Diagnosis

- Generalized maculopapular skin rash.
- Mucous membrane lesions, including patches and ulcers.
- Weeping papules (condylomas) in moist skin areas.
- Generalized nontender lymphadenopathy.
- Fever.
- Meningitis, hepatitis, osteitis, arthritis, iritis.
- Many treponemes in scrapings of mucous membrane or skin lesions by immunofluorescence or darkfield microscopy.
- Serologic tests for syphilis always positive.

General Considerations & Treatment

The secondary stage of syphilis usually appears a few weeks (or up to 6 months) after development of the chancre, when sufficient dissemination of *T pallidum* has occurred to produce systemic signs (fever, lymphadenopathy) or infectious lesions at sites distant from the site of inoculation. The most common manifestations are skin and mucosal lesions. The skin lesions are nonpruritic, macular, papular, pustular, or follicular (or combinations of any of these types), though the maculopapular rash is the most common. The skin lesions usually are generalized; involvement of the palms and soles is especially suspicious. Annular lesions simulating ringworm are observed in blacks. Mucous membrane lesions range from ulcers and papules of the lips, mouth, throat, genitalia, and anus ("mucous patches") to a diffuse redness of the pharynx. Both skin and mucous membrane lesions are highly infectious at this stage. Specific lesions—**condylomata lata**—are fused, weeping papules on the moist areas of the skin and mucous membranes.

Meningeal (aseptic meningitis or acute basilar meningitis), hepatic, renal, bone, and joint invasion may occur, with resulting cranial nerve palsies, jaundice, nephrotic syndrome, and periostitis. Alopecia (moth-eaten appearance) and uveitis may also occur.

All serologic tests for syphilis are positive in almost all cases. The cutaneous and mucous membrane lesions often show *T pallidum* on darkfield microscopic examination. A transient cerebrospinal fluid pleocytosis is seen in 30-70% of patients with secondary syphilis, though only 5% have positive serologic cerebrospinal fluid reactions. There may be evidence of hepatitis or nephritis (immune complex type). Circulating immune complexes exist in the blood and are deposited in blood vessel walls.

Skin lesions may be confused with the infectious exanthems, pityriasis rosea, and drug eruptions. Visceral lesions may suggest nephritis or hepatitis due to other causes. The diffusely red throat may mimic other forms of pharyngitis.

Treatment is as for primary syphilis unless central nervous system or ocular disease is present, in which case a lumbar puncture should be performed and, if positive, treatment is as for neurosyphilis (see below). Isolation of the patient is important.

3. Relapsing Syphilis (Early Latent Syphilis)

The essentials of diagnosis are the same as in secondary syphilis.

The lesions of secondary syphilis heal spontaneously, but secondary syphilis may relapse if undiagnosed or inadequately treated. These relapses may include any of the findings noted under secondary syphilis: skin and mucous membrane, neurologic, ocular, bone, or visceral. Unlike the usual asymptomatic neurologic involvement of secondary syphilis, neurologic relapses may be fulminating, leading to death. Relapse is almost always accompanied by a rising titer in quantitative serologic tests; indeed, a rising titer may be the first or only evidence of relapse. About 90% of relapses occur during the first year after infection.

Treatment is as for primary syphilis unless central nervous system disease is present.

4. Late Latent ("Hidden") Syphilis

Essentials of Diagnosis

- No physical signs.
- History of syphilis with inadequate treatment.
- Positive serologic tests for syphilis.

General Considerations & Treatment

Latent syphilis is the clinically quiescent phase during the interval after disappearance of secondary lesions and before the appearance of tertiary symptoms. Early latency is defined as the first year after infection, during which time most infectious lesions recur ("relapsing syphilis"); after the first year, the patient is said to be in the late latent phase. Transmission to the fetus, however, can probably occur in any phase. There are (by definition) no clinical manifestations during the latent phase, and the only significant laboratory findings are positive serologic tests. A diagnosis of latent syphilis is justified only when the cerebrospinal fluid is entirely negative, x-ray and physical examination shows no evidence of cardiovascular involvement, and false-positive tests for syphilis have been ruled out. The latent phase may last from months to a lifetime.

It is important to differentiate latent syphilis from a false-positive serologic test for syphilis, which can be due to the many causes listed above.

Treatment of late latent syphilis or latent syphilis of unknown duration is with benzathine penicillin G, 2.4 million units three times at 7-day intervals (total dose: 7.2 million units). The only alternative to penicillin for therapy of late latent syphilis is doxycycline, 100 mg twice daily, or tetracycline, 500 mg four times a day, both for 28 days. If there is evidence of cerebrospinal fluid involvement, a lumbar puncture should be performed and, if positive, the patient should receive treatment as for neurosyphilis. Only a small percentage of serologic tests will be appreciably altered by treatment with penicillin. The treatment of this stage of the disease is intended to prevent the late sequelae.

5. Late (Tertiary) Syphilis

Essentials of Diagnosis

- Infiltrative tumors of skin, bones, liver (gummas).
- Aortitis, aneurysms, aortic regurgitation.
- Central nervous system disorders, including meningovascular and degenerative changes, paresthesias, shooting pains, abnormal reflexes, dementia, or psychosis.

General Considerations

This stage may occur at any time after secondary syphilis, even after years of latency, and is seen in about one-third of untreated patients ([Table 34-3](#)). Late lesions probably represent, at least in part, a delayed hypersensitivity reaction of the tissue to the organism and are usually divided into two types: (1) a localized gummatous reaction, with a relatively rapid onset and generally prompt response to therapy ("benign late syphilis") and (2) diffuse inflammation of a more insidious onset that characteristically involves the central nervous system and large arteries, is often fatal if untreated, and is at best arrested by treatment. Gummas may involve any area or organ of the body but most often the skin or long bones. Cardiovascular disease is usually manifested by aortic aneurysm, aortic regurgitation, or aortitis. Various forms of diffuse or localized central nervous system involvement may occur.

Late syphilis must be differentiated from neoplasms of the skin, liver, lung, stomach, or brain; other forms of meningitis; and primary neurologic lesions.

Although almost any tissue and organ may be involved in late syphilis, the following are the most common types of involvement.

Skin

Cutaneous lesions of late syphilis are of two varieties: (1) multiple nodular lesions that eventually ulcerate (lues maligna) or resolve by forming atrophic, pigmented scars and (2) solitary gummas that start as painless subcutaneous nodules, then enlarge, attach to the overlying skin, and eventually ulcerate.

Mucous Membranes

Late lesions of the mucous membranes are nodular gummas or leukoplakia, highly destructive to the involved tissue.

Skeletal System

Bone lesions are destructive, causing periostitis, osteitis, and arthritis with little or no associated redness or swelling but often marked myalgia and myositis of the neighboring muscles. The pain is especially severe at night.

Eyes

Late ocular lesions are gummatous iritis, chorioretinitis, optic atrophy, and cranial nerve palsies, in addition to the lesions of central nervous system syphilis.

Respiratory System

Respiratory involvement by late syphilis is caused by gummatous infiltrates into the larynx, trachea, and pulmonary parenchyma, producing discrete pulmonary densities. There may be hoarseness, respiratory distress, and wheezing secondary to the gummatous lesion itself or to subsequent stenosis occurring with healing.

Gastrointestinal System

Gummas involving the liver produce the usually benign, asymptomatic hepar lobatum. A picture resembling Laennec's cirrhosis is occasionally produced by liver involvement. Gastric involvement can consist of diffuse infiltration into the stomach wall or focal lesions that endoscopically and microscopically can be confused with lymphoma or carcinoma. Epigastric pain, early satiety, regurgitation, belching, and weight loss are common symptoms.

Cardiovascular System

Cardiovascular lesions (10-15% of late syphilitic lesions) are often progressive, disabling, and life-threatening. Central nervous system lesions are often present also. Involvement usually starts as an arteritis in the supracardiac portion of the aorta and progresses to cause one or more of the following: (1) narrowing of the coronary ostia, with resulting decreased coronary circulation, angina, and acute myocardial infarction; (2) scarring of the aortic valves, producing aortic regurgitation with its water-hammer pulse, aortic diastolic murmur, frequent aortic systolic murmur, cardiac hypertrophy, and eventually congestive heart failure; and (3) weakness of the wall of the aorta, with saccular aneurysm formation and associated pressure symptoms of dysphagia, hoarseness, brassy cough, back pain (vertebral erosion), and occasionally rupture of the aneurysm. Recurrent respiratory infections are common as a result of pressure on the trachea and bronchi.

Treatment of tertiary syphilis (excluding neurosyphilis; see below) is as for late latent syphilis. Reversal of positive serologic tests does not usually occur. A second course of penicillin therapy may be given if necessary. There is no known method for reliable eradication of the treponeme from humans in the late stages of syphilis. Viable spirochetes are occasionally found in the eyes, in cerebrospinal fluid, and elsewhere in patients with "adequately" treated syphilis, but claims for their capacity to cause progressive disease are speculative.

Neurosyphilis

Neurosyphilis (15-20% of late syphilitic lesions; often present with cardiovascular syphilis) is also a progressive, disabling, and life-threatening complication. It develops more commonly in men than in women and in whites than in blacks.

A. Classification

There are four clinical types.

1. Asymptomatic neurosyphilis—This form is characterized by spinal fluid abnormalities (positive spinal fluid serology, increased cell count, occasionally increased protein) without symptoms or signs of neurologic involvement.

2. Meningovascular syphilis—This form is characterized by meningeal involvement or changes in the vascular structures of the brain (or both), producing symptoms of chronic meningitis (headache, irritability), cranial nerve palsies (basilar meningitis), unequal reflexes, irregular pupils with poor light and accommodation reflexes, and, when large vessels are involved, cerebrovascular accidents. The cerebrospinal fluid shows increased cells (100-1000/uL), elevated protein, and usually a positive serologic test for syphilis. The symptoms of acute meningitis are rare in late syphilis.

3. Tabes dorsalis—This form is a chronic progressive degeneration of the parenchyma of the posterior columns of the spinal cord and of the posterior sensory ganglia and nerve roots. The symptoms and signs are impairment of proprioception and vibration sense, Argyll Robertson pupils (which react poorly to light but well to accommodation), and muscular hypotonia and hyporeflexia. Impairment of proprioception results in a wide-based gait and inability to walk in the dark. Paresthesias, analgesia, or sharp recurrent pains in the muscles of the leg ("shooting" or "lightning" pains) may occur. Crises are also common in tabes: gastric crises, consisting of sharp abdominal pains with nausea and vomiting (simulating an acute abdomen); laryngeal crises, with paroxysmal cough and dyspnea; urethral crises, with painful bladder spasms; and rectal and anal crises. Crises may begin suddenly, last for hours to days, and cease abruptly. Neurogenic bladder with overflow incontinence is also seen. Painless trophic ulcers may develop over pressure points on the feet. Joint damage may occur as a result of lack of sensory innervation (Charcot joint). The cerebrospinal fluid may have a normal or increased cell count (3-200/uL), elevated protein, and variable results of serologic tests.

4. General paresis—This is generalized involvement of the cerebral cortex with insidious onset of symptoms. There is usually a decrease in concentrating power, memory loss, dysarthria, tremor of the fingers and lips, irritability, and mild headaches. Most striking is the change of personality; the patient becomes slovenly, irresponsible, confused, and psychotic. The cerebrospinal fluid findings resemble those of tabes dorsalis. Combinations of the various forms of neurosyphilis (especially tabes and paresis) are not uncommon.

B. Special Considerations in Treatment of Neurosyphilis

It is most important to prevent neurosyphilis by prompt diagnosis, adequate treatment, and follow-up of early syphilis. Indications for lumbar puncture vary depending upon the stage of the disease and the host's immune status. In early syphilis (primary and secondary syphilis and early latent syphilis of less than 1 year's duration), invasion of the central nervous system by *T pallidum* with cerebrospinal fluid abnormalities occurs commonly, but neurosyphilis rarely develops in patients who have received the standard therapy outlined above. Thus, unless clinical symptoms and signs of neurosyphilis or ophthalmologic involvement (uveitis, neuroretinitis, optic neuritis, iritis) is present, a lumbar puncture in early syphilis is not recommended as part of the routine evaluation. In latent syphilis, the decision to perform a lumbar puncture should be individualized. Routine lumbar puncture for all patients is not indicated since the yield is low and findings rarely influence therapeutic decisions. Cerebrospinal fluid evaluation is recommended, however, in the later stages of syphilis if neurologic or ophthalmologic symptoms and signs are present, if therapy other than with penicillin is to be given, if the patient is HIV-positive (see next section), if there is evidence of treatment failure (see discussion above), if there is evidence of active tertiary syphilis (aortitis, iritis, optic atrophy, the presence of a gumma, etc), or if the serum nontreponemal antibody titer is = 1:32. In the presence of definite cerebrospinal fluid or neurologic abnormalities, one should treat for neurosyphilis. The pretreatment clinical and laboratory evaluation should include neurologic, ocular, cardiovascular, psychiatric, and cerebrospinal fluid examinations.

The regimen of 2.4 million units of benzathine penicillin intramuscularly weekly for three consecutive weeks results in low to undetectable cerebrospinal fluid levels of penicillin, and treatment failures have been described when this regimen has been used to treat neurosyphilis. For these reasons, present recommendations for the therapy of neurosyphilis employ higher doses of short-acting penicillin in order to achieve better penetration and higher levels of drug in the cerebrospinal fluid. Recommended regimens include 18-24 million units per day of aqueous crystalline penicillin G given as 3-4 million units intravenously every 4 hours or as a continuous infusion for 10-14 days. Alternatively, 2.4 million units of procaine penicillin can be given intramuscularly once daily along with 500 mg of probenecid orally four times daily, both for 10-14 days. Because of concerns about slowly dividing organisms that may persist after only 10-14 days of therapy, many experts recommend subsequent administration of 2.4 million units of benzathine penicillin intramuscularly once weekly for 3 weeks as additional therapy. Ceftriaxone, 2 g intramuscularly or intravenously once daily for 10-14 days, can be used as an alternative to penicillin. Since other regimens for neurosyphilis have not been adequately studied, if the patient has a history of an IgE-mediated reaction to penicillin, he or she should be skin-tested for allergy to penicillin and, if positive, desensitized.

All patients should have spinal fluid examinations at 6-month intervals until the cell count is normal. Response may be gauged by clinical improvement and reversal of cerebrospinal fluid changes. A second course of penicillin therapy may be given if the cell count has not decreased at 6 months or is not normal at 2 years. Not infrequently, there is progression of neurologic symptoms and signs despite high and prolonged doses of penicillin. It has been postulated that these treatment failures are related to the unexplained persistence of viable *T pallidum* in central nervous system or ocular lesions in at least some cases.

6. Syphilis in HIV-Infected Patients

Because syphilis has variable clinical manifestations and an unpredictable course, evaluation of case reports of unusual clinical or laboratory manifestations of syphilis in HIV-infected patients is difficult. Although unusual serologic responses have been reported in HIV-positive patients, including high titers of nontreponemal tests, delayed appearance of positive titers, and false-negative tests, most HIV-positive patients respond serologically in somewhat the same way as noninfected patients. Thus, interpretation of serologic tests should be the same for HIV-positive and HIV-negative individuals. Some recommend that all HIV-positive men be screened twice a year by RPR or VDRL to identify latent disease and to appropriately stage individuals. By establishing a serologic history, unnecessary lumbar punctures required for latent syphilis of unknown duration can be avoided. Because of concerns about false-negative serologic tests or a delayed immunologic response, if the diagnosis of syphilis is suggested on clinical grounds but reagin tests are negative, alternative tests should be performed. These tests include darkfield examination of lesions and direct fluorescent antibody staining for *T pallidum* of lesion exudate or biopsy specimens.

The diagnosis of neurosyphilis in HIV-infected patients is complicated by the fact that cerebrospinal fluid abnormalities are frequently seen and may be due to neurosyphilis or HIV infection itself. The significance of these abnormalities is unknown, and similar abnormalities are frequently seen in non-HIV-infected patients with primary or secondary syphilis. Despite occasional reports of HIV-infected patients who progress to develop neurosyphilis despite appropriate therapy for early disease, the vast majority of HIV-infected patients with primary or secondary syphilis respond appropriately to currently recommended regimens. Thus, although some recommend a cerebrospinal fluid examination for all HIV-positive patients with syphilis, such testing is probably not needed in those with early disease. In contrast, a lumbar puncture should be performed in HIV-positive patients if they have late latent syphilis or syphilis of unknown duration, if neurologic signs are present, or if they have failed therapy. As discussed above, the same criteria for failure apply to HIV-positive and HIV-negative patients, and re-treatment regimens are the same.

Treatment of HIV-positive patients with primary and secondary syphilis is the same as for HIV-negative patients. Because of concerns about the adequacy of this therapy, some experts recommend additional therapy with 2.4 million units of benzathine penicillin intramuscularly weekly for 3 weeks instead of single-dose therapy. Because of ongoing concerns about adequacy of therapy, careful clinical and serologic follow-up should be done at 3, 6, 9, 12, and 24 months.

HIV-infected patients with late latent syphilis, syphilis of unknown duration, and neurosyphilis should be treated like HIV-negative individuals, with follow-up at 6, 12, 18, and 24 months.

Because clinical experience in treating HIV-infected patients with syphilis is based on penicillin regimens, few options exist for treating the penicillin-allergic patient. For primary, secondary, and early latent syphilis, doxycycline or tetracycline regimens can be used. For late latent syphilis, latent syphilis of unknown duration, and neurosyphilis, penicillin regimens should be used even if this requires skin testing and desensitization.

7. Syphilis in Pregnancy

All pregnant women should have a nontreponemal serologic test for syphilis at the time of the first prenatal visit. In women suspected of being at increased risk for syphilis or for populations in which there is a high prevalence of syphilis, additional nontreponemal tests should be performed during the third trimester at 28 weeks and again at delivery. The serologic status of all women who have delivered should be known before discharge from the hospital. Seropositive women should be considered infected and should be treated unless prior treatment with fall in antibody titer is medically documented.

The preferred treatment is with penicillin in dosage schedules appropriate for the stage of syphilis (see above). Penicillin prevents congenital syphilis in 90% of cases, even when treatment is given late in pregnancy. Tetracycline and doxycycline are contraindicated in pregnancy. Erythromycin should not be used because of failure to eradicate infection in the fetus, and insufficient data are available to justify a recommendation for ceftriaxone or azithromycin. Thus, women with a history of penicillin allergy should be skin-tested and desensitized if necessary.

The infant should be evaluated immediately, as noted below, and at 6-8 weeks of age.

8. Congenital Syphilis

Congenital syphilis is a transplacentally transmitted infection that occurs in infants of untreated or inadequately treated mothers. The physical findings at birth are quite variable: The infant may have many or only minimal signs or even no signs until 6-8 weeks of life (delayed form). The most common findings are on the mucous membranes and skin—maculopapular rash, condylomas, mucous membrane patches, and serous nasal discharge (snuffles). These lesions are infectious; *T pallidum*

can easily be found microscopically, and the infant must be isolated. Other common findings are hepatosplenomegaly, anemia, or osteochondritis. These early active lesions subsequently heal, and if the disease is left untreated it produces the characteristic stigmas of syphilis—interstitial keratitis, Hutchinson's teeth, saddle nose, saber shins, deafness, and central nervous system involvement.

The presence of negative serologic tests at birth in both the mother and the infant usually means that the newborn is free of infection. However, recent infection near the time of delivery may result in negative tests because there has been insufficient time to develop a serologic response. Thus, one must maintain a high index of suspicion in infants who present with delayed onset of symptoms despite negative serologic tests at birth, especially in infants born to high-risk mothers (HIV-positive, illicit drug users). All infants born to mothers with positive nontreponemal and treponemal antibody titers should have blood drawn for an RPR or VDRL test and, if positive, referred to a pediatrician for further evaluation and therapy.

■ **NON-SEXUALLY TRANSMITTED TREPONEMATOSES**

A variety of treponemal diseases other than syphilis occur endemically in many tropical areas of the world. They are distinguished from disease caused by *T pallidum* by their nonsexual transmission, their relatively high incidence in certain geographic areas and among children, and their tendency to produce less severe visceral manifestations. As in syphilis, organisms can be demonstrated in infectious lesions with darkfield microscopy or immunofluorescence but cannot be cultured in artificial media; the serologic tests for syphilis are positive, including the newer tests such as CAPTIA Syph G; the diseases have primary, secondary, and sometimes tertiary stages; and penicillin is the drug of choice. There is evidence that infection with these agents may provide partial resistance to syphilis and vice versa. Treatment with penicillin in doses appropriate to primary syphilis (eg, 2.4 million units of benzathine penicillin G intramuscularly) is generally curative in any stage of the non-sexually transmitted treponematoses. In cases of penicillin hypersensitivity, tetracycline, 500 mg four times a day for 10-14 days, is usually the recommended alternative.

YAWS (FRAMBESIA)

Yaws is a contagious disease largely limited to tropical regions that is caused by *T pallidum* subsp *pertenue*. It is characterized by granulomatous lesions of the skin, mucous membranes, and bone. Yaws is rarely fatal, though if untreated it may lead to chronic disability and disfigurement. Yaws is acquired by direct nonsexual contact, usually in childhood, although it may occur at any age. The "mother yaw," a painless papule that later ulcerates, appears 3-4 weeks after exposure. There is usually associated regional lymphadenopathy. Six to 12 weeks later, secondary lesions that are raised papillomas and papules that weep highly infectious material appear and last for several months or years. Painful ulcerated lesions on the soles are frequent and are called "crab yaws." Late gummatous lesions may occur, with associated tissue destruction involving large areas of skin and subcutaneous tissues. The late effects of yaws, with bone change, shortening of digits, and contractions, may be confused with similar changes occurring in leprosy. Central nervous system, cardiac, or other visceral involvement is rare. See above for therapy.

PINTA

Pinta is a non-sexually transmitted spirochetal infection caused by *Treponema carateum*. It occurs endemically in rural areas of Latin America, especially in Mexico, Colombia, and Cuba, and in some areas of the Pacific. A nonulcerative, erythematous primary papule spreads slowly into a papulosquamous plaque showing a variety of color changes (slate, lilac, black). Secondary lesions resemble the primary one and appear within a year after it. These appear successively, new lesions together with older ones; are commonest on the extremities; and later show atrophy and depigmentation. Some cases show pigmentary changes and atrophic patches on the soles and palms, with or without hyperkeratosis, that are indistinguishable from "crab yaws." Very rarely, central nervous system or cardiovascular disease is observed late in the course of infection. See above for therapy.

ENDEMIC SYPHILIS

Endemic syphilis is an acute or chronic infection caused by an organism indistinguishable from *T pallidum* subsp *endemicum*. It has been reported in a number of countries, particularly in the eastern Mediterranean area, often with local names: bejel in Syria, Saudi Arabia, and Iraq, and dichuchwa, njovera, and siti in Africa. It also occurs in Southeast Asia. The local forms have distinctive features. Moist ulcerated lesions of the skin or oral or nasopharyngeal mucosa are the most common manifestations. Generalized lymphadenopathy and secondary and tertiary bone and skin lesions are also common. Deep leg pain points to periostitis or osteomyelitis. In the late stages of disease, destructive gummatous lesions similar to those seen in yaws can develop, resulting in loss of cartilage and saber shin deformity. Cardiovascular and central nervous system involvement are rare. See above for therapy.

■ **MISCELLANEOUS SPIROCHETAL DISEASES**

RELAPSING FEVER

Relapsing fever is endemic in many parts of the world. The main reservoir is rodents, which serve as the source of infection for ticks (eg, ornithodoros). The distribution and seasonal incidence of the disease are determined by the ecology of the ticks in different areas. In the United States, infected ticks are found throughout the West, especially in mountainous areas, but clinical cases are uncommon in humans.

The infectious organism is a spirochete, *Borrelia recurrentis*, though other poorly characterized borrelia-like organisms can cause similar disease. It may be transmitted transovarially from one generation of ticks to the next. The spirochetes occur in all tissues of the tick, and humans can be infected by tick bites or by rubbing crushed tick tissues or feces into the bite wound. Tick-borne relapsing fever is endemic but is not transmitted from person to person. Different species (or strain) names have been given to borrelia in different parts of the world where the organisms are transmitted by different ticks.

When an infected person harbors lice, the lice become infected with borrelia by sucking blood. A few days later, the lice serve as a source of infection for other persons. Large epidemics may occur in louse-infested populations, and transmission is favored by crowding, malnutrition, and cold climate.

Clinical Findings

A. Symptoms and Signs

There is an abrupt onset of fever, chills, tachycardia, nausea and vomiting, arthralgia, and severe headache. Hepatomegaly and splenomegaly may develop, as well as various types of rashes. Delirium occurs with high fever, and there may be various neurologic and psychic abnormalities. The attack terminates, usually abruptly, after 3-10 days. After an interval of 1-2 weeks, relapse occurs, but often it is somewhat milder. Three to ten relapses may occur before recovery.

B. Laboratory Findings

During episodes of fever, large spirochetes are seen in blood smears stained with Wright's or Giemsa's stain. The organisms can be cultured in special media but rapidly lose pathogenicity. The spirochetes can multiply in injected rats or mice and can be seen in their blood.

A variety of anti-borrelia antibodies develop during the illness; sometimes the Weil-Felix test for rickettsioses and nontreponemal serologic tests for syphilis may also be falsely positive. Infection with *Borrelia recurrentis* can cause false-positive indirect fluorescent antibody and Western blot tests for *Borrelia burgdorferi*, and some cases may be misdiagnosed as Lyme disease. Cerebrospinal fluid abnormalities occur in patients with meningeal involvement. Mild anemia and thrombocytopenia are common, but the white blood cell count tends to be normal.

Differential Diagnosis

The manifestations of relapsing fever may be confused with malaria, leptospirosis, meningococcemia, yellow fever, typhus, or rat-bite fever.

Prevention

Prevention of tick bites (as described for rickettsial diseases) and delousing procedures applicable to large groups can prevent illness. Arthropod vectors should be controlled if possible.

An effective means of chemoprophylaxis has not been developed.

Treatment

A single dose of tetracycline or erythromycin, 0.5 g orally, or a single dose of procaine penicillin G, 400,000-600,000 units intramuscularly, probably constitutes adequate treatment for louse-borne relapsing fevers. Because of higher relapse rates, tick-borne disease is treated with 0.5 g of tetracycline or erythromycin given four times daily for 5-10 days. Jarisch-Herxheimer reactions occur commonly following treatment and may be life-threatening. Treatment with aspirin—but not hydrocortisone—may ameliorate this reaction. The Jarisch-Herxheimer reaction is mediated in part by tumor necrosis factor, and administration of antibody to this cytokine prior to antibiotic therapy is effective in preventing the reaction.

Prognosis

The overall mortality rate is usually about 5%. Fatalities are most common in old, debilitated, or very young patients. With treatment, the initial attack is shortened and relapses are largely prevented.

RAT-BITE FEVER (SPIRILLARY RAT-BITE FEVER, SODOKU)

Rat-bite fever is an uncommon acute infectious disease caused by *Spirillum minus*. It is transmitted to humans by the bite of a rat. Inhabitants of rat-infested slum dwellings and laboratory workers are at greatest risk.

Clinical Findings

A. Symptoms and Signs

The original rat bite, unless secondarily infected, heals promptly, but 1 to several weeks later the site becomes swollen, indurated, and painful; assumes a dusky purplish hue; and may ulcerate. Regional lymphangitis and lymphadenitis, fever, chills, malaise, myalgia, arthralgia, and headache are present. Splenomegaly may occur. A sparse, dusky-red maculopapular rash appears on the trunk and extremities in many cases, and there may be frank arthritis.

After a few days, both the local and systemic symptoms subside, only to reappear again in a few more days. This relapsing pattern of fever for 3-4 days alternating with afebrile periods lasting 3-9 days may persist for weeks. The other features, however, usually recur only during the first few relapses.

B. Laboratory Findings

Leukocytosis is often present, and the nontreponemal test for syphilis is often falsely positive. The organism may be identified in darkfield examination of the ulcer exudate or aspirated lymph node material; more commonly, it is observed after inoculation of a laboratory animal with the patient's exudate or blood. It has not been cultured in artificial media.

Differential Diagnosis

Rat-bite fever must be distinguished from the rat bite-induced lymphadenitis and rash of streptobacillary fever. Clinically, the severe arthritis and myalgias seen in streptobacillary disease are rarely seen in disease caused by *S minus*. Reliable differentiation requires an increasing titer of agglutinins against *Streptobacillus moniliformis* or identification of the causative organism. Rat-bite fever must also be distinguished from tularemia, rickettsial disease, *Pasteurella multocida* infections, and relapsing fever by identification of the causative organism.

Treatment

Treat with procaine penicillin G, 600,000 units intramuscularly every 12 hours, or tetracycline hydrochloride, 0.5 g every 6 hours for 10-14 days. Give supportive and symptomatic measures as indicated.

Prognosis

The reported mortality rate of about 10% should be markedly reduced by prompt diagnosis and antimicrobial treatment.

LEPTOSPIROSIS

Leptospirosis is an acute and often severe infection that frequently affects the liver or other organs and is caused by *Leptospira interrogans*, which is a diverse organism consisting of 23 serogroups and over 200 serovars. The three most common serovars of infection are *Leptospira icterohaemorrhagiae* of rats, *Leptospira canicola* of dogs, and *Leptospira pomona* of cattle and swine. Several other varieties can also cause the disease, but *L icterohaemorrhagiae* causes the most severe illness. The disease is worldwide in distribution, and the incidence is higher than usually supposed. The leptospires are often transmitted to humans by the ingestion of food and drink contaminated by the urine of the reservoir animal. The organism may also enter through minor skin lesions and probably via the conjunctiva. Recreational cases have followed swimming or rafting in contaminated water, and occupational cases occur among sewer workers, rice planters, abattoir workers, and farmers. Sporadic urban cases have been seen in the homeless exposed to rat urine. The incubation period is 2-20 days.

Clinical Findings

A. Symptoms and Signs

Anicteric leptospirosis is the more common and milder form of the disease and is often biphasic. The initial or "septicemic" phase begins with abrupt fever to 39-40°C, chills, abdominal pain, severe headache, and myalgias, especially of the calf muscles. There may be marked conjunctival suffusion. Leptospires can be isolated from blood, cerebrospinal fluid, and tissues. Following a 1- to 3-day period of improvement in symptoms and absence of fever, the second or "immune" phase begins. Leptospires are absent from blood and cerebrospinal fluid but are still present in the kidney, and specific antibodies appear. A recurrence of symptoms is seen as in the first phase of disease with the onset of meningitis. Uveitis (which can be unilateral or bilateral and usually involves the entire uveal tract), rash, and adenopathy may occur. A rare but severe manifestation is hemorrhagic pneumonia. The illness is usually self-limited, lasting 4-30 days, and complete recovery is the rule.

Icteric leptospirosis (Weil's syndrome) (usually caused by *L icterohaemorrhagiae*) is the most severe form of the disease, characterized by impaired renal and hepatic function, abnormal mental status, hemorrhagic pneumonia, hypotension, and a 5-10% mortality rate. Symptoms and signs often are continuous and not biphasic.

Pretibial fever, a mild form of leptospirosis caused by *Leptospira autumnalis*, occurred during World War II at Fort Bragg. In pretibial fever, there is patchy erythema on the skin of the lower legs or generalized rash occurring with fever.

Leptospirosis with jaundice must be distinguished from hepatitis, yellow fever, and relapsing fever.

B. Laboratory Findings

The leukocyte count may be normal or as high as 50,000/uL, with neutrophils predominating. The urine may contain bile, protein, casts, and red cells. Oliguria is not uncommon, and in severe cases uremia may occur. Elevated bilirubin and aminotransferases are seen in 75% and elevated creatinine (> 1.5 mg/dL) in 50%. In cases with meningeal involvement, organisms may be found in the cerebrospinal fluid during the first 10 days of illness. Early in the disease, the organism may be identified by darkfield examination of the patient's blood or by culture on a semisolid medium (eg, Fletcher's EMJH). Cultures take 1-6 weeks to become positive. The organism may also be grown from the urine from the tenth day to the sixth week. Diagnosis is usually made by means of serologic tests, of which several are available. Agglutination tests (microscopic, using live organisms, and macroscopic, using killed antigen) become positive after 7-10 days of illness, peak at 3-4 weeks, and may persist at high levels for many years. Thus, to make a diagnosis, a fourfold or greater rise in titer must be documented. The agglutination tests are cumbersome to perform and require trained personnel. Indirect hemagglutination, enzyme immunosorbent assay (EIA), and ELISA tests are also available. The IgM EIA is particularly useful in making an early diagnosis, as it is positive as early as 2 days into illness, a time when the clinical manifestations may be nonspecific, and it is extremely sensitive and specific (93%). PCR methods (presently investigational) appear to be sensitive, specific, positive early in disease, and able to detect leptospiral DNA in blood, urine, cerebrospinal fluid, and aqueous humor. Serum CK is usually elevated in leptospirosis patients and normal in hepatitis patients.

Complications

Myocarditis, aseptic meningitis, renal failure, and pulmonary infiltrates with hemorrhage are not common but are the usual causes of death. Iridocyclitis may occur.

Treatment

Various antimicrobial drugs, including penicillin and tetracyclines, show antileptospiral activity. Penicillin (eg, 6 million units daily intravenously) is the drug of choice in severe leptospirosis and is especially effective if started within the first 4 days of illness. Jarisch-Herxheimer reactions may occur. Observe for evidence of renal failure, and treat as necessary. Doxycycline, 100 mg twice daily for 7 days, is also effective as therapy if started early, but this agent is most often used in mild to moderate disease. Effective prophylaxis consists of doxycycline, 200 mg orally once weekly during the risk of exposure.

Prognosis

Without jaundice, the disease is almost never fatal. With jaundice, the mortality rate is 5% for those under age 30 and 30% for those over age 60.

LYME DISEASE (LYME BORRELIOSIS)

Essentials of Diagnosis

- Erythema migrans, a flat or slightly raised red lesion that expands with central clearing.
- Headache or stiff neck.
- Arthralgias, arthritis, and myalgias; arthritis is often chronic and recurrent.
- Wide geographic distribution, with most United States cases in the Northeast, mid-Atlantic, Upper Midwest, and Pacific coastal regions.

General Considerations

This illness, named after the town of Old Lyme, Connecticut, is caused by the spirochete *Borrelia burgdorferi* and is transmitted to humans by ixodid ticks that are part of the *Ixodes ricinus* complex. Four genomic groups of the *B burgdorferi sensu lato* group have been identified: *B burgdorferi sensu stricto*, which causes disease in North America and less commonly in Europe and Asia; *B garinii*, and *B afzelii*, which are the predominant etiologic agents of Lyme disease in Europe and Asia; and the newly named *B bissettii* sp nov found in California. Lyme disease is the most common vector-borne disease in the United States and is being reported with increasing frequency, but the true incidence is not known as overreporting remains a problem. In 2000 there were 17,730 cases reported from 44 states and the District of Columbia, an increase of 8% over 1999. Most cases (over 95%) were reported from the mid-Atlantic, northeastern, and North Central regions of the country. As in years past, cases were reported from states without known enzootic cycles of *B burgdorferi*, raising questions about the accuracy of diagnosis. Because clinical manifestations are nonspecific and because laboratory diagnosis is insensitive early in the illness (see below), many patients are diagnosed with Lyme disease who do not have it. In a Lyme disease clinic at a major teaching hospital in an endemic area, only 23% of patients referred for active disease were found to have it. The consequences of overdiagnosis and overtreatment of Lyme disease are substantial. Individuals previously treated for Lyme disease, whether they actually had the disease or not, were avid users of the health care system, with multiple office visits to several different physicians resulting in numerous prescriptions for unnecessary antibiotics and frequent days of missed work. (The overreporting and overdiagnosis of Lyme disease is in part explained by the discovery of a nonculturable spirochete in the Lone Star tick [*Amblyomma americanum*]). This organism produces a Lyme disease-like illness with a skin lesion very similar to that of erythema migrans. As the Lone Star tick is found in the Midwest and Southern areas where enzootic cycles for *B burgdorferi* have not been reported, cases of Lyme disease reported from these areas are probably due to this newly discovered organism.

The vector of Lyme disease varies geographically and is *Ixodes scapularis* (also known as *I dammini*) in the northeastern, North Central, and mid-Atlantic regions of the United States; *Ixodes pacificus* on the West Coast; *Ixodes ricinus* in Europe; and *Ixodes persulcatus* in Asia. The disease also occurs in Australia. Mice and deer make up the major animal reservoir of *B burgdorferi*, but other rodents and birds may also be infected. Domestic animals such as dogs, cattle, and horses can also develop clinical illness, usually manifested as arthritis.

Ticks feed once during each of their three stages of life. Larval ticks feed in late summer, nymphs in the following spring and early summer, and adults during the fall. In the northeastern United States and the mid-Atlantic states, the preferred host for the nymphs and larvae is the white-footed mouse (the black-striped mouse in Europe). This animal is tolerant of infection—a fact that is critical in maintaining infection, since the mouse can remain spirochetemic and transmit the agent to the larvae the following spring after being infected by the nymphal form in early summer. Adult ticks prefer the white-tailed deer as host. Although only 20-25% of nymphs harbor spirochetes compared with 50-65% of adults, most infections occur in the spring and summer (when nymphs are active), and fewer cases occur in the cooler months (October to April), when adults feed. This is probably due to the greater abundance of nymphs; greater human outdoor activity in spring and summer, when nymphs feed; and the fact that adult ticks are larger, easier to detect by the human host, and thus can be removed before disease is transmitted. Less than 1% of larvae are infected with spirochetes, and transmission of the disease through contact with larvae is unlikely. In the western United States, the *Ixodes pacificus* nymph prefers to feed on lizards, which are not susceptible to infection. It is only the few nymph and larval ticks that feed on wood rats, which can be infected, that are capable of transmitting disease.

The increased incidence of Lyme disease is due in part to the resurgence of the once-decimated deer population, the spread of tick vectors to new areas (infected ixodes ticks have been isolated from migratory birds), and the encroachment of suburbs on once rural areas, bringing humans and ticks into closer proximity. Factors contributing to increased reporting include enhanced provider awareness and better laboratory surveillance.

Under experimental conditions, ticks must feed for 24 hours or longer to transmit infections. Human epidemiologic studies have indicated that the incidence of disease is significantly higher when tick attachment is for longer than 72 hours than if it is less than 72 hours, though rare cases have been documented with attachment of less than 24 hours. In addition, the percentage of ticks infected varies on a regional basis. In the Northeast and Midwest, 15-65% of *I scapularis* ticks are infected with the spirochete; in the western United States, only 2% of *I pacificus* are infected. These are important epidemiologic features in assessing the likelihood that tick exposure will result in disease. Exposure to *I pacificus* is unlikely to result in disease, since so few ticks are infected, but this is not true of exposure to *I scapularis*. Eliciting a history of brushing a tick off the skin (ie, the tick was not feeding) or removing a tick on the same day as exposure (ie, the tick did not feed long enough) decreases the likelihood that infection will develop, since the vast majority of cases occur when ticks feed for at least 24 hours.

Ixodes ticks are smaller than the more common dog ticks (*Dermacentor variabilis*). Larvae are less than 1 mm in size, and the adult female is 2-3 mm in size, with a red body and black legs. After a blood meal, ticks can reach two to three times their unengorged size. Because the tick is so small, the bite is usually painless and goes unnoticed. After feeding, the tick drops off in 2-4 days. If a tick is found, it should be removed immediately. The best way to accomplish this is to grab the mouth part—not the body—where it enters the skin with a fine-tipped tweezers and pull firmly and repeatedly until the tick releases its hold. Saving the tick in a bottle of alcohol for future identification may be useful, especially if symptoms develop.

Congenital infection has been documented, but the exact frequency and manifestations have not been clearly defined. Similarly, because the organism can be latent, it is not known if women infected prior to becoming pregnant can activate the disease and transmit infection to the fetus. In one retrospective study, 5 of 19 pregnancies complicated by Lyme disease resulted in an adverse outcome, but all of the outcomes were different and could not be conclusively linked to infection. Several serosurveys involving over 2000 pregnant women in endemic areas have not found any association between seropositivity in prospective mothers and the prevalence of congenital malformations, fetal death, and prematurity. Thus, if *B burgdorferi* causes a congenital syndrome like some other spirochetal illnesses, it must be extremely uncommon.

Clinical Findings

The typical clinical description of Lyme disease divides the illness into three stages: stage 1, flu-like symptoms and a typical skin rash (**erythema migrans**); stage 2, weeks to months later, Bell's palsy or meningitis; and stage 3, months to years later, arthritis. The problem with this simplified scheme is that there is a great deal of overlap, and the skin, central nervous system, and musculoskeletal system can be involved early or late. A more accurate classification divides disease into early and late manifestations and specifies whether disease is localized or disseminated.

A. Symptoms and Signs

1. Stage 1, early localized infection—Stage 1 infection is characterized by erythema migrans. About 1 week after the tick bite (range, 3-30 days; median 7-10 days), a flat or slightly raised red lesion appears at the site, which is commonly seen in areas of tight clothing such as the groin, thigh, or axilla. This lesion expands over several days. Although originally described as a lesion that progresses with central clearing ("bull's-eye" lesion), often there is a more homogeneous appearance or

even central intensification. About 10-20% of patients either do not have typical skin lesions or the lesions go unnoticed. A flu-like illness with fever, chills, and myalgia occurs in about half of patients. Even without treatment, the symptoms and signs of erythema migrans resolve in 3-4 weeks. Although the classic lesion of erythema migrans is not difficult to recognize, atypical forms can occur that may lead to misdiagnosis. Vesicular, urticarial, and evanescent erythema migrans have all been reported. Similarly, chemical reactions to tick and spider bites, drug eruptions, urticaria, and staphylococcal and streptococcal cellulitis have been mistaken for erythema migrans.

2. Stage 2, early disseminated infection—In stage 2, the spirochete may spread in the patient's blood or lymph to cause a wide variety of symptoms and signs. This usually occurs within days to weeks after inoculation of the organism. The most common manifestations involve the skin, central nervous system, and musculoskeletal system. In about half of patients, secondary lesions develop that are not associated with a tick bite. These lesions are similar in appearance to the primary lesion but are usually smaller. A rare skin lesion (1% of patients) seen primarily in Europe is borrelia lymphocytoma. This presents as a small reddish nodule or plaque on the ear in children and on the nipple in adults. Headache and stiff neck can occur, as well as migratory pains in joints, muscles, and tendons. Fatigue and malaise are common. Generally, the neurologic and musculoskeletal symptoms are intermittent and last only hours to a few days, whereas fatigue is persistent. After hematogenous spread, the organism sequesters itself in certain areas and produces focal symptoms. Some patients experience cardiac (4-10% of patients) or neurologic (10-20% of patients) manifestations. Involvement of the heart includes myopericarditis, with atrial or ventricular arrhythmias and heart block. Neurologic disease is most commonly manifested as aseptic meningitis with mild headache and neck stiffness, Bell's palsy, or encephalitis with irritability, personality change, and forgetfulness that can wax and wane. Even in the absence of symptoms, seeding of the central nervous system can occur. Peripheral neuropathy (sensory or motor), transverse myelitis, and mononeuritis multiplex have also been described. Conjunctivitis, keratitis, and, rarely, panophthalmitis can occur.

3. Stage 3, late persistent infection—Stage 3 infection occurs months to years after the initial infection and again primarily manifests itself as musculoskeletal, neurologic, and skin disease. Up to 60% of patients develop musculoskeletal complaints. Clinical manifestations are quite variable and include (1) joint and periarticular pain without objective findings (perhaps a manifestation of fibromyalgia that may be triggered by Lyme disease); (2) frank arthritis, mainly of large joints, that is chronic or recurrent over years (recurrences become less severe, less frequent, and shorter with time); and (3) chronic synovitis, which may result in permanent disability. The pathogenesis of chronic Lyme arthritis may be an immunologic phenomenon rather than persistence of infection. The observations that individuals with chronic arthritis have an increased frequency of HLA-DR4 gene expression, antibodies to OspA and OspB protein in joint fluid (major outer surface proteins of *B burgdorferi*), lack *B burgdorferi* DNA in synovial fluid as detected by polymerase chain reaction (PCR), and often fail to respond to antibiotics—all support the inference of an immunologic mechanism.

Both the central and the peripheral nervous systems may be involved. Subacute encephalopathy, characterized by memory loss, mood changes, and sleep disturbance, is the most common chronic neurologic manifestation. An axonal polyneuropathy, manifested as distal sensory paresthesias or radicular pain, can occur either alone or, more commonly, in association with encephalopathy. Most of these patients have objective signs of disease when tested by electromyography. A rare form of chronic neurologic dysfunction—leukoencephalitis—presents with cognitive dysfunction, spastic paraparesis, ataxia, and bladder dysfunction. This form of the disease is seen more commonly in Europe than in the United States.

The cutaneous manifestation of late infection, which can occur up to 10 years after infection, is **acrodermatitis chronica atrophicans**. It has been described mainly in Europe and is due to infection with *Borrelia afzelii*, a species that commonly causes disease in Europe but not the United States. There is usually bluish-red discoloration of a distal extremity with associated swelling. These lesions become atrophic and sclerotic with time and eventually resemble localized scleroderma. At least two cases of diffuse fasciitis with eosinophilia, a rare entity that resembles scleroderma, have been associated with infection with *B burgdorferi*.

B. Laboratory Findings

The diagnosis of Lyme disease is based on both clinical manifestations and laboratory findings. The National Surveillance Case Definition specifies a person with exposure to a potential tick habitat (within the 30 days just prior to developing erythema migrans) with (1) erythema migrans diagnosed by a physician or (2) at least one late manifestation of the disease and (3) laboratory confirmation as fulfilling the criteria for Lyme disease.

Laboratory confirmation requires detection of specific antibodies to *B burgdorferi* in serum, either by indirect immunofluorescence assay (IFA) or enzyme-linked immunosorbent assay (ELISA); the latter is now preferred, because it is more sensitive and specific. A Western blot assay that can detect both IgM and IgG antibodies is used as a confirmatory test. IgM antibody appears first 2-4 weeks after onset of erythema migrans, peaks at 6-8 weeks, and then declines to low levels after 4-6 months of illness. The presence of IgM antibody in patients with prolonged symptoms persisting for several months is likely to be a false-positive result. IgG occurs later (6-8 weeks after onset of disease), peaks at 4-6 months, and may remain elevated at low levels indefinitely despite appropriate therapy and resolution of symptoms. A two-test approach is now recommended for the diagnosis of active Lyme disease. All specimens positive or equivocal by ELISA or IFA should be tested by Western immunoblot. When Western immunoblot is done during the first 4 weeks of illness, both IgM and IgG should be tested. If a patient with suspected early Lyme disease has negative serologic studies, acute and convalescent titers should be obtained since up to 50% of patients with early disease can be antibody-negative in the first several weeks of illness. A fourfold rise in antibody titer would be diagnostic of recent infection. In patients with later stages of disease, almost all are antibody-positive. False-positive reactions in the ELISA and IFA have been reported in juvenile rheumatoid arthritis, rheumatoid arthritis, systemic lupus erythematosus, infectious mononucleosis, subacute infective endocarditis, syphilis, relapsing fever, leptospirosis, enteroviral and other viral illnesses, and patients with gingival disease (presumably because of cross-reactivity with oral treponemes). False-negative serologic reactions occur early in illness, and antibiotic therapy early in disease can abort subsequent seroconversion. Other investigational tests include an antibody-capture ELISA, which appears to be more specific and sensitive than the routine ELISA or IFA, especially in early disease. It is positive in up to 90% of patients with stage 1 disease. It is difficult to perform and is presently available only in reference and research laboratories. Use of flagellar antigen, which produces an early immune response, to detect antibodies by both ELISA and immunoblotting may improve the ability to detect early disease and is under investigation. Detection of immune complexes (specific antibody directed against *B burgdorferi* antigens) may be useful in diagnosing early disease and determining whether positive IgG serology is due to previous infection or active disease.

Caution should be exercised in interpreting serologic tests. Serologic tests are not subject to national standards, and interlaboratory variation of results is a major problem. In addition, some laboratories perform tests that are entirely unreliable and should never be used to support the diagnosis of Lyme disease (eg, the Lyme urinary antigen test). In addition, testing is often done in patients with nonspecific symptoms such as headache, arthralgia, myalgia, fatigue, and palpitations. Even in endemic areas, the pretest probability of having Lyme disease is low in these patients, and the probability of a false-positive test result is greater than that of a true-positive. For these reasons, the American College of Physicians has established guidelines for laboratory evaluation of patients with suspected Lyme disease:

(1) The diagnosis of early Lyme disease is clinical (ie, exposure in an endemic area, with physician-documented erythema migrans), and does *not* require laboratory confirmation. (Tests are often negative at this stage.)

(2) Late disease requires objective evidence of clinical manifestations (recurrent brief attacks of mono- or oligoarticular arthritis of large joints; lymphocytic meningitis, cranial neuritis [Bell's palsy], peripheral neuropathy, or, rarely, encephalomyelitis—but *not* headache, fatigue, paresthesias, or stiff neck alone; atrioventricular conduction defects with or without myocarditis; and laboratory evidence of disease (two-stage testing with ELISA and Western blot, as described above).

(3) Patients with nonspecific symptoms without objective signs of Lyme disease should *not* have serologic testing done. It is in this setting that false-positive tests occur more commonly than true-positives.

(4) The role of serologic testing in neuroborreliosis is unclear, as sensitivity and specificity of cerebrospinal fluid serologic tests have not been determined. However, it is rare for a patient with neuroborreliosis to have positive serologic tests on cerebrospinal fluid without positive tests on serum (see below).

(5) Other tests such as the T cell proliferative assay, PCR testing, and urinary antigen detection have not yet been studied well enough to be routinely used (see discussion below).

Positive cultures for *B burgdorferi* can be obtained early in the course of disease. Aspiration of erythema migrans lesions has yielded positive cultures in up to 30% of cases, whereas culture of a 2-mm punch biopsy is positive in 50-70%. PCR of a skin biopsy is even more sensitive, with positivity rates of 80%. In early disease, blood cultures are positive in up to 50% if large volumes (9 mL) are used, but cerebrospinal fluid is rarely culture-positive. The ability to culture organisms from skin lesions is greatly influenced by antibiotic therapy. Even a brief course of several days will result in negative cultures. Special silver staining of chronically inflamed synovial tissue demonstrates spirochetes in one-third of patients.

PCR is very specific for detecting the presence of borrelia DNA, but sensitivity is variable and depends on which body fluid is tested and the stage of the disease. In general, PCR is more sensitive than culture, especially in chronic disease. Up to 85% of synovial fluid samples are positive in active arthritis. In contrast, 38% of cerebrospinal fluid samples in acute neuroborreliosis are PCR-positive, and only 25% are positive in chronic neuroborreliosis. The significance of a positive reaction is unclear. Whether a positive PCR indicates persistence of viable organisms that will respond to further treatment or is a marker for residual DNA (not active infection) has not been clarified. In chronic Lyme arthritis, some have suggested that a positive PCR indicates active infection that requires further therapy, while others have found a positive reaction despite months of therapy, suggesting that the presence of DNA is indicative of an autoimmune arthritis.

The diagnosis of neuroborreliosis is often difficult since clinical manifestations, such as subtle memory impairment, may be difficult to document. Most patients with neuroborreliosis have a history of previous erythema migrans or mono- or polyarticular arthritis, and the vast majority have antibody present in serum. When cerebrospinal fluid is sampled, there may not be evidence of an inflammation (pleocytosis, elevated protein), but localized antibody production, ie, a ratio of cerebrospinal fluid to serum antibody of > 1.0, can often be demonstrated. The role of other tests such as PCR in detection of DNA or ELISA in detecting the presence

of OspA antigen is unclear, but in difficult cases these tests can be performed and, if positive, help establish the diagnosis. In addition, many patients with neuroborreliosis will have a peripheral neuropathy that may be detected by electromyography. In the absence of any of the above findings, it is difficult to make the diagnosis of central nervous system borrelia infection.

Nonspecific laboratory abnormalities can be seen, particularly in early disease. The most common are an elevated sedimentation rate of > 20 mm/h seen in 50% of cases and mildly abnormal liver function tests present in 30%. The abnormal liver function tests are transient and return to normal within a few weeks of treatment. A mild anemia, leukocytosis (11,000-18,000/uL), and microscopic hematuria have been reported in 10% or less of patients.

Prevention

Simple preventive measures such as avoiding tick-infested areas, covering exposed skin with long-sleeved shirts and wearing long trousers tucked into socks, wearing light-colored clothing, using repellents, and inspecting for ticks after exposure will greatly reduce the number of tick bites. Environmental controls directed at limiting ticks on residential property would be helpful, but trying to limit the deer, tick, or white-footed mouse populations over large areas is not feasible.

Routine use of prophylactic antibiotics following tick bites is not recommended. Analysis of the cost-effectiveness of prophylactic therapy suggests that antibiotics administered for 2 weeks would be beneficial in preventing illness in endemic areas, where the risk of acquiring disease following a tick bite is 3.6% or greater. However, prospective studies designed to examine the effect of prophylaxis have shown conflicting results. Two studies have shown no benefit of prophylaxis, but one study resulted in a decrease in erythema migrans from 3.2% in patients given placebo to 0.4% in those given a single 200-mg dose of doxycycline following a documented tick bite from *I. scapularis*. Since most patients who develop Lyme disease are symptomatic and since treatment of early disease prevents late sequelae, it is reasonable to reserve treatment for patients who develop symptoms rather than to routinely administer prophylactic antibiotics unless the risk is extremely high (endemic area, documented ixodes tick bite, feeding at least 40 hours). Exceptions might include situations where the follow-up is uncertain, the patient is extremely anxious, the patient is a pregnant woman, or the tick was engorged when removed.

A highly effective (75% efficacy) recombinant vaccine (LYMErix, SmithKline Beecham) using a conserved region of *Borrelia burgdorferi* known as outer surface protein A (OspA) has been removed from the market. Low sales were cited as the reason for withdrawal. However, initial controversy surrounding the vaccine concerned the theoretical possibility of inducing an autoimmune arthritis in recipients. Despite the fact that no cases of vaccine-induced arthritis had been documented, concerns about potential legal actions probably contributed to the decision to withdraw the product.

Treatment

Antibiotic sensitivity of *B. burgdorferi* has been established in vitro. Tetracycline is effective against the spirochete, but penicillin is only moderately so. Erythromycin is effective in vitro but has been disappointing in clinical trials. Ampicillin, ceftriaxone, azithromycin, cefuroxime, and imipenem are also effective in vitro, but aminoglycosides, ciprofloxacin, and rifampin are not.

Present recommendations for therapy are outlined in [Table 34-4](#). In general, infection confined to skin is treated for 2-3 weeks. For central nervous system disease (with the exception of Bell's palsy), intravenous therapy is used. Other organ system involvement usually responds to oral medication. For erythema migrans, oral antibiotic therapy shortens the duration of rash and prevents late sequelae. Doxycycline, 100 mg twice daily, is most commonly used and has the advantage of being active against ehrlichia. Amoxicillin is also effective and is recommended for pregnant or lactating women and for those who cannot tolerate doxycycline. Cefuroxime axetil, 500 mg twice daily, is as effective as doxycycline, 100 mg twice daily, but because of its cost it should be considered an alternative choice for those who cannot tolerate doxycycline or amoxicillin or for those in whom the drugs are contraindicated. Erythromycin and azithromycin are less effective, associated with higher rates of relapse, and are not recommended as first-line therapy. Isolated Bell's palsy (without meningitis or peripheral neuropathy) can be treated with doxycycline or amoxicillin for 2-3 weeks. Although therapy does not affect the rate of resolution of the cranial neuropathy, it does prevent development of late manifestations of disease.

The need for a lumbar puncture in patients with seventh nerve palsy is controversial. Some perform lumbar puncture on all patients with Bell's palsy and others only if there are symptoms or signs of meningitis. If meningitis is present, therapy with a parenteral antibiotic is indicated. Ceftriaxone, 2 g intravenously once daily for 14-28 days, is most commonly used, but penicillin, 18-24 million units daily in six divided doses, is equally efficacious. First- and second-degree heart block can be treated with oral agents, but third-degree block should be treated with ceftriaxone or penicillin and the patient should be admitted to the hospital for monitoring.

Therapy of arthritis is difficult because some patients fail to respond to any therapy, and those who do respond may do so slowly. Oral agents (doxycycline or amoxicillin) are as effective as intravenous regimens (ceftriaxone or penicillin). A reasonable approach to the patient with Lyme arthritis is to start with oral therapy and if this fails (persistent or recurrent joint swelling) to re-treat with an oral regimen for an additional 4 weeks or to switch to an intravenous regimen for 2-4 weeks. Re-treatment should be delayed for several months because of the slow resolution of joint symptoms. If arthritis persists after re-treatment, symptomatic therapy with nonsteroidal anti-inflammatory agents is recommended. For severe refractory pain, synovectomy may be required.

Based on the limited published data, therapy of Lyme disease in pregnancy should be the same as therapy in other patients with the exception that doxycycline should not be used.

Clinicians are often confronted with patients with nonspecific symptoms (such as fatigue and myalgias) and positive serologic tests for Lyme disease who request (or demand) therapy for their illness. It is important in managing these patients to remember (1) that the diagnosis of Lyme disease is primarily a clinical one, and nonspecific symptoms alone are not diagnostic; (2) that serologic tests are fraught with difficulty (as noted above), and in areas where disease prevalence is low, false-positive serologic tests are much more common than true-positive tests; and (3) that parenteral therapy with ceftriaxone for 2-4 weeks is costly (approximately \$5000) and has been associated with significant adverse effects (cholelithiasis). Parenteral therapy should be reserved for those most likely to benefit, ie, those with cutaneous, neurologic, cardiac, or rheumatic manifestations that are characteristic of Lyme disease.

Coinfections

Lyme disease, babesiosis ([Chapter 35](#)), and human granulocytic ehrlichiosis ([Chapter 32](#)) are endemic in similar areas of the country and are transmitted by the same tick, *Ixodes scapularis*. Coinfection with two or even all three of these organisms can occur, causing a clinical picture that is not "classic" for any of these diseases. The presence of erythema migrans is highly suggestive of Lyme disease, whereas flu-like symptoms without rash are more suggestive of babesiosis or ehrlichiosis. The complete blood count is usually normal in Lyme disease, but in patients with Lyme disease and babesiosis, anemia and thrombocytopenia are more common. Patients with Lyme disease and ehrlichiosis are more likely to have leukopenia. Patients with Lyme disease and babesiosis may have longer-lasting and more severe symptoms. Thus, persistent symptoms after what appears to be appropriate therapy for Lyme disease should raise the possibility of coexisting babesiosis.

Prognosis

Most patients respond to appropriate therapy with prompt resolution of symptoms within 4 weeks. With adequate therapy, only a small percentage of patients will fail to respond or will develop a late relapse. True treatment failures are thus uncommon, and in most cases re-treatment or prolonged treatment of Lyme disease is instituted because of misdiagnosis or misinterpretation of serologic results (both IgG and IgM antibodies can persist for prolonged periods despite adequate therapy) rather than inadequate therapy. The terms "chronic Lyme disease" or "post-Lyme disease syndrome" have been applied to patients with documented Lyme disease who have been adequately treated but have persistent nonspecific symptoms such as fatigue, arthralgias, myalgias, and neurocognitive complaints. These entities are poorly defined, and the patients comprise a heterogeneous group. Although there is a tendency to treat these patients with multiple or prolonged courses of oral or intravenous antibiotics, there are no data suggesting that this is efficacious, and the prolonged use of antibiotics in this setting is emphatically discouraged. It is important to remember also that most areas endemic for Lyme disease are also endemic for babesiosis and ehrlichiosis. Coinfection with the etiologic agents of these diseases may be associated with more severe symptoms than infection with either agent alone and is another possible explanation for failure to respond to therapy directed at Lyme disease.

The long-term outcome of adult patients with Lyme disease is generally favorable, but some patients have chronic complaints. Joint pain, memory impairment, and poor functional status secondary to pain are common subjective complaints in patients with Lyme disease, but physical examination and neurocognitive testing fail to document the presence of these symptoms as objective sequelae. Similarly, in highly endemic areas, patients with a diagnosis of Lyme disease commonly complain of pain, fatigue, and inability to perform certain physical activities when followed for several years. However, these complaints occur just as commonly in age-matched controls without a history of Lyme disease. Attempts to document chronic cardiac disease in patients treated for Lyme disease also have been unsuccessful. Long-term outcome of treated neuroborreliosis is favorable, with complete recovery in 75% of patients. Of remaining individuals, only 12% had sequelae that affected their daily activities.

Table 34-1. Stages of syphilis and common clinical manifestations.

Primary syphilis

Genital ulcer: painless ulcer with clean base and firm indurated borders
Regional lymphadenopathy

Secondary syphilis

Skin and mucous membranes
Rash: diffuse (including palms and soles), macular, papular, pustular, and combinations
Condylomata lata
Mucous patches: painless, silvery ulcerations of mucous membrane with surrounding erythema
Generalized lymphadenopathy
Constitutional symptoms
Fever, usually low-grade
Malaise
Anorexia
Arthralgias and myalgias
Central nervous system
Asymptomatic
Symptomatic
Headache
Meningitis
Cranial neuropathies (II-VIII)
Ocular
Iritis
Iridocyclitis
Other
Renal: glomerulonephritis, nephrotic syndrome
Liver: hepatitis
Bone and joint: arthritis, periostitis

Late syphilis

Late benign (gummatous): granulomatous lesion usually involving skin, mucous membranes and bones, but any organ can be involved
Cardiovascular
Aortic insufficiency
Coronary ostial stenosis
Aortic aneurysm
Neurosyphilis
Asymptomatic
Meningovascular
Seizures
Hemiparesis or hemiplegia
Tabes dorsalis
Impaired proprioception and vibratory sensation
Argyll Robertson pupil
Shooting pains
Ataxia
Romberg's sign
Urinary and fecal incontinence
Charcot joint
Cranial nerve involvement (II-VIII)
General paresis
Personality changes
Hyperactive reflexes
Argyll Robertson pupil
Decreased memory
Slurred speech
Optic atrophy

Table 34-4. Treatment of Lyme disease.

Manifestation	Drug and Dosage
Tick bite	No treatment in most circumstances (see text); observe
Erythema migrans	Doxycycline, 100 mg twice daily or amoxicillin, 500 mg three times daily or cefuroxime axetil, 500 mg twice daily, all for 3-4 weeks
Neurologic disease Bell's palsy	Doxycycline, or amoxicillin as above for 2-3 weeks
Other central nervous system disease	Ceftriaxone, 2 g IV once daily or penicillin G, 18-24 million units daily IV in 6 divided doses; or cefotaxime, 2 g IV every 8 hours all for 2-4 weeks
Cardiac disease First-degree block (PR < 0.3 s)	Doxycycline or amoxicillin as above for 2-3 weeks
High-degree atrioventricular block	Ceftriaxone or penicillin G as above for 2-3 weeks
Arthritis	Doxycycline, or amoxicillin as above for 4 weeks
Oral dosage	
Parenteral dosage	Ceftriaxone or penicillin G as above for 2-4 weeks
Acrodermatitis chronicum atrophicans	Doxycycline or amoxicillin as above for 4 weeks
"Chronic Lyme disease" or "post-Lyme disease syndrome"	Symptomatic therapy

■ I. PROTOZOAL INFECTIONS

AFRICAN TRYPANOSOMIASIS (SLEEPING SICKNESS)

Essentials of Diagnosis

- History of exposure to tsetse flies, with bite lesion.*

Hemolympathic stage:*

- Irregular fevers, headaches, joint pains, malaise, pruritus, papular skin rash, edemas.
- Posterior cervical or generalized lymphadenopathy; hepatosplenomegaly.
- Anemia, weight loss.
- Trypanosomes in blood or lymph node aspirates; positive serology.

Meningoencephalitic stage:

- Insomnia, motor and sensory disorders, abnormal reflexes, somnolence to coma.
- Trypanosomes and increased white cells and protein in cerebrospinal fluid.

*Usually absent or unnoticed in *T b gambiense* infections.

General Considerations

African trypanosomiasis is caused by *Trypanosoma brucei rhodesiense* and *Trypanosoma brucei gambiense*, both hemoflagellates. The organisms are transmitted by bites of tsetse flies (*Glossina* species), which inhabit shaded areas along streams and rivers. Trypanosomes ingested in a blood meal undergo a developmental period of 18-35 days in the fly; when the fly feeds again on a new mammalian host, the infective stage is injected. Human disease occurs locally throughout tropical Africa from south of the Sahara to about 20° south latitude. *T b gambiense* infections are in the moist sub-Saharan savanna and riverine forests of west and central Africa up to the eastern Rift Valley. *T b rhodesiense* occurs to the east of the Rift Valley in the savannah of east and southeast Africa and along the shores of Lake Victoria.

T b rhodesiense infection is primarily a zoonosis of game animals; humans are infected sporadically. Humans are the principal mammalian host for *T b gambiense*; it is uncertain whether there is an animal reservoir, but domestic animals can be infected. A third trypanosome, *T brucei brucei*, infects only wild and domestic animals.

The disease is spreading and becoming increasingly more serious; an estimated 100,000 deaths occur yearly. Of new infections yearly, approximately 100,000 are Gambian but only several hundred Rhodesian. Among visitors to the East African game parks, infections are rare, with about one case a year appearing in the USA.

Clinical Findings

A. Symptoms and Signs

T b rhodesiense infections go through three stages: chancre, hemolympathic, and encephalitic. The hemolympathic period, which usually begins within 3-10 days after appearance of the chancre, is generally readily diagnosed by detecting the parasite. Rhodesiense infection is much more virulent, and untreated patients die within weeks to months. Gambiense infection, however, usually goes through a long asymptomatic period in which a chancre is rare, the hemolytic stage may be absent or go unnoticed, and parasites are more difficult to find. When gambiense symptoms do become manifest in weeks to months, they are often initially mild and ignored by the patient; but with progression, death occurs in up to several years.

1. The trypanosomal chancre—In *T b rhodesiense* infections, this is a local pruritic, painful inflammatory reaction (3-10 cm) with regional lymphadenopathy that appears about 48 hours after the tsetse fly bite and lasts 2-4 weeks.

2. The hemolympathic (early) stage—High fever, severe headache, joint pains, and malaise recur at irregular intervals corresponding to waves of parasitemia. Between febrile episodes there are symptom-free periods that last up to 2 weeks. Transient rashes may appear, often pruritic and papular or circinate. Examination reveals mild enlargement of the liver and spleen, and edema (peripheral, pleural, ascites, etc). Enlarged, rubbery, and painless lymph nodes occur in 75% of patients. In *T b gambiense*, only the posterior cervical group (Winterbottom's sign) may be enlarged. With progression of the disease, there is weight loss and debilitation. Myocardial involvement may appear early in Rhodesian infection, and the patient may succumb to myocarditis before meningoencephalitic signs appear.

3. The meningoencephalitic (late) stage—This stage appears within a few weeks or months of onset of Rhodesian infection, but in Gambian infection, sleeping sickness develops more insidiously, starting 6 months to several years after onset. Insomnia, anorexia, personality changes, apathy, and headaches are the early findings. A variety of motor or tonus disorders may develop, including tremors and disturbances of speech, gait, and reflexes; somnolence appears late. The patient becomes severely emaciated and, finally, comatose. Death often results from secondary infection.

B. Laboratory Findings

Anemia, increased sedimentation rate, thrombocytopenia, and increased serum globulin are common. Eosinophilia is not seen. Definitive diagnosis requires identifying motile organisms in wet films and after Giemsa or Wright staining of thin and thick blood films; of aspirates of bite lesions, lymph nodes, or bone marrow; or of cerebrospinal fluid. Because the number of trypanosomes in blood fluctuates (they may be undetectable 3 out of 5 days but are more common during febrile periods), multiple anticoagulated specimens should be examined daily for as many as 15 days using 10-15 mL for centrifugation; the trypanosomes are concentrated in the buffy coat. Other diagnostic tests with blood are intraperitoneal inoculation of rodents (sensitive but only effective for *T b rhodesiense*), culture, Millipore filtration, and DEAE-cellulose anion exchange centrifugation. Only soft lymph nodes should be selected for aspiration (25-gauge needle); after the node is gently kneaded, the aspirate is examined immediately for motile organisms.

Cerebrospinal fluid is clear and shows an increase in pressure, lymphocytes, and protein. Large eosinophilic plasma cells (Mott cells) are rarely seen but are considered pathognomonic. With progression of the disease, the parasite is more likely to be found in cerebrospinal fluid than in blood or lymph nodes. To detect the organism, the fluid should be examined within 20 minutes (to avoid parasitic lysis) and centrifuged twice (doubles sensitivity), inoculated into an experimental animal, and cultured.

Several antibody detection assays are used epidemiologically and for case-finding for Gambian infections. False-positive results can be due to animal trypanosomes that are noninfectious to humans. A field-adapted card agglutination test (sensitivity about 96%, specificity high) detects circulating and cerebrospinal fluid antigen. Positive results of these antigen and antibody tests should be followed by parasitic confirmatory testing. Circulating IgM antibody becomes positive about 12 days after infection; its titers may fluctuate or be undetectable during brief periods of excess antigen, and a negative test does not rule out infection. In late central nervous system disease, though both circulating antibody and parasitemia may fall below detectable levels, serologic tests of the cerebrospinal fluid (including IgM) may prove useful.

Differential Diagnosis

Trypanosomiasis may be mistaken for a variety of other diseases, including malaria, influenza, pneumonia, infectious mononucleosis, leukemia, lymphoma, the arbovirus encephalitides, and psychosis. Serologic tests for syphilis may be falsely positive in trypanosomiasis.

Treatment

Because all of the drugs used (except eflornithine) are highly toxic (mortality during drug treatment can reach 5-10%), specific detection of the organism is a prerequisite for treatment; immunoassays are insufficient to make the diagnosis.

Suramin and pentamidine do not adequately cross the blood-brain barrier and cannot be used when the central nervous system is involved; melarsoprol and eflornithine, however, do pass the barrier. Melarsoprol causes a reactive encephalopathy in up to 20% of patients (corticosteroids are partially protective) and a 4-12% mortality. Systemic eflornithine is highly effective and associated with only mild toxicity in early and late *T b gambiense* infections, but it should not be used for *T b rhodesiense* infection, as its efficacy for this parasite is inconsistent. Eflornithine is expensive, and its continued availability (from WHO) is uncertain. In the USA,

eflornithine has been approved for topical use to remove facial hair; suramin and melarsoprol are available only from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, GA 30333. Telephone: 404-639-3670; 404-639-2888 evenings, weekends, and holidays.

A. Early Disease, the Hemolymphatic Stage

A drug of choice for both parasites is intravenous suramin (100-200 mg [test dose], then 1 g on days 1, 3, 7, 14, and 21). Alternative drugs of choice only for *T b gambiense* are intravenous eflornithine (400 mg/kg/d in four divided doses for 14 days, followed by 300 mg/kg/d orally for 3-4 weeks; cure rate 97%) or pentamidine (4 mg/kg/d intramuscularly for 7-10 days; cure rate 93%).

B. Late Disease With Central Nervous System Involvement

Drugs of choice for both parasites are intravenous melarsoprol, 2-3.6 mg/kg/d for 3 days; after 1 week, 3.6 mg/kg for 3 days; repeat after 10-21 days. Relapse rates for Gambian infections, formerly low (5-8%), have markedly increased as melarsoprol drug resistance has risen sharply in some areas of Africa, where failure rates approach 27%. Alternative treatments only against *T b gambiense* are eflornithine (as above) or intravenous tryparsamide, 30 mg/kg (maximum: 2 g) every 5 days for 12 injections, plus intravenous suramin, 100-200 mg (test dose), followed by 10 mg/kg every 5 days for 12 injections; the treatment may be repeated in 1 month.

Proper follow-up to ensure detection of the encephalitic stage requires initial cerebrospinal fluid examination, repeat studies at intervals during treatment, 3 months after treatment, and then at 6-month intervals for 2 years.

Prevention

Individual prevention in endemic areas should include wearing long sleeves and trousers, avoiding dark-colored clothing, and using mosquito nets while sleeping. Repellents have no effect. Pentamidine is used in chemoprophylaxis (controversial) only against the Gambian type. In *T b rhodesiense* infection, pentamidine may suppress early symptoms, resulting in late recognition of the disease. Excretion of pentamidine is slow; therefore, one intramuscular injection (4 mg/kg, maximum 300 mg) protects for 3-6 months. The drug is toxic and should only be used for persons at high risk (ie, those with constant, heavy exposure to tsetse flies in areas with known transmission of Gambian disease). For gambiense infection, performing serologic tests every 6 months during exposure and for 3 years afterward is the safest method for detecting the disease at an early stage. Gambian control depends on detecting and treating the largely asymptomatic human reservoir.

Prognosis

Most patients—even those with advanced disease—recover following treatment. Relapses are uncommon (about 2%). When therapy is started late, irreversible brain damage or death is common. Most persons with African trypanosomiasis will die if untreated.

AMERICAN TRYPANOSOMIASIS (CHAGAS' DISEASE)

Essentials of Diagnosis

Acute stage:

- Inflammatory lesion at site of inoculation; prolonged fever, tachycardia, hepatosplenomegaly, lymphadenopathy, signs of myocarditis.
- Parasites in peripheral blood, positive serologic tests.

Chronic stage:

- Heart failure with cardiac arrhythmias; decreased intensity of heart sounds; episodes of thromboembolism.
- In some regions, dysphagia, severe constipation, and radiologic evidence of megaesophagus or megacolon.
- Positive xenodiagnosis or hemoculture, positive serologic tests; abnormal ECG.

General Considerations

Chagas' disease is caused by *Trypanosoma cruzi*, a protozoan parasite of humans and wild and domestic animals. *T cruzi* occurs only in the Americas; it is found in wild animals and to a lesser extent in humans from southern South America to southern USA. An estimated 16 million people are infected, mostly in rural areas, resulting in about 45,000 deaths yearly. The disease is often acquired in childhood; the proportion of infected persons increases with age. In many countries in South America, Chagas' disease is the most important cause of heart disease. In southern USA, although the organism has been found in triatomine bugs and wild and domestic animals, only five confirmed instances of local transmission have been reported. However, a large number of immigrants from endemic areas of Latin America (particularly Central America) are infected (estimated 50,000-100,000). A handful of infections following blood transfusion have been reported.

T cruzi is transmitted by reduviid (triatomine) bugs infected by ingesting blood from animals or humans who have circulating trypanosomes. Multiplication occurs in the digestive tract of the bug; infective forms are eliminated in feces. Infection in humans occurs through "contamination" with bug feces; the parasite penetrates the skin (generally through the bite wound), mucus membranes, or the conjunctiva. Transmission can also occur by blood transfusion or in utero.

The trypanosomes first multiply close to the point of entry. They then enter the bloodstream as trypanosomes and later invade cells and assume the leishmanial form. The organism has a predilection for myocardium, smooth muscle, and central nervous system glial cells. Multiplication causes cellular destruction, inflammation, and fibrosis.

In South America, a major eradication program based on improved housing, use of residual pyrethroid insecticides, and screening of blood donors has achieved striking reductions in infections in children.

Clinical Findings

A. Symptoms and Signs

Although infection continues for many years—probably for life—as many as 70% of persons remain asymptomatic. The **acute stage**, seen principally in children, lasts 2-4 months and leads to death in up to 10% of cases. The earliest findings are at the site of inoculation either in the eye—Romana's sign (unilateral bipalpebral edema, conjunctivitis, local lymphadenopathy)—or in the skin—a chagoma (furuncle-like lesion with local lymphadenopathy). Subsequent findings include fever, malaise, headache, hepatomegaly, mild splenomegaly, and generalized lymphadenopathy. Acute myocarditis may lead to biventricular failure, but arrhythmias are rare. Meningoencephalitis is limited to young children and is often fatal.

A **latent period** (indeterminate phase) may last from 10 to 30 years in which the patient is asymptomatic but in which serologic tests and sometimes parasitologic examination confirm the presence of the infection.

The **chronic stage** is usually manifested by cardiac disease in the third and fourth decades of life, characterized by arrhythmias, congestive heart failure (often with prominent right-sided findings), ventricular aneurysms, and systemic or pulmonary embolization originating from mural thrombi. Valvular lesions are absent. Sudden cardiac arrest in young persons may occur and is attributed to ventricular fibrillation. Megacolon and megaesophagus, caused by damage to nerve plexuses in the bowel or esophageal wall, occur in some areas of Chile, Argentina, and Brazil; findings include dysphagia, regurgitation, constipation, sigmoid volvulus, and parotid gland hypertrophy. Megasyndromes can also affect the urinary tract.

In immunosuppressed persons—including infrequently in AIDS patients and transplant recipients—latent Chagas' disease may reactivate. Common findings are cardiomyopathy and brain lesions indistinguishable from cerebral toxoplasmosis.

B. Laboratory Findings

Diagnosis is by parasitologic and serologic methods. Trypanosomes can be detected in most acute and congenital cases and in up to 40% of chronic infections. In the *acute stage*, the organism may be found (1) as motile trypanosomes in anticoagulated blood, (2) as Giemsa-stained trypanosomes in anticoagulated blood used to prepare thin and thick or buffy coat films, or (3) by blood culture or animal inoculation. Occasionally, amastigotes can be found in tissue aspirates or biopsies of chagomas or lymph nodes by direct examination, staining, or culture. In the *chronic stage*, however, the organism is rarely found directly but may be detected by culture, animal inoculation, or xenodiagnosis. The latter consists of permitting uninfected laboratory-reared bugs of the local major vector to feed on the patients and then examining their intestinal contents for trypanosomes. Culture in appropriate media is kept for 30 days; animal inoculation is in 3-day-old to 10-day-old laboratory mice or rats. *Trypanosoma rangeli*, a nonpathogenic blood trypanosome also found in humans in Central America and northern South America, must not be mistaken for *T cruzi* trypomastigotes.

Several highly sensitive IgG serologic tests (hemagglutination inhibition, complement fixation, ELISA, immunofluorescence, Western blot, others) are routinely used and are of presumptive value when positive. However, two or three of these tests should be done because both false-negative (including some cases of depressed immune response) and false-positive tests are common. The latter may occur in other infections—including leishmaniasis, malaria, syphilis, and *T rangeli* infection—and in autoimmune diseases. For the ELISA and immunofluorescence tests, sensitivity is 93-98% and specificity (excluding leishmaniasis) is 99%. Antibodies of the IgM class are elevated early in the acute stage but are replaced by IgG antibodies as the disease progresses. Maximum titers are reached in 3-4 months; thereafter, titers can remain positive at a low level for life. In chronic infections, when circulating organisms are difficult to find, the polymerase chain reaction and DNA methods may facilitate diagnosis; these tests may also prove useful in assessing effectiveness of therapy (clearance of parasites), whereas serologic tests do not. Immunoassays are being evaluated to detect urine and blood antigens. The most important electrocardiographic abnormalities are right bundle branch block and arrhythmias. In certain regions of South America, radiologic examination may show megaesophagus, megacolon, or cardiac enlargement with characteristic apical aneurysms.

Treatment

Treatment of Chagas' disease is inadequate because the two drugs used, nifurtimox and benznidazole, are potentially toxic, must be used for long periods, and are ineffective against chronic infection. In acute disease and congenital infections, the drugs are effective in reducing the duration and severity of infection, but cure is achieved in only about 70% of patients. In the chronic phase, although parasitemia may disappear in up to 70% of patients, treatment does not alter the serologic reaction, cardiac function, or progression of the disease. Nevertheless, treatment should be attempted in all *T cruzi*-infected persons regardless of clinical status or time since infection.

Nifurtimox is given orally in daily doses of 8-10 mg/kg in four divided doses after meals for 90-120 days. It generally produces gastrointestinal complaints, weight loss, tremors, and peripheral neuropathy. Hallucinations, pulmonary infiltrates, and convulsions are rare. In the USA, nifurtimox is available only from the Parasitic Disease Drug Service, Centers for Disease Control, Atlanta 30333 (404-639-3670). Benznidazole—not available in the USA—is given at a dosage of 5 mg/kg/d for 60 days. Its side effects include granulocytopenia, rash, and peripheral neuropathy. The drug is better tolerated by children.

In the chronic stage, digoxin is not well tolerated. The most effective antiarrhythmic drug is amiodarone. Cardiac pacemakers are used for atrioventricular block. Amiodarone and angiotensin-converting enzyme inhibitors may result in better survival in selected patients. In endemic areas, blood should not be used for transfusion unless at least two serologic tests are negative; otherwise, blood can be treated with gentian violet to kill the parasites.

Prognosis

Acute infections in infants and young children are often fatal, particularly when the central nervous system is involved. Adults with chronic heart disease also may ultimately succumb to the disease.

AMEBIASIS

Essentials of Diagnosis

- Mild to moderate colitis: recurrent diarrhea and abdominal cramps, sometimes alternating with constipation; mucus may be present; blood is usually absent.
- Severe colitis: semiformal to liquid stools streaked with blood and mucus, fever, colic, prostration; ileus, perforation with peritonitis, and hemorrhage occur.
- Hepatic amebiasis: fever, hepatomegaly, pain, localized tenderness.
- Laboratory findings: amebas in stools or in abscess aspirate; serologic tests positive with severe colitis or hepatic abscess, which is readily imaged by ultrasonography or CT scan.

General Considerations

Though the causative protozoan parasite *Entamoeba histolytica* was once considered a single species with varying virulence, it is now recognized that the entamoeba complex contains two morphologically identical species: (1) *E dispar* (about 90% of the complex), which remains in the colon as a stable commensal that is avirulent and produces an asymptomatic carrier state; and (2) *E histolytica*, which shows varying degrees of virulence ranging from a commensal state in the colon—in which it does not cause disease, yet is potentially invasive—to being invasive of the intestinal wall, resulting in acute diarrhea or dysentery or chronic diarrhea. *E histolytica* may also be carried by the blood to the liver, where it may produce hepatic abscess. Rarely, the lungs, brain, other organs, or perianal skin may be infected.

Both *E histolytica* and *E dispar* exist as two forms in the lumen and mucosal crypts of the large bowel: identical-appearing cysts (10-14 μ m) and motile trophozoites (12-50 μ m). In the absence of diarrhea, trophozoites encyst in the large bowel. Trophozoites passed into the environment die rapidly, but cysts remain viable in soil and water for several weeks to months at appropriate temperature and humidity.

The infections are present worldwide but are most prevalent and severe in subtropical and tropical areas under conditions of crowding, poor sanitation, and poor nutrition. Using the new taxonomy, prevalence estimates have changed. Of 500 million persons worldwide infected with entamoeba, most are infected with *E dispar* and an estimated 10% (50 million) with *E histolytica*. Invasive *E histolytica* may constitute 5 million cases, with mortality in the range of 100,000 per year.

Humans are the only established host and are universally susceptible. Only cysts are infectious, since after ingestion they survive gastric acidity which destroys trophozoites. Transmission occurs through ingestion of cysts from fecally contaminated food or water. Flies and other arthropods also serve as mechanical vectors; to an undetermined degree, transmission results from contamination of food by the hands of food handlers. Where human excrement is used as fertilizer, it is often a source of food and water contamination. Person-to-person contact is also important in transmission; therefore, all household members as well as an infected person's sexual partner should have their stools examined. In communal settings such as mental hospitals (but not child day care centers), prevalence rates as high as 50% have been reported. Amebiasis is rarely epidemic, but urban outbreaks have occurred because of common-source water contamination. Although entamoeba infections occur frequently among homosexuals, in the developed countries these infections are usually due to the *E dispar* and do not require treatment. In AIDS, *E histolytica* infection does not become an opportunistic infection.

Fulminant infections may occur in pregnancy and in young children. Corticosteroids and other immunosuppressive drugs given in error for inflammatory bowel disease may convert a commensal infection into an invasive one.

The characteristic intestinal lesion is the amebic ulcer, which can occur anywhere in the large bowel (including the appendix) and sometimes in the terminal ileum but predominates in the cecum, descending colon, and the rectosigmoid colon—areas of greatest fecal stasis. Trophozoites invade the colonic mucosa by means of their ameboid movement and proteolytic secretions and induce necrosis to form the characteristic flask-shaped ulcers. Ulcers are usually limited to the muscularis, but if penetration to the serous layer occurs, bowel perforation, local abscess, or generalized peritonitis may result. In fulminating cases, ulceration may be extensive, and the bowel becomes thin and friable. Hepatic abscesses range from a few millimeters to 15 cm or larger, usually are single, occur more often in the right lobe (particularly the upper portion), and are more common in men.

Clinical Findings

A. Symptoms and Signs

Amebiasis is classified into intestinal and extraintestinal disease and further subdivided into the clinical syndromes described below. Some patients have an acute onset of severe diarrhea as early as 8 days (commonly 2-4 weeks) after infection. Others may be asymptomatic or have mild intestinal infection for months to several years before either intestinal symptoms or liver abscess appears. Transition may occur from one type of intestinal infection to another, and each may give rise to hepatic abscess, or the intestinal infection may clear spontaneously.

1. Intestinal amebiasis—

a. Asymptomatic infection—In most infected persons, the organism lives as a commensal, and the carrier is without symptoms.

b. Mild to moderate colitis (nondysenteric colitis)—A few stools a day are passed that are semiformed and have no blood. There may be abdominal cramps, flatulence, fatigue, and weight loss; fever is uncommon. Periods of remission and recurrence may last days to weeks or longer; during remissions, the patient may have constipation. Abdominal examination may show distention, hyperperistalsis, and tenderness. In some patients with chronic infection, the colon is thick and palpable, particularly over the cecum and descending colon. Toxic products released as a result of the bowel infection may induce periportal inflammation, mild hepatomegaly, and low-grade liver enzyme abnormalities but without demonstrable trophozoites in the liver.

c. Severe colitis (dysenteric colitis)—As the severity of intestinal infection increases, the number of stools increases, and they change from semiformed to liquid with streaks of blood beginning to appear. With larger numbers of stools, 10-20 or more, little fecal material is present, but blood (fresh or dark) and bits of necrotic tissue become increasingly evident. With increasing severity, the patient may become prostrate and toxic, with fever up to 40.5 °C, and have colic, tenesmus, vomiting, generalized abdominal tenderness, and nonspecific hepatic enlargement and tenderness. Rare complications include appendicitis, bowel perforation, fulminating colitis, massive mucosal sloughing, and hemorrhage. Death may follow.

d. Localized ulcerative lesions of the colon—Bowel ulcerations limited to the rectal area may result in passage of formed stools with bloody exudate. Ulcerations limited to the cecum may induce mild diarrhea and simulate appendicitis. Amebic appendicitis, in which the appendix is extensively involved but not the remainder of the large bowel, is rare.

e. Localized granulomatous lesions of the colon (ameboma)—This occurs as a result of excessive production of granulation tissue in response to amebic infection, either in the course of dysentery or slowly in chronic intestinal infection. These masses may present as an irregular tumor (single or multiple) projecting into the bowel or as an annular constricting mass up to several centimeters in length. Clinical findings (pain, obstructive symptoms, and hemorrhage) and x-ray findings may simulate colonic carcinoma, tuberculosis, or lymphogranuloma venereum. At endoscopy, the mass is deep red and bleeds easily, and biopsy specimens show granulation tissue and *E histolytica*; the number of organisms may be relatively few. Antiamebic drugs are usually adequate treatment; surgical removal of the lesion without prior or immediate postoperative drug therapy is likely to result in death from disseminated disease.

2. Extraintestinal amebiasis—

a. Hepatic amebiasis—Amebic liver abscess, although a relatively infrequent (3-9%) consequence of intestinal amebiasis, is not uncommon given the large number of intestinal infections. A large proportion of patients with liver abscess do not have concurrent intestinal symptoms, nor can they recall having had chronic intestinal symptoms. The onset of symptoms can be sudden or gradual, ranging from a few days to many months. Cardinal manifestations are fever (often high), pain (continuous, stabbing, or pleuritic, and sometimes severe), and an enlarged and tender liver. Patients may also experience malaise or prostration, sweating, chills, anorexia, and weight loss. The liver enlargement may present subcostally, in the epigastrium, as a localized bulging of the rib cage, or, as a result of enlargement against the dome of the diaphragm, it may produce coughing and findings at the right lung base (dullness to percussion, rales, and diminished breath sounds). Intercostal tenderness is common. Localizing signs on the skin may be an area of edema or a point of maximum tenderness. Without prompt treatment, the abscess may rupture into the pleural, peritoneal, or pericardial space or other contiguous organs, and death may follow.

b. Other extraintestinal infections—Skin infections may develop in the perianal area. Metastatic infection may rarely occur throughout the body, particularly the lungs, brain, and genitalia.

B. Laboratory Findings

1. Intestinal amebiasis—Diagnosis of intestinal amebiasis is made by finding the organism or antigen in stool (antigen detection is more sensitive). A standard approach is to examine three specimens microscopically (preserved or fresh) and to test one for antigen. In microscopic examinations, trophozoites and cysts of *E histolytica* and *E dispar* cannot be distinguished from each other but can be distinguished from the other intestinal protozoa. In coproantigen testing, however, the TechLab *Entamoeba* test does differentiate the two organisms, whereas most other commercial tests do not. The TechLab test has a sensitivity of 93% and a specificity of 97% but requires fresh or frozen stool specimens; preserved stool cannot be used.

Serologic testing sometimes facilitates the diagnosis. Additionally and where available, the specialized research methods of polymerase chain reaction and culture can be employed. Polymerase chain reaction is more sensitive and specific than microscopy or culture and is 100% specific for the two entamoeba species. Culture, which is difficult to perform, can isolate the two species, which are then differentiated by a variety of specialized techniques.

Microscopic examination of stools. Microscopic examination is relatively insensitive and does not differentiate the two entamoeba species. Testing three specimens obtained under optimal conditions followed by concentration and staining methods will generally detect only 80% of entamoeba complex infections; three additional tests will raise the diagnostic rate to 90%. Trophozoites predominate in liquid stools, cysts in formed stools. A standard procedure is to collect three specimens at 2-day intervals or longer, with one of the three obtained after a laxative such as (1) sodium sulfate or phosphate (Fleet's Phospho-Soda), 30-60 g in a glass of water; or (2) bisacodyl 5-15 mL. Oil laxatives should not be used. Because trophozoites rapidly autolyze, stools should be examined within 30 minutes or immediately mixed with a preservative. If the patient has received specific therapy, antibiotics, antimalarials, antidiarrheal preparations (containing bismuth, kaolin, or magnesium hydroxide), barium, or mineral oil, specimen collection should be delayed.

Bowel examination. Colonoscopy is preferred over sigmoidoscopy. The bowel should not be cleansed by laxative or enema as this washes exudate from the ulcers and destroys trophozoites. Typically, there are no findings in mild intestinal disease; in severe disease, ulcers may be found that are 1 mm to 2 cm across, with intact intervening mucosa. If present, exudate should be collected with a glass pipette (not with cotton, to which trophozoites may adhere) or by scraping with a metal curette and examined immediately for motile trophozoites and for *E histolytica* antigen. In some centers, rectal biopsy (from the edge of the ulcer) has enhanced diagnosis; biopsy specimens are best examined by immunofluorescence methods.

Serology. Serologic tests are positive only in the case of *E histolytica* infection. Testing is usually not recommended in mild to moderate intestinal infection as it lacks sensitivity and does not differentiate present from past infection. The indirect hemagglutination and immunofluorescent tests have been replaced by the ELISA and enzyme immunoassays, which are positive in about 70% of patients with active intestinal disease (the frequency is lower in mild colitis, higher in dysentery) and in about 10% of asymptomatic *E histolytica* cyst passers; false-positive results are rare. The tests remain positive for as long as 10 years after successful treatment. The agar gel immunodiffusion test, though less sensitive, is rapidly conducted and may detect current infection because it becomes negative 3-6 months after eradication of the organism.

Other tests. Detection of trophozoites that contain ingested red blood cells is nearly diagnostic for invasive *E histolytica* but may be confused with the occasional *E dispar* or macrophage that also contains the red blood cells. Many patients with amebic colitis test positive for occult blood, whereas findings for fecal leukocytes are noncontributory. The white blood cell count can reach 20,000/uL or higher in amebic dysentery but is not elevated in mild colitis. A low-grade eosinophilia is occasionally present.

2. Hepatic abscess—Elevation of the right dome of the diaphragm and the size and location of the abscess can be determined by ultrasonography (usually round or oval nonhomogeneous lesions, abrupt transition from normal liver to the lesion, hypoechoic center with diffuse echoes throughout the abscess), CT (well-defined, round, low-density lesions with an internal, nonhomogeneous structure), MRI, and radioisotope scanning. After intravenous injection of contrast material, CT may show a hyperdense halo around the periphery of the abscess. Gallium scans, only infrequently useful, show a cold spot (sometimes with a bright rim) as opposed to the increased gallium uptake in the center of pyogenic abscesses. Serologic tests are almost always positive (except early in the infection). Examination of stools for antigen and the organism is frequently negative. The white count ranges from 15,000 to 25,000/uL. Eosinophilia is not present. Liver function test abnormalities, when present, are usually minimal. As CT, MRI, and sonography do not distinguish amebic and pyogenic abscesses, percutaneous aspiration may be indicated; this is best done by an image-guided needle (risks described below). The aspirate is divided into serial 30- to 50-mL aliquots, but only the last sample is examined for amebas, as the organisms are found at the edge of the cyst. Detection of amebic antigen in aspirate appears to be very sensitive; studies are under way to evaluate tests for circulating antigen.

Differential Diagnosis

Amebiasis should be considered in patients with acute or chronic diarrhea (including cases associated with only mild changes in bowel habits; in patients who have an

exposure history, including travel or household or sexual exposure); liver abscess; and annular lesions of the colon. All patients with presumed inflammatory bowel disease should be tested for antibodies, by multiple stool examinations for antigen and the organism, and by colonoscopy with biopsy because of the risk of overwhelming amebic disease if corticosteroid therapy were to be given in the presence of amebiasis. The differential diagnosis of amebic liver abscess includes pyogenic abscess, echinococcal cyst, benign cyst, and hepatocellular carcinoma.

Treatment

The decision to treat is based on a composite of data including (1) finding entamoeba cysts or trophozoites and, when feasible (rarely), differentiating *E histolytica* from *E dispar*; (2) testing for *E histolytica* antigen in stool or hepatic abscess aspirate; and (3) testing for serum antibody, which, if positive, could represent old infection.

The choice of drug depends on the clinical presentation and the site of drug action. Treatment may require the concurrent or sequential use of several drugs. [Table 35-1](#) outlines a preferred and an alternative method of treatment for each clinical type of amebiasis.

The **tissue amebicides** dehydroemetine and emetine act on organisms in the bowel wall and in other tissues but not on amebas in the bowel lumen. Chloroquine is active principally against amebas in the liver. The **luminal amebicides** diloxanide furoate (not available in the USA), iodoquinol, and paromomycin act on organisms in the bowel lumen but are ineffective against amebas in the bowel wall or other tissues. Oral tetracycline inhibits the bacterial associates of *E histolytica* and thus has an indirect effect on amebas in the bowel lumen and bowel wall but not in other tissues; parenteral antibiotics have little efficacy at any site. Metronidazole (or tinidazole, which is not available in the USA) is unique in that it is effective both in the bowel lumen and in the bowel wall and other tissues, including the central nervous system. However, metronidazole when used alone for bowel infections is not sufficient as a luminal amebicide, for it fails to cure up to 50% of infections.

A. Asymptomatic Intestinal Infection

In asymptomatic cyst-passers, if stool antigen and serum antibody tests are negative, it can be presumed that the patient has an *E dispar* infection, which should not be treated. Nevertheless, an unrecognized commensal *E histolytica* infection could be present. Cure rates for *E histolytica* infection with a single course of diloxanide furoate or iodoquinol are 80-85%. Within endemic areas, asymptomatic carriers generally are not treated because of the frequency of reinfection.

B. Mild to Moderate Intestinal Disease

In patients with intestinal symptoms and entamoeba in the stool in whom *E dispar* and *E histolytica* cannot be differentiated, if both stool antigen and serum antibody tests are negative it is possible that the latter tests are false negatives and that an *E histolytica* infection is present. In such cases, it is often best to proceed with anti-*E histolytica* treatment. Metronidazole plus a luminal amebicide is the treatment of choice. Alternatives are set forth in [Table 35-1](#). The minimum dose of chloroquine needed to destroy trophozoites carried to the liver or to eradicate an undetected early-stage liver abscess is not established.

C. Severe Intestinal Disease

Fluid and electrolyte therapy and opioids to control bowel motility are necessary adjuncts. The latter are used cautiously because of the risk of toxic megacolon.

D. Hepatic Abscess

There is no clinical evidence of metronidazole-resistant *E histolytica*, though it can be induced experimentally. Chloroquine has been included in treatment to avoid rare long-term failures. Regarding rare short-term metronidazole failures, if a satisfactory clinical response does not occur in 3 days, the abscess should be drained for therapeutic purposes and to exclude pyogenic abscess. Continued failure to achieve an adequate clinical response requires changing to the potentially toxic alternative drug dehydroemetine (or emetine) plus chloroquine. Treatment also requires a luminal amebicide (diloxanide furoate or iodoquinol), whether or not the organism is found in the stool. Antibiotics are added for concomitant bacterial liver abscess, although metronidazole itself is highly effective against anaerobic bacteria, a major cause of bacterial liver abscesses. Imaging defects in the liver disappear slowly (range: 3-13 months) after treatment; some calcify.

Most patients treated with metronidazole for an amebic liver cyst do not require therapeutic percutaneous drainage; when needed, the catheter method is preferred. Indications are a large abscess, threatening rupture; the presence of a left lobe abscess (which is associated with a higher rate of severe complications); and the absence of medical response after 3 days of metronidazole therapy. The risks of aspiration or catheter drainage are bacterial superinfection, bleeding, peritoneal spillage, and inadvertent puncture of an infected hydatid cyst.

E. Adverse Drug Reactions

Metronidazole often induces transient nausea, vomiting, headache, or a metallic taste in the mouth; if alcohol is taken during or shortly after treatment, a disulfiram-like reaction may occur. Drug interactions with some commonly used drugs (cimetidine, some anticoagulants, phenytoin, phenobarbital, lithium) have been reported. Metronidazole increases the rate of naturally occurring tumors in mice but not in nonrodent species. Prudence dictates that metronidazole be given to pregnant or nursing mothers only if other drugs cannot be used.

Dehydroemetine and emetine cause nausea, vomiting, and pain at the injection site. They are also cardiotoxic, with a narrow range between therapeutic and toxic effects; dehydroemetine may be the safer of the two drugs. The tetracyclines should not be used in pregnancy; erythromycin stearate and paromomycin are alternatives. Paromomycin may cause mild gastrointestinal symptoms, infrequently intense diarrhea, and rarely overgrowth of nonsusceptible organisms. Paromomycin should be used with caution in ulcerated bowel conditions and is not used in the presence of significant renal disease. Iodoquinol produces a mild, transient diarrhea. It should be taken with meals; used with caution in patients with optic neuropathy, renal, or thyroid disease; and discontinued in the event of iodine toxicity (dermatitis, fever). The neurotoxicity seen with extended treatment does not occur at the standard 3-week dosage. Diloxanide usage commonly results in flatulence.

Follow-Up Care

In follow-up, examine at least three stools at 2- to 3-day intervals, starting 2-4 weeks after the end of treatment. For some patients, colonoscopy and reexamination of stools within 3 months may be indicated.

Postdysenteric colitis is an uncommon sequela of severe amebic colitis. Following adequate treatment, diarrhea continues and the mucosa may be reddened and edematous, but no ulcers or organisms are found. Most such cases are self-limited, with permanent remission in weeks to months. Uncommonly, severe and unremitting diarrhea may represent ulcerative colitis triggered by the amebic infection.

Prevention & Control

Prevention requires safe water supplies, sanitary disposal of human feces, adequate cooking of foods, protection of foods from fly contamination, washing hands after defecation and before preparing or eating foods, and, in endemic areas, avoidance of foods that cannot be cooked or peeled. Water supplies can be boiled (briefly) or treated with iodine (0.5 mL tincture of iodine per liter for 20 minutes, or longer if the water is cold); cysts are resistant to standard concentrations of chlorine. Filters are also available to purify drinking water. Disinfection dips for fruits and vegetables are not advised, and no drug is safe or effective in prophylaxis.

Prognosis

The mortality rate from untreated amebic dysentery, hepatic abscess, or ameboma may be high. With chemotherapy instituted early in the course of the disease, the prognosis is good.

INFECTIONS WITH PATHOGENIC FREE-LIVING AMEBAS

The pathogenic free-living amebas cause three syndromes: (1) meningoencephalitis, (2) granulomatous encephalitis and other granulomatous lesions, and (3) keratitis.

Primary Amebic Meningoencephalitis

Primary amebic meningoencephalitis is a fulminating, hemorrhagic, necrotizing meningoencephalitis with a limited purulent exudate. It occurs in healthy children and young adults and is rapidly fatal. It is caused by free-living amebas, most commonly by the ameboflagellate *Naegleria fowleri*. Other causes are *Balamuthia mandrillaris* and the acanthamoeba species (see below), both of which may have a predilection for immunocompromised patients.

N fowleri is a thermophilic organism found in fresh and polluted warm lake water, domestic water supplies, swimming pools, thermal water, and sewers. Most patients give a history of exposure to fresh water; dust is also a possible source. Nasal and throat swabs have shown a carrier state, and serologic surveys suggest that inapparent infections occur.

The organism apparently invades the central nervous system through the cribriform plate. The incubation period varies from 2 to 15 days. Early symptoms include headache, fever, and lethargy, often associated with rhinitis and pharyngitis. Vomiting, disorientation, and other signs of meningoencephalitis develop within 1 or 2 days, followed by coma and then death on the fifth or sixth day. No distinctive clinical features distinguish the infection from acute bacterial meningoencephalitis. At autopsy, some victims have a nonspecific myocarditis.

Lumbar or ventricular cerebrospinal fluid contains several hundred to 25,000 leukocytes/uL (50-100% neutrophils) and erythrocytes (up to several thousand/ uL). Protein is usually somewhat elevated, and glucose is normal or moderately reduced. If conventional examinations for bacteria and fungi are negative, the fluid is examined for free-living amebas. Phase contrast is preferred. A wet mount examined by an ordinary optical microscope with the aperture restricted or condenser down will enhance contrast and refractility; a warm stage is not needed. The fluid should not be centrifuged at speeds over $150 \times g$ (5 minutes) or refrigerated, as this tends to immobilize the amebas (7-14 um). Their brisk motility distinguishes them from leukocytes of various types, which they closely resemble. Staining, culture, and mouse inoculation should be performed. Serologic testing is only useful epidemiologically; patients die before antibodies are detectable.

Precise species identification is based on morphology, demonstration of flagellate transformation (*Naegleria* only), and various immunologic methods.

Six well-documented survivors of *N fowleri* infection have been reported. One was treated with intravenous and intrathecal amphotericin B and another with a combination of amphotericin B, miconazole, and oral rifampin.

In *B mandrillaris* infections, the usual course is subacute, with death occurring within 1 week to several months. Culture has not been effective, and no treatment is available.

Acanthamoeba Infections

A. Granulomatous Lesions

Free-living amebas of the genus *Acanthamoeba* are found in soil and in fresh, brackish, and thermal water as trophozoites (15-45 um) or cysts (10-25 um). Several species, including *S castellanii* and *A culbertsoni*, cause a number of poorly defined syndromes, especially in debilitated or immunosuppressed patients: (1) subacute and chronic multifocal granulomatous necrotizing encephalitis leading to death in weeks to months, (2) skin lesions (ulcers or hard nodules in which ameba may be detected), and (3) granulomatous dissemination to many tissues. Portals of entry may include the skin, eyes, or respiratory tract. A commensal nasal carrier state is established.

The encephalitis presents with mental status abnormalities, meningismus, and neurologic features of a space-occupying lesion. Focal consolidation on chest films and cerebrospinal fluid lymphocytosis may be present. Antemortem diagnosis has been made by culture, brain biopsy, or cerebrospinal fluid wet mounts using specific fluorescent stains. No treatment has been effective, but ketoconazole, miconazole, itraconazole, sulfonamides, clotrimazole, pentamidine, paromomycin, propamidine, neomycin, amphotericin B, or flucytosine can be tried.

B. Keratitis

Hundreds of cases of acanthamoeba keratitis and some of uveitis have been documented; most were associated with wearing contact lenses, others with penetrating corneal trauma or exposure to contaminated water. Suggestive features include (1) a waxing and waning clinical course over several months with severe ocular pain, photophobia, tearing, blurred vision, and conjunctival injection; (2) partial or 360-degree paracentral stromal ring infiltrate on ophthalmologic examination; (3) recurrent corneal epithelial breakdown; and (4) a corneal lesion refractory to the usual medications. Typically, the keratitis progresses slowly over months and can lead to blindness. The diagnosis can be confirmed by vigorously scraping the cornea with a swab or platinum-tipped spatula. The material is microscopically examined (1) as a wet preparation for cysts and motile trophozoites, (2) after staining, (3) by immunofluorescent techniques, and (4) after being cultured using various media. Isolates can be identified by isoenzyme analysis and DNA profiles and tested for drug sensitivity. Serologic tests have not been shown to be useful. Many cases of acanthamoeba keratitis are misdiagnosed as viral keratitis.

With early treatment, many patients can expect cure and a good visual result. Topical propamidine isethionate (0.1%) with either chlorhexidine digluconate (0.02%), polyhexamethylene biguanide, or neomycin-polymyxin B-gramicidin has been used successfully. Topical miconazole has also been used. Oral itraconazole or ketoconazole can be added for deep keratitis. Use of corticosteroid therapy is controversial. In spite of medical treatment, penetrating keratoplasty is often necessary to excise diseased tissue; corneal grafting can be done after the amebic infection has been eradicated.

Prevention requires immersion of contact lenses in disinfectant solutions or by heat sterilization. The lens should not be cleaned in homemade saline solutions nor be worn while swimming.

BABESIOSIS (PIROPLASMOSIS)

Babesiae are tick-borne protozoal parasites of wild and domestic animals worldwide. Babesiosis in humans (recognized in 1959) is a rare intraerythrocytic infection caused by two babesia species. In Europe, where the infection is caused by *Babesia divergens*, 30 cases have been reported. In the USA, infection is caused by *B microti*, and over 300 cases have been described; however, a single case of *B divergens* infection was recently reported from Kentucky. Serosurveys and limited confirmations of isolates suggest infection with *B microti* or other species in Taiwan, China, Egypt, South Africa, Mexico, and South America. In the USA, *B microti* infections have been reported from coastal and island areas of northeastern and mid-Atlantic states as well as from Wisconsin, Minnesota, Missouri, Washington, and California. Antibody prevalence of 3-8% in serosurveys indicates a high level of subclinical infection. New babesia species or strains (WA1 and others) have been described in humans in California, Washington, and Georgia. Natural hosts for *B microti* are various wild and domestic animals, particularly the white-footed mouse and white-tailed deer. With extension of the deer's habitat, the range of human infection is increasing as well.

Humans are infected as a result of *Ixodes scapularis* (also called *Ixodes dammini*) tick bites (mainly nymphal) but also by blood transfusion and perinatally. Coinfections with Lyme disease and ehrlichiosis occur. Without passing through an exoerythrocytic stage, *B microti* enters the red blood cell and multiplies, resulting in cell rupture followed by infection of other cells.

The incubation period is 1 week to several months; parasitemia is evident in 2-4 weeks. Patients usually do not recall the tick bite. The illness is characterized by irregular fever, chills, headache, diaphoresis, cough, arthralgia, myalgia, and fatigue but is without malaria-like periodicity of symptoms. Other symptoms may occur including nausea, vomiting, jaundice, arthralgia, and emotional lability. Most patients have a moderate hemolytic anemia, and some have hemoglobinuria, hepatosplenomegaly, or thrombocytopenia. Although parasitemia may continue for months, with or without symptoms, the disease is self-limited; and, after several weeks to months (rarely to 18 months), most patients recover without sequelae. Severe complications, including acute respiratory, cardiac, and renal failure, are most likely to occur in older or splenectomized persons; mortality can reach 5-9% among those hospitalized.

All *B divergens* infections (in Europe, transmitted by *I ricinus*) have been in splenectomized patients. These infections progress rapidly with high fever, severe hemolytic anemia, jaundice, hemoglobinuria, and renal failure; death rates are over 40%.

Diagnosis is established by identification of the intraerythrocytic parasite (2-3 um) on Wright- or Giemsa-stained thick and thin blood smears; no gametocytes and no intracellular pigment are seen. A single red cell may contain different stages of the parasite, and parasitemia can exceed 10%. Repeated smears may be necessary. The organism must be differentiated from malarial parasites, particularly *Plasmodium falciparum*. As low-level babesia parasitemia is easily missed, isolation can be attempted by intraperitoneal inoculation of blood into hamsters or gerbils. Antibody is detectable within 1-4 weeks after onset of symptoms and persists for 6-12 months. Testing with specific antigens in the immunofluorescent test is relatively species-specific, with a titer of 1:1024 or greater considered diagnostic; antibody titers against plasmodium are generally low or absent. Detection of specific IgM antibody confirms the diagnosis. The polymerase chain reaction method, where available, is more sensitive for low parasitemias but of equal specificity. Other findings include hemolytic anemia, thrombocytopenia, low-grade leukocytosis or leukopenia, and abnormal liver and renal function tests. Imaging studies may detect morphologic changes in the spleen.

No drug treatment is fully satisfactory. Although *B microti* infections in patients with intact spleens are usually self-limiting and can be treated asymptotically, it is now recommended that all patients—even those mildly ill—should be treated with a 7- to 10-day course of quinine (650 mg three times a day) plus clindamycin (1.2 g twice daily intravenously or 650 mg orally three times a day). A second mode of treatment with fewer side effects is with azithromycin (500 mg twice daily for 3 days followed by 500 mg daily for 7 days) plus atovaquone (750 mg twice daily for 7-10 days). Exchange transfusion with antibiotics has been successful in several severely ill asplenic patients with parasitemia greater than 10%. Management of *B divergens* infection can be attempted with exchange transfusion and clindamycin-quinine therapy.

BALANTIDIASIS

Balantidium coli is a large ciliated intestinal protozoan found worldwide, but particularly in the tropics. Pigs are considered the reservoir host, but the agent has been found in other animals and in insects. The disease is rare in humans, occurring as an acute or chronic infection (sporadic or in outbreaks) resulting from ingestion of cysts passed in stools of humans or swine. In the new host, the cyst wall dissolves and the trophozoite may invade the mucosa and submucosa of the terminal ileum, appendix, and large bowel, causing abscesses and irregularly rounded ulcerations. Many infections are asymptomatic and need not be treated. Chronic recurrent diarrhea, alternating with constipation, is most common, but mild to moderate diarrhea to severe dysentery with bloody mucoid stools, tenesmus, and colic may occur. Rare instances of infection in the lung, liver, and vagina have been reported.

Diagnosis is established by finding trophozoites in liquid stools, cysts in formed stools, or the trophozoite in scrapings or biopsy of ulcers of the large bowel. Specimens must be examined rapidly or placed in preservative.

The treatment of choice is tetracycline hydrochloride, 500 mg four times daily for 10 days. The alternative drug is iodoquinol (diiodohydroxyquin), 650 mg three times daily for 21 days. Occasional success has also been reported with metronidazole (750 mg three times daily for 5 days) or paromomycin (25-30 mg/kg [base] in three divided doses for 5-10 days).

In properly treated mild to moderate symptomatic cases, the prognosis is good, but in spite of treatment, fatalities have occurred in severe infections as a result of intestinal perforation or hemorrhage.

COCCIDIAL & MICROSPORIDIAL INFECTIONS: CRYPTOSPORIDIOSIS, ISOSPORIASIS, CYCLOSPORIASIS, & SARCOCYSTOSIS

Coccidiosis and microsporidiosis are intracellular infections of intestinal epithelial cells by spore-forming protozoa. Various species are the etiologic agents for microsporidiosis (see below). The causes of coccidiosis are *Cryptosporidium parvum*, *Isospora belli*, *Cyclospora cayetanensis*, and *Sarcocystis bovi hominis* and *S sui hominis*; all but the sarcocystis species complete their life cycle in a single host. Many of these infections occur worldwide, particularly in the tropics and in regions where hygiene is poor. They are causes of traveler's diarrhea; endemic childhood gastroenteritis (particularly in malnourished children in developing countries); institutional and community outbreaks of diarrhea; and acute and chronic diarrhea in immunosuppressed patients, including those with AIDS, in whom infection can be life-threatening. Clustering occurs in households, day care centers, and among sexual partners. Diarrhea in non-AIDS patients—sporadic, epidemic, and traveler's—is more likely to be due to cryptosporidia and less often to cyclospora or microsporidia. Diarrhea in AIDS is more commonly due to the microsporidia, *Enterocytozoon bieneusi*, and *Encephalitozoon* (formerly *Septata*) *intestinalis*, but cryptosporidium, isospora, and cyclospora are also important causes.

The infectious agents are oocysts (spores) transmitted directly from person to person or by contaminated water or food. Ingested oocysts release sporozoites that invade and multiply in enterocytes, primarily in the small bowel. Liberated merozoites reinvade other cells in the process of asexual intracellular multiplication. Eventually, sexual stages are released; following fertilization, immature oocysts form which are then shed in feces. The oocysts mature on exposure to air and can remain viable in a moist environment for months to years.

The isospora and cyclospora species found in humans appear to be distinct to humans only. Cryptosporidiosis is a zoonosis in which infections in farm animals (cattle, goats, turkeys, and others) can be transmitted to humans; however, most human infections are acquired from humans. Recently, molecular techniques have shown that humans are occasionally infected by species of cryptosporidium other than just *C parvum*. Cyclospora and probably isospora require time outside the host to sporulate and become infectious.

Although the small bowel is the usual location of infection, other sites can be involved. Colon infection is common in cryptosporidiosis and has been reported with microsporidiosis. In AIDS patients, biliary tract infections may occur in cryptosporidiosis, cyclosporiasis, microsporidiosis, and isosporiasis and may result in either a sclerosing, cholangitis-like syndrome or an acalculous cholecystitis. Disseminated disease and corneal infections occur with several microsporidial species.

The pathogenesis of these diarrheas is not well understood. No enterotoxin has been identified. Voluminous secretory or malabsorption diarrhea (including vitamin B₁₂, D-xylose, and fat absorption dysfunction) can result. Although histologic examination of the small bowel can be normal, with intense infection there may be dense inflammatory infiltration accompanied by blunting to atrophy of the villi and crypt hyperplasia. The infections are nonulcerative and noninvasive except for *E intestinalis*, which can be invasive.

Clinical Findings

A. Symptoms and Signs

Generally, the forms of diarrhea caused by the coccidial and microsporidial agents are clinically indistinguishable from each other. In immunocompetent persons, infection varies from no symptoms, to a mild diarrhea with flatulence and bloating, to severe and frequent watery diarrhea in which the onset may be explosive. Mucus may be present in stools, but no microscopic or gross blood. Other findings may include low-grade fever, malaise, anorexia, abdominal cramps, vomiting, and myalgia. These symptoms are generally self-limited, lasting a few days to several weeks (sometimes longer for isosporiasis). Weight loss can be marked. Parasitologic clearance, however, may take several months.

In immunologically deficient patients, the diarrhea can be profuse (up to 15 L daily has been reported), with cholera-like watery movements, accompanied by severe malabsorption, electrolyte imbalance, and marked weight loss; fever is uncommon. Mucus is seen in the stools, but blood and leukocytes are seldom present. The diarrhea may recur or persist, and passage of organisms continues for months to indefinitely.

B. Laboratory Findings

In diagnosis, three stool specimens should be obtained fresh and in preservative over 5-7 days and processed by a variety of flotation or concentration methods to detect the distinctive oocysts (differences are based on size and intracellular location). A modified acid-fast stain is used for cryptosporidia, cyclospora, and isospora; in microsporidiosis, a modified trichrome or Weber stain. Clinicians should realize when ordering ova and parasite examinations that laboratories—unless specifically requested to do so—do not normally include the specialized tests needed to detect coccidia and microsporidia. The organisms can sometimes also be detected by duodenal aspiration or biopsy. For diagnosis of biliary disease, ultrasonography is used initially, followed when necessary by endoscopic retrograde cholangiopancreatography.

Specific Diseases

A. Cryptosporidiosis

The organism is highly infectious (relatively few parasites can induce infection) and readily transmitted in health and day care settings and in households. The incubation period appears to be 5-21 days. Oocysts passed in stools are fully sporulated and infectious; therefore, hospitalized patients should be isolated and stool precautions strictly observed. The prevalence of asymptomatic human carriers in the USA is estimated to be about 1.5%. Outbreaks are of particular concern, as exemplified by the 1993 epidemic in Milwaukee in which 400,000 persons became ill. Since chlorine disinfection of water is not effective, adequate filtration is required. However, because of the oocysts' small size (2-5 µm), filtration is difficult and unreliable (the < 1-µm filters used frequently become obstructed).

In AIDS, infection may involve any part of the gastrointestinal tract, including the biliary tract (sclerosing cholangitis has been described); respiratory tract infection, hepatitis, pancreatitis, lymphadenopathy, and hepatosplenomegaly may occur, as well as multisystem involvement. Diagnosis is by detecting the organism by the modified acid-fast staining method; a minimum of two concentrated specimens should be tested. Commercially available antigen detection kits improve on the diagnosis: direct fluorescent antibody methods have sensitivities and specificities of 99-100%; enzyme immunoassays have sensitivities and specificities of 93-100%. Some of the kits can be used with both fresh and frozen specimens; others, however, can only be used if the specimen is fresh. Where available, the polymerase chain reaction offers an alternative mode of diagnosis. Tests for serum antibody are useful epidemiologically but not for patient diagnosis.

Stools rarely show white or red blood cells. Blood leukocytosis and eosinophilia are uncommon. Radiologic changes have been reported in the stomach, intestines, and bile ducts in severe disease. In AIDS patients with unexplained diarrhea, the organism should also be looked for in sputum and bronchoalveolar lavage fluid; specimens obtained from lung tissue have sometimes been positive.

B. Isosporiasis

I belli oocysts in feces are 20-30 × 10-20 um. Opinion differs about whether the oocyst can be transmitted directly from person to person by anal-oral sexual contact or if it must pass into the environment and mature to its infectious stage. Outbreaks have occurred in day care centers and mental institutions. The incubation period is 7-11 days. A hemorrhagic ulcerative colitis has been described.

Diagnosis by stool examination is often difficult, for the organisms may be scanty even in the presence of significant symptoms. Because of their buoyancy, oocysts must be looked for just beneath the coverslip using direct smears or concentrated specimens. Confirmation is by acid-fast staining. Frequently, diagnosis can be made only after duodenal aspiration or duodenal biopsy of multiple specimens. Serologic tests are available.

C. Cyclosporiasis

C cayetanensis oocysts (8-10 um) must undergo a period of sporulation in the environment before they become infectious. Although humans appear to be the only species that are carriers of *C cayetanensis*, this is an unsettled question. Transmission is by fecally contaminated food and water, generally in tropical and subtropical areas; outbreaks in the USA have been attributed to imported fresh fruit and leafy vegetables. Children, HIV-AIDS patients, and travelers are the more commonly recognized hosts. Diarrhea begins after an incubation period of 2-11 days; rarely, the organisms invade the biliary tree, and Reiter's syndrome has been attributed to the infection. Oocysts can be identified in concentrated stool specimens by examination of wet mounts under phase microscopy, by use of modified acid-fast stains (oocysts are variably acid-fast), by the modified safranin stain, or by autofluorescence with ultraviolet light microscopy. Antibodies have been detected, and titers increase during convalescence.

D. Sarcocystosis

Sarcocystis is a two-host coccidian. Human disease occurs as two syndromes, both rare: (1) an enteric infection in which humans are the definitive host and (2) a muscle infection in which humans are an intermediate host. In the enteric form, sporocysts (9-16 um) passed in human feces are not infective for humans but must be ingested by cattle or pigs. Humans become infected by eating poorly cooked beef or pork containing oocysts of *Sarcocystis bovi hominis* or *Sarcocystis sui hominis*, respectively. Organisms enter intestinal epithelial cells and are transformed into oocysts that release sporocysts into the feces. Clinically, the intestinal infection is often asymptomatic or causes mild but protracted diarrhea; an eosinophilic necrotizing enteritis has been reported. Diagnosis is by stool concentration methods.

The muscle form of sarcocystosis results when humans ingest sporocysts in feces from an infected carnivore that has eaten prey which harbored sarcocysts. The sporocysts liberate sporozoites that invade the intestinal wall and are disseminated to skeletal muscle. This results in subcutaneous and muscular inflammation lasting several days to 2 weeks and the finding of swellings at these sites, sometimes associated with local erythema, tenderness and myalgia, fever, and eosinophilia. Diagnosis is by routine histologic methods. Sarcocysts are often asymptomatic, however, such as those found incidentally at autopsy in cardiac muscle.

E. Microsporidiosis

Microsporidia are obligate intracellular protozoans (0.5-2 um × 1-4 um) that are pathogens of arthropods, fish, and vertebrates. Many infections are of zoonotic origin from domestic and wild animals, but human-to-human transmission has been documented. Infection is mainly by ingestion of the spores but also by inhalation or finger contamination of the eyes. At least 11 species are known to infect humans; disease is seen mainly in immunoincompetent persons, particular those with AIDS. In chronic AIDS diarrhea, the two most common intestinal parasites are *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis*. These parasites can also cause biliary infection (cholangitis, cholecystitis). In immunocompetent persons, the diarrhea due to these parasites (including traveler's diarrhea) is self-limited. *Encephalitozoon intestinalis*, *Enterocytozoon cuniculi*, *Enterocytozoon hellem*, and *Vittaforma corneae* can disseminate to many tissues, including the sinuses, lungs, liver, urinary tract, and brain. In *E cuniculi* infection, MRI has shown contrast-enhancing brain lesions. Most of the above parasites and others have been found as a nonpathogenic carrier state or as a cause of keratoconjunctivitis. *Pleistophora* species and *Trachipleistophora hominis* cause a myositis associated with high elevations of creatine phosphokinase, lactate dehydrogenase, and myoglobin. Thus, microsporidia should be considered in infections in immunoincompetent persons in whom no other infectious agent can be found.

Microsporidia are detected in feces, body fluids (including duodenal fluid), and tissue biopsies (intestinal epithelium, cornea, conjunctiva, bronchi, and others) by light microscopy using various staining methods, particularly trichrome and Weber's chromotrope- based stains, followed by confirmatory fluorescence staining. In conducting stool examinations, after concentration, slide preparations should be very thin, stained for 90 minutes, and examined at × 1000 (or higher) magnification. In specialized laboratories, culture, molecular assays, and electron microscopic confirmation of histologic findings may be available. Although specific antibodies have been detected for some species, serologic diagnosis is controversial and of limited use.

Treatment

Most acute infections in immunocompetent persons are self-limited and do not require treatment. Supportive treatment for severe or chronic diarrhea includes fluid and electrolyte replacement and, in chronic cases, parenteral nutrition.

In **isosporiasis**, effective treatment has been described using (1) trimethoprim (160 mg) and sulfamethoxazole (800 mg) (TMP-SMZ) four times daily for 10 days and then twice daily for 3 weeks; or (2) sulfadiazine, 4 g, and pyrimethamine, 35-75 mg, in four divided doses daily, plus leucovorin calcium, 10-25 mg daily, for 3-7 weeks. In immunocompromised patients, it may be necessary to continue a maintenance dose indefinitely with TMP-SMZ three times weekly or Fansidar once weekly. Efficacy in primary infection has also been reported for furazolidone (400 mg/d for 10 days), roxithromycin, ciprofloxacin, nitrofurantoin, metronidazole, quinacrine, pyrimethamine, albendazole with ornidazole, and diclazuril.

In the treatment of **cyclosporiasis**, TMP (160 mg)-SMZ (800 mg) twice daily for 7 days is effective; in HIV infections, higher doses (four times daily for 10 days) and long-term maintenance (three times weekly) are needed. For patients intolerant of TMP-SMZ, ciprofloxacin can be tried. In **microsporidiosis**, the encephalitozoon species often respond to albendazole (400 mg two or three times daily for several weeks up to 3 months). In *E bieneusi* infection and in the various causes of disseminated disease, albendazole can be tried; although it has not had good success, amelioration may result. For ocular lesions, some infections respond to oral albendazole plus fumagillin eyedrops.

No treatment has been successful for **sarcocystosis** or **cryptosporidiosis**. In cryptosporidiosis, vigorous treatment of underlying AIDS may relieve the parasitic diarrhea; other drugs that have been tried are roxithromycin (300 mg twice daily for 4 weeks), spiramycin (1 g three times daily for 2 weeks or longer), paromomycin (25-35 mg/kg/d in three or four divided doses; duration uncertain), zidovudine (AZT), azithromycin (600 mg daily), octreotide, eflornithine, letrazuril, nitazoxamide, and hyperimmune bovine colostrum.

Prevention

Measures to reduce exposure to these organisms are recommended for immunocompromised patients. These include reduced exposure to swimming in fresh water and boiling of drinking water (1 minute) or use of a filter that removes particles over 1 um in size.

GIARDIASIS

- Most infections are asymptomatic.
- In some cases, acute or chronic diarrhea, mild to severe, with bulky, greasy, frothy, malodorous stools, free of blood and pus.
- Upper abdominal discomfort, cramps, distention, excessive flatus, and lassitude.
- Cysts and occasionally trophozoites in stools.
- Trophozoites in duodenal fluid.

General Considerations

Giardiasis is a protozoal infection of the upper small intestine caused by the flagellate *Giardia lamblia* (also called *G intestinalis* and *G duodenalis*). The parasite occurs worldwide, most abundantly in areas with poor sanitation. In the USA and Europe, the infection is the most common intestinal protozoal pathogen; the USA estimate is of 100,000 to 2.5 million new infections yearly and 5000 hospital admissions. Occurrence is particularly high among children.

The organism occurs in feces as a symmetric, heart-shaped flagellated trophozoite measuring 10-25 × 6-12 um and as a cyst measuring 11-14 × 7-10 um. Only the cyst form is infectious by the oral route; trophozoites are destroyed by gastric acidity. Humans are a reservoir for the infection; animals, including dogs, cats, beavers, and other mammals have been implicated but not confirmed as reservoirs or zoonotic sources of infection. Under suitable moist, cool conditions, cysts can survive in the environment for weeks to months. The infectious dose is low, requiring as few as ten cysts.

Cysts are transmitted as a result of fecal contamination of water or food, by person-to-person contact, or by anal-oral sexual contact. Multiple cases are common in households, children's day care centers (often the nidus for spread of organisms to the community), and mental institutions. Outbreaks occur as a result of contamination of water supplies. Giardiasis is a well-recognized problem in special groups including travelers abroad, campers who drink water from USA streams, male homosexuals, and persons with impaired immune states. Giardiasis has not been, however, an opportunistic infection in AIDS.

After the cysts are ingested, trophozoites emerge in the duodenum and jejunum. Infrequently, they cause epithelial damage, atrophy of villi, hypertrophic crypts, and extensive cellular infiltration of the lamina propria; mucosal invasion is rare; hematogenous dissemination does not occur. Hypogammaglobulinemia, low secretory IgA levels in the gut, achlorhydria, and malnutrition favor the development of infection. Gastric giardiasis may represent reflux from the duodenum or localized infection.

Clinical Findings

A. Symptoms and Signs

A large proportion of infected persons (especially children) remain asymptomatic cyst carriers, and their infection clears spontaneously. *Giardia* should be considered in most cases of diarrhea, especially where it is prolonged and associated with marked weight loss. Syndromes include (1) acute diarrhea, (2) chronic diarrhea, and (3) malabsorption. The incubation period is usually 1-3 weeks but may be longer. The illness may begin gradually or suddenly. The acute phase may last days or weeks, but it is usually self-limited, although cyst excretion may be prolonged. In a few patients, the disorder may become chronic and last for years.

In both the acute and chronic forms, diarrhea ranges from mild to severe; most often it is mild. There may be no complaints other than of one bulky, loose bowel movement a day, often after breakfast. With larger numbers of movements, the stools become increasingly watery but are usually free of blood and pus; they are copious, frothy, malodorous, and greasy. The diarrhea may be daily or recurrent; if recurrent, stools may be normal to mushy during intervening days, or the patient may be constipated. Weight loss is frequent; weakness may occur. Infants and young children may show impaired growth and development. Less common are anorexia, nausea and vomiting, midepigastria discomfort and cramps (often after meals), belching, flatulence, borborygmi, and abdominal distention.

Malabsorption occasionally develops in the acute or chronic stage. Findings may include fat- and protein-losing enteropathy and vitamin A, vitamin B₁₂, and disaccharidase deficiencies and marked weight loss. Certain extraintestinal manifestations (arthritis, anterior uveitis, urticaria) have been attributed to giardiasis infections, but a pathophysiologic relationship has not been established. Recent reports suggest that giardia infections in AIDS may be more frequent and severe than previously thought.

B. Laboratory Tests

Using stool specimens, diagnosis is (1) by standard ova and parasite examination or (2) by immunoassay by two methods: one for antigen (the enzyme immunoassay; sensitivity 94-100%, specificity 100%), and the other by detecting the organism using monoclonal antibody reagent (the direct fluorescent antibody assay for cysts; sensitivity and specificity of about 100%). Trophozoites can also be found in duodenal fluid. Immunoassays are the preferred diagnostic method if only giardia is being sought; otherwise, three stool specimens should be examined for ova and parasites. Some immunoassays require fresh or frozen stool and cannot be used with preserved specimens; additionally, some assays detect only cysts or only trophozoites. With cure, the immunoassay normally reverts to negative. Sometimes warranted is a search for organisms in the duodenum by (1) the duodenal string test (Entero-Test), (2) duodenal aspiration, (3) endoscopic brush cytology, or (4) duodenal biopsy (a mucosal imprint for staining should be made before sectioning). Tests for serum antibody are not recommended because of lack of sensitivity and specificity.

Detection of the parasites in feces can be difficult because the number of organisms passed varies considerably from day to day. At the onset of infection, patients may have symptoms for about a week before organisms can be detected; in chronic diarrhea, stool examinations can be persistently negative. Three stool specimens collected at intervals of 2 days or longer should be examined following concentration methods. One specimen will detect 50-75% of cases and three specimens about 90%. Unless the specimens can be submitted within an hour, they should be preserved immediately in a fixative. Purges do not increase the likelihood of finding the organism. Use of barium, antibiotics, antacids, kaolin products, or oily laxatives may temporarily (about 10 days) reduce the number of parasites or interfere with detection.

There is no eosinophilia, and the white blood cell count is normal. Radiologic examination of the small bowel is usually normal.

Treatment

Although controversial, treatment of asymptomatic patients should be considered since they can transmit the infection to others and may occasionally become symptomatic themselves. In selected cases, it may be best to wait a few weeks before starting treatment, as some infections will clear spontaneously. In the presence of a presumptive diagnosis but negative stool specimens, an empirical course of treatment is sometimes indicated.

Treatment is effective with tinidazole, metronidazole, quinacrine, or furazolidone. As none of the agents cure more than 90% of infections (80% for furazolidone), re-treatment with an alternative drug may be needed. Single-dose tinidazole (not available in the USA) is the drug of choice because it is as effective as a course of the other drugs. In follow-up, two or more stools are analyzed weekly starting 2 weeks after therapy.

All of these drugs occasionally have unpleasant side effects. The potential for carcinogenicity of furazolidone, metronidazole, and tinidazole appears to be negligible based on over two decades of use. Because of its rare potential for severe toxicity, quinacrine should be used only when no other drug is available.

A. Tinidazole

(Not available in the USA.) A dose of 2 g given once has had reported cure rates of 90-100%. Adverse reactions consist of mild gastrointestinal side effects in about 10% of patients; headache and vertigo are less common.

B. Metronidazole

The dose is 250 mg three times daily for 5-7 days. Metronidazole may cause gastrointestinal symptoms, headache, dizziness, a metallic taste, and candidal overgrowth, in addition to a disulfiram-like reaction in alcohol users. In the USA, metronidazole for giardiasis treatment is only available for off-label use.

C. Furazolidone

The dose is 100 mg (in suspension) four times daily for 7-10 days. Gastrointestinal symptoms, fever, headache, rash, and a disulfiram-like reaction with alcohol occur. Furazolidone can cause mild hemolysis in glucose-6-phosphate dehydrogenase-deficient persons.

D. Quinacrine (Mepacrine)

The dose is 100 mg three times daily after meals for 5-7 days. The drug has a bitter taste. Gastrointestinal symptoms, headache, and dizziness are common; harmless yellowing of the skin is infrequent. Toxic psychosis and exfoliative dermatitis are rare but may be severe. Quinacrine is contraindicated in psoriasis or in persons with a history of psychosis. Although quinacrine is not generally available in the USA, it can be obtained from two pharmacies: 800-247-9767.

E. Others

Albendazole (400 mg daily for 5 days) has shown cure rates that range from 10% to 95%. Reports with **paromomycin** (25-35 mg/kg/d in three divided doses for 7 days) have been mixed; because the drug is not absorbed, it has been proposed for use in pregnancy.

Prevention

There is no effective chemoprophylaxis for giardiasis. Since community chlorination (0.4 mg/L) of water is relatively ineffective for inactivating cysts, filtration is required. For hikers, bringing water to a boil for 1 minute is adequate; halogenation with iodine or filtration with a pore size less than 1 µm can also be used. Relying on iodine halogenation is no longer recommended by the Centers for Disease Control and Prevention. In day care centers, appropriate disposal of diapers and frequent hand washing are essential.

Prognosis

With treatment and successful eradication of the infection, there are no sequelae. Without treatment, severe malabsorption may rarely contribute to death from other causes.

LEISHMANIASIS

Leishmaniasis is infection by species of the genus *Leishmania*. The disease is a zoonosis transmitted by bites of sand flies (2 mm) (*Phlebotomus* [Old World leishmaniasis] and *Lutzomyia* [New World leishmaniasis] species) from the wild animal reservoir (eg, rodents, Canidae, sloths, marsupials) and domestic dogs (they can die from *L. infantum* infections) to humans; however, kala azar is transmitted directly from humans to humans. Leishmaniae have two distinct forms in their life cycle: (1) In mammalian hosts, the parasite is found in its amastigote form (Leishman-Donovan bodies, 2 × 5 µm) within mononuclear phagocytes. When sand flies feed on an infected host, the parasitized cells are ingested with the blood meal. (2) In the sand fly vector, the parasite converts to, multiplies, and is then transmitted during feeding as a flagellated extracellular promastigote (10-15 µm).

Four clinical syndromes occur, with overlap between them, and each syndrome is caused by more than one species. The speciation of leishmaniasis is complex (about 20 species are known to infect humans) and unsettled, and some species, not all of which are noted below, can cause more than one syndrome.

Visceral leishmaniasis (kala azar), usually fatal without treatment, is characterized by hepatosplenomegaly and anemia and is caused mainly by the *L. donovani* group of agents: *L. donovani*, *L. infantum*, and *L. chagasi*.

Old World cutaneous leishmaniasis—moist or dry cutaneous leishmaniasis—is caused mainly by *L. tropica*, *L. major*, and *L. aethiopica*. **New World cutaneous leishmaniasis** is caused by the *L. mexicana* complex.

Mucocutaneous leishmaniasis (espundia), characterized by an initial cutaneous ulcer that is followed in months to years by destructive nasopharyngeal lesions, is caused by the *Leishmania (viannia)* group of agents, principally by *L. (v) braziliensis* and rarely by *L. (v) panamensis*.

Diffuse cutaneous leishmaniasis is a state of deficient cell-mediated immunity, in which the widespread, leprosy-like skin lesions are generally progressive and refractory to treatment. The causative organisms are the *L. mexicana* complex in the New World and *L. aethiopica* in the Old World.

In tropical and temperate zones, an estimated 12 million persons are infected with leishmaniasis; 1.5-2 million new cases occur yearly, of which more than 1 million are cutaneous and 500,000 visceral disease. The incidence of disease is increasing in many endemic areas. Severity of infection ranges from subclinical or minimally pathologic (self-curing or easily treated cutaneous lesions) to persistent, disfiguring cutaneous and mucocutaneous lesions to potentially fatal visceral disease. Imported infections into the USA each year include about 40 cutaneous infections and several cases of visceral leishmaniasis.

Leishmania results in lifelong latent infection. If immunoparesis supervenes, leishmaniae can become opportunistic pathogens through reactivation or new infection. More than 1000 coinfections with HIV-visceral leishmaniasis have been reported from 25 countries, but the problem is worse in southern Europe (France, Italy, Spain, Portugal), where up to 17% of people with AIDS have coinfections. Coinfections are being increasingly reported with other leishmania species elsewhere in the world. In such cases, diagnostic criteria may be altered (leishmania antibodies become undetectable and, in visceral disease, splenomegaly may not occur); in treatment, drug side effects may exaggerate. Antiviral treatment may prevent exacerbation of latent leishmania infections and may also reduce findings in active leishmaniasis.

Diagnosis

Definitive diagnosis is by finding (1) the intracellular nonflagellated amastigote in Giemsa-stained biopsies from skin, mucosal lesions, liver, or lymph nodes; or from aspirates from spleen (the most sensitive site, but also a risky procedure), bone marrow, or lymph nodes; or (2) the flagellated promastigote state in culture of these tissue. Occasionally, the organisms are seen in mononuclear cells of Giemsa-stained smears of the buffy coat. Culture requires up to 21 days using specialized media; where available, species identification can then be made by molecular methods. Golden hamster or Balb/c mouse inoculation of the nose, footpad, or tail base may also be used and requires 2-12 weeks of observation. Serologic tests (ELISA, indirect fluorescent antibody, direct agglutination, others) and the leishmanin (Montenegro) skin test (not licensed in the USA) may facilitate diagnosis, but none are sufficiently sensitive or specific to be used alone or for speciation purposes. Cross-reactions occur with Chagas' disease. Polymerase chain reaction assays have high diagnostic sensitivity. Specimens from skin lesions should be obtained through intact skin (cleansed with 70% alcohol) at a raised edge of an ulcer margin. Local anesthesia can be used. To obtain tissue fluid for staining, press blood out of the site with two fingers, incise a 3-mm slit, and then scrape with the blade. When doing a biopsy, an impression smear is made, a portion is macerated for culture, and the remainder is reserved for pathologic sections. For needle aspiration, sterile preservative-free saline is inserted with a 23- to 27-gauge needle; the aspirate is then cytospun at 800 *g* for 5 minutes.

Treatment

Treatment is less than adequate because of drug toxicity, long courses required, and frequent need for hospitalization. The drug of choice is a pentavalent antimonial, either sodium stibogluconate or meglumine antimoniate; resistance and treatment failures are increasing in frequency. Second-line drugs used in cases unresponsive to the antimonials—but potentially more toxic—are amphotericin B and pentamidine. New lipid-formulated amphotericins permit a shorter course of treatment with less toxicity and high effectiveness. AmBisome, recently approved for use in the USA, is considered by some workers to be the drug of choice for the treatment of visceral leishmaniasis but is very expensive. Miltefosine, an oral drug, has recently been approved in India for the treatment of visceral leishmaniasis.

A. Sodium Stibogluconate

Sodium stibogluconate is provided as a solution that contains 100 mg of antimony (Sb) per milliliter; only fresh solutions should be used. A generic formulation of sodium stibogluconate—at one-fourteenth the cost—has been shown to be equivalent in efficacy and safety to Pentostam. Treatment is started with a 200-mg Sb test dose followed by 20 mg Sb/kg/d; although dosages greater than 20 mg/kg should not be given, there is no upper limit to the total daily dose. The drug can be administered as a 5% solution intramuscularly (may be locally painful), but intravenous administration is preferred (cough may occur) when the volume is high, as is the case for most adults. Meglumine antimoniate (85 mg Sb/mL) is equal in efficacy and toxicity when used in equivalent Sb doses (20 mg Sb/kg/d). The appropriate volume of drug is mixed with 50 mL of 5% dextrose in water and infused over at least a 10-minute interval. The selected drug is given on consecutive days: 28 days for visceral and mucocutaneous leishmaniasis and 20 days for cutaneous leishmaniasis. In certain regions of the world, because of resistance, longer courses are indicated. Although few side effects occur initially, they are more likely to appear with cumulative doses. Most common are gastrointestinal symptoms, fever, myalgia, arthralgia, phlebitis, and rash; hemolytic anemia, hepatitis, renal and heart damage, and pancreatitis are rare. Patients should be monitored weekly for the first 3 weeks and twice weekly thereafter by serum chemistries, complete blood counts, and electrocardiography. Therapy is discontinued if the following occur: aminotransferases three to four times normal levels or significant arrhythmias, corrected QT intervals greater than 0.50 s, or concave ST segments. Relapses should be treated at the same dosage level for at least twice the previous duration. In the USA, the only drug available is stibogluconate, obtainable from the Parasitic Drug Service, Centers for Disease Control and Prevention, Atlanta, GA 30333 (404-639-3670).

B. Amphotericin B

For the treatment of visceral leishmaniasis, the parenteral dosage of AmBisome (a liposomal formulation now approved for use in the USA) is 3 mg/kg/d on days 1-5, 14, and 21 and may be repeated; the dosage for immunoincompetent persons is 4 mg/kg/d on days 1-5, 10, 17, 24, 31, and 38. A recent report indicated that comparable effectiveness could be achieved with lower doses over a shorter period; cumulative doses of 3.75 or 7.5 mg/kg were given in five divided doses over 5 days. Single-dose treatment is under evaluation. Infusion-related side effects include gastrointestinal symptoms, fever, chills, dyspnea, hypotension, and hepatic and renal toxicity. The dosage for cutaneous and mucosal leishmaniasis has not been established. Conventional amphotericin B deoxycholate, as given in India, is slow infusion (4-6 hours) of 1 mg/kg daily for 20 days; this dosage achieved 99% cure rates but with side effects as above; an alternative dosage is 0.5-1 mg/kg/d or every

second day intravenously for up to 8 weeks.

C. Pentamidine Isethionate

Pentamidine isethionate, 2-4 mg/kg intramuscularly (preferable) or intravenously, is given daily or on alternate days (fifteen doses for visceral and four doses for cutaneous leishmaniasis). For some forms of visceral leishmaniasis, it may be necessary to repeat treatment using up to twice the dose, but resistance may persist.

D. Paromomycin (Aminositidine)

When this drug was applied topically in various formulations in cutaneous leishmaniasis, it had variable success that differed by region. One ointment preparation is paromomycin 15% and methylbenzethonium chloride 12% in soft paraffin, applied twice daily for 15 days; skin reactions may occur. The ointment cannot be used in regions of mucocutaneous leishmaniasis as it does not prevent metastatic disease. In parenteral treatment of refractory visceral leishmaniasis, paromomycin is showing promise but has the potential for causing severe renal or otic toxicity.

E. Miltefosine

Miltefosine, an alkyl phospholipid, is the first oral drug for the treatment of leishmaniasis. Approved for use in India for visceral leishmaniasis at a daily dose of 100-150 mg for 4 weeks, it has resulted in 95% cure rates. Side effects included vomiting (40%), diarrhea (20%), and occasional transient elevations of aminotransferases, BUN, and creatinine. The drug is not recommended in pregnancy. Preliminary reports have also shown efficacy in cutaneous leishmaniasis.

Prevention & Control

Infection occurs when humans encroach on sand fly habitats—warm, humid microclimates, including rodent burrows, rock piles, or tree holes; these are often in sylvatic areas near forests or semiarid ecosystems. Biting is generally at twilight or at night but may occur in shaded areas during the day. Personal protection may fail but is partially accomplished by clothing (pants, long sleeves) that covers exposed skin, permethrin applied to clothing, deet repellent (see under Malaria), avoidance of endemic areas (especially at night), use of mosquito coils, and use of fine-mesh sand fly netting for sleeping (may be too warm in tropical areas). Although sand flies can traverse the mesh of standard mosquito nets, insecticide-impregnated nets may prevent this. Often useful in control are destruction of animal reservoir hosts, mass treatment of humans in kala azar-prevalent areas, residual insecticide spraying in domestic and peridomestic areas, and keeping dogs and other domesticated animals out of the house, particularly at night.

1. Visceral Leishmaniasis (Kala Azar)

Visceral leishmaniasis is infection of the reticuloendothelial system, resulting in fever, hepatosplenomegaly, and pancytopenia. More than 500,000 cases occur yearly. The disease is caused mainly by the *Leishmania donovani* complex: (1) *L donovani* (eastern India, Bangladesh, Southeast Asia, Sudan, Ethiopia, Kenya, scattered foci in sub-Saharan Africa, the central Asian part of Russia, and northern and eastern China); (2) *L infantum* (Mediterranean littoral, Middle East, China, central and southwestern Asia, Ethiopia, Sudan, Afghanistan, Pakistan); and (3) *L chagasi* (South America, Central America, Mexico). The number of cases is increasing, particularly in Sudan, Bangladesh, Brazil, and Nepal. In each locale, the disease has its own peculiar clinical and epidemiologic features. Two other species—*L tropica* in the Middle East, the Mediterranean littoral, Kenya, India, and western Asia and *L amazonensis* in the Amazon Basin—cause visceral leishmaniasis in a few patients, generally in a milder form. Although humans are the major reservoir, animal reservoirs such as the dog, other canids, and rodents are important. The incubation period is usually 4-6 months (range: 10 days to 24 months).

A local nonulcerating nodule at the site of the bite may precede systemic manifestations but usually is inapparent. The onset may be acute (as early as 2 weeks after infection) or insidious. Fever often peaks twice daily, with chills and sweats, weakness, weight loss, cough, and diarrhea. The spleen progressively becomes huge, hard, and nontender. The liver is somewhat enlarged, and generalized lymphadenopathy is common. Hyperpigmentation of skin, especially on the hands, feet, abdomen, and forehead, is marked in light-skinned patients. In blacks, there may be warty eruptions or skin ulcers. Petechiae, bleeding from the nose and gums, jaundice, edema, and ascites may occur. Wasting is progressive; death, often due to intercurrent infection, occurs within months to 1-2 years. In some regions, oral and nasopharyngeal or cutaneous manifestations occur with or without visceral involvement.

In HIV-infected persons—with or without AIDS—visceral leishmaniasis can be an opportunistic infection. Numerous cases have been reported from the Mediterranean area and some from South America. These patients may have a shorter duration of symptoms, no fever or splenomegaly, and a poor response to treatment.

The diagnosis can sometimes be made by demonstrating the organism in buffy coat preparations of blood, preferably obtained at night. More commonly, definitive diagnosis depends on Giemsa-stained smears, touch preparations, culture, or animal inoculation of aspirates of sternal marrow or iliac crest, liver, enlarged lymph nodes, or spleen. Although splenic aspiration is the most sensitive test, because of its hazard (intra-abdominal bleeding and death) it should be reserved for last and should be performed only by experienced persons; contraindications are a soft spleen in the acute phase, a prolonged prothrombin time, and platelet counts under 40,000/uL. In immunocompetent persons, serologic tests are sensitive (> 90%) but false positives may occur, especially in malaria and typhoid fever. The direct agglutination IgM test and the ELISAs become positive early; the immunofluorescent IgG test becomes positive in most persons at a titer of 1:256 or higher. After treatment, the tests remain positive for months, though in immunoincompetent persons titers may be low or undetectable. The leishmanin skin test is always negative during active disease and becomes positive months to years after recovery. The polymerase chain reaction test has excellent sensitivity and specificity. Other characteristic findings are progressive leukopenia (seldom over 3000/uL after the first 1-2 months), with lymphocytosis and monocytosis, normochromic anemia, thrombocytopenia, and eosinopenia. There is a marked increase in total protein up to or greater than 10 g/dL owing to an elevated IgG fraction; serum albumin is 3 g/dL or less. Liver function tests show hepatocellular damage. Proteinuria may be present.

The differential diagnosis includes leukemia, lymphoma, tuberculosis, histoplasmosis, infectious mononucleosis, brucellosis, malaria, typhoid, schistosomiasis, African trypanosomiasis, tropical splenomegaly syndrome, and cirrhosis.

Sodium stibogluconate (20 mg/kg/d for 30 days, sometimes longer) is the drug of choice. Whereas Mediterranean kala-azar may respond to 10-15 doses of stibogluconate (one per day), the disease in Kenya, Sudan, and India requires at least 30 days of treatment. With incomplete response or relapse, the treatment should be repeated for 60 days. Drug resistance is now so high in parts of Bihar state, India, that cure rates are only 10-35%. For refractory cases, amphotericin B is the alternative drug; however, to achieve reduction in its side effects, the lipid formulation (available in the USA) is preferred if the high cost can be accepted (see above for doses). A third alternative drug is pentamidine; its efficacy has so declined in India that the drug is seldom used there. Miltefosine, a new oral treatment (approved for use in India; not available in the USA) has shown cure rates to 95% (see above for dosage, side effects, and contraindications).

Without treatment, the fatality rate reaches 90%. Early diagnosis and treatment reduces mortality to 2-5%. Relapses (up to 10% in India and 30% in Kenya) are most likely to occur within 6 months after completion of treatment.

Post-kala azar dermal leishmaniasis may appear after apparent cure in the Indian subcontinent and east Africa. It may simulate leprosy, as multiple hypopigmented macules or nodules develop on preexisting lesions. Erythematous patches may appear on the face. Leishmaniae are present in the skin. Antimony treatment should be tried but is often ineffective.

2. Cutaneous Leishmaniasis

Cutaneous swellings appear 2 weeks to several months after sand fly bites and can be single or multiple. Depending on the leishmanial species and host immune response, lesions begin as small papules and develop into nonulcerated dry plaques or large encrusted ulcers with well-demarcated raised and indurated margins. Satellite lesions may be present. The lesions are painless unless secondarily infected. Local lymph nodes may be enlarged. Systemic symptoms are rare, but a low-grade fever of short duration may be present at the onset. For most species, healing usually occurs spontaneously in months to 1-3 years, starting with central

granulation tissue that spreads peripherally. Pyogenic complications may be followed by lymphangitis or erysipelas. Contraction of scars can cause deformities and disfigurement, especially if lesions are on the face.

Definitive diagnosis is made by identification of the organisms (see above). Microscopic examination of skin scrapings has limited sensitivity, particularly in chronic infections. Where available after culture, species identification should be done by molecular methods. The skin test becomes positive within 3 months and remains positive for life; false positives occur. Serologic tests are unreliable. Antibody may be undetectable or may appear only at low levels after 4-6 weeks; cross-reactions occur, including with leprosy.

The differential diagnosis includes tuberculosis, leprosy, fungal infections, yaws, syphilis, neoplasms, and sarcoidosis.

Diffuse cutaneous leishmaniasis is caused by the *L. mexicana* complex and *L. aethiopica*. Nonulcerating lesions resembling lepromatous leprosy occur over the entire body. The skin test is negative, but amastigotes are abundant. In spite of repeated doses of antimony, pentamidine, or amphotericin, cures are rare.

Old World Cutaneous Leishmaniasis

Agents of Old World cutaneous leishmaniasis are of four species. *L. tropica* is the agent responsible for an urban infection of dogs and humans. It is found in the Middle East, northwestern India, East Africa, central Asian area of the former Soviet Union, Afghanistan, Pakistan, Turkey, Armenia, Greece, and southern France and Italy. The incubation period is 2 months or longer, and healing is complete in 1-2 years. The lesions of *L. tropica* infection tend to be single and dry, to ulcerate slowly or not at all, and to persist for a year or longer. **Leishmaniasis recidivans** is a relapsing form of *L. tropica* infection in which the primary lesion nearly heals, lateral spread with central healing follows, and scarring can be extensive; it is associated with hypersensitivity and a strongly positive skin test but scarce amastigotes. Visceral involvement by *L. tropica* has been reported rarely (including after troop exposure in Operation Desert Storm) and is relatively resistant to antimony treatment.

L. major infection causes lesions in dry or desert rural areas and is primarily a disease of desert rodents. Human disease occurs in the Middle East, central Asian area of the former Soviet Union, Arabian peninsula, Afghanistan, and Africa (North, East, and sub-Saharan Africa from Senegal to Sudan and Kenya). The lesions are characterized by multiple, wet, rapidly ulcerating sores with crusting. Spontaneous healing is generally complete in 6-12 months.

L. aethiopica infection occurs in the Ethiopian and Kenyan highlands. Ulceration is rare; spontaneous healing is slow over several years. An uncommon complication is diffuse cutaneous leishmaniasis, an anergic form with nodular lesions and high parasite count. Treatment has sometimes been successful with sodium stibogluconate plus recombinant interferon gamma.

L. donovani sometimes causes cutaneous disease with visceral manifestations.

Treatment: Old World leishmaniasis, especially in the Middle East, is generally self-healing in about 6 months and does not metastasize to the mucosa. Thus, it may be justified to withhold treatment if the lesions are small, in an unobtrusive place, and appear to be healing. Parenteral sodium stibogluconate (20-28 days) should be used to treat patients with large or multiple lesions or if the lesions are on cosmetically or functionally important areas (eg, the wrist). Complete healing may not be evident until weeks after the first or second course of treatment. Amphotericin B desoxycholate and pentamidine are used for failures. Pentamidine is often effective against *L. aethiopica* lesions and ketoconazole (400-600 mg/d for 4-6 weeks) against *L. major* and *L. (V) panamensis*. Other treatments for less severe disease are physical measures (local cryotherapy or heat therapy, electrocoagulation, surgical removal) and intralesional injection of sodium stibogluconate. Paromomycin ointment may also be effective against *L. tropica*.

New World Cutaneous Leishmaniasis

The *L. mexicana* complex consists of *L. mexicana* (Texas—about 20 locally acquired human infections have been reported—Oklahoma, Arizona, Mexico, Central America), *L. amazonensis* (Amazonian basin, Venezuela, Panama, Trinidad), *L. chagasi* (Central and South America), and other species (Venezuela and Dominican Republic). The *Leishmania (viannia)* group consists of *L. braziliensis* (Central and South America), *L. panamensis* (Central America and northeastern South America), and *L. guyanensis* (South America).

L. mexicana and *L. braziliensis* infections generally result from forest-related activities or from residence in dwellings situated near forests. *P. panamensis* is also found in drier habitats. In parts of South America, several leishmania species are now transmitted in domestic environments.

Most New World cutaneous lesions are ulcers, but vegetative, verrucous, or nodular lesions may occur also. *L. mexicana* ("chiclero's ulcer") in the Yucatan and Central America produces destructive lesions on the ear cartilage. Up to 80% of *L. braziliensis* cutaneous lesions progress to espundia (see below); some *L. braziliensis* complex strains also show a chain of palpable local lymph nodes, and some *L. mexicana* and South American strains can cause diffuse cutaneous leishmaniasis.

Treatment: In New World *L. mexicana* infections from Mexico and Central America, solitary nodules or ulcers in inconspicuous sites generally will heal spontaneously. Variable success has been had with paromomycin ointment (see above), ketoconazole, heat application, or metronidazole (750 mg three times daily for 10 days). Preliminary trials with oral miltefosine (150 mg/d for 3-4 weeks) had reported cure rates of 94%. Other drugs continue under evaluation. Lesions on the ear, face, or hands should be treated with sodium stibogluconate but usually require only a 12- to 14-day course. Cutaneous lesions acquired in regions of mucocutaneous leishmaniasis may be due to *L. braziliensis* or *L. panamensis* and should be treated with a full course of sodium stibogluconate.

Hepburn NC: Management of cutaneous leishmaniasis. Curr Opin Infect Dis 2001;14:151. [PMID: 11979125]

3. Mucocutaneous Leishmaniasis (Espundia)

Mucocutaneous leishmaniasis occurs in lowland forest areas and is caused by the *Leishmania (viannia)* group of organisms, usually by *L. (V) braziliensis* (Central and South America; most cases are in Brazil, Bolivia, and Peru) and rarely by *L. (v) panamensis* (Central and northeastern South America) or *L. (v) peruviana* (Peru). The initial lesion, single or multiple, is on exposed skin; at first it is papular (can be pruriginous or painful), then nodular, and later may ulcerate or become wart-like or papillomatous. Local healing follows, with scarring within several months to a year. Subsequent naso-oral involvement occurs in a small proportion of patients either by direct extension or, more often, metastatically to the mucosa. It may appear concurrently with the initial lesion, shortly after healing, or after many years. The mucosa of the anterior part of the nasal septum is generally the first area to be involved. Extensive destruction of the soft tissues and cartilage of the nose, oral cavity, and lips may follow and may extend to the larynx and pharynx. Secondary bacterial infection is common. Regional lymphangitis, lymphadenitis, fever, weight loss, keratitis, and anemia may be present.

Although they are difficult to find, diagnosis is by detecting amastigotes in scrapings, biopsy impressions or histologic sections, or aspirated tissue fluid. Also, the organism grows with difficulty in culture or after inoculation of hamsters; if positive, speciation should be attempted. The leishmanin skin test is useful if it produces a fully developed papule in 2-3 days that disappears after a week. Standard serologic tests are often not useful; a direct agglutination for IgM antibodies may become positive in 4-6 weeks and subsequently an IgG test, but at low titer. Polymerase chain reaction is promising. Main considerations in differential diagnosis are paracoccidioidomycosis and other fungal infections, polymorphic reticulosis, Wegener's granulomatosis, lymphoma, and nasopharyngeal carcinoma, yaws, syphilis, and sarcoidosis.

Treatment

This group of parasites should be treated because of their potential for developing into mucocutaneous disease. Failure rates are high, however, even when a full course (28 days) of sodium stibogluconate treatment is used (see above). If repeated and extended antimony treatment fails, amphotericin B desoxycholate or pentamidine is used. Under evaluation are the liposomal formulations of amphotericin B and combined antimony and gamma interferon treatment. Corticosteroids may be needed to control local inflammation due to release of antigens. Antibiotics are usually needed to treat associated bacterial or fungal infections. Successful treatment was recently reported for pentoxifylline plus a pentavalent antimonial drug.

MALARIA

Essentials of Diagnosis

- History of exposure in a malaria-endemic area.
- Periodic attacks of sequential chills, fever, and sweating.
- Headache, myalgia, splenomegaly; anemia, leukopenia.
- Characteristic parasites in erythrocytes, identified in thick or thin blood films.
- Complications of falciparum malaria: Cerebral findings (mental disturbances, neurologic signs, convulsions), hemolytic anemia, hyperpyrexia, secretory diarrhea or dysentery, dark urine, anuria.

General Considerations

Four species of the genus *Plasmodium* are responsible for human malaria: *P vivax*, *P malariae*, *P ovale*, and *P falciparum*. Although the disease has been eradicated from most temperate zone countries, it continues to be endemic in many parts of the tropics and subtropics, and imported cases occur in the USA and other countries free of transmission. Malaria is present in parts of Mexico, Haiti, Dominican Republic, Central and South America, Africa, the Middle East, the Indian subcontinent, Southeast Asia, China, and Oceania. *P vivax* and *P falciparum* are responsible for most infections and are found throughout the malarious regions; *P falciparum* is the predominant species in Africa and the only plasmodium in Haiti and the Dominican Republic. *P malariae* is also widely distributed but is less common. *P ovale*, although generally rare, seems to replace *P vivax* in West Africa. *P vivax* infection is uncommon among blacks because their red blood cells do not have the Duffy factor surface antigen. Worldwide, malaria causes clinical illness in about 300 million people and results in an estimated 1-3 million deaths annually, mainly in children in sub-Saharan Africa. Currently, malaria is increasing and also is appearing in areas where it had disappeared. An estimated 30,000 travelers from the developed world are infected yearly with malaria, and several hundred die. The USA experiences each year 1000 or more imported infections with different species; a few cases of locally acquired, mosquito-transmitted infection from an imported case; and an average of four deaths mostly due to falciparum malaria. Most of the imported infections are acquired in tropical Africa.

Malaria is transmitted from human to human by the bite of infected female *Anopheles* mosquitoes. Congenital transmission and acquisition by blood transfusion also occurs. Other than the mosquito, there are no animal reservoirs for human malaria.

The mosquito becomes infected by ingesting blood containing the sexual forms of the parasite (micro- and macrogametocytes). After a developmental phase in the mosquito, sporozoites in the salivary glands are inoculated into humans when the mosquito next feeds. The first stage of development in humans, the exoerythrocytic stage, takes place in the liver. In all four infections, the sporozoites invade hepatocytes to mature as tissue schizonts. However, in *P vivax* and *P ovale* infections only—but not in induced infections with these parasites—some sporozoites enter hepatocytes to become dormant hypnozoites; activation of the hypnozoites 6-8 months later results in a primary infection or in relapse. When liver schizonts escape from the liver into the bloodstream, they invade red blood cells, multiply, and 48 hours later (or 72 with *P malariae*) cause the red cells to rupture, releasing a new crop of parasites (merozoites). Within the bloodstream, this cycle of invasion, multiplication, and red cell rupture may be repeated many times.

In *P falciparum* and *P malariae* malaria, the liver infection ceases spontaneously in less than 4 weeks; thereafter, multiplication is confined to the red cells. Thus, 4 weeks after departure from an endemic area, treatment that eliminates these species from the red cells will cure the infection. Cure of *P vivax* and *P ovale* malaria, however, requires treatment to eradicate infection from both red cells and liver hypnozoites.

The incubation period after exposure or after stopping chemoprophylaxis is, for *P falciparum*, approximately 12 days (range: 9-60 days); for *P vivax* and *P ovale*, 14 days (range: 8-27 days [initial attacks for some temperate strains may not occur for up to 8 months]); and for *P malariae*, 30 days (range: 16-60 days). Untreated *P falciparum* infections can persist for up to 1.5 years but usually end in 6-8 months; *P vivax* and *P ovale* infections persist for as long as 5 years; and *P malariae* infections have lasted for as long as 50 years. Protective immunity results from infection but decays after several years if reinfection does not occur.

Clinical Findings

A. Symptoms and Signs

Typical malarial attacks show sequentially, over 4-6 hours, shaking chills (the cold stage); fever (the hot stage) to 41 °C or higher; and marked diaphoresis (the sweating stage). Associated symptoms may include fatigue, headache, dizziness, gastrointestinal symptoms (anorexia, nausea, slight diarrhea, vomiting, abdominal cramps), myalgia, arthralgia, backache, and dry cough. These symptoms appear to be due in large part to release of tissue necrosis factor and other cytokines during schizogony.

Either from the onset or with progression of the disease, the attacks may show an every-other-day (tertian) periodicity in vivax, ovale, or falciparum malaria or an every-third-day (quartan) periodicity in malariae malaria. Splenomegaly usually appears when acute symptoms have continued for 4 or more days; the liver is frequently mildly enlarged. The patient may be tired between attacks but otherwise feels well. After this primary episode, recurrences are common, each separated by a latent period.

Because of its frequent and severe complications, *P falciparum* is the more serious infection and causes the most deaths, sometimes within 24 hours. In severe falciparum infections, red blood cell parasitemia is higher than 3-5%. Severe disease results in part from intense sequestration and cytoadherence of parasitized red cells in capillaries and postcapillary venules. Complications include (1) cerebral malaria with edema (headache, mental disturbances, neurologic signs, retinal hemorrhages, convulsions, delirium, coma); (2) hyperpyrexia; (3) hemolytic anemia; (4) noncardiogenic pulmonary edema; (5) acute tubular necrosis and renal failure—rarely, this is associated with blackwater fever (dark urine), which most commonly is due to severe hemolysis following quinine treatment; (6) acute hepatopathy, with centrilobular necrosis and jaundice; (7) hypoglycemia; (8) cardiac dysrhythmias; (9) gastrointestinal syndromes (including secretory diarrhea and dysentery); (10) lactic acidosis; and (11) water and electrolyte imbalance. The prognosis is poor if more than 20% of infected red cells contain mature parasites or if more than 5% of neutrophils contain pigment. Gram-negative bacteremia may contribute to death.

Immunologic disorders resulting from chronic infection are tropical splenomegaly and nephrotic syndrome (the latter due to *P malariae* only). Malaria infections do not appear to act as an opportunistic infection in AIDS patients, with the possible exception of malaria infection in pregnancy.

B. Laboratory Findings

Thick and thin blood films, Giemsa- or Wright-stained, are the mainstay of diagnosis—clinical diagnosis is only 20-60% reliable compared with microscopy. Blood from finger sticks or from the earlobe are preferred sources but should be free-flowing and uncontaminated by alcohol; if venipuncture blood is used, it should be examined shortly after it is drawn to avoid changes in morphology. Specimens should be obtained at about 8-hour intervals for 3 days, including during and between febrile periods.

Because antibody becomes detectable only 8-10 days after onset of symptoms, serologic tests are not recommended in diagnosis of acute attacks. The tests may be useful, however, when repeated blood films are negative. As antibody persists for 10 or more years, serology is rarely useful in the differential diagnosis of chronic infection or in distinguishing between current and past infection.

Alternative diagnostic tests—some commercially available and others still under evaluation—have the disadvantages of cost and complexity. Some are sensitive only to *P falciparum*, including two antigen detection methods: an ELISA and a rapid, simply accomplished dipstick format (90% specific and sensitive). Other tests are a quantitative buffy coat centrifugal system (does not readily differentiate the species), the polymerase chain reaction (highly sensitive and species-specific), and an indirect fluorescent antibody test (which uses the four organisms as antigens and is highly sensitive and specific).

During paroxysms, there may be transient leukocytosis. Leukopenia develops subsequently, with a relative increase in large mononuclear cells. The number of red cells infected seldom exceeds 2% of total cells. However, in severe falciparum malaria, parasitemia may reach 30% or higher; mature sexual forms disappear (sequestered in the microcirculation); hepatic function tests often become abnormal; and hemolytic jaundice, thrombocytopenia, and marked anemia with reticulocytosis may develop.

Differential Diagnosis

Uncomplicated malaria must be distinguished from a variety of other causes of fever, splenomegaly, anemia, or hepatomegaly. Often considered are influenza, urinary tract infections, typhoid fever, infectious hepatitis, dengue, kala azar, amebic liver abscess, leptospirosis, and relapsing fever. Malaria complications can mimic many diseases.

Prevention

Prevention is based on evaluating the risk of exposure to infection, preventing mosquito bites, and chemoprophylaxis. Advice should also be given regarding medical care if malaria-like symptoms occur while traveling. All persons who will be exposed should receive chemoprophylaxis. Travelers should be advised that in spite of all precautions, no prophylactic regimen gives complete protection. Fever or other symptoms can develop in malaria as early as 6 days (range: 6-60 days) after exposure or stopping prophylaxis; for *P vivax* infections, the delay may be up to 8-12 months.

A. Consultative Resources Regarding Risks, Chemoprophylaxis, and Treatment

Consultation with a center working on malaria may be necessary to obtain up-to-date information on malaria treatment and risk and prophylaxis by country. A World Health internet source is <http://www.who.int/ith/>. A source of information and advice in the USA is the Malarial Branch, Centers for Disease Control and Prevention (CDC), Atlanta, Georgia. Sites that provide recorded prophylaxis information for the public are telephone, 888-232-3224; fax response, 888-232-3299; and Internet, <http://www.cdc.gov> (choose the Travelers' Health category). For health care professionals: additional information on prophylaxis or for management of acute attacks, phone 770-488-7788; after business hours, 404-639-2888. See also CDC and WHO references, below.

B. Risk of Exposure

The risk of exposure to mosquitoes may be difficult to estimate since it varies by climate, rainy season, altitude, degree of mosquito control in urban versus rural areas, and according to whether exposure will occur during the time malaria mosquitoes are biting. Travel to urban areas of Central and South America and Southeast Asia entails minimal risk, and chemoprophylaxis is often not recommended for travelers to these areas.

C. Preventing Mosquito Bites

When out of doors between dusk and dawn (the primary feeding time for anopheles mosquitoes), protective measures should be used: Clothing should cover most of the body, and deet (*N,N*-diethyl-3-methylbenzamide) mosquito repellent should be applied to exposed areas every 3-4 hours. To minimize the slight risk of toxic encephalopathy from deet, it should be applied sparingly and only to exposed skin and outer clothing; avoid high concentrations (over 30%) of the repellent; avoid inhalation and contamination of eyes, mouth, wounds, or irritated skin; and wash skin after coming indoors. The Ultrathon formulation provides a reduced concentration of deet (33%) with extended protection (12 hours). Living quarters should preferably be air-conditioned or be well screened; if screening is not available, mosquito bed nets should be used at night, preferably ones impregnated every 6 months with permethrin (0.2 g/m²) (Permonone) or deltamethrin. To kill mosquitoes in living quarters, use an antimosquito pyrethrum-containing spray or a powdered insecticide dispenser of pyrethroid tablets or burn pyrethroid mosquito coils. Garments can also be impregnated (sprayed or soaked) with permethrin, which repels for several weeks.

D. Advice Regarding Treatment if Malaria-Like Febrile Symptoms Occur While Traveling

The traveler should insist that blood smears be done and, if negative, repeated at intervals. If malaria is suspected but blood smears cannot be done, malaria treatment should be started empirically.

Emergency ("standby") self-treatment is a recognized resource for individuals who may be exposed to malaria and for whom medical attention cannot be provided within 24 hours. Such persons are advised beforehand to carry medication for self-treatment if they develop fever or flu-like symptoms. However, *it is imperative that medical follow-up be sought promptly*. Patients should be given written instructions. The choice among available drugs depends on the anticipated type of exposure to drug-resistant *P falciparum* (see above for areas of resistance): (1) in chloroquine-sensitive areas, for persons who have taken no prophylaxis, use the chloroquine 3-day course of treatment (see [Table 35-3](#)); (2) in chloroquine-resistant areas without Fansidar resistance, use Fansidar (three tablets once only); or (3) in areas with Fansidar resistance, use Malarone (atovaquone plus proguanil) (four tablets daily for 3 days). Mefloquine, halofantrine, and quinine are not recommended because of their potential for toxicity.

Drugs Used in Chemoprophylaxis & Treatment (Tables 35-2 and 35-3)

A. Drug Classification

By chemical groups, some of the major antimalarial drugs are as follows: **4-aminoquinolines**—chloroquine, hydroxychloroquine, amodiaquine;* **diaminopyrimidines**—pyrimethamine, trimethoprim; **biguanides**—proguanil# (chlorguanide,* chlorproguanil*); **8-aminoquinolines**—primaquine; **cinchona alkaloids**—quinine, quinidine; **sulfonamides**—sulfadoxine, sulfadiazine, sulfamethoxazole; **sulfones**—dapson; **4-quinoline-carbinolamines**—mefloquine; and **antibiotics**—tetracycline, doxycycline, clindamycin; and **others**—halofantrine,* artemisinin (qinghaosu)* and its derivatives, and atovaquone.# Pyrimethamine and proguanil are known as **antifolates**, since they inhibit dihydrofolate reductase of plasmodia. **Drug combinations** used to treat chloroquine-resistant *P falciparum* malaria include Fansidar (pyrimethamine plus sulfadoxine), Maloprim (pyrimethamine plus dapson), and Malarone (atovaquone plus proguanil). Chloroquine combined with proguanil has been used in prophylaxis in sub-Saharan Africa but is no longer recommended by the Centers for Disease Control and Prevention. Artemisinin and its derivatives are being evaluated in combination with mefloquine or other drugs.

*Not available in the USA but available in some countries.

#Available in the USA but approved for antimalarial use only as the combination drug atovaquone/proguanil (Malarone).

The effectiveness of antimalarial drugs differs with different species of the parasite and with different stages of the life cycle. Drugs that act in the liver to eliminate developing exoerythrocytic schizonts or latent hypnozoites are called **tissue schizonticides** (primaquine). Those that act on blood schizonts are **blood schizonticides** or **suppressive agents** (eg, chloroquine, amodiaquine, proguanil, pyrimethamine, mefloquine, quinine, quinidine, halofantrine, artemisinin and its derivatives) and atovaquone. **Gametocides** are drugs that prevent infection of mosquitoes by destroying gametocytes in the blood (eg, primaquine for *P falciparum* and chloroquine for *P vivax*, *P malariae*, and *P ovale*). **Sporonticidal** agents are drugs that render gametocytes noninfective in the mosquito (eg, pyrimethamine, proguanil).

None of the drugs prevent infection (ie, are true **causal prophylactic drugs**). However, proguanil, chlorproguanil, atovaquone and primaquine—and to some extent the antibiotics—prevent maturation of the early *P falciparum*. Blood schizonticides destroy circulating plasmodia and thus prevent malarial attacks (**suppressive prophylaxis**) and, when given weekly for 4 weeks after departure from the endemic area, result in cure of *P falciparum* and *P malariae* infections. Only primaquine destroys the hypnozoites of *P vivax* and *P ovale* and, when given with a blood schizonticide, prevents relapse from infection with these parasites and thus effects **radical cure (terminal prophylaxis)**.

B. Parasite Resistance to Drugs

To slow the development of resistance, antimalarial drugs are increasingly being used in combination, eg, atovaquone-proguanil (Malarone) and artemisinin derivatives with mefloquine.

1. P falciparum resistance—Multidrug resistance (resistance to two or more drugs of different chemical classes)—most commonly resistance to chloroquine and the antifolates—is particularly frequent in East Africa, in focal areas of the Amazon basin, and in Southeast Asia. In areas bordering Thailand, mefloquine resistance is frequently present as well.

a. Chloroquine—Strains of *P falciparum* resistant to chloroquine have been confirmed or are probably present in all malarious areas except Haiti, the Dominican Republic, rural areas of Mexico, Central America north and west of the Panama Canal, North Africa, and most of the Middle East (resistance is present, however, in Oman, Yemen, Saudi Arabia, United Arab Emirates, and Iran). Countries with resistance in southern and eastern Africa are Kenya, Malawi, Mozambique, Tanzania, Uganda, and South Africa. In regions of resistance, some strains of *P falciparum* are only partially resistant to the drug, as manifested by temporary subsidence of symptoms and transient decrease or disappearance in asexual parasitemia, followed by return of both after several days to weeks.

b. Pyrimethamine-sulfadoxine (Fansidar)—Fansidar resistance is present at high levels in Southeast Asia, southern China, and the Amazon basin. Lower degrees are reported in sub-Saharan Africa (more in the east than the west), western Oceania, and parts of the Indian subcontinent and the Pacific coast of South America. Fansidar shows no cross-resistance with other antimalarial drugs.

c. Pyrimethamine or proguanil—Resistance to either of these drugs when used alone is common in most endemic areas, but the degree and distribution are not accurately known.

d. Mefloquine—Sporadic or low levels of mefloquine resistance have been reported from Southeast and southern Asia and parts of Africa, South America, the Middle East, and Oceania. Along the Thai-Burmese and Thai-Cambodian borders, however, the frequency reaches 30-60%.

e. Quinine and quinidine—Variable degrees of decreased responsiveness have been reported sporadically in Southeast Asia (particularly in the border regions of Thailand) and western Oceania and rarely in sub-Saharan Africa and South America.

f. Halofantrine—A high degree of resistance has been reported in eastern Thailand. Strains resistant to halofantrine are sometimes resistant to mefloquine as well.

g. Malarone—Rare instances of *P falciparum* resistance to Malarone have been reported worldwide.

h. Artemisinin derivatives—There are no known artemisinin-resistant *P falciparum* strains.

2. *P vivax* resistance—

a. Antifolates—Resistance of *P vivax* blood schizonts to pyrimethamine and proguanil, including the pyrimethamine-containing drugs Fansidar and Maloprim, has been reported in many areas of the world, particularly Southeast Asia.

b. Primaquine—Partial resistance of some strains of *P vivax* hepatic schizonts to primaquine has been reported in areas of Southeast Asia, (17% failure rate in Thailand), Papua New Guinea (30%), the Amazon Basin, Central America, and Somalia (43% in American military personnel). Treatment is usually successful with a higher dose (30 mg of base daily for 14 days) or a longer course (15 mg of base daily for 28 days).

c. Chloroquine—There are reports from Indonesia and Papua New Guinea of *P vivax* blood schizonts resistant to chloroquine. Decreased susceptibility is also appearing in the Solomon Islands, Myanmar, India, Thailand, Guyana, Brazil, Colombia, and Peru. Mefloquine, Malarone, halofantrine, or quinine plus doxycycline appear to be effective in treatment.

3. *P ovale* and *P malariae*—These forms have not shown resistance.

C. Selected Drugs: Indications, Limitations, and Adverse Side Effects

1. Chloroquine phosphate—Chloroquine is the drug of choice in chemoprophylaxis and in treatment for all forms of malaria except for infections due to resistant strains of *P falciparum* and *P vivax* (see above). However, in *P vivax* and *P ovale* infections, primaquine is needed to eradicate the persistent liver phases and thus prevent relapse.

Oral chloroquine is usually well tolerated when used for malaria prophylaxis or treatment and is safe to use in pregnancy. Transient gastrointestinal symptoms, mild headache, pruritus (especially in blacks), dizziness, blurred vision, anorexia, malaise, and urticaria may occur; taking the drug after meals or in divided twice-weekly doses may reduce these side effects.

In parenteral treatment of severely ill patients, quinine, quinidine, or the parenteral artemisinin derivatives are the preferred drugs. If none are available, chloroquine can be given intramuscularly or intravenously. However, parenteral chloroquine can be severely toxic unless it is given in small amounts (3.5 mg [base]/kg) intramuscularly every 6 hours or by slow intravenous infusion.

Rare reactions from oral chloroquine include impaired hearing, psychosis, convulsions, blood dyscrasias, skin reactions, hypotension, and hemolysis in G6PD-deficient persons. When given in large doses for prolonged periods as an anti-inflammatory agent in autoimmune diseases, chloroquine has caused ocular damage. Theoretically, a total cumulative dosage of 100 g (base) may be critical in the development of ocular, ototoxic, and myopathic effects. However, with weekly long-term administration of chloroquine, serious eye damage has not been confirmed; therefore, periodic eye examinations may no longer be indicated. Chloroquine should be used with caution in patients who have histories of liver damage, alcoholism, or neurologic or hematologic disorders. It is contraindicated in patients with psoriasis. Chloroquine suppresses the immune response to the rabies vaccine.

Certain antacids and antidiarrheal agents (kaolin, calcium carbonate, and magnesium trisilicate) should not be taken within about 4 hours before or after chloroquine administration, since they interfere with its absorption.

2. Mefloquine hydrochloride—Mefloquine, a quinoline methanol derivative, is used for oral prophylaxis and treatment of chloroquine-resistant and multidrug-resistant *P falciparum* malaria. In treatment, it is used only for mildly to moderately ill patients; severely ill patients require parenteral treatment with an alternative drug. Mefloquine has strong schizonticidal activity against the four malarial parasites (except for some *P falciparum* strains that are resistant to it)—but it is not active against *P falciparum* gametocytes or the hepatic stages of *P vivax* or *P ovale*, which require a course of primaquine. With weekly doses of mefloquine, the steady-state drug level is reached in about 7 weeks, and adverse reactions thus may not appear for 3-7 weeks. The steady-state interval can be reduced to 4 days, revealing adverse reactions within a week, by giving an initial course of 250 mg daily for 3 days followed by the standard weekly dose; this, however, is not standard practice.

With the lower doses used in prophylaxis, frequent (25-50%) minor and transient side effects are nausea, vomiting, epigastric pain, diarrhea, headache, dizziness, syncope, and extrasystoles. A small proportion of patients (up to 4%) experience anxiety, mood changes, insomnia, and nightmares. Severe neuropsychiatric symptoms are rare (estimated 1:10,000 to 1:1500). If prophylaxis is continued for more than a year, periodic liver function and ophthalmologic tests should be done. With treatment doses—particularly over 1000 mg—gastrointestinal symptoms and fatigue are more likely to occur, and the frequency of severe neuropsychiatric symptoms (visual disturbances, vertigo, tinnitus, insomnia, restlessness, anxiety, depression, confusion, disorientation, acute psychosis, or seizures) may be of the order of 1:1200. In experimental animals, the drug affects fertility and is teratogenic; it also causes degenerative changes in the epididymis in rats and in the lens and retina of some species. In human males, however, no deleterious effects on spermatozoa were found, and no effects have been noted in the human retina or lens. Because the drug may affect fine motor coordination and spatial orientation, caution in its use is recommended for pilots, drivers, and machinery operators.

Mefloquine is contraindicated in the presence of a cardiac conduction abnormality, liver impairment, or a history of a psychiatric or neurologic disorder, including epilepsy. Also contraindicated is concurrent administration of mefloquine with quinine, quinidine, chloroquine, or halofantrine. If these drugs precede use of mefloquine, 12 hours should elapse before mefloquine is started; however, because of the long elimination half-life of mefloquine (13-26 days), extreme caution is required because of arrhythmias if one of these drugs is used to treat malaria after mefloquine has been taken. Concurrent administration with tetracyclines or ampicillin results in increased mefloquine blood levels.

The development of neuropsychiatric symptoms during prophylaxis is an indication for stopping the drug. Patients taking anticonvulsant drugs may have breakthrough seizures. The drug is no longer contraindicated when beta-blockers and calcium channel blockers are taken. CDC has recently advised that mefloquine can be used throughout pregnancy; nevertheless, its use during the first trimester should be based on risk-benefit assessment. Women of childbearing potential who take mefloquine for antimalarial prophylaxis should preferably avoid conception for the duration of mefloquine usage and for 2 months after the last dose.

Note: The tablet formulation in the USA contains 250 mg of the salt (= 228 mg of base). However, in Canada and many other countries, the tablets contain 274 mg of the salt (= 250 mg of base). Mefloquine should not be taken on an empty stomach and should be taken with 8 oz of water.

3. Malarone—Malarone—atovaquone 250 mg and proguanil 100 mg—is a fixed-combination oral medication recently approved in the USA for prophylaxis and treatment of multidrug-resistant falciparum malaria, *P vivax*, and *P ovale*; effectiveness against *P malariae* has not been determined. In a limited number of studies in nonimmune adults, Malarone's prophylactic efficacy was 98% against *P falciparum* and 84% against *P vivax*. In treatment, its use is currently limited to uncomplicated malaria; its effectiveness in cerebral and other forms of complicated disease remains to be determined.

Malarone's components, proguanil and atovaquone, used together, are synergistic, but failures are frequent to either component used alone. Because the agents are effective against the liver and blood stages of *P falciparum*, only 7 days of treatment are needed after leaving an endemic area, and primaquine is not required to eradicate a falciparum infection. In *P vivax* and *P ovale* infections, however, in which the components are effective only against the erythrocytic stage, primaquine must be used to eradicate the exoerythrocytic forms. Malarone supersedes Fansidar as the preferred drug for standby treatment (see above).

Malarone appears to be better tolerated than chloroquine or mefloquine. The drug is taken orally with food or milk to increase absorption of atovaquone and to reduce gastrointestinal toxicity (nausea, vomiting, epigastric discomfort, headache). These symptoms may also be reduced by giving the drug in divided doses twice daily. Other side effects include headache, rash, and mild reversible elevations of liver aminotransferases. One case of anaphylaxis has been reported. There are insufficient data to allow Malarone to be used in pregnancy. Concomitant administration of Malarone with rifampin, tetracycline, or metoclopramide is associated with 40-50% reductions in atovaquone plasma levels.

4. Primaquine phosphate—Primaquine is used to prevent relapse by eliminating persistent liver forms of *P vivax* or *P ovale* in patients who have had an acute attack and for individuals returning from an endemic area who have probably been exposed to malaria. However, in persons with a low probability of exposure, it is preferable to avoid primaquine's potential toxicity by not giving the drug. Instead, such patients are advised to seek medical evaluation in the event of malaria-like symptoms, which usually occur within 2 years after infection but can occur up to 4 years after. Because primaquine is effective against the liver stages of all malarial parasites, it has been reevaluated recently for chemoprophylaxis when taken daily. A prophylactic efficacy of 85-95% has been shown against *P falciparum* and *P vivax* with apparent safety in long-term use, though the drug is not licensed for this indication. Primaquine is sometimes given as a single 45- mg (base) dose to eliminate *P falciparum* gametocytes.

Primaquine is generally well tolerated. Occasional side effects of the drug are gastrointestinal disturbances, headache, dizziness, or neutropenia. Primaquine should not be used in pregnancy (risk of hemolytic disease in the fetus), in autoimmune disorders, or concurrently with quinine.

All patients should be tested for glucose-6-phosphate dehydrogenase (G6PD) deficiency before therapy is begun and followed carefully during treatment; this is

because primaquine may cause mild, self-limited hemolysis or marked hemolysis (pallor, weakness, abdominal pain, dark urine) or methemoglobinemia. G6PD deficiency is most common among persons of Mediterranean, African, or certain East Asian extractions. Patients with severe G6PD deficiency (< 10% residual enzyme activity) should not receive primaquine. For individuals with 10-60% residual activity, it is generally safe to give combined primaquine phosphate, 78.9 mg (45 mg base), and chloroquine phosphate, 0.5 g (0.3 g base), weekly for 8 weeks. However, for persons suspected of having the Mediterranean or Canton forms of G6PD deficiency, it may be preferable not to give primaquine but to treat attacks of malaria with chloroquine as they occur. Under development is tafenoquine, a congener of primaquine; it is more slowly eliminated than primaquine and is probably less toxic.

5. Quinine—Oral quinine sulfate in conjunction with another drug (see [Table 35-3](#)) is used to treat malaria due to multidrug-resistant strains of *P falciparum*; however, compliance with the 7-day course is poor because of quinine side effects.

Because quinine is an irritant to the gastric mucosa, it should be taken with food. Mild to moderate quinine toxicity (cinchonism) is manifested by headache, nausea, slight visual disturbances, dizziness, and mild tinnitus. These symptoms may abate as treatment continues and usually do not require discontinuation of treatment. Where available, quinine blood levels can be monitored; desired plasma levels are 5-10 ug/mL. Severe cinchonism requiring temporary or permanent discontinuation of therapy is rare and begins to appear at plasma levels greater than 7 ug/mL; findings include fever, skin eruptions, deafness, marked visual abnormalities (scotomas, diplopia, contracted visual fields, retinal vessel spasticity, optic atrophy, blindness), other central nervous system abnormalities (vertigo, somnolence, confusion, seizures), disturbances in cardiac rhythm or conduction, massive intravascular hemolysis with renal failure (blackwater fever), agranulocytosis, and thrombocytopenia.

Parenteral quinine dihydrochloride is used in the treatment of severe attacks of malaria due to *P falciparum* strains sensitive or resistant to chloroquine. The drug is given intravenously at a slow rate (see [Table 35-3](#)); rapid infusions may be severely toxic. The drug should be used with extreme caution and only for patients who cannot take the medication orally; appropriate oral therapy should be started as soon as possible. Infusions may cause thrombophlebitis. In the USA, parenteral quinine is no longer available and parenteral quinidine gluconate is used instead.

Manufacturers' recommendations for drug interactions (including aluminum-containing antacids, digoxin, anticoagulants, and cimetidine) should be consulted. Quinine is safe to use in pregnancy. Systemic clearance of quinine slows in proportion to the severity of the disease.

6. Quinidine gluconate—Quinidine is the dextrorotatory diastereoisomer of quinine. The two drugs are equally efficacious in parenteral treatment of severe malaria ([Table 35-3](#)). The two drugs are also similar with regard to toxicity and drug interactions, but quinidine has a greater cardiosuppressant effect. The principal adverse effect of quinine and quinidine in severe malaria is hypoglycemia, which usually develops after 24 hours of treatment; it is a particular problem in pregnancy.

7. Halofantrine—Halofantrine is a schizonticide for all four malaria species, including multidrug-resistant *P falciparum*. The drug is not active against hepatic stages or gametocytes. It is used only in oral treatment and not for severe malaria. Infrequent to rare, minor side effects are abdominal pain, diarrhea, cough, rash, and pruritus. The drug should not be given from 1 hour before to 3 hours after a meal, because fatty food enhances and results in irregular absorption. Halofantrine is not used for prophylaxis or standby treatment because of this variable bioavailability; because the standard dose prolongs the QT_c interval; and because there have been rare reports of ventricular arrhythmias, sometimes fatal. The drug should not be used in the presence of preexisting cardiac conduction defects, long QT intervals, recent (4 weeks) usage of or concomitant treatment with mefloquine, or treatment with other drugs that prolong the QT interval (ie, quinine, quinidine, chloroquine, tricyclic antidepressants, neuroleptic drugs, terfenadine, astemizole). Because halofantrine is embryotoxic in animals, it should not be given to pregnant women. Halofantrine is widely available abroad; in the USA, however, although approved by the FDA, it has not been marketed.

8. Pyrimethamine-sulfadoxine (Fansidar)—Fansidar is supplied as tablets that contain pyrimethamine (25 mg) and sulfadoxine (500 mg). Fansidar's limitations are that it is effective only against susceptible strains of *P falciparum* (see above); its low efficacy against *P vivax*, *P ovale*, or *P malariae*; and the fact that it is slow-acting. Fansidar is no longer used for weekly prophylaxis because of rare reports of severe cutaneous toxicity and death. However, in single-dose treatment, Fansidar is generally well tolerated. Cutaneous reactions are more common in persons who are HIV-positive.

Current indications for Fansidar are (1) as a single dose (slow-acting) in conjunction with quinine (rapid-acting) in treatment of sensitive strains of acute chloroquine-resistant falciparum malaria and (2) in presumptive self-treatment of malaria (see above).

Fansidar is contraindicated for individuals with known sulfonamide sensitivity and those in the last month of pregnancy (the sulfadoxine component, which has a long half-life, can cause kernicterus in the newborn). The drug should be used with caution in the presence of impaired renal or hepatic function, in patients with G6PD deficiency (hemolysis occurs in some), and in those with severe allergic disorders or bronchial asthma. If folic acid is needed, ingestion should be delayed 1 week to avoid an inhibitory effect on the antimalarial action of Fansidar.

9. Doxycycline—Doxycycline is effective against chloroquine-sensitive and chloroquine-resistant *P falciparum*, *P vivax*, and (apparently) against *P ovale* and *P malariae*. It is used prophylactically against chloroquine-resistant and mefloquine-resistant falciparum malaria in Thailand and adjacent countries and elsewhere for patients who cannot tolerate mefloquine ([Table 35-2](#)). Doxycycline is also used as an adjunct drug with quinine for the treatment of resistant falciparum malaria ([Table 35-3](#)). Side effects include infrequent gastrointestinal symptoms (take with meals—but not at bedtime—plus copious amounts of water to avoid esophageal irritation; avoid milk, which reduces absorption); candidal vaginitis (advise carrying a self-treatment antifungal regimen, either vaginal suppositories or cream); and rare photosensitivity (prevention may be achieved by use of sunscreens that absorb ultraviolet radiation (UVA) and by avoidance of exposure to direct sunlight as much as possible). The drug is contraindicated in pregnancy, in nursing mothers, in children under 8 years of age, and in persons with hepatic dysfunction. No data are available on the long-term use of the drug.

10. Artemisinin (qinghaosu) and its derivatives—Artemisinin and its derivatives are available in some countries but not in the USA. The drugs are rapid-acting and effective against all malarial parasites and are gametocidal, but they are not active against the persistent liver stages of *P vivax* and *P ovale*. Artesunate, considered the most rapid-acting form, is water-soluble and is given orally or by intravenous infusion. Other parenteral preparations are oil-soluble artemether (erratically absorbed) and the newly marketed artemotil. Rectal suppository formulations are sometimes available. Having shown no parasite resistance, the artemisinin drugs are the only agents that remain reliably active against multidrug-resistant *P falciparum*, including agents resistant to quinine. The drugs are used only to treat acute malaria, including severe malaria; however, because of their short half-lives, they cannot be used in prophylaxis. As recrudescences are common after treatment (50%), the drugs are not used alone but in combination with a long-acting drug (eg, mefloquine). Mild adverse events—symptoms that also occur in malaria—are headache, gastrointestinal symptoms, pruritus, and fever. Instances of allergic reactions have been described. Animal studies suggest a potential for embryotoxicity (opinions differ on the safety of the drug in pregnancy) and central nervous system toxicity (but this has not been demonstrated in human prospective studies). A new combination drug, lumefantrine (120 mg) combined with artemether (20 mg), when given as six doses over 3-5 days to a relatively small group of uncomplicated falciparum malaria cases, was well tolerated and showed cure rates of 98%.

11. Proguanil—Proguanil (chlorguanide, Paludrine; not available in the USA), 200 mg/d, is a schizonticide against three of the malaria parasites (unknown degree against *P malariae*) and has some causal prophylactic action but it is no longer used alone. Proguanil (100 mg) in combination with atovaquone (250 mg) (Malarone) has recently been approved in the USA for prophylaxis and treatment of multidrug-resistant falciparum malaria. Proguanil (100 mg daily) in combination with chloroquine (0.5 g weekly) for prophylaxis in areas with low-intensity chloroquine-resistant *P falciparum* is no longer recommended in this text. Rarely reported side effects are nausea, vomiting, hair loss, and mouth ulcers. The drug is safe to use in pregnancy; it should not be used in persons with hepatic or renal dysfunction.

Chemoprophylaxis for Nonimmune Populations

See [Table 35-2](#) for methods and dosages and under the individual drugs (above) for details on cautions, contraindications, and toxicities.

Antimalarials should be taken with water at mealtime. The selected drug should be tested for side effects in advance of departure (to allow time for selection of an alternative drug if necessary) and started sufficiently in advance of exposure that a satisfactory prophylactic blood level is achieved. On returning home, primaquine is given to eradicate persistent liver stages of *P vivax* or *P ovale* if there has been significant exposure to these parasites (see above under Primaquine).

A. Chemoprophylaxis in Regions Where *P falciparum* Is Sensitive to Chloroquine

1. Drug of choice—Chloroquine prevents attacks for all forms of malaria and is curative for *P falciparum* and *P malariae* when taken for 4 weeks after leaving the endemic area. For persons who cannot tolerate chloroquine, reducing the dose to 250 mg twice weekly or switching to hydroxychloroquine sulfate (400 mg [salt]) can be tried.

2. Alternative drugs—Mefloquine, Malarone, and doxycycline are alternatives to chloroquine. Schizonticides *not used for chemoprophylaxis* are halofantrine (erratic absorption and variable bioavailability), Fansidar (hypersensitivity reactions with rare deaths), amodiaquine (agranulocytosis and toxic hepatitis), pyrimethamine (widespread resistance of both *P falciparum* and *P vivax*), artemisinin and related drugs (short duration of action), proguanil by itself (resistance), and generally quinine (toxicity).

B. Chemoprophylaxis in Regions Where *P falciparum* Is Resistant to Chloroquine

1. Drugs of choice—Mefloquine is preferred, but it has more side effects. Alternative drugs are Malarone and doxycycline.

2. Second alternative drugs—There is continuing evaluation of primaquine (30 mg base) starting 1 day before entering the endemic area, daily while there, and for 7 days afterward. The drug is not licensed for this use in the USA and is contraindicated in pregnancy and in persons with G6PD deficiency. Under evaluation is tafenoquine, an analog of primaquine that is more potent than the parent drug and will require only weekly doses. Under exceptional circumstances, chloroquine and proguanil plus an emergency standby drug (see above) can be considered but are less efficacious—or use of daily quinine.

C. Chemoprophylaxis in Southeast Asia

Multidrug *P falciparum* resistance is extensive in Southeast Asia. The drugs of choice are doxycycline, Malarone (limited supporting data), and artesunate-mefloquine. Chloroquine and Fansidar cannot be used throughout the region, and resistance to mefloquine and halofantrine has increased significantly.

D. Prophylaxis for Pregnant Women

Pregnant women should be protected; malaria infection during pregnancy may be particularly severe. Drugs contraindicated in pregnancy are doxycycline, Malarone, and primaquine. Therefore, the best course is weekly chloroquine (or hydroxychloroquine) with or without proguanil. In areas of chloroquine-resistant malaria, mefloquine can be used except that data are limited on its safety in the first trimester. Generally, therefore, travel by pregnant women to resistant areas is not recommended.

E. Emergency Self-Treatment

In selected instances, medication should be provided for emergency self-treatment of breakthrough attacks (see above).

Treatment of Acute Attacks

See under individual drugs and [Table 35-3](#) for dosages.

A. General Considerations

At times when parasitologic confirmation is not readily available, it may be necessary to start treatment immediately based only on clinical findings. Patients with falciparum infections should be hospitalized. It is important to determine whether a patient has been treated with antimalarials in the previous 1-2 days (3 weeks for mefloquine because of its slow excretion) to avoid the risk of overdose or adverse drug interactions. In the event of mefloquine prophylaxis or treatment failure, it is hazardous—although it may be essential—to use quinine, quinidine, or halofantrine ([Table 35-3](#)); under these circumstances, the safest drug to use is artemisinin or one of its derivatives (not available in the USA).

It is essential to determine the density of parasites on the blood smear (as a measure of severity of infection) and to recheck at least twice daily. Within 48-72 hours after start of treatment, patients usually become afebrile and improve clinically; within 48 hours, parasitemia is generally reduced by about 75% (though there may be an initial increase during the first 6-12 hours). If there is no improvement within 48-72 hours for mild infections or 24 hours for severe ones or if there is increasing asexual parasitemia after 1-2 days (in the presence of adequate drug ingestion and retention), parasite resistance to the drug must be assumed and treatment changed.

B. Drug Treatment of All Forms of Malaria Except *P falciparum* and *P vivax* Strains Resistant to Chloroquine ([Table 35-3](#))

1. Elimination of asexual erythrocytic parasites—Infection by all four species of malaria is treated with oral chloroquine. Alternative oral drugs if chloroquine cannot be tolerated are mefloquine, Malarone, quinine sulfate (plus doxycycline, clindamycin, or Fansidar), atovaquone plus doxycycline, or halofantrine.*

If the patient is severely ill, treat with intravenous quinine dihydrochloride* or quinidine gluconate, parenteral preparations of artemisinin derivatives,* or parenteral chloroquine. Start oral therapy with chloroquine as soon as possible.

2. Eradication of *P vivax* or *P ovale* infections—This is accomplished with a standard course of primaquine ([Table 35-3](#)) except in regions of rare partial resistance, where a higher dosage or longer course of treatment is needed (see above).

3. Elimination of persistent gametocytemia—Gametocytes of *P vivax*, *P ovale*, and *P malariae* can be eliminated by chloroquine. Gametocytes of *P falciparum* are eliminated by a single dose of 26.3 mg of primaquine salt.

4. Treatment of semi-immunes—Treatment of attacks in semi-immune patients generally requires shorter courses of drug treatment.

C. Drug Treatment of Falciparum Malaria Acquired in Areas Where *P falciparum* Is Resistant to Chloroquine

Start treatment with oral quinine sulfate and a second drug ([Table 35-3](#)) (but not Fansidar if the infection was acquired in an area with Fansidar resistance). Alternative drugs are mefloquine, Malarone, artesunate* followed by mefloquine, or atovaquone plus doxycycline. In Southeast Asia, mefloquine used alone and halofantrine may not be effective because of multidrug resistance.

If the patient is severely ill, treat with intravenous quinine or quinidine ([Table 35-3](#)). A second drug (doxycycline or clindamycin) should also be given parenterally. Oral treatment with quinine plus the antibiotic should be started as soon as possible. An alternative approach is parenteral artesunate* or artemether* followed by mefloquine (not highly effective in Southeast Asia).

*Not available in the USA but available in some countries.

D. Special Measures for Management of Severe *P falciparum* Malaria

(See references for further details.) Severe and complicated falciparum malaria is a medical emergency that requires hospitalization, intensive care with monitoring of electrolytes and acid-base balance, and immediate treatment without waiting for all laboratory results to become available. Indications for parenteral treatment are (1) failure to ingest or retain drugs, (2) cerebral malaria, (3) multiple complications, and (4) peripheral asexual parasitemia of 5% (250,000/uL) or higher. When possible, parenteral treatment should be intravenously, but quinine, artesunate, and chloroquine can be given intramuscularly; chloroquine can also be given subcutaneously. Black urine suggests hemoglobinuria. Renal failure, metabolic acidosis, pulmonary edema, gram-negative sepsis, jaundice, severe anemia, and shock may ensue. Rehydration of the patient should be done with great caution, particularly in the first 24 hours, since overhydration may precipitate noncardiogenic pulmonary edema. In general, 2-3 L of fluid is required the first day, followed by 10-20 mL/kg/d; intake and output should be carefully recorded. After rehydration, the central venous pressure should be maintained at approximately 5 cm of water (pulmonary artery occlusion pressure < 15 mm Hg). Early dialysis may be necessary for renal failure and then sustained for 4-7 days or longer. Blood glucose levels should be monitored every 6 hours during the acute and early convalescent period, since hypoglycemia may be severe, either as a result of the malaria infection or the use of quinine or quinidine; treatment is with 50 mL of 50% dextrose (1-2 mL/kg) followed by maintenance infusion of 5-10% dextrose. Low glucose levels should be rechecked hourly. In cerebral malaria, one should maintain the airway and exclude other treatable causes of coma (hypoglycemia, bacterial meningoencephalitis). The presence of papilledema is a contraindication to lumbar puncture. With convulsions, one should maintain the airway and treat with diazepam (0.15 mg/kg intravenously or 0.5 mg/kg rectally) or with paraldehyde (0.1 mL/kg intramuscularly, preferably dispensed from a glass syringe). The temperature is kept below 38.5 °C using acetaminophen (paracetamol) plus tepid sponging and fanning. Patients with clinically significant disseminated intravascular coagulation should be treated with fresh whole blood, clotting factors, or platelets as needed. For hematocrits below 20% or hemoglobins below 7 g/dL, transfusion of fresh whole blood or packed cells is required. Bacterial infections are common (eg, pneumonia, cystitis, salmonellosis). Exchange transfusion (5-10 L) should be considered when more than 10% of red blood cells are parasitized (5% if severe dysfunction of other organs is present). Corticosteroids, aspirin, other anti-inflammatory agents, dextran, norepinephrine, and heparin should not be used.

Follow-Up for *P falciparum* Malaria

Blood films should be checked daily until parasitemia clears; check weekly thereafter for 4 weeks to observe for recrudescence of infection.

Prognosis

The uncomplicated and untreated primary attack of *P vivax*, *P ovale*, or *P falciparum* malaria usually lasts 2-4 weeks; that of *P malariae* about twice as long. Attacks of each type of infection may subsequently recur (once or many times) before the infection terminates spontaneously. With prompt antimalarial therapy, the prognosis is generally good, but in *P falciparum* infections, when severe complications such as cerebral malaria develop, the prognosis is poor (14-17% mortality) even with treatment. It is now recognized that after cerebral malaria, residual neurologic deficits can occur.

TOXOPLASMOSIS

Essentials of Diagnosis

Acute primary infection:

- Fever, malaise, headache, lymphadenopathy (especially cervical), myalgia, arthralgia, stiff neck, sore throat; occasionally, rash, hepatosplenomegaly, retinochoroiditis, confusion; in various combinations.
- Positive serologic tests with high and rising IgG and IgM.
- Isolation of *Toxoplasma gondii* from blood or body fluids; tachyzoites in histologic sections of tissue or cytologic preparations of body fluids.

Acute primary or recrudescent infection in immunocompromised patients:

- Central nervous system mass lesions; retinochoroiditis, pneumonitis, myocarditis less common; sometimes other findings as above.
- Positive IgG titers moderately high; IgM antibody usually absent. Tissue diagnosis as above.

General Considerations

T gondii, an obligate intracellular protozoan, is found worldwide in humans and in many species of animals and birds. The parasite is a coccidian of cats, the definitive host, and exists in three forms: The *trophozoite* (tachyzoite) (3×7 μ m) is the rapidly proliferating form in tissues and body fluids that causes acute disease. The trophozoites can enter and multiply in most mammalian nucleated cells. The *cyst*, containing viable bradyzoites, is the latent form that can persist indefinitely as a chronic infection and is found particularly in muscle and nerve tissue. The *oocyst* is the form passed only in the feces of the cat family. In the intestinal epithelium of cats, a sexual cycle occurs, with subsequent release of oocysts for 3-14 days; cats may, however, become reinfected and excrete oocysts multiple times. The oocysts, which contain infective sporozoites, are infectious within 12 hours to several days after passage and can remain infective in moist soil for weeks or months.

Human infection results (1) from ingestion of cysts in raw or undercooked meat; (2) from ingestion of oocysts in contaminated food or water, by careless handling of contaminated cat litter, or from soil by soil-eating children; (3) from transplacental transmission of trophozoites; or (4) rarely, from direct inoculation of trophozoites, as in blood transfusion. Reservoirs of human infection are rodents and birds eaten by cats and infected domestic animals used for food. Antibody prevalence rates range from less than 5% in some parts of the world (absence of cats and minimal ingestion of meat) to 15-29% in the USA and over 80% in France.

On ingestion, bradyzoites (from cysts) or sporozoites (from oocysts) invade multiple cell types and propagate as trophozoites; cell death and inflammation follow, but true granulomas do not form.

Clinical Findings

A. Symptoms and Signs

Over 80% of primary infections are asymptomatic. The incubation period for symptomatic persons is 1-2 weeks. Generally, on recovery, both asymptomatic and symptomatic infections persist as chronic latent (cyst) infections. Reactivation occurs almost exclusively in severely immunocompromised patients.

The clinical manifestations of toxoplasmosis may be grouped into four syndromes:

1. Primary infection in the immunocompetent host—Most symptomatic infections are acute, mild, febrile multisystem illnesses that resemble infectious mononucleosis. Lymphadenopathy, usually nontender, particularly of the head and neck, is the most common finding. Other features in various combinations are malaise, myalgia, arthralgia, headache, sore throat, and maculopapular or urticarial rash. Hepatosplenomegaly may occur. Rarely, severe cases are complicated by pneumonitis, meningoencephalitis, hepatitis, myocarditis, and retinochoroiditis. Symptoms may fluctuate, but most patients recover spontaneously within a few months.

2. Congenital infection—Congenital transmission occurs only as a result of infection (generally asymptomatic) in a nonimmune woman during pregnancy. Infection has been detected in up to 1% of women during pregnancy; 15-60% of such infections, the incidence varying by trimester, are transmitted to the fetus, but only a small percentage result in abortions or stillbirths or in active disease in premature or full-term, live-born infants. Though fetal infection may occur in any trimester, it is more severe early in pregnancy. Among all congenital infections, less than 15% show severe brain or eye damage at birth; however, of the apparently normal newborns, more than 85% will develop brain or eye sequelae later in life. Treatment of the mother reduces the congenital infection rate by about 60%. See specialized sources for clinical manifestations and approach to diagnosis.

3. Retinochoroiditis—This develops gradually weeks to years after congenital infection (the preponderant form, which is generally bilateral) or rarely after an acquired infection in a young child (generally unilateral). Acquired infections in older children and adults rarely progress to retinochoroiditis. The inflammatory process persists for weeks to months as focally necrotic retinal lesions (yellow or white patches with blurred margins). Visual defects, which include blurring, central defects, and scotomas, are accompanied by pain and photophobia. Rarely, progression may result in glaucoma and blindness. With healing, white or dark-pigmented scars may result. Panuveitis may accompany retinochoroiditis.

4. Reactivated disease in the immunologically compromised host—Reactivated toxoplasmosis occurs in patients with AIDS, cancer, or those given immunosuppressive drugs. The infection may present in specific organs (brain, lungs, and eye most commonly, but also heart, skin, gastrointestinal tract, and liver) or as disseminated disease. Between 30% and 50% of AIDS patients seropositive for past toxoplasma infection will develop meningeal (uncommon), mass (single or multiple), or diffuse intracerebral toxoplasma lesions associated with clinical findings of fever, headache, altered mental status, seizures, and focal (or, infrequently, nonfocal) neurologic deficits (see also [Chapter 31](#)).

B. Laboratory Findings

Diagnosis depends principally on serologic tests, which are sensitive and reliable. However, diagnosis is occasionally made from tissue (blood, bone marrow aspirates, cerebrospinal fluid sediment, sputum, and other tissues or body fluids or placental tissue) either by (1) demonstration of trophozoites or characteristic histology, (2) isolation of the organism in mice (more sensitive) or in tissue culture (more rapid, 3-6 days), or (3) amplification of *T gondii* DNA by polymerase chain reaction (PCR). Infrequently used is detection of circulating antigen or antigen in serum and body fluids. Interpretation of the results and deciding which patients should be treated or when to advise termination of a pregnancy may require assistance from a reference or research laboratory with large experience in toxoplasmosis.

1. Histology—Cysts or trophozoites may be directly identified in blood (buffy coat from centrifuged heparinized blood), other tissues, or body fluids by staining with standard stains or with specific antibody marked with fluorescein. Demonstration of cysts in biopsied tissue does not establish a causal relationship to clinical illness, since cysts may be found in both acute and chronic infections. However, finding tachyzoites confirms active infection. In the placenta, fetus, or newborn, the presence of cysts does indicate congenital infection.

2. Serologic tests—The Sabin-Feldman dye test, indirect hemagglutination, indirect immunofluorescence (IFA), ELISA, and other tests can be done on blood, cerebrospinal fluid, aqueous humor, and other body fluids. The dye test is the standard but is rarely used because of laboratory safety factors; though extremely sensitive and specific, it does not separate IgM from IgG antibody. The ELISA, immunosorbent, and IFA tests do separate IgM and IgG antibody. IgM antibody appears 1-2 weeks after start of infection, reaches a peak at 6-8 weeks, and then gradually declines over 18 months. As IgM antibody can persist for 5 years or longer, a positive finding does not necessarily represent recent infection; however, a negative finding does rule out acute infection acquired in recent months. Maternal IgM is normally unable to cross the intact placenta; antibody which does pass through a leak has a half-life of only 3-5 days. IgG antibody appears within 1-2 weeks, peaks in 1-2 months, and may persist at high titers for many years and then at low levels for life. When positive, it reliably indicates present or past infection; a negative result reliably rules out either time frame.

The following are selected serologic and other findings in specific toxoplasmosis syndromes:

a. Acute infection in immunocompetent persons—In screening, test initially for IgG antibody, which reliably establishes the presence or absence of infection. In a few patients, antibody may not be detectable within 3 weeks of initial infection; if acute disease is suspected, test again in 3 weeks. The diagnosis is established by seroconversion from negative to positive or by a fourfold rise in serologic titers by any test. Acute infection can also be diagnosed by detection of tachyzoites in tissue, isolation of organism, or amplification of its DNA in blood or body fluids. The presence of circulating ELISA-IgA also favors the diagnosis of acute infection; the test is not available in the USA. A presumptive diagnosis is based on a single IgM titer of over 1:64 and a very high IgG titer (> 1:1000). However, because of the relatively high frequency of false-positive IgM tests, confirmatory testing should always be done, preferably in a reference laboratory.

b. Recrudescence infection in immunosuppressed patients—In AIDS patients, toxoplasma can sometimes be isolated from the blood. Alternatively, definitive diagnosis is only by finding toxoplasma organisms in cerebrospinal fluid (Wright-Giemsa stain or by PCR amplification) or by brain biopsy. To avoid the latter, empirical antibiotic treatment is generally started after presumptive evidence is obtained by MRI (the more sensitive test) or CT scan (typically: multiple, isodense or hypodense, ring-enhancing mass lesions). Single-photon emission CT is under evaluation as a highly specific diagnostic method. Antibody titers cannot be depended on, since most patients have IgG titers that reflect past infection, significant rises are infrequent, and IgM antibody is rare. Absence of IgG does not rule out the diagnosis of toxoplasmic retinochoroiditis. The cerebrospinal fluid may show mild pleocytosis (predominantly lymphocytes and monocytes), elevated protein, and normal glucose. (See also [Chapter 31](#).)

c. Toxoplasmic retinochoroiditis—This is usually associated with stable, usually low IgG titers and no IgM antibody. If IgG antibody in aqueous humor is higher than in the serum, the diagnosis is supported.

d. Congenital infection—The most useful tests for confirmation of fetal infection are ultrasound examination, amniocentesis for detection of toxoplasma DNA in amniotic fluid by PCR, and cordocentesis for detection of IgM-specific antibody. A negative result for IgM antibody does not exclude the diagnosis. Postpartum, however, a positive IgM after 1 week is diagnostic; IgG antibody, however, is nearly always present if the mother is positive, but that passively transferred antibody disappears in 6-12 months.

3. Other laboratory findings—Leukocyte counts are normal or reduced, often with lymphocytosis or monocytosis with rare atypical cells, but there is no heterophil antibody. Chest radiographs may show interstitial pneumonia. In cerebral imaging studies in HIV-infected persons, toxoplasmosis typically appears as multiple lesions with a predilection for the basal ganglion.

Differential Diagnosis

In acute febrile disease, consider cytomegalovirus infection, infectious mononucleosis, and other causes of pneumonitis, myocarditis, myositis, hepatitis, and splenomegaly. With lymphadenopathy, possibilities include sarcoidosis, tuberculosis, tularemia, lymphoma, cat-scratch disease, and metastatic carcinoma. With brain lesions in the immunosuppressed host, consider lymphoma, tuberculoma, brain abscess, metastatic carcinoma, and fungal lesions.

Treatment

A. Approach to Treatment

In immunocompetent hosts, the lymphadenopathic form of the disease is usually not treated unless findings are severe or persistent or there is overt visceral disease. If treatment is started, it should continue for 3-4 weeks and the patient reevaluated. Serologic tests are not useful for evaluating response to treatment.

Since most episodes of retinochoroiditis are self-limited, opinions vary on indications for and type of treatment. (See specialized texts.)

Immunocompromised patients with active infection (primary or recrudescence) must be treated. See [Chapter 31](#) for details. Therapy should continue for 4-6 weeks after cessation of symptoms, which may require up to a 6-month course, to be followed by drug prophylaxis as long as immunosuppression persists. In HIV-infected persons, acute toxoplasmosis must be treated, followed by continued prophylaxis; in patients who have a positive IgG toxoplasma serology but are asymptomatic, prophylaxis is desirable.

Congenitally infected newborns should be treated; for details on management, see specialized sources.

B. Choice of Drugs

The treatment of choice in nonimmunocompromised patients is pyrimethamine, 25-100 mg once daily, plus either trisulfapyrimidines (4-6 g/d in four divided doses) or sulfadiazine, 1-1.5 g four times daily; continue this treatment for 3-4 weeks. Folinic acid (leucovorin), 10-25 mg with each dose of pyrimethamine, should be given concurrently to avoid bone marrow suppression. Patients should be screened for a history of sulfonamide sensitivity (skin rashes, gastrointestinal symptoms, hepatotoxicity). To prevent crystal-induced nephrotoxicity, good urine output should be maintained; alkalization with sodium bicarbonate may also be useful. Pyrimethamine side effects include headache and gastrointestinal symptoms. Platelet and white blood cell counts should be performed at least twice weekly. Clindamycin (600 mg four times daily) may be a useful alternative drug; because it concentrates in the choroid, it is also used in the treatment of ocular disease. Atovaquone (750 mg three or four times daily), dapsone, other macrolides, and immunotherapy are under evaluation.

To decrease the incidence of fetal infection in toxoplasmosis in pregnancy—it is not possible to eliminate all infections—spiramycin is given at a dosage of 3 g daily in four divided doses for 3-4 weeks. Because spiramycin does not reliably cross the placenta, if fetal infection is shown to be already present and fetal treatment is planned, treatment should include sulfadiazine (4 g/d in divided doses) and pyrimethamine (25/mg/d in divided doses plus folinic acid, 5-15 mg/d). The latter two drugs should not be given if the patient is within the first 12-14 weeks of pregnancy, when pyrimethamine can be teratogenic. Spiramycin is not effective in other forms of toxoplasmosis. In the USA, the drug is available from the manufacturer.

For the treatment of central nervous system toxoplasmosis in HIV-infected and immunocompromised persons, see [Chapter 31](#).

Prevention

Freezing of meat to -20 °C for 2 days or heating throughout to 60 °C for 4 minutes kills cysts in tissues. Hands, kitchen surfaces, and cooking utensils must be thoroughly cleaned after contact with raw meat. Under appropriate environmental conditions, oocysts passed in cat feces can remain infective for a year or more. Thus, children's play areas, including sandboxes, should be protected from cat (and dog) feces; hand washing is indicated after contact with soil potentially contaminated by animal feces. Indoor cats should be fed only dry, canned, or cooked meat. Litter boxes should be changed daily, as freshly deposited oocysts are not infective for 48 hours.

Pregnant women should have their serum examined for toxoplasma IgG and IgM antibody. If the IgM test is negative but an IgG titer is present and less than 1:1000, no further evaluation is necessary. Those with negative titers should take measures to prevent infection—preferably by having no further contact with cats and cat litter, by thoroughly cooking meat, and by hand washing after handling raw meat and before eating or touching the face. For seronegative women who continue to have significant environmental exposure, serologic screening should be conducted several times during pregnancy.

Prognosis

The outlook for acute toxoplasmosis in adults is excellent as long as the patient is immunocompetent. In immunosuppressed patients, the disease is usually fatal if untreated; improvement results if treatment is started early, but recrudescence is common. Chronic asymptomatic infection is usually benign.

SCHISTOSOMIASIS (BILHARZIASIS)

Essentials of Diagnosis

- Exposure to infection in an endemic area.
- Acute phase: Abrupt onset (2-6 weeks postexposure) of abdominal pain, weight loss, headache, malaise, chills, fever, myalgia, diarrhea (sometimes bloody), dry cough, hepatomegaly, and eosinophilia.
- Chronic phase: Either (1) diarrhea, abdominal pain, blood in stool, hepatomegaly or hepatosplenomegaly, and bleeding from esophageal varices (*Schistosoma mansoni* or *Schistosoma japonicum* infection); or (2) terminal hematuria, urinary frequency, and urethral and bladder pain (*Schistosoma haematobium* infection).
- Depending on species, characteristic eggs in feces, urine, or scrapings or biopsy of rectal or bladder mucosa.

General Considerations

Schistosomiasis, which infects more than 200 million persons worldwide, induces severe consequences in 20 million persons annually, resulting in up to 200,000 deaths. The disease is caused mainly by three blood flukes (trematodes). *S. mansoni*, which causes intestinal schistosomiasis, is widespread in Africa and occurs in the Arabian peninsula, South America (Brazil, Venezuela, Suriname), and the Caribbean (including Puerto Rico but not Cuba). Vesical (urinary) schistosomiasis, caused by *S. haematobium*, is found throughout the Middle East and Africa. Asiatic intestinal schistosomiasis, due to *S. japonicum*, is important in China and the Philippines, and a small focus is present in Sulawesi, Indonesia, but transmission in Japan has been interrupted. A number of schistosome species of animals sometimes infect humans, including *Schistosoma intercalatum* in central Africa and *Schistosoma mekongi* in the Mekong delta in Thailand, Cambodia, and Laos. In the USA, an estimated 400,000 immigrants are infected, but transmission does not occur because appropriate snail intermediate hosts are absent.

Mammals are important reservoirs for *S. japonicum*. Humans are the main reservoir for *S. mansoni* and *S. haematobium*; the few animal species infected with *S. mansoni* are not epidemiologically important.

In the life cycle involving humans, the adult worms live in terminal venules of the bowel (*S. mansoni*, *S. japonicum*) or bladder (*S. haematobium*). When eggs passed in feces or urine reach fresh water, a larval form is released that subsequently infects snails, the intermediate host. After development, infective larvae (cercariae) leave the snails, enter water, and infect exposed persons through the skin or mucous membranes. After penetration, the cercariae become schistosomula larvae that reach the portal circulation in the liver, where they rapidly mature. After a few weeks, adult worms pair, mate, and migrate mainly to terminal venules of specific veins, where females deposit their eggs. By means of lytic secretions, some eggs reach the lumen of the bowel or bladder and are passed with feces or urine. Others are retained in the bowel or bladder wall, while still others are carried in the circulation to the liver, lung, and (less often) to other tissues.

Except for the allergic response in the acute syndrome (see below), disease is primarily due to delayed hypersensitivity. Antigens released by the eggs stimulate a local T cell-dependent granulomatous response, followed by a strong fibrotic reaction. Live worms produce no lesions and rarely cause symptoms. The type or degree of tissue damage and symptoms varies with the intensity of infection (worm burden), host genetic factors, site of egg deposition, concurrent infection (eg, hepatitis B), and duration of infection.

S. mansoni adults migrate to the inferior mesenteric veins of the large bowel and *S. japonicum* to the superior and inferior mesenteric veins in the large and small bowel. Ulcers and polyps (common only in Egypt) result from granuloma formation and fibrosis in the bowel wall. Egg accumulation in the liver may result in periportal fibrosis and portal hypertension of the presinusoidal type, but liver function typically remains intact even in advanced disease. Portal-systemic collateralization due to portal hypertension can result in embolization of eggs to the lungs, with subsequent endarteritis, pulmonary hypertension, and cor pulmonale. Because greater numbers of eggs are produced by *S. japonicum*, the resulting disease is often more severe.

Adult *S. haematobium* mature in the venous plexus of the bladder, ureters, rectum, prostate, and uterus. Ulcers and polyps result from granuloma formation and fibrosis in the bladder wall, and eggshell remnants may calcify. Stricture or distortion of the ureteral orifices or terminal ureters may result in hydroureter, hydronephrosis, and ascending infection. Lesions in the pelvic organs rarely progress to extensive fibrosis and infection. Eggs are carried to the liver or lungs, but severe pathologic changes in these organs are less frequent than in *S. mansoni* and *S. japonicum* infections.

In size, adult *S. mansoni* are 6-13 × 1 mm. The prepatent period—from cercarial penetration until appearance of eggs in feces—is about 50 days. The life span of the worms ranges from 5 to 30 years or more.

Clinical Findings

A. Symptoms and Signs

Although a large proportion of infected persons have light infections (< 100 eggs per gram of feces) and are asymptomatic, an estimated 50-60% have symptoms and 5-10% have advanced organ damage. In children, schistosomal infections may contribute to decreased nutritional status and growth retardation. Persons with concomitant AIDS and schistosomiasis can be treated effectively and safely for the latter infection.

1. Cercarial dermatitis—Following cercarial penetration, clinical findings progress from a localized itchy erythematous or petechial rash to macules and papules that last up to 5 days. Most cases occur in fresh or marine water (worldwide) and are due to skin invasion by bird schistosome cercariae, parasites that do not mature in humans and do not cause systemic symptoms. The syndrome is uncommon with human schistosome infections.

2. Acute schistosomiasis (Katayama fever)—This syndrome, primarily an allergic response to the developing schistosomes, may occur with the three schistosomes (rare with *S. haematobium*). The syndrome is usually not seen in natives but does occur in travelers, especially to Africa. The incubation period is 2-7 weeks, with serology becoming positive some weeks later followed by ova appearing in the stools. The severity of illness ranges from mild to (rarely) life-threatening. In addition to fever, malaise, urticaria, diarrhea (sometimes bloody), myalgia, dry cough, leukocytosis, and marked eosinophilia, the liver and spleen may be temporarily enlarged. The patient again becomes asymptomatic in 2-8 weeks.

3. Chronic schistosomiasis—This stage begins 6 months to several years after infection. In *S. mansoni* and *S. japonicum* infections, findings include diarrhea, abdominal pain, irregular bowel movements, blood in the stool, a hard enlarged liver, and splenomegaly. With subsequent slow progression over 5-15 years or longer, the following may appear: anorexia, weight loss, weakness, polypoid intestinal tumors, and features of portal and pulmonary hypertension. Immune complex glomerulonephritis may also occur.

In *S. haematobium* infection, early symptoms of urinary tract disease are frequency and dysuria, followed by terminal hematuria and proteinuria. Frank hematuria may be recurrent. Sequelae may include bladder polyp formation, cystitis, chronic salmonella infection, pyelitis, pyelonephritis, urolithiasis, hydronephrosis due to ureteral obstruction, renal failure, and death. Severe liver, lung, genital, or neurologic disease is rare. Bladder cancer has been associated with vesicular schistosomiasis.

4. Other complications—Portal hypertension may result in a contracted liver, splenomegaly, pancytopenia, esophageal varices, and variceal bleeding. Abnormal liver function, jaundice, ascites, and hepatic coma are end-stage findings. Pulmonary hypertension with cor pulmonale and edema due to right heart failure may supervene. Large bowel complications include stricture, granulomatous masses, and persistent salmonella infection; colonic polyposis is manifested by bloody diarrhea, anemia, hypoalbuminemia, and clubbing. Transverse myelitis, epilepsy, or optic neuritis may result from circulation of eggs or ectopic worms.

B. Laboratory Findings

Screening and diagnosis require testing for eggs in feces and urine (which may be irregular in excretion and require repeated testing), for occult blood in feces and urine, for protein and leukocytes in urine, and serology. Ova collected in fresh, nonpreserved specimens should be examined for internal detail or by the hatching test to determine that some are alive and that the infection therefore warrants treatment.

1. Eggs—Definitive diagnosis is by finding characteristic live eggs in excreta or mucosal biopsy.

In *S. haematobium* infection, eggs may be found in the urine or, less frequently, in the stools. Eggs are sought in urine specimens collected between 9 AM and 2 PM or in 24-hour collections. They are processed either by examination of the sediment or preferably by membrane filtration. Occasionally, eggs are sought by vesical mucosa biopsy.

In *S mansoni* and *S japonicum* infections, eggs may be found in stool specimens by direct examination, but some form of concentration is usually necessary; the Kato-Katz quantitative method is preferred over formal ether concentration. One stool examination can reach 70% sensitivity and four, 92%. If results are negative, rectal mucosal biopsy of inflamed or granulomatous lesions or random biopsy specimens at two or three sites of normal mucosa may yield the diagnosis. Biopsy specimens should be examined both as crush preparations between two glass slides and histologically. If eggs are found, a quantitative test should be done after collecting a 24-hour urine or stool; heavy infections are those with counts over 400 eggs per gram.

2. Serologic tests—ELISA, immunoblot, and other tests are used in screening and may detect some egg-negative or ectopic infections. Deficiencies of the tests are that they are commonly negative early in infection and, as they remain positive for long periods of time, do not distinguish active from past infection. The Centers for Disease Control and Prevention uses a "fast ELISA" for screening (specificity 99%; sensitivity varies by parasite: *S mansoni* [99%], *S haematobium* [95%], *S japonicum* [> 50%]) and a Western blot (specificity 100%) for confirmation and speciation. Positive tests do not correlate with worm burden. Accumulating research evidence supports the view that detection of antigen in blood and urine is sensitive, correlates with intensity of infection, and can distinguish old from new infection—and that loss of circulating antigen 5-10 days after treatment is indicative of cure. Skin testing is no longer recommended.

3. Other tests—Anemia is common. Eosinophilia, common during the acute stage, usually is absent in the chronic stage. In *S mansoni* and *S japonicum* infections, barium swallow, esophagoscopy, barium enema or colonoscopy, chest x-ray, or an ECG may be indicated. Ultrasound examination of the liver may show the pathognomonic pattern of periportal fibrosis and replaces the need for liver biopsy. The clinical settings in which ultrasonography is most useful are (1) evaluation of portal hypertension, (2) distinguishing schistosomiasis from cirrhosis, and (3) documenting regression of lesions following treatment; in early infections, however, findings are inconsistently present.

In *S haematobium* infection, occult hematuria can often be detected either microscopically or by reagent strip test, particularly if the first portion of the urine specimen is evaluated. In advanced disease, cystoscopy may show "sandy patches," ulcers, and areas of squamous metaplasia; lower abdominal plain films may show calcification of the bladder wall or ureters. Sonography is considered the imaging technique of choice but may fail to show the calcification. CT—which may demonstrate pathognomonic "turtleback" calcifications—intravenous pyelography, and retrograde cystography and pyelography may be useful.

Differential Diagnosis

Early intestinal schistosomiasis may be mistaken for amebiasis, bacillary dysentery, or other causes of diarrhea and dysentery. Later, the various causes of portal hypertension or of bowel polyps must be considered. In endemic areas, vesical schistosomiasis must be differentiated from other causes of urinary symptoms such as genitourinary tract cancer, bacterial infections of the urinary tract, nephrolithiasis, and the like.

Treatment

A. Medical Treatment

Treatment should be given only if live ova are identified. The safety and effectiveness of current drugs make it possible to treat all active infections orally, including advanced disease, and without concern for serious side effects. Praziquantel can be used to treat all species; alternative drugs of choice are oxamniquine for *S mansoni* and metrifonate for *S haematobium*. Under study are the use of artemisinin and its derivatives for prophylaxis and treatment of acute attacks; controversy continues about whether praziquantel plus corticosteroids are safe and effective. Instances of both oxamniquine and praziquantel resistance have been recognized in some localities.

After treatment, periodic laboratory follow-up for continued passage of eggs is essential, starting at 3 months and continuing at intervals for 1 year; if found, viability should be determined, since dead eggs are passed for some months.

1. Praziquantel—Cure rates of 85% and higher are achieved at 6 months for *S haematobium*, *S mansoni*, and *S japonicum* infections, with marked reduction in egg counts (> 90%) in those not cured. Immature schistosomes (2-5 weeks) are largely insensitive to praziquantel.

The praziquantel dosage is 20 mg/kg—give twice in 1 day for *S haematobium* and *S mansoni* and three times in 1 day for *S japonicum* and *S mekongi*. The dosages should be given at 4- to 6-hour intervals with water after a meal; the tablets should not be chewed.

Mild and transient side effects persisting for hours to 1 day are common and include malaise, headache, dizziness, and anorexia. Less frequent are fatigue, drowsiness, nausea, vomiting, generalized abdominal pain, loose stools, pruritus, urticaria, arthralgia and myalgia, and low-grade fever. Minimal elevations of liver enzymes have occasionally been reported. The drug should not be used in pregnancy, and because of drug-induced dizziness, patients should not drive and should be cautioned if their work requires physical coordination or alertness. In areas where cysticercosis may coexist with a schistosomal infection being treated with praziquantel, treatment is best conducted in a hospital to monitor for death of cysticerci, which may be followed by neurologic complications. Recently reported for praziquantel are comutagenic effects with several mutagens and carcinogens; the authors conclude that the import of these findings needs further study. Reduced susceptibility of *S mansoni* to praziquantel has been reported from some areas of Africa.

2. Oxamniquine—Oxamniquine is highly effective only in *S mansoni* infections. For strains in the western hemisphere and western Africa, a dose of 15 mg/kg is given once. Some experts recommend 40-60 mg/kg/d in two or three divided doses for 2-3 days in all of Africa and in the Arabian peninsula. The drug is administered with food; when divided doses are needed, they are separated by 6-8 hours. Cure rates are 70-95%, with marked reduction in egg counts in those not cured. Side effects occur within hours: dizziness is most common; less frequent are drowsiness, nausea and vomiting, diarrhea, abdominal pain, and headache. An orange or red discoloration of the urine may occur. Rarely reported is central nervous system stimulation with behavioral changes, hallucinations, or seizures; patients should be observed for 2 hours after ingestion of the drug for appearance of these findings. Since the drug makes some patients dizzy or drowsy, it should be used with caution in patients whose work or activity requires mental alertness. Instances of parasite resistance to the drug have been reported. Because the drug has shown mutagenic and embryotoxic effects, it is contraindicated in pregnancy.

3. Others—Artemisinin compounds (used in malaria treatment) are being evaluated. They are effective against the juvenile stages of the parasite and may become useful in prophylaxis. Treatment studies of *S haematobium* infection show artesunate to be considerably less effective than praziquantel. Metrifonate, effective against *S haematobium*, has been withdrawn from the market.

B. Surgical Measures

In selected instances, surgery may be indicated for removal of polyps and for obstructive uropathy. For bleeding esophageal varices, sclerotherapy is the treatment of choice; whether some patients may benefit from propranolol treatment is under evaluation. As a last resort in patients who have repeated bleeding, shunting procedures (esophagogastric devascularization with splenectomy or distal—but not proximal—splenorenal shunt) are used, though their effectiveness and relative usefulness are not well established. Severe pancytopenia is an indication for splenectomy.

Prognosis

With treatment, the prognosis is excellent in early and light infections. There may be shrinkage or elimination of bladder and bowel ulcerations, granulomas, and polyps and reduction in fibrosis by sonography. In advanced disease with extensive involvement of the intestines, liver, bladder, or other organs, the outlook is poor even with treatment. In endemic areas, mass treatment of children diminishes the risk of developing severely diseased organs, even though reinfection may occur.

FASCILOPSIASIS

The large intestinal fluke, *Fasciolopsis buski*, is a common parasite of humans and pigs in central and southern China, Taiwan, Southeast Asia, Indonesia, eastern India, and Bangladesh. When eggs shed in stools reach water, they hatch to produce free-swimming larvae that penetrate and develop in the flesh of snails. Cercariae subsequently escape from the snails and encyst on various water plants. Humans are infected by eating these plants uncooked (usually water chestnuts, bamboo shoots, or caltrops). Adult flukes (length 2-7.5 cm) mature in about 3 months and live in the small intestine attached to the mucosa or buried in mucous secretions. The number of parasites ranges from a few to several thousand.

After an incubation period of 2-3 months, manifestations of gastrointestinal irritation appear in all but light infections. Symptoms in severe infections include nausea, anorexia, upper abdominal pain, and diarrhea, sometimes alternating with constipation. Ascites and edema of the face and lower extremities may occur later; the

physiologic mechanism is not understood. Intestinal obstruction, ileus, cachexia, and extreme prostration have been described.

Diagnosis depends on finding characteristic eggs or, occasionally, flukes in the stools. Leukocytosis with moderate eosinophilia is common. No serologic test is available. Because the adult worms live for only 6 months, absence from the endemic area for a longer period makes the diagnosis unlikely.

The drug of first choice is praziquantel, 25 mg/kg three times in 1 day only. The alternative drug is niclosamide (not available in the USA), administered as for taeniasis but given every other day for three doses.

In light infections—even without treatment—the prognosis is good; generally, spontaneous cure occurs within 1 year. In rare cases—particularly in children—heavy infections with severe toxemia have resulted in death from cachexia or intercurrent infection.

Graczyk TK et al: Fasciolopsiasis: is it a controllable food-borne disease? Parasitol Res 2001;87:80. [\[PMID: 11199855\]](#)

FASCIOLIASIS

Infection by *Fasciola hepatica*, the sheep liver fluke, results from ingestion of encysted metacercariae on watercress or other aquatic vegetables or in water. A wide range of herbivorous mammals are reservoir hosts. The disease in humans probably occurs worldwide but is most prevalent in sheep-raising countries, particularly where raw salads are eaten. The infection has been reported from Europe, mainland USA, Hawaii, the West Indies, the Middle East, China, Siberia, and North, East and South Africa. Eggs of the worm, passed in host feces into fresh water, release a miracidium that infects snails; the snails subsequently release cercariae that in turn encyst as metacercariae on vegetation (some cercariae become metacercariae directly in the water) to complete their life cycle. The adult flukes are leaf-shaped and measure 3 × 1.5 cm.

In humans, metacercariae excyst, penetrate and migrate through the liver, and mature in the bile ducts, where they cause local parenchymal necrosis and abscess formation. Although the infection is usually mild, three clinical syndromes can develop: acute, chronic latent, and chronic obstructive. The acute illness, associated with migration of immature larvae through the liver, shows an enlarged and tender liver, high fever, leukocytosis, and marked eosinophilia (to 90%). Pain may be present in the epigastrium or right upper quadrant, and the patient may experience headache, anorexia, vomiting, myalgia, urticaria, and other allergic reactions. Jaundice, cachexia, and prostration may appear in severe illness. Anemia and hypergammaglobulinemia are common; other liver function tests may be abnormal. Early diagnosis is difficult in the acute phase because eggs are not found in the feces for 3-4 months. The chronic latent phase may be asymptomatic or characterized by hepatomegaly and other acute findings. The chronic obstructive phase takes place if the extrahepatic bile ducts are occluded, producing a clinical picture similar to that of sclerosing cholangitis, biliary cirrhosis, or choledocholithiasis. Occasionally, adult flukes migrate and produce lesions and symptoms in ectopic sites.

Diagnosis is established by detecting characteristic eggs in the feces; repeated examinations may be necessary. Sometimes the diagnosis can only be made by finding eggs in biliary drainage and, in rare instances, only after liver biopsy or at surgical exploration. Exogenous transient fecal carriage can occur as a result of ingestion of egg-containing cow or sheep liver. Percutaneous biliary drainage has been used in diagnosis, and ultrasonography and cholangiography may show adult parasites in the gallbladder or ducts. Eosinophilia is characteristic, and hypergammaglobulinemia and abnormal liver function tests may be present. Serologic tests are often useful in presumptive diagnosis, particularly in the acute phase (before eggs have appeared) or in ectopic infection. The "fast" ELISA and immunoblot tests are 95-100% sensitive and highly specific, though cross-reactions occur with schistosomiasis. Serum and coproantigen tests are promising. Successful treatment correlates with a decline in antibody titer.

Evidence is increasing that triclabendazole (Fasinex—available in the USA from Novartis Agribusiness), a veterinary fasciolicide, is the drug of choice. At present, it is used in humans only on an experimental basis; 10 mg/kg given for 2 days with food achieves a cure rate of 80% with an absence of side effects. Instances of *F hepatica* resistance to triclabendazole in domestic animals has been reported. Bithionol (given as for paragonimiasis) is the alternative drug of choice; its deficiencies are its long course, failure rates of up to 50%, and frequent adverse reactions. Albendazole trials continue, but that drug also has shown high failure rates. An initial report suggests high effectiveness with low side effects for nitazoxanide, a veterinary anthelmintic. Reports on praziquantel have been variable; generally, it is ineffective even when used for up to 7 days at a dose of 25 mg/kg three times daily with a 4- to 6-hour interval between doses. If triclabendazole, bithionol, or praziquantel is not effective, dehydroemetine or emetine hydrochloride in dosages used for amebic liver abscess may help; both drugs are potentially toxic, but dehydroemetine may be less so. For any of these drugs, the destruction of parasites followed by release of antigen in sensitized patients may evoke symptoms.

Bithionol and dehydroemetine are available in the USA only from the Parasitic Disease Drug Service, Centers for Disease Control, Atlanta, GA 30333.

In endemic areas, aquatic plants should not be eaten raw; washing does not destroy the metacercariae, but cooking will. Drinking water must be boiled (1 minute) or purified.

CLONORCHIASIS & OPISTHORCHIASIS

Infection by *Clonorchis sinensis*, the Chinese liver fluke, is endemic in areas of Japan, Korea, China, Taiwan, Southeast Asia, and the far eastern part of Russia. Over 20 million people are affected. Opisthorchiasis is caused by worms of the genus *Opisthorchis*, generally either *O felineus* (central, eastern, and southern Europe, eastern Asia, Southeast Asia, India) or *O viverrini* (Thailand, Laos, Vietnam). Clinically and epidemiologically, opisthorchiasis and clonorchiasis are identical.

Certain snails are infected when they ingest eggs shed into water in human or animal feces. Larval forms escape from the snails, penetrate the flesh of various freshwater fish, and encyst as metacercariae. Fish-eating wild and domestic mammals—including dogs, cats, and pigs—and humans maintain the life cycle. Human infection results from eating such fish, either raw or undercooked. Pickling, smoking, or drying may not suffice to kill the metacercariae. In humans, the ingested parasites excyst in the duodenum and ascend the bile ducts into the medium and small biliary radicals, but also into the larger ducts and the gallbladder, where they mature and remain throughout their lives (15-25 years), shedding eggs in the bile. In size, the worms are 7-20 × 1.5-3 mm. In the chronic stage of infection, there is progressive bile duct thickening, periductal fibrosis, dilation, biliary stasis, and secondary infection. Little fibrosis occurs in the portal tracts.

Most patients harbor few parasites and are asymptomatic. Among symptomatic patients, an acute and chronic syndrome occurs. Acute symptoms follow entry of immature worms into the biliary ducts and may persist for several weeks. Findings include malaise; low-grade fever; an enlarged, tender liver; pain in the hepatic area or epigastrium; urticaria; arthralgia; leukocytosis; eosinophilia; an elevated serum alanine aminotransferase; and jaundice. The acute syndrome is difficult to diagnose, since ova may not appear in the feces until 3-4 weeks after onset of symptoms.

In chronic infections, findings include weakness, anorexia, epigastric pain, diarrhea, prolonged low-grade fever, intermittent episodes of right upper quadrant pain, localized hepatic area tenderness, and progressive hepatomegaly; liver function tests are normal except in severe cases.

Complications include intrahepatic bile duct calculi that may lead to recurrent pyogenic cholangitis, biliary abscess, or endophlebitis of the portal-venous branches. Although focal initially, this may gradually result in destruction of the liver parenchyma, fibrosis, and, in a few patients, cirrhosis with jaundice and ascites. Chronic cholecystitis, cholelithiasis, and a nonfunctional, enlarged gallbladder may occur. Flukes may also enter the pancreatic duct, causing acute pancreatitis or cholelithiasis. Cholangiocarcinoma has been causally linked with prolonged clonorchis and opisthorchis infection.

Diagnosis is made by finding characteristic eggs in stools (repeated tests may be necessary) or duodenal aspirate (sensitivity approaches 100%); endoscopic retrograde cholangiopancreatography may be indicated. In severe infection, the number of eggs per gram of feces may not reflect the heavy worm burden. In complete biliary obstruction, eggs can be detected in bile only by needle aspiration or at surgery. In advanced chronic disease, (1) liver function tests will indicate parenchymal damage; (2) CT and sonography may show diffuse dilation of small intrahepatic bile ducts with no or minimal dilation of the large intra- and extrahepatic ducts; and (3) transhepatic cholangiograms may show alternating stricture and dilation of the biliary tree, with worms visualized as filling defects. Where available, of the several evaluated serologic tests, the ELISA is preferred (sensitivity, 77%); however, unless a specific monoclonal antibody is used, cross-reactions are common with other trematode and cestode infections, tuberculosis, and liver cancer. During the chronic stage, leukocytosis varies according to the intensity of infection; eosinophilia may be present.

The drug of choice is praziquantel. With a dosage of 25 mg/kg three times daily for 2 days (with a 4- to 6-hour interval between doses), cure rates over 95% can be anticipated for clonorchis infections. One day of treatment may be sufficient for opisthorchis infections. (For side effects, see Schistosomiasis, above.) Albendazole, at a dosage of 400 mg twice daily for 7 days, appears to be less effective (cures, 40-65%). In relapsing cholangitis, antibiotics are indicated to cover biliary pathogens.

The disease is rarely fatal, but patients with advanced infections and impaired liver function may succumb more readily to other diseases. The prognosis is good for light to moderate infections.

PARAGONIMIASIS

Paragonimus westermani, the lung fluke, commonly infects humans (estimated 20 million) throughout the Far East (prevalence in Korea has reached 4%); foci are also present in West Africa, South and Southeast Asia, the Pacific Islands, Indonesia, and New Guinea. Many carnivores and omnivores in addition to humans serve as reservoir hosts for the adult fluke (8-16 × 4-8 × 3-5 mm). About a dozen other paragonimus species also infect humans in China, Japan, Mexico, and Central and South America.

Eggs reaching water, either in sputum or feces, hatch in 3-6 weeks. Released miracidia penetrate and develop in snails. Emergent cercariae encyst as metacercariae in the tissues of crabs and crayfish. Human infection results if metacercariae are ingested when the crustaceans are eaten raw or pickled or food, vessels, drinking water, or fingers become contaminated. The metacercariae excyst in the small intestine and penetrate the peritoneal cavity. Most migrate through the diaphragm and enter the peripheral lung parenchyma; some may lodge in the brain (about 1% of all cases) or at other ectopic sites. In the lungs, the parasite becomes encapsulated by granulomatous fibrous tissue, reaching up to 2 cm in diameter. The lesion, which usually opens into a bronchiole, may subsequently rupture, resulting in expectoration of eggs, blood, and inflammatory cells. Rarely, the eggs may also enter the general circulation and produce ectopic lesions in any tissue. The prepatent period until appearance of expectorated eggs is about 6 weeks. *P szechuanensis* in China has a propensity to migrate and produce subcutaneous nodules.

In pulmonary infections, most persons have light to moderate worm burdens and are asymptomatic. In symptomatic cases, low-grade fever and dry cough are present initially; subsequently, pleuritic pain is common, and a rusty, blood-flecked, viscous sputum or frank hemoptysis may occur. Following slow progression, complications of bronchitis, bronchiectasis, bronchopneumonia, lung abscess, fibrosis, and pleural thickening or effusion may appear.

Only a minority of patients with cerebral infections present with acute disease, usually manifested by meningitis. In chronic central nervous system disease, seizures, cranial neuropathies, or meningoencephalitis may occur; death can follow. Parasites in the peritoneal cavity or the intestinal wall may cause abdominal pain, diarrhea or dysentery, and a palpable tumor mass. Migratory subcutaneous nodules (a few millimeters to 1 cm in diameter) occur with about 10% of *P westermani* infections and up to 60% of *Paragonimus skrjabini* infections.

Pulmonary disease is diagnosed by finding (1) characteristic eggs in sputum (rusty sputum is nearly pathognomonic), feces, bronchoscopic washings, biopsy specimens, or pleural fluid; or (2) adult flukes in subcutaneous nodules or other surgical specimens. If eggs are not found after multiple direct sputum examinations, they may be detectable in a 24-hour sputum collection processed by alkaline sodium hypochlorite concentration. Stool examination for eggs has low sensitivity. Serologic tests are conducted using serum, cerebrospinal fluid, and pleural effusion fluid; the sensitivity and specificity of the ELISA are 99% and 97% and of the immunoblot 96% and 99%. The tests do not differentiate active from prior infection; a newly reported IgM test may do so. Most treated and cured patients become seronegative. Antigen detection assays are promising. Eosinophilia (sometimes to a high level) and low-grade leukocytosis are common. Chest films may show infiltrates, fibrosis, nodules, cavitary lesions, pleural thickening or effusion, or calcifications. By CT, round, low-attenuation cystic lesions (5-15 mm) filled with fluid or gas are seen within the consolidation.

In acute cerebral disease, CT shows multilocular, ring-like enhancement with surrounding low-density areas. In chronic cerebral disease, plain skull films often show round or oval-shaped calcifications, sometimes surrounded by low-density areas. Cerebrospinal fluid may be turgid or bloody, with numerous eosinophils, and eggs may be found. The EEG is almost always abnormal.

Paragonimiasis and tuberculosis must be differentiated, though chest x-ray appearance alone does not make the distinction. Since paragonimus ova are destroyed by Ziehl-Neelsen stain for acid-fast bacilli, the sputum should first be examined for the eggs. The presence of a large number of eosinophils or Charcot-Leyden crystals in sputum suggests paragonimiasis.

In pulmonary paragonimiasis, praziquantel is the drug of choice (25 mg/kg after meals three times daily for 3 days, with a 4- to 6-hour interval between doses). (For side effects, see above under Schistosomiasis.) Bithionol is the alternative drug (30-50 mg/kg, given on alternate days for 10-15 doses; the daily dose should be divided into a morning and evening dose). Side effects are frequent but generally mild and transient. Gastrointestinal side effects, particularly diarrhea, occur in most patients. Liver function should be tested serially. Bithionol is available in the USA only from the Parasitic Disease Drug Service, Centers for Disease Control, Atlanta, GA 30333. Antibiotics may be necessary for secondary pulmonary infection. Cure rates of over 90% can be anticipated for both praziquantel and bithionol. Triclabendazole, a veterinary fasciolicide, is under investigation at a dosage of 5 mg/kg once daily for 3 days.

In the acute stage of cerebral paragonimiasis, particularly meningitis, praziquantel or bithionol may be effective. With death of parasites, severe local reactions may occur; corticosteroids should therefore be given as in cerebral cysticercosis. In the chronic stage, both surgical removal of the parasites and drug usage are likely to be ineffective in diminishing neurologic symptoms.

■ CESTODE INFECTIONS

TAPEWORM INFECTIONS (SEE ALSO CYSTICERCOSIS AND ECHINOCOCCOSIS, BELOW.)

Classification

Six tapeworms infect humans frequently. The large tapeworms are *Taenia saginata* (the beef tapeworm, up to 25 m in length), *Taenia solium* (the pork tapeworm, 7 m), and *Diphyllobothrium latum* (the fish tapeworm, 10 m). The small tapeworms are *Hymenolepis nana* (the dwarf tapeworm, 25-40 mm), *Hymenolepis diminuta* (the rodent tapeworm, 20-60 cm), and *Dipylidium caninum* (the dog tapeworm, 10-70 cm). Four of the six tapeworms occur worldwide; the pork and fish tapeworms have more limited distribution. Humans are the only definitive host of *T saginata* and *T solium*.

An adult tapeworm consists of a head (scolex), a neck, and a chain of individual segments (proglottids) in which eggs form in mature segments. The scolex is the attachment organ and generally lodges in the upper part of the small intestine.

Multiple infections are the rule for small tapeworms and may occur for *D latum*; however, it is rare for a person to harbor more than one or two of the taeniae.

A. Beef Tapeworm

The infection occurs in most countries with beef husbandry but is highly endemic in parts of the Far East, central and eastern Africa, and the central Asian area of the former Soviet Union. Gravid segments of *T saginata* in the human intestine detach themselves from the chain and are passed in feces to soil. When proglottids or eggs are ingested by grazing cattle or other domesticated bovines, the eggs hatch to release embryos that encyst in muscle as cysticerci. Humans are infected by eating raw or undercooked beef containing viable cysticerci, *Cysticercus bovis*. In the human intestines, the cysticercus develops into an adult worm.

B. Pork Tapeworm

This tapeworm is particularly prevalent in Mexico, Latin America, the Iberian Peninsula, the Slavic countries, Africa, Southeast Asia, India, and China. In the USA and Canada, human infection is rare, usually encountered in persons infected abroad; cysticercosis in hogs is uncommon. The infection is no longer found in northwestern Europe. The life cycle of *T solium* is similar to that of *T saginata* except that pigs ingest human feces containing proglottids and eggs to become the host of the larval stage. Humans become infected when they eat undercooked pork containing viable *C cellulosae*. Humans are also the intermediate host when they become infected with the larval stage (see Cysticercosis, below) by accidentally ingesting eggs in human feces; the eggs are immediately infectious. Transmission of eggs may occur as a result of autoinfection (hand to mouth), direct person-to-person transfer, ingestion of food or drink contaminated by eggs, or (rarely) regurgitation of proglottids into the stomach.

C. Fish Tapeworm

D latum is found in temperate and subarctic lake regions in many areas of the world, including northern Europe, Canada, Alaska, the Pacific Coast of the USA, Japan, Taiwan, Siberia, Manchuria, Australia, southern South America, and southern Africa. Eggs passed in human feces that reach fresh water are taken up first by

crustaceans that in turn are eaten by fish, both of which are intermediate hosts. Human infection results from eating raw or inadequately cooked brackish or freshwater fish, including salmon. Nonhuman reservoir hosts include dogs, bears, and other fish-eating mammals.

D. Dwarf Tapeworm

H nana is the most common cestode. It can reach high prevalence, particularly in children, in regions of the world with poor fecal hygiene and in closed institutions. Humans are the definitive host of the human strain of the parasite; rodent-adapted strains occur in rodents. The life cycle is unusual in that both larval and adult stages are found in the human intestine, internal autoinfection can occur, and generally there is no intermediate host. Transmission usually results from eggs transferred directly from human to human (the eggs are immediately infective) but sometimes involves fomites, water, or food or the swallowing of fleas or beetles infected with the larval stage. *H nana* infections in children are usually lost spontaneously in adolescence.

E. Rodent Tapeworm

H diminuta is a common parasite of rodents. Many arthropods (eg, rat fleas, beetles, and cockroaches) serve as intermediate hosts. Humans—most commonly young children—are infected by accidentally swallowing the infected arthropods, usually in cereals or stored products.

F. Dog Tapeworm

D caninum infection generally occurs in young children in close association with infected dogs or cats. Transmission results from swallowing the infected intermediate hosts, ie, fleas or lice.

Clinical Findings

A. Signs and Symptoms

1. Large tapeworms—Large tapeworm infections are generally asymptomatic. Occasionally, vague gastrointestinal symptoms (eg, nausea, diarrhea, abdominal pain) and systemic symptoms (eg, fatigue, hunger, dizziness) have been attributed to the infections. Vomiting of proglottid segments or obstruction of the bile duct, pancreatic duct, or appendix is rare.

Some persons (mostly Scandinavian residents) who harbor the fish tapeworm develop a macrocytic megaloblastic anemia accompanied by thrombocytopenia and mild leukopenia. Gastric acidity is normal. The anemia is a result of the worm's competing with the host for vitamin B₁₂. Clinical findings are indistinguishable from those of pernicious anemia and include glossitis, dyspnea, tachycardia, and neurologic findings (numbness, paresthesias, disturbances of coordination, impairment of vibration and position sense, and dementia).

2. Small tapeworms—Light infections are generally asymptomatic. Heavy infections, particularly with *H nana*, may cause diarrhea, abdominal pain, anorexia, vomiting, weight loss, and irritability.

B. Laboratory Findings

Infection by a beef or pork tapeworm is often discovered by the patient finding segments in stool, clothing, or bedding. To determine the species, proglottid segments are either flattened between glass slides and examined microscopically for anatomic detail or differentiated by enzyme electrophoresis of glucose phosphate isomerase. Eggs are only infrequently present in stools, but the perianal cellophane tape test, as used to diagnose pinworm, is sometimes useful in detecting *T saginata* eggs. However, taenia eggs look alike and do not permit species differentiation except by specialized methods. Detection of taenia-specific antigens in stool, currently a research method, may become the most sensitive method for detecting infection.

Fish tapeworm is diagnosed by finding characteristic operculated eggs in stool; repeat examinations and concentration may be necessary. Proglottids are occasionally vomited or passed in feces; their internal morphology is diagnostic. The presence of hydrochloric acid in the stomach differentiates tapeworm anemia from pernicious anemia; in both conditions, the Schilling test is abnormal.

H nana and *H diminuta* infections are diagnosed by finding characteristic eggs in feces; proglottids are usually not seen. *D caninum* infection is diagnosed by detection of proglottids (the size of melon seeds) in feces or after their active migration through the anus.

Serologic tests are not available for tapeworm infections; an ELISA for detection of coproantigens is under evaluation.

Treatment

A. Specific Measures

Although niclosamide (not available in the USA) and praziquantel are both drugs of choice for most tapeworm infections, praziquantel is more effective in hymenolepiasis, and some workers consider it to be somewhat more effective in taeniasis. In areas endemic for neurocysticercosis, a dose of praziquantel of 5 mg/kg or higher carries a small risk of activating the lesions. Niclosamide preferably should not be used in pregnancy.

1. *T saginata* and *D latum*—Praziquantel in a single dose of 10 mg/kg achieves cure rates of about 99%. At this dose, side effects (see under Schistosomiasis, above) are minimal. With a single dose of four tablets (2 g) of niclosamide, cure rates over 90% can be anticipated. The drug is given in the morning before the patient has eaten. The tablets *must be chewed thoroughly* and swallowed with water. Eating may be resumed in 2 hours. Niclosamide usually produces no side effects.

Pre- and posttreatment purges are not used for either drug. The anemia and neurologic manifestations of *D latum* respond to vitamin B₁₂ as used in treatment of pernicious anemia.

2. *T solium*—The choice of drugs and methods of treatment are as above. Neither drug kills eggs released from disintegrating segments; therefore, to avoid the theoretical possibility of cysticercosis from hatching eggs, give a moderate purgative 2-3 hours after treatment to rapidly eliminate segments and eggs from the bowel. The patient must be instructed about the need after defecation for careful washing of the hands and perianal area and for safe disposal of feces for 4 days following therapy.

3. *H nana*—Praziquantel, the drug of choice, produces 95% cure rates with a single 25-mg/kg dose. Niclosamide, the alternative drug, produces cure rates of 75% when given at the above dosage for 5-7 days; some workers repeat the course 5 days later.

4. *H diminuta* and *D caninum*—Treatment is with niclosamide or praziquantel in dosages as for *H nana*. Cure rates are not established.

B. Follow-Up Care

In treatment of large tapeworm infections, a disintegrating worm is usually passed within 24-48 hours of treatment. Since efforts are not generally made to recover and identify the scolex, cure can be presumed only if regenerated segments have not reappeared 3-5 months later. If it is preferred that parasitic cure be established immediately, the head (scolex) must be found in posttreatment stools; a laxative is given 2 hours after treatment, and stools must be collected in a preservative for 24 hours. To facilitate examination, toilet paper must be disposed of separately.

Prevention & Prognosis

C cellulosae is killed by cooking at 65 °C or freezing at -20 °C for 12 hours; *C bovis* at 56 °C or -10 °C for 5 days. Pickling is not adequate. Because the prognosis is often poor in cerebral cysticercosis (see below), *T solium* infections must be immediately eradicated.

Dick TA et al: Diphyllbothriasis: update on human cases, foci, patterns and sources of human infections and future considerations. Southeast Asian J Trop Med Public Health 2001;32(Suppl 2):59. [PMID: 12041607]

Juan JO et al: Comparative clinical studies of nitazoxanide, albendazole and praziquantel in the treatment of ascariasis, trichuriasis and hymenolepiasis in children from Peru. Trans R Soc Trop Med Hyg 2002;96:193. [PMID: 12055813]

CYSTICERCOSIS

Essentials of Diagnosis

- History of exposure to *Taenia solium* in an endemic region; concomitant or past intestinal tapeworm infection.
- Seizures, headache, and other findings of a focal space-occupying central nervous system lesion.
- Subcutaneous or muscular nodules (5-10 mm); calcified lesions on x-rays of soft tissues.

- Calcified or uncalcified cysts by CT scan or MRI; positive serologic tests.

General Considerations

Human cysticercosis is infection by the larval (cysticercus) stage of the tapeworm *T solium* (see above). Worldwide, an estimated 20 million persons are infected and 50,000 deaths occur yearly. Antibody prevalence rates to 10% are recognized in some endemic areas. In the USA in recent years, hundreds of cases annually have been recognized in immigrants and travelers.

The natural history of the infection is incompletely known. Cysticerci complete their development within 2-4 months after larval entry and live for months to years. Several factors give rise to symptomatology: Initially, a live larva grows within a thin-walled 10-20 mm cyst (the vesicular cyst) but remains minimally antigenic, causes little or no perilesional inflammation, and does not enhance with contrast media on neuroimaging. Attached to the inner wall of the cyst is an invaginated protoscolex with four suckers and a crown of hooks. When host immune response or chemotherapy causes gradual death of the cyst, marked inflammation and pericyst edema can occur, producing a ring-like or nodular area of enhancement with contrast media (the granulomatous or enhancing cyst); concurrent events include cyst enlargement, mechanical compression, increased intracranial pressure, cerebrospinal fluid changes, and sometimes a vasculitis that results in small cerebral infarcts. The immune response is intense in many patients, but some show a remarkable tolerance. Later, as the cyst degenerates over 2-7 years, it may become undetectable with imaging or be replaced by fibrosis with calcification that is detectable.

Locations of cysts in order of frequency are the central nervous system (where cysts at different life cycle stages—live, transitional, dead—may be present at the same time), subcutaneous tissues and striated muscle, vitreous humor of the eye, and, rarely, other tissues.

Clinical Findings

A. Signs and Symptoms

1. Neurocysticercosis—In many patients, cysts remain asymptomatic. When symptomatic, the incubation period is highly variable (usually from 1 to 5 years but sometimes shorter). Manifestations are due to mass effect, inflammatory response, or obstruction of the brain foramina and ventricular systems. Neurologic findings are varied and nonspecific, in large part determined by the number and location of the cysts.

a. Acute invasive stage (cysticercotic encephalitis)—This rare event, occurring shortly after invasion, results from extensive acute spread of cysticerci to the brain parenchyma. Fever, headache, myalgia, marked eosinophilia, and coma may occur.

b. Parenchymal cysts—Cysticerci can present singly or multiply and may be scattered or in clumps. Findings include epilepsy (focal or generalized), focal neurologic deficits, intracranial hypertension (intense headache, vomiting, papilledema, visual loss), and altered mental status. Seizures usually do not occur until the cyst or cysts have begun to die. Episodic symptoms have been associated with edema around calcified lesions.

c. Subarachnoid space cysts and meningeal cysts—Small to large cysts are generally located in the cortical sulci or basal cisterns. The arachnoid is the principal basal membrane affected. Adhesive arachnoiditis may result in obstructive hydrocephalus, intracranial hypertension, arterial thrombosis leading to transient ischemia or stroke, and cranial nerve dysfunction (most often of the optic nerve).

d. Ventricular cysts—Ventricular cysts may float freely (usually singly) within the ventricles or cerebral aqueduct or may be attached to the ventricular wall. They are usually asymptomatic but can cause increased intracranial pressure as a result of intermittent or total blockage.

e. Racemose cysts—These are rare aberrant forms that are multiple-branched, nonencysted, and lack a scolex; they present as grape-like irregular clusters and may reach over 10 cm in diameter. They generally are found in the ventricular and basal subarachnoid spaces, where they cause marked adhesive arachnoiditis and often obstructive hydrocephalus.

f. Spinal cord cysts—Cysts can be extraspinal or intraspinal and can cause arachnoiditis (meningitis, radiculopathy) or pressure symptoms.

2. Ophthalmocysticercosis—Usually there is a single cyst, free-floating in the vitreous or under the retina. Presenting symptoms include periorbital pain, scotomas, and progressive deterioration of visual acuity. Findings may include disk hemorrhage and edema, retinal detachment, iridocyclitis, and chorioretinitis. MRI but not CT may assist in diagnosis; immunologic tests are negative.

3. Subcutaneous and striated muscle cysticercosis—Subcutaneous cysts are usually asymptomatic; they present as nodules that tend to appear and disappear, or they may die and calcify and be detected on plain radiographs.

B. Diagnostic Criteria and Laboratory Tests

Definitive diagnosis of neurocysticercosis is (1) by CT or MRI detection of brain or spinal cord cystic lesions that show the scolex ("hole-with-dot") image; (2) by visualization of the parasite by ophthalmoscopic examination (subretinal or in the anterior chamber); or (3) by finding the parasite in histologic sections of brain or spinal cord tissue (not usually recommended). Ranging from highly suggestive to compatible with the diagnosis are various combinations of other major and minor findings (criteria): (1) lesions on neuroimaging studies, (2) positive immunologic tests with serum or cerebrospinal fluid, (3) resolution of intracranial cystic lesions either spontaneously or after treatment, (4) cysticercosis outside the central nervous system, (5) clinical history, and (6) epidemiologic findings (personal history of a tapeworm, tapeworm in a household contact, travel in an endemic area).

1. Imaging—Plain radiographs of muscle may detect oval or linear calcified lesions (4-10 × 2-5 mm). The lesions are usually multiple, sometimes in the hundreds, and the long axes of the cysts are nearly always in the plane of the surrounding muscle fibers. Plain skull films may demonstrate one or more cerebral calcifications (generally 5-10 mm; sometimes 1-2 mm when only the scolex is calcified).

The most useful procedures for examining the skull are imaging initially by nonenhanced CT and then by MRI and enhanced CT. CT patterns include (1) vesicular cysts (viable cysts with no host immune reaction), which are rounded areas of low density with little or no enhancement after contrast medium; (2) colloidal cysts (dead or dying cysts with host immune reaction), which are hypodense or isodense lesions surrounded by edema associated with ring-like or nodular enhancement; and (3) granuloma or calcifications (dead cysts), which are often several millimeters in diameter but variable in size. Signs of increased intracranial pressure and diffuse brain edema may also be seen. A combination of images is often found, owing to different developmental stages. As compared with CT, MRI has superior resolution for vesicular cysts (isodense, similar to cerebrospinal fluid) and for colloidal cysts (hyperdense). However, CT is superior for granulomas and calcifications, the most frequent presentations of cysticercosis, which MRI may miss. The MRI sometimes detects pathognomonic 2- to 4-mm nodules (protoscoleces) within cyst fluid. Intraventricular cysts (isodense) are not seen on noncontrast CT but require intraventricular contrast medium. Spinal cysticercosis is evaluated by CT myelography or MRI.

2. Immunologic tests—With serum, the enzyme-linked immunoelectrotransfer blot (EITB) assay has nearly 100% specificity and 94-98% sensitivity. Both parameters are paradoxically lower, however, when the test is performed on cerebrospinal fluid. However, the test's sensitivity drops to about 50% if only one live cyst is present and is also low in patients with only calcified cysts. Where the EITB assay is not available, the older ELISA has a 63% specificity and 65% sensitivity with serum; the ELISA with cerebrospinal fluid has a high specificity (95%) and sensitivity (87%) for both IgM and IgG antibody. As antibodies persist after cyst death, neither the EITB nor ELISA distinguishes current from past infection, and these tests cannot be used to monitor therapy; however, another ELISA (under study) to detect circulating antigen may do so.

3. Other laboratory tests—Cerebrospinal fluid typically shows increased protein, decreased glucose, and a cellular reaction of mainly lymphocytes and eosinophils; eosinophilia that may be over 20% is diagnostically important. Lumbar puncture is contraindicated, however, in case of increased intracerebral pressure. The EEG may be abnormal. Though the patient usually no longer harbors a tapeworm, all family members should examine their stools over several days for passage of proglottids, and stool specimens should be examined for proglottids and eggs.

Differential Diagnosis

The differential diagnosis includes tuberculoma, primary or metastatic tumor, hydatid disease, vasculitis, chronic fungal disorders, pyogenic brain abscess, toxoplasmosis and other parasitic diseases, and neurosyphilis. CT and MRI findings of cystic lesions without a scolex, single or multiple ring or nodular enhancing lesions, or parenchymal round calcifications may also be found in some of these other diseases.

Treatment

Treatment should be individualized based on the number and location of cysts and their viability. Medical treatment, which is usually preferable to surgery, is most effective for parenchymal cysts; less effective for intraventricular, subarachnoid, or racemose cysts. When only one or a few live parenchymal cysts are present, the evidence is still insufficient to establish that medical treatment is preferable to symptomatic management followed by normal death of the parasites. Some clinicians

wait 3 months with selected patients to see if cysts will spontaneously disappear without treatment. Although single enhancing lesions are likely to do well when treated only with anticonvulsants, some experts do add albendazole or praziquantel treatment; however, patients with only calcified cysts do not need these drugs.

Albendazole and praziquantel are both effective in treatment. Albendazole is preferred because its course of treatment is shorter (1 week) than that of praziquantel (2 weeks); because albendazole is less expensive; and because coadministration of albendazole and a steroid (to treat inflammation) results in increased albendazole absorption, whereas combined use of praziquantel and a steroid greatly decreases plasma levels of praziquantel. Both drugs are given with fatty meals, which increases absorption fourfold to fivefold. Treatment should be conducted in hospital. Between the second and fifth days after starting treatment, increased inflammatory reactions around dying parasites may be manifested by meningismus, headache (analgesics may be sufficient for mild symptoms), vomiting, hyperthermia, mental changes, and convulsions; decompensation with death is very rare. It remains controversial whether to give steroids concomitantly to avoid or diminish this reaction or to use them only if marked symptoms appear or increase. Even when steroids are given prospectively, the inflammatory reaction may occur. Prednisone, 1 mg/kg/d in two or three divided doses, starting 1-2 days before use of the drug and continuing at diminishing doses for about 14 days afterward, is one regimen. The reaction usually subsides in 48-72 hours, but continuing severity may require steroids in higher dosage and mannitol. For patients with seizures, anticonvulsants should be given during drug treatment and probably for an indefinite time afterward.

Cure rates following treatment (disappearance of cysts and clearing of symptoms) ranged up to 85% for albendazole and 50-60% for praziquantel. Of the remaining patients, many have amelioration of symptoms, including intracranial hypertension and seizures.

A. Medical Measures

1. Albendazole—The dosage is 400 mg twice daily with a fatty meal. The duration of treatment is unsettled. Seven to 14 days may be sufficient for some patients, but a longer course (up to 28 days) is advisable at present; it can be repeated as necessary. Up to 3 months of treatment may be needed for ventricular and subarachnoid cysts. For albendazole side effects, see below under Hydatid Disease.

2. Praziquantel—Give 50 mg/kg/d in three divided doses for 15 days. Phenytoin, phenobarbital, carbamazepine, cimetidine, and corticosteroids, when administered with praziquantel, reduce serum levels of the latter; high doses of praziquantel have been tried in these circumstances. Ingestion with a high-carbohydrate meal enhances absorption.

B. Other Measures

Seizures are treated with anticonvulsant drugs. During the acute phase of cysticercotic encephalitis, if intracranial hypertension is present, mannitol (2 g/kg/d) and corticosteroids are used but albendazole and praziquantel are withheld. Surgery has successfully removed accessible orbital, cisternal, ventricular, cerebral, meningeal, and spinal cord cysts. Obstructive hydrocephalus requires cerebrospinal fluid diversion plus a corticosteroid. Subarachnoiditis and vasculitis are treated with albendazole or praziquantel plus a corticosteroid. Albendazole or praziquantel, when used with ocular or spinal medullary lesions, may cause irreversible damage even when corticosteroids are given.

Prognosis

The fatality rate for untreated neurocysticercosis is about 50%; survival time from onset of symptoms ranges from days to many years. Drug treatment has reduced the mortality rate to about 5-15%. Surgical procedures to relieve intracranial hypertension along with use of steroids to reduce edema improve the prognosis for those not effectively treated with the drugs.

ECHINOCOCCOSIS (HYDATID DISEASE, HYDATIDOSIS)

Human echinococcosis results from parasitism by the larval stage of four *Echinococcus* species, of which *E granulosus* (cystic hydatid disease) and *E multilocularis* (alveolar hydatid disease) are the most important. Minor species are the polycystic species, *E vogeli* (polycystic hydatid disease) and *E oligarthrus*, both from Central and South America. Echinococcosis is a zoonosis in which humans are an intermediate host of the larval stage of the parasite. The definitive host is a carnivore (all of which, except for the lion, are Canidae) that harbors the adult tapeworm in the small intestine; the carnivore becomes infected by ingesting the larval form in tissue of the intermediate host. The intermediate hosts, chiefly herbivorous mammals but also humans, become infected by ingesting tapeworm eggs passed in carnivore feces. The larval stage is referred to as a hydatid cyst.

1. Cystic Hydatid Disease (Unilocular Hydatid Disease)

Essentials of Diagnosis

- History of exposure to dogs associated with livestock in a hydatid-endemic region.
- Avascular cystic tumor of liver, lung, or, infrequently, bone, brain, or other organs as detected by imaging procedures.
- Symptoms and signs of a space-occupying mass.
- Positive serologic tests.

General Considerations

Human infection with *E granulosus* is common throughout southern South America, the Mediterranean littoral and the Middle East, central Asia, and East Africa. Endemic foci are in eastern Europe, Russia, Australia, New Zealand, India, and the United Kingdom; in North America, foci have been reported from the western USA, the lower Mississippi valley, Alaska, and northwestern Canada.

The pastoral strain—which is more pathogenic to humans—has a transmission cycle in which dogs are the definitive host, and sheep (usually) but also cattle and other domestic livestock are intermediate hosts. However, the strain in horses, pigs, and camels may be of low or no infectivity for humans. The sylvatic, or northern, strain is maintained in wolves and wild ungulates (moose and reindeer) in northern Alaska, Canada, Scandinavia, and Eurasia.

Human infection occurs when eggs passed in dog feces are accidentally swallowed. Liberated embryos penetrate the intestinal mucosa, enter the portal bloodstream, and are carried to the liver where they become hydatid cysts (65% of all cysts). Some larvae reach the lung (25%) and develop into pulmonary hydatids. Infrequently, cysts form in the brain, bones, skeletal muscles, kidneys, spleen, or other tissues. Cysts of the sylvatic strain tend to localize in the lungs.

The cyst wall has three layers: an inner germinal layer that gives rise within the cyst to germinal elements, a supporting intermediate layer, and an outer layer produced by the host. In the liver, cysts may increase in size 1-30 mm in diameter per year and become enormous, but symptoms generally do not develop until they reach about 10 cm. Some cysts die spontaneously; others may persist unchanged for years. Part or all of the inner layer of hepatic and splenic cysts may calcify, which does not necessarily mean cyst death.

Clinical Findings

A. Symptoms and Signs

A liver cyst may remain silent for 10-20 or more years until it becomes large enough to be palpable, to be visible as an abdominal swelling, to produce pressure effects, or (rarely) to produce symptoms due to leakage or rupture. There may be right upper quadrant pain, nausea, and vomiting. The effects of pressure may result in biliary obstruction, with secondary bacterial cholangitis, cirrhosis, and portal hypertension. If a cyst ruptures suddenly, anaphylaxis and death may occur. If fluid and hydatid particles escape slowly, allergic manifestations may result, including a rise in the eosinophil count. Rupture can occur into the pleural, pericardial, or peritoneal space or into the duodenum, colon, or renal pelvis. Dissemination of germinal elements may be followed by the development of multiple secondary cysts. A characteristic clinical syndrome may follow intrabiliary extrusion of cyst contents—jaundice, biliary colic, and urticaria.

Pulmonary cysts cause no symptoms until they leak; become large enough to obstruct a bronchus, causing segmental collapse; or erode into a bronchus and rupture.

Brain cysts produce symptoms earlier and may cause seizures or symptoms of increased intracranial pressure. Cysts in the bone marrow or spongiosa do not have a host layer, are irregular in shape, erode osseous tissue, and present as pain or as spontaneous fracture. The bones most often affected are the vertebrae; many of these patients develop epidural extension with compression of the spinal cord and paraplegia. Because 20% of patients have multiple cysts, upon diagnosis each patient should be screened for cysts in the liver, spleen, kidneys, lungs, brain, bones, skin, tongue, vitreous, and other tissues.

B. Imaging

The method of choice for liver and splenic cysts is sonography (specificity 90%) followed by CT (gives better information about location and depth of cyst). The cysts can also be defined by MRI; scintillation scan and angiography are rarely used. Cysts may present as solitary lesions with interior echoes or as multilocular cysts with daughter cysts. Nearly pathognomonic is the presence within a hydatid cyst of daughter cysts; they must be distinguished, however, from blood clots within the cavity of a simple cyst. Spotty calcified densities or a calcified cyst wall may be seen in the liver or spleen. Chest films may show an elevated diaphragm. Pulmonary cysts are best detected by chest films (calcification of the wall is rare); CT and MRI can also be done. An intravenous urogram or bone scan may detect cysts at other sites.

C. Laboratory Findings

The immunoblot test, where available, is the test of choice (95% specific and 91% sensitive for liver cysts); the arc 5 test is also diagnostic. In both tests, cross-reactions can occur in 5-25% of patients with *T solium* cysticercosis infections. Several other serologic tests (ELISA and indirect hemagglutination and immunofluorescence) are useful for screening, but both false-negative and false-positive results are common. Persons from whom cysts have been completely removed and carriers of calcified or dead cysts may become seronegative. False-negative tests occur with about 50% of solitary lung cysts, more often with bone cysts, and most often with brain or splenic cysts. Testing for antigen in serum or hydatid cyst fluid is now available. Although hydatid cyst aspiration was contraindicated in the past, ultrasonic percutaneous aspiration followed by injection of a scolical agent with the use of oral albendazole is now being increasingly used in diagnosis. Eosinophilia is uncommon except after cyst rupture. The intracutaneous skin test has been abandoned because of poor specificity.

Differential Diagnosis

Noninfected hydatid cysts of the liver need to be differentiated from simple epithelial cysts and bacterial and amebic abscesses. Hydatid cysts in any site may be mistaken for a variety of malignant and nonmalignant tumors and cysts. In the lung, a cyst may be confused with cavitary tuberculosis. Allergic symptoms arising from cyst leakage may resemble those associated with many other diseases.

Treatment & Prevention

Surgery was formerly the definitive approach to therapy but has now been partially supplanted by anthelmintic treatment. Decision-making between the two modes of treatment must take into account (1) current surgical mortality rates (up to 4%), postoperative complications (10-25%), and recurrence rates after surgery (11-30%); and (2) cure rates after albendazole treatment of about 32%. One approach is to give a course of albendazole to selected asymptomatic patients whose cysts are small and not in danger of rupture. If, after 6-9 months, the cyst has not disappeared or clearly died, it can then be removed surgically.

A. Surgical Treatment

Operative treatment of liver cysts involves several problems: total removal of all infective components of the cyst, avoiding cyst content spillage, selection of a scolical agent to be placed within the cyst, management of communications between the cyst and biliary tract (if present), management of the residual cavity, and minimizing the risk of operation. The main surgical options available for liver cysts are partial hepatic resection, pericystectomy, and cystectomy. Surgery for pulmonary cysts includes extrusion of cysts (Barrett's technique), pericystectomy, and lobectomy. Scolical solutions, which include cetrimide (5%), hypertonic saline (20%), silver nitrate (0.5%), ethanol (70-95%), and sodium hypochlorite (3.75%), have come under criticism because of their potential for direct and indirect toxicity (an estimated 20% of cysts are thought to communicate with the biliary tract). Preoperatively, to reduce the risk of recurrence due to spillage, two drugs (taken with meals) are used for 1 month: albendazole, 10 mg/kg/d in two divided doses, and praziquantel, 25 mg/kg/d. Postoperatively, albendazole should be continued for 1 month; the additional use of praziquantel is under evaluation. Pulmonary cysts are treated by surgery plus chemotherapy. The treatment of bone cysts is by combined curettage, lavage, instillation of sterilization substances, and chemotherapy.

B. Drug Treatment

Albendazole is the drug of choice; mebendazole is no longer recommended in this text for hydatid disease treatment.

1. Albendazole—Albendazole is more readily absorbed than mebendazole; this permits a lower dosage of albendazole to be used, yet its active metabolite, the sulfoxide, reaches effective concentrations in cyst wall and fluid. A current regimen is four tablets (800 mg) daily in divided doses with meals for 3 months; continue for up to 6 months if there is evidence of a response. In multiple studies, apparent cure (shrinkage or disappearance of cysts) was approximately 30%, and improvement was 45%. To be emphasized, however, is that some of these changes result from the natural history of the disease. Relapses occur and should be re-treated, but long-term follow-up results have not been determined. Bone cysts are more refractory and may require a year of treatment. In the 3-month courses, drug side effects include reversible low-grade aminotransferase elevations (15%), leukopenia to 2900/uL (2%), rare gastrointestinal symptoms (including pain at cyst sites), dizziness or headache, alopecia, rash, and pruritus. Anaphylaxis has been reported once and eosinophilia rarely, probably related to cyst fluid leakage. Two deaths attributed to long-term albendazole use have been reported. Liver function tests and complete blood counts should be monitored weekly. The drug is contraindicated in pregnancy.

2. Praziquantel—Praziquantel kills protoscoleces within hydatid cysts but does not affect the germinal membrane. The drug is being evaluated as adjunctive therapy with albendazole both pre- and postsurgery to protect against cyst spillage.

C. Percutaneous Aspiration and Injection of a Scolical Agent

Under ultrasonic guidance, this approach is indicated in the treatment of accessible cysts in patients who are inoperable or refuse surgery and are not candidates for a chemotherapeutic trial. The procedure is contraindicated for cysts that communicate with the biliary tree, those that are superficially loculated, or those that have thick internal septal divisions. Complications are infection or leakage at the aspiration site followed by an allergic reaction or dissemination of the infection. Several thousand patients have now had the procedure while covered by oral albendazole. One case of anaphylaxis has been reported. Follow-up has not been sufficiently long to permit assessment of therapeutic efficacy or risk of spillage.

D. Prevention

In endemic areas, prevention is by prophylactic treatment of pet dogs with 5 mg/kg of praziquantel at monthly intervals to remove adult tapeworms and by health education to prevent feeding of offal to dogs.

Prognosis

About 15% of untreated patients eventually die because of the disease or its complications.

2. Alveolar Hydatid Disease (Multilocular Hydatid Disease)

Alveolar hydatid disease results from infection by the larval form of *Echinococcus multilocularis* and occurs only in the northern hemisphere. The life cycle involves foxes as definitive host and microtine rodents as intermediate host. Domestic dogs and cats can also become infected with the adult tapeworm when they eat infected wild rodents. Human infection is by accidental ingestion of tapeworm eggs passed in fox or dog feces. The disease in humans has been reported in parts of central Europe, much of Siberia, northern Japan, northwestern Canada, and western Alaska. Recent information has extended the Old World range southward to Iran and northern India and China. Increasing numbers of cases have been reported from central North America (eleven USA states and four Canadian provinces). The primary localization of alveolar cysts is in the liver, where they may extend locally or metastasize to other tissues. The larval mass has poorly defined borders and behaves like a neoplasm; it infiltrates and proliferates indefinitely by exogenous budding of the germinative membrane, producing an alveolus-like pattern of microvesicles. Pulmonary involvement is rare, usually occurring by direct extension from the liver. X-rays show hepatomegaly and characteristic scattered areas of radiolucency often outlined by 2- to 4-mm calcific rings. The serologic tests using affinity-purified antigen (ELISA and Western blot) are usually positive at high titer and differentiate *E granulosa* from *E multilocularis*. Treatment is by surgical removal of the entire larval mass when possible, accompanied by drug treatment. Ninety percent of patients with nonresectable masses die within 10 years. Long-term drug therapy (5 years to life) is with albendazole (preferred) (800 mg/d in divided doses) or with mebendazole (40 mg/kg/d in divided doses with fatty meals); the drugs inhibit growth of the parasite and have extended patient survival, but larval tissue is not completely destroyed.

■ **NEMATODE (ROUNDWORM) INFECTIONS**

ANISAKIASIS

Anisakiasis is larval invasion of the stomach or intestinal wall by anisakid nematodes. In the acute form, the infection may mimic surgical abdomen; in the chronic form, mild symptoms may persist for weeks to years.

Definitive hosts are marine mammals, including whales, seals, and dolphins. Eggs discharged with feces are ingested by crustaceans, in which larvae develop that are infective for squids, mackerel, herring, cod, halibut, rockfish, salmon, tuna, and other marine fish. In the fish, in which infection rates can reach 80%, the larvae pass to the musculature and are able to transfer from fish to fish along the food chain, eventually reaching a marine mammal, where they mature into the adult stage.

Humans are infected when they ingest larvae in marine fish or squid eaten raw, undercooked, salted, or lightly pickled. Larvae liberated in the stomach attach to or partially penetrate the gastric or intestinal mucosa (small bowel is more common; colon is rare), resulting in localized ulceration, edema, and eosinophilic granuloma formation; eventually, the parasite dies. Rarely, worms are coughed up and expectorated or penetrate the gut wall, enter the peritoneal cavity, and migrate. Most larvae, however, probably fail to cause infection and are passed in feces. Although the larvae sometimes develop to the adult stages, gravid females are not found in humans.

The infection occurs worldwide, but most cases have been reported in Japan and the Netherlands, with a few in the United States, Scandinavia, Chile, and other fish-eating countries. Regional foods eaten raw such as sashimi in Japan, pickled herring in the Netherlands, and ceviche (seviche) in Latin America are common vehicles of infection.

Clinical Findings

A. Symptoms and Signs

The majority of acute cases present as gastric anisakiasis. Occasionally, acute infection is followed by a chronic course.

1. Acute gastric anisakiasis—Within hours after larval ingestion, the patient experiences nausea, vomiting, and epigastric pain that progressively becomes more severe. Allergic reactions, including rare anaphylaxis, can occur; chest pain and hematemesis are rare.

2. Acute intestinal anisakiasis—Within 1-7 days, colicky pain appears in the lower abdomen, often localized at the ileocecal region, accompanied by diarrhea, nausea, vomiting, diffuse abdominal tenderness, and mild fever.

3. Chronic disease—For weeks to several years, symptoms may continue that mimic gastric ulcer, gastritis, gastric tumor, bowel obstruction, or inflammatory bowel disease.

B. Laboratory Findings

Stools may show occult blood, but eggs are not produced. Mild leukocytosis and eosinophilia may be present. ELISA and RAST serologic tests may be helpful but are not reliable in chronic disease.

C. Imaging and Endoscopy

In acute infection, gastroscopy is preferred because the larvae sometimes can be seen and removed from the stomach. X-rays of the stomach may show a localized edematous, ulcerated area with an irregularly thickened wall, decreased peristalsis, and rigidity. Double contrast technique may show the threadlike larvae. Small bowel x-rays may show thickened mucosa and segments of stenosis with proximal dilation. Ultrasound examination of gastric and intestinal lesions may also be useful.

In the chronic stage, x-rays and endoscopy of the stomach—but not of the bowel—may be helpful. The diagnosis is often made only at laparotomy with surgical removal of the parasite. Serologic reagents have been developed but are not commercially available. A rise in IgE levels is consistent with the diagnosis.

Prevention & Treatment

Prevention is by avoidance of ingestion of raw or incompletely cooked squid or marine fish, especially salmon, rockfish, herring, and mackerel; early evisceration of fish is recommended. Larvae within fish may with difficulty be seen as colorless, tightly coiled or spiraled worms in 3-mm whorls or as reddish or pigmented larvae lying open in muscles or viscera. The larvae are killed by temperatures above 60 °C or by freezing at -20 °C for 24 hours (7 days is advised by some workers). Smoking procedures that do not bring the temperature to 60 °C, marinating in vinegar, and salt-curing are not reliable.

There is no drug treatment, although a single report suggests efficacy for albendazole. Except where larvae can be removed by fiberoptic gastroscopy or colonoscopy, treatment of acute and chronic lesions is limited to symptomatic measures; symptoms generally improve in 1-2 weeks. Surgical excision of the worm may be necessary in severe cases.

ANGIOSTRONGYLIASIS

1. Angiostrongyliasis cantonensis (Eosinophilic Meningoencephalitis)

A nematode of rats, *Angiostrongylus cantonensis*, is the causative agent of a form of eosinophilic meningoencephalitis. It has been reported from Hawaii and other Pacific islands, Southeast Asia, Japan, China, Taiwan, Hong Kong, Australia, Egypt, Madagascar, Nigeria, Bombay, Cuba, Puerto Rico, Bahamas, Brazil, and New Orleans.

Human infection results from the ingestion of infective larvae contained in uncooked food—either the intermediate mollusk hosts (snails, slugs, planarians) or transport hosts that have ingested mollusks (crabs, shrimp, fish). Leafy vegetables contaminated by small mollusks or by mollusk slime may also be the source of infection, as can fingers during collection and preparation of snails for cooking. The mollusks become infected by ingesting larvae excreted in feces of infected rodents, the definitive host.

The incubation period in humans is 1-3 weeks. Ingested larvae (0.5 × 0.025 mm) invade the central nervous system, where, during migration, they may cause extensive tissue damage; at their death, a local inflammatory reaction ensues. The usual clinical findings are those of meningoencephalitis, including severe headache, fever, neck stiffness, nausea and vomiting, and multiple neurologic findings, particularly asymmetric transient cranial neuropathies. Worms in the spinal cord may result in sensory abnormalities in the trunk or extremities; worms have also been seen in the eye.

The spinal fluid characteristically shows elevated protein, eosinophilic pleocytosis, and normal glucose. Occasionally, the parasite can be recovered from spinal fluid. Peripheral eosinophilia with a low-grade leukocytosis is common. A serologic test is available from the Centers for Disease Control and Prevention. CT and MRI may show a central nervous system lesion.

The differential diagnosis includes tuberculosis, coccidioid or aseptic meningitis, syphilis, lymphoma, gnathostomiasis, cysticercosis, paragonimiasis, echinococcosis, and schistosomiasis japonicum.

No specific treatment is available; however, levamisole, albendazole (400 mg twice daily for 7 days), thiabendazole (25 mg/kg three times daily for 3 days; this dose may be toxic and need to be reduced), mebendazole (100 mg twice daily for 5 days), or ivermectin can be tried. Theoretically, parasite deaths may exacerbate central nervous system inflammatory lesions. Symptomatic treatment with analgesics or corticosteroids may be necessary. The illness usually persists for weeks to months, the parasite dies, and the patient then recovers spontaneously, usually without sequelae. However, fatalities have been recorded.

Prevention is by rat control; by cooking of snails, prawns, fish, and crabs for 3-5 minutes or by freezing them (-15 °C for 24 hours); and by examining vegetables for

mollusks before eating. Washing contaminated vegetables to eliminate larvae contained in mollusk mucus is not always successful.

Prociv P et al: Neuro-angiostrongyliasis: unresolved issues. Int J Parasitol 2000;30:1295. [PMID: 11113256]

Wang X et al: A clinical study of eosinophilic meningoencephalitis caused by angiostrongyliasis. Chin Med J (Engl) 2002;115:1312. [PMID: 12411101]

2. *Angiostrongylus costaricensis*

Angiostrongylus costaricensis, which causes an eosinophilic ileocolitis, has been identified in humans (predominantly children) in Mexico, Central America, Venezuela, Brazil, and the USA (Texas). The known geographic range of the parasite in rodents (the definitive host) extends from northern South America to Texas. Infection occurs from ingestion of the larvae in the intermediate host (slugs, snails) or from food contaminated by larvae in slug or snail mucus. In humans, the larvae mature in the mesenteric vessels. The inflammatory response to adult worms, larvae, and eggs can be severe, resulting in a marked eosinophilic granulomatous reaction and intestinal vasculitis and ischemic necrosis. Most cases involve the ileocecal region, appendix, ascending colon, and regional nodes, but other organs can be affected, including the liver and testes. Findings include fever, right lower quadrant abdominal pain and a mass, leukocytosis, and eosinophilia. Some patients have relapsing symptoms that can continue for months. Bowel complications include perforation, bleeding, incomplete or complete obstruction, and infarction. Neither eggs nor larvae are passed in stool; a latex agglutination serologic test has been devised. The intra-abdominal mass can mimic tumor. There is no specific treatment; albendazole, thiabendazole, or mebendazole can be tried (as above). Operative treatment is frequently necessary.

Dekumyoy P et al: Angiostrongyliasis: analysis of antigens of *Angiostrongylus costaricensis* adult worms versus IgG from infected patients with *Angiostrongylus cantonensis*. Southeast Asian J Trop Med Public Health 2000;31(Suppl 1):48. [PMID: 11414459]

ASCARIASIS

Essentials of Diagnosis

- Pulmonary phase: Transient cough, dyspnea, wheezing, urticaria, with eosinophilia and transient pulmonary infiltrates.
- Intestinal phase: Vague upper abdominal discomfort; occasional vomiting, abdominal distention.
- Eggs in stools; worms passed per rectum, nose, or mouth.

General Considerations

Ascaris lumbricoides is the most common of the intestinal helminths; an estimated 1 billion people are infected worldwide. It is cosmopolitan in distribution and is found in high prevalence wherever there are low standards of hygiene and sanitation (including focally in southeastern USA) or where human feces are used as fertilizer. The infection is specific for humans and occurs in all age groups. Heavy worm burdens, however, are usually seen only in children, in whom there may be reduced nitrogen, fat, and D-xylose absorption and reduced mucosal lactate activity resulting in decreased growth rates.

Adult worms live in the upper small intestine. After fertilization, the female produces enormous numbers of eggs that pass in feces. Direct transmission between humans does not occur, as the eggs must remain on the soil for 2-3 weeks before they become infective. Thereafter, they can survive for years. Infection occurs through ingestion of mature eggs in fecally contaminated food and drink. The eggs hatch in the small intestine, releasing motile larvae that penetrate the wall of the small intestine and reach the right heart via the mesenteric venules and lymphatics. From the heart they move to the lung, burrow through the alveolar walls, and migrate up the bronchial tree into the pharynx, down the esophagus, and back to the small intestine. Egg production begins 60-75 days after ingestion of infective eggs. Adult worms (20-40 cm × 3-6 mm) live for 1 year or more.

Clinical Findings

A. Symptoms and Signs

As a result of their migration and induction of hypersensitivity, larvae in the lung cause capillary and alveolar damage, which may result in low-grade fever, nonproductive cough, blood-tinged sputum, wheezing, dyspnea, and substernal pain. There may be urticaria and localized rales. Rarely, larvae lodge ectopically in the brain, kidney, eye, spinal cord, and other sites and may cause symptoms referable to those organs.

Small numbers of adult worms in the intestine usually produce no symptoms. With heavy infection, peptic ulcer-like symptoms or vague pre- or postprandial abdominal discomfort may be seen. Adult worms may also migrate with heavy infections; they may be coughed up, vomited, or emerge through the nose or anus. They may also force themselves into the common bile duct, pancreatic duct, appendix, diverticula, and other sites, which may lead to cholangitis, cholecystitis, pyogenic liver abscess, pancreatitis, or obstructive jaundice. With very heavy infestations, masses of worms may cause intestinal obstruction, volvulus, intussusception, or death. During typhoid fever, worms may penetrate the weakened bowel wall. Rare cases of lung abscess or laryngeal obstruction with suffocation have been described. Moderate to high worm loads have been associated with stunting of growth in children. Periodic treatment of children with albendazole for multiple intestinal parasitism has resulted in improved nutrition.

B. Imaging

During the larval migratory phase, chest radiographs may show transitory, patchy, ill-defined asymmetric infiltrations (Löffler's syndrome). Intestinal infection is sometimes established by chance, when radiologic examination of the abdomen (with or without barium) shows the presence of worms. The diagnosis of biliary ascariasis can be made by endoscopic retrograde cholangiopancreatography, which has the therapeutic potential of removing the worms, and by ultrasonography. In intestinal obstruction, plain abdominal films show air-fluid levels and multiple linear images of ascarides in dilated bowel loops; ultrasonography can also demonstrate the dilated bowel and worm mass.

C. Laboratory Findings

During the pulmonary phase, eosinophils may reach 30-50% and remain high for about a month; larvae are occasionally found in sputum. During the intestinal phase, diagnosis usually depends upon finding the characteristic eggs in feces. Occasionally, an adult worm spontaneously passed per rectum or orally reveals an unsuspected infection. Serologic tests are not useful; there is no eosinophilia in the intestinal phase.

Differential Diagnosis

Pulmonary ascariasis with eosinophilia must be differentiated from nonparasitic causes (asthma, Löffler's syndrome, eosinophilic pneumonia, allergic bronchopulmonary aspergillosis) and parasitic causes (tropical pulmonary eosinophilia, toxocariasis, strongyloidiasis, hookworm, paragonimiasis). Ascaris-induced pancreatitis, appendicitis, and diverticulitis, must be differentiated from other causes of inflammation of these tissues. Postprandial dyspepsia may simulate duodenal ulcer, hiatal hernia, gallbladder disease, or pancreatic disease.

Treatment

Albendazole and pyrantel pamoate are the treatments of choice. The drugs listed below do not require pre- or posttreatment purges. Stools should be rechecked at 2 weeks and patients re-treated until all ascarids are removed. Ascariasis, hookworm, and trichuriasis infections, which often occur together, may be treated simultaneously by albendazole, mebendazole, or oxantel-pyrantel pamoate.

Treatment with anthelmintics can cause worms to migrate before they die. Because anesthesia stimulates worms to hypermotility, they should be removed in advance in infected patients undergoing elective surgery. In pregnancy, ascariasis should be treated after the first trimester.

Drug treatment should not be used in the migratory phase. In intestinal obstruction or biliary ascariasis, surgery may be avoided by nasogastric suction followed by a standard dose of an anthelmintic given via the tube. In biliary ascariasis, endoscopic removal of the worm under ultrasonographic guidance is often successful; treatment by injection of a solution of albendazole or piperazine into the common duct followed by systemic treatment has also been effective.

A. Albendazole

In light infections, a single dose of albendazole (400 mg) results in cure rates over 95%; in heavy infections, however, a 2- to 3-day course is indicated. Side effects, including migration of ascaris through the nose or mouth, are rare. Albendazole is available in the USA, though not approved for this indication. The drug is contraindicated in pregnancy.

B. Pyrantel Pamoate

Pyrantel pamoate as a single oral dose of 10 mg base/kg (maximum, 1 g) results in 85-100% cure rates. It may be given before or after meals. Infrequent and mild side effects include vomiting, diarrhea, headache, dizziness, and drowsiness.

C. Mebendazole

Although mebendazole is highly effective when given in a dosage of 100 mg twice daily before or after meals for 3 days, a single 500 mg dose is often sufficient. Gastrointestinal side effects are infrequent. The drug is contraindicated in pregnancy.

D. Piperazine

The dosage for piperazine (as the hexahydrate) is 75 mg/kg body weight (maximum, 3.5 g) for 2 days in succession, giving the drug orally before or after breakfast. For heavy infestations, treatment should be continued for 4 days in succession or the 2-day course should be repeated after 1 week.

Gastrointestinal symptoms and headache occur occasionally; central nervous system symptoms (temporary ataxia and exacerbation of seizures) are rare. Allergic symptoms have been attributed to piperazine. The drug should not be used for patients with hepatic or renal insufficiency or in those with a history of seizures or chronic neurologic disease.

E. Levamisole

Levamisole, available in the USA but not approved for this indication, is highly effective as a single oral dose of 150 mg. Occasional mild and transient side effects are nausea, vomiting, abdominal pain, headache, and dizziness.

Prognosis

The complications caused by wandering adult worms require that all ascaris infections be treated and eradicated.

CUTANEOUS LARVA MIGRANS (CREEPING ERUPTION)

Cutaneous larva migrans, prevalent throughout the tropics and subtropics, including southeastern USA, is caused by larvae of the dog and cat hookworms, *Ancylostoma braziliense* and *Ancylostoma caninum*. A number of other animal hookworms, gnathostomiasis, and strongyloidiasis are rarely also causative agents. Moist sandy soil (eg, beaches, children's sand piles) contaminated by dog or cat feces is a common site of infection. The infection is also reported in travelers to tropical beaches, among whom delayed onset beyond several weeks has been described.

At the site of larval entry, particularly on the hands or feet, up to several hundred minute, intensely pruritic erythematous papules appear. Two to 3 days later, serpiginous eruptions appear as the larvae migrate at a rate of several millimeters a day; the parasite lies slightly ahead of the advancing border. The process may continue for weeks; the lesions may become severely pruritic, vesiculate, encrusted, or secondarily infected. Without treatment, the larvae eventually die and are absorbed.

The diagnosis is based on the characteristic appearance of the lesions and the frequent presence of eosinophilia. Biopsy is usually not indicated.

Mild transient cases may not require treatment. For mild cases, thiabendazole, if available, can be applied topically three times daily for 5 or more days as a 15% cream, which can be formulated in a hygroscopic base using crushed 500-mg tablets. For more severe cases, oral treatment is indicated. Highly effective and nearly free of side effects are ivermectin (200 ug/kg given for 1 or 2 days) and albendazole (400 mg twice daily for 3-5 days or 400 mg daily for 7 days). Thiabendazole, given orally as for strongyloidiasis, is a less satisfactory alternative drug because it has toxic side effects in about one-third of patients. With treatment, progression of the lesions and itching are usually stopped within 48 hours. Antihistamines are helpful in controlling pruritus; antibiotic ointment or oral preparation may be necessary to treat secondary infections.

DRACUNCULIASIS (GUINEA WORM INFECTION, DRACUNCULOSIS, DRACONTIASIS)

Dracunculiasis is an infection of connective and subcutaneous tissues by the nematode *Dracunculus medinensis*. It occurs only in humans and is a major cause of disability. Since the start of the WHO eradication program, the number of infected persons has declined about 97% from over 3 million to 100,000. Endemic areas have been the Indian subcontinent; West and Central Africa north of the equator; and Saudi Arabia, Iran, and Yemen. The two remaining endemic foci are southern Sudan and northern Ghana. All ages are affected, and prevalence may reach 60%.

Infection occurs by swallowing water containing the infected intermediate host, the crustacean cyclops (copepods, water fleas). In the stomach, larvae escape from the crustacean and mature in subcutaneous connective tissue. After mating, the male worm dies and the gravid female (60-80 cm × 1.7-2.0 mm) moves to the surface of the body, where its head reaches the dermis and provokes a blister that ruptures on contact with water. Intermittently over 2-3 weeks, whenever the ulcer comes in contact with water, the uterus discharges great numbers of larvae, which are ingested by copepods. Most adult worms are gradually extruded; some worms retract and reemerge; and others die in the tissues, disintegrate, and may provoke a severe inflammatory reaction. Infection does not induce protective immunity.

Clinical Findings

A. Symptoms and Signs

Infection may be at several sites. Patients are asymptomatic during the 9- to 14-month incubation period except in the last 1-2 weeks, when the worm reaches and becomes palpable in the skin and a blister develops around its anterior end. Several hours before the head appears at the skin surface, local erythema, burning, pruritus, and tenderness often develop at the site of emergence. There may also be a 24-hour systemic allergic reaction (pruritus, fever, nausea and vomiting, dyspnea, periorbital edema, and urticaria). After rupture, the tissues surrounding the ulceration frequently become indurated, reddened, and tender. Because most lesions appear on the leg or foot, patients often must give up walking and working for days to several months. Uninfected ulcers heal in 4-6 weeks. The worm rarely reaches ectopic sites.

Secondary infections, including tetanus, are common. Deep "cold" abscesses may result at the sites of dying, nonemergent worms. Ankle and knee joint infections with resultant deformity are common complications.

B. Laboratory Findings

When an emerging adult worm is not visible in the ulcer or under the skin, the diagnosis may be made by detection of larvae in smears from discharging sinuses. Immersion of an ulcer in cold water stimulates larval expulsion. Eosinophilia is usually present. Skin and serologic tests are not useful. Calcified worms can be recognized on radiographs.

Treatment

All persons in an endemic area should be actively immunized against tetanus.

A. General Measures

The patient should be at bed rest with the affected part elevated. Cleanse the lesion, control secondary infection with topical antibiotics, and change dressings twice daily.

B. Manual Extraction

Traditional extraction of emerging worms by gradually rolling them out a few centimeters each day on a small stick is still useful, especially when done along with chemotherapy and use of aseptic dressings. The process appears to be facilitated by placing the affected part in water several times a day. If the worm is broken during removal, however, secondary infection almost always results, leading to cellulitis, abscess formation, or septicemia.

C. Anthelmintic Therapy

The following drugs have an anti-inflammatory effect but do not kill the adults or the larvae. This effect may alleviate symptoms, reduce duration of infection, facilitate worm removal, or expedite their spontaneous extrusion.

1. Metronidazole, 250 mg three times daily for 10 days, causes only minimal toxicity. (See under Amebiasis.)
2. Mebendazole, 400-800 mg daily for 6 days, can be tried.
3. Thiabendazole, 25 mg/kg twice daily for 2-3 days after meals, frequently causes side effects, sometimes severe (see under Strongyloidiasis, below).

D. Surgical Removal

Preemergent female worms can sometimes be surgically removed intact under local anesthesia if not firmly embedded in deep fascia or around tendons.

Prevention & Control

The disease is prevented by use of only noncontaminated drinking water. This can be accomplished either by (1) preventing contamination of community water supplies through use of tube wells, hand pumps, or cisterns or treating water sources with temephos; or (2) filtering water through finely woven cloth (eg, nylon nets of 100-um pore size); or (3) boiling water.

Cairncross S et al: Dracunculiasis (Guinea worm disease) and the eradication initiative. Clin Microbiol Rev 2002;15:223. [PMID: 11932231]

ENTEROBIASIS (PINWORM INFECTION)

Essentials of Diagnosis

- Nocturnal perianal and vulvar pruritus, insomnia, irritability, restlessness.
- Vague gastrointestinal symptoms.
- Eggs demonstrable by cellulose tape test; worms visible on perianal skin or in stool.

General Considerations

Enterobius vermicularis (8-13 × 0.5 mm) is common worldwide. Humans, the only host, can harbor a few to hundreds of worms. Young children are affected more often than adults, and multiple infections occur in households and institutions with young children. High rates have been recorded in homosexual men, but the infection does not become opportunistic in HIV. A second species, *Enterobius gregorii*, has been described in England.

The adult worms inhabit the cecum and adjacent bowel areas, lying loosely attached to the mucosa. Gravid females migrate through the anus to the perianal skin and deposit eggs in large numbers. The eggs become infective in a few hours and may then infect others or be autoinfective if transferred to the mouth by contaminated food, drink, fomites, or hands. After being swallowed, the eggs hatch in the duodenum, and the larvae migrate down to the cecum. Retroinfection occasionally occurs when the eggs hatch on the perianal skin and the larvae migrate through the anus into the large intestine. The development of a mature ovipositing female from an ingested egg requires about 3-4 weeks. Eggs remain viable for 2-3 weeks outside the host. The life span of the worm is 30-45 days.

Clinical Findings

A. Symptoms and Signs

Many patients are asymptomatic. The most common and important symptom is perianal pruritus (particularly at night), due to the presence of the female worms or deposited eggs. Insomnia, restlessness, enuresis, and irritability are common symptoms, particularly in children. Many mild gastrointestinal symptoms have also been attributed to enterobiasis, but the association is difficult to prove. At night, worms may occasionally be seen near the anus. Perianal scratching may result in excoriation and impetigo. Adults sometimes report a "crawling" sensation in the anal area. Rarely, worm migration—including migration through the female genital tract or into the urethra—results in ectopic inflammation (vulvovaginitis, diverticulitis, appendicitis, cystitis) or granulomatous reactions (colon, genital tract, peritoneum, and elsewhere). Colonic ulceration and eosinophilic colitis have been reported.

B. Laboratory Findings

Diagnosis is made by finding eggs on the perianal skin (eggs are seldom found on stool examination). The most reliable method is by applying a short strip of sealing cellulose pressure-sensitive tape (eg, Scotch Tape) to the perianal skin and then spreading the tape on a slide for low-power microscopic study; toluene is used to clear the preparation. Three such preparations made on consecutive mornings before bathing or defecation will establish the diagnosis in about 90% of cases. Before the diagnosis can be ruled out, five to seven such examinations are necessary. Nocturnal examination of the perianal area or gross examination of stools may reveal adult worms, which should be placed in preservative, alcohol, or saline for laboratory examination. The worms can sometimes be seen on anoscopy. Eosinophilia is rare.

Differential Diagnosis

Pinworm pruritus must be distinguished from similar pruritus due to mycotic infections, allergies, hemorrhoids, proctitis, fissures, strongyloidiasis, and other conditions.

Treatment

A. General Measures

Symptomatic patients should be treated, and in some situations all members of the patient's household should be treated concurrently, since for each overt case there are usually several inapparent cases. Generally, however, treatment of all nonsymptomatic cases is not necessary. Careful washing of hands with soap and water after defecation and again before meals is important. Fingernails should be kept trimmed close and clean and scratching of the perianal area avoided. Ordinary washing of bedding will usually kill pinworm eggs; some workers recommend daily washing.

B. Specific Measures

Treatment with the following drugs should be repeated at 2 and 4 weeks. Albendazole, mebendazole, and pyrantel pamoate are the drugs of choice and can be given with or without food. Albendazole and mebendazole should not be used in pregnancy. Piperazine, although effective, is not recommended because treatment requires 1 week. Thiabendazole is not recommended because it causes frequent side effects which rarely are severe and life-threatening.

1. Albendazole is available in the USA though not approved for this indication. It may reach a 100% cure rate when given as a single 400-mg dose. Abdominal pain and diarrhea are rare.
2. Mebendazole as a single 100-mg dose is also highly effective. It should be chewed for best effect. Gastrointestinal side effects are infrequent.
3. Pyrantel pamoate is highly effective, with cure rates of over 95%. It is administered as a 10-mg (base)/kg (maximum, 1 g) dose. Infrequent side effects include vomiting, diarrhea, headache, dizziness, and drowsiness. In the USA, pyrantel is available as self-medication for pinworm infection.

Prognosis

Although annoying, the infection is benign. Cure is readily attainable with one of several effective drugs. Reinfection is common, especially in children, because of continued exposure outside the home.

FILARIASIS

More than 130 million people are infected with lymphatic filariasis in 73 tropical and subtropical countries, and an estimated 1 million new persons, mainly children, are infected yearly. The disease is caused by three filarial nematodes: *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*. The filarial infections are among the most important ones worldwide that cause a high degree of disability. *W bancrofti* is widely distributed in the tropics and subtropics of both hemispheres and on Pacific islands and is transmitted by *Culex*, *Aedes*, and *Anopheles* mosquitoes. *B malayi* is transmitted by *Mansonia* and *Anopheles* mosquitoes of South India, Sri Lanka, Southeast Asia, South China, the northern coastal areas of China, and South Korea. *B timori* is found on the southeastern islands of Indonesia.

No animal reservoir hosts are known for *W bancrofti* or *B timori*; cats, monkeys, and other animals may harbor *B malayi*. Mosquitoes become infected by ingesting microfilariae with a blood meal; at subsequent feedings, they can infect new susceptible hosts. Over months, adult worms (females, 8-9 cm × 0.2-0.3 mm) mature and live (up to 2 decades) in or near superficial and deep lymphatics and lymph nodes and produce large numbers of viviparous circulating microfilariae, which may be seen in the blood starting 6-12 months after infection.

Pathologic changes in lymph vessels are due to host immunologic reactions to developing and mature worms; also implicated are bacterial and fungal superinfections. Living microfilariae generally cause no lesions, with the exception of tropical pulmonary eosinophilia. Rapid death of microfilariae, however, does produce findings, and an abscess may form at the site of a dying adult worm.

Dirofilariasis, infection by *Dirofilaria immitis*, the dog heartworm, has been reported in the USA, Japan, and Australia. Nodules have been found in the skin or as solitary 1-4.5 cm (usually 2 cm) "coin" lesions in the periphery of the lungs; they are rarely calcified. The serologic test for filariasis is positive, but there is no microfilaremia. Eosinophilia is seen in 15% of patients.

Other filarial worms. Several other species infect humans—*Mansonella perstans*, *Mansonella streptocerca*, and *Mansonella ozzardi*—but usually without causing important findings.

Clinical Findings

A. Symptoms and Signs

The incubation period is generally 8-16 months in expatriates but may be longer in indigenous persons. Many infections remain asymptomatic, with or without microfilariae.

1. Acute disease—Episodes of fever (filarial fever), with or without inflammation of lymphatics and nodes, occur at irregular intervals and last for several days. Characteristically, the adenolymphangitis presents as retrograde extension from the affected node (unlike ascending bacterial lymphangitis). With disease progression, epididymitis and orchitis as well as involvement of pelvic, abdominal, or retroperitoneal lymphatics may also occur intermittently. Lymph node enlargement may persist. In travelers, allergic-like findings (hives, rashes, eosinophilia) and lymphangitis and lymphadenitis are more likely to be present.

2. Chronic disease—Obstructive phenomena occur as a result of interference with normal lymphatic flow; this includes hydrocele, scrotal lymphedema, lymphatic varices and elephantiasis, particularly of the extremities, genitals, and breasts. Chyluria may result from rupture of distended lymphatics into the urinary tract. Manifestations seen in some patients include lymphadenopathy or moderate hepatomegaly or splenomegaly.

3. Occult disease—A small proportion of infected persons develop occult disease, in which the classic clinical manifestations and microfilaremia are not present but microfilariae are present in the tissues.

In **tropical pulmonary eosinophilia**, microfilariae of *W bancrofti* or *B malayi* are sequestered in the lungs but not found in the blood. The condition is characterized by episodic nocturnal coughing or wheezing, dyspnea, low-grade fever, scant expectoration, hypereosinophilia, high filarial antibody titers and IgE levels, diffuse miliary lesions or increased bronchovascular markings on chest films, and a response to diethylcarbamazine treatment (6 mg/kg daily for 21 days). Relapses (in 20%) require re-treatment with up to 12 mg/kg daily for up to 30 days. If untreated, the condition can progress to chronic pulmonary fibrosis.

B. Laboratory Findings

Diagnosis of active infection is made by finding microfilariae in blood (or hydrocele fluid), a positive antigen test (only available for *W bancrofti*), or by ultrasound. In indigenous persons, microfilariae are rare in the first 2-3 years, abundant as the disease progresses, and again rare in the obstructive stage. In persons from nonendemic areas, inflammatory reactions may be prominent in the absence of microfilariae. Microfilariae of *W bancrofti* are found in the blood chiefly at night (nocturnal periodicity 10 PM to 2 AM), except for a nonperiodic variety in the South Pacific. *B malayi* microfilariae are usually nocturnally periodic but in Southeast Asia may be present at all times, with a slight nocturnal rise. Anticoagulated blood specimens are collected at times related to the periodicity of the local strain. Specimens may be stored at ambient temperatures until examined in the morning by wet film for motile larvae and by Giemsa-stained smears—thick for sensitivity and thin for specific morphology. A formalin-anionic detergent preservative can also be used. If these are negative, the blood specimens should be concentrated by the Knott concentration or membrane filtration technique. Where available, screening for antigenemia for *W bancrofti* should be done. ELISA and immunochromatographic card tests are sensitive (96-100%) and specific (nearly 100%) and thus are particularly useful for amicrofilaremic persons and for daytime examination of blood. A rapid dipstick test has shown a 97% sensitivity and 99% specificity for *B malayi*, and a polymerase chain reaction assay has been developed for both *W bancrofti* and *B malayi*.

Other serologic tests may be helpful in screening. A negative test usually rules out present or past infection, but false-positive tests occur with other filarial and helminthic infections, including ascariasis. An indirect hemagglutination titer of 1:128 and a bentonite flocculation titer of 1:5 in combination are considered the minimum significant titers. ELISA-IgG and -IgE tests are also available. Eosinophil counts may be elevated. Live adult worms can be detected by high-frequency ultrasound of the scrotum (up to 80% of infected men) and of the female breast. In differential diagnosis, lymphangiography (potentially damaging to the lymphatics) and radionuclide lymphoscintigraphy may be useful lymphatic imaging methods.

Treatment

A. Drug Treatment

Of the three drugs that are available, diethylcarbamazine and albendazole have slow macrofilaricidal action, whereas diethylcarbamazine and ivermectin are microfilaricidal. Recently started is a mass drug treatment program involving 80 countries that aims to reduce lymphatic filariasis disability and to achieve its worldwide eradication by 2020. Infected persons are given five consecutive annual doses; albendazole plus ivermectin are used in Africa and albendazole plus diethylcarbamazine elsewhere in the world.

Also under evaluation is a remarkable approach to treatment based on the recent recognition that wolbachia bacteria are obligate intracellular infections of all of the filarial species. In animal models and in early human studies, host tetracycline or doxycycline treatment leads to death of the bacteria followed by loss of worm viability.

1. Diethylcarbamazine—Diethylcarbamazine rapidly kills blood microfilariae but only slowly kills or injures adult worms. Cure may require multiple 12-day courses (2 mg/kg three times a day after meals, starting with small doses, and gradually increasing over 3-4 days). At this dose, the drug rarely produces direct toxicity. However, adverse immunologic reactions to dying microfilariae and adult worms are common—more so with brugian than with bancroftian filariasis. Reactions are local (lymphadenitis, abscess, ulceration) and systemic (fever, headache, myalgia, dizziness, malaise, and other allergic responses). Antipyretics and analgesics may be helpful. In areas where onchocerciasis or loiasis is also prevalent, the use of diethylcarbamazine is commonly contraindicated because of the potential for severe reactions to dying microfilariae of those parasites; instead, in Africa, albendazole plus ivermectin can be used. Diethylcarbamazine availability in the USA is only from the Parasitic Diseases Drug Service, Centers for Disease Control, Atlanta, GA 30333; phone 404-639-3670.

2. Ivermectin—Effective only as a microfilaricide, ivermectin is given as a single 200-ug/kg dose and repeated in 6 months. Diethylcarbamazine must also be given in order to kill the adult worms.

3. Albendazole—When used as a microfilaricide, albendazole is given at a dosage of 400 mg. For effective macrofilaricidal action, 400 mg is given twice daily for 3 weeks. The drug is free of significant side effects but is generally contraindicated in pregnancy.

B. Other Treatments

During acute inflammatory episodes, it is controversial whether to treat and whether drug usage will shorten the attack. General measures include rest, antibiotics for secondary infections, use of postural drainage, elastic stockings and pressure bandages for leg edema, and suspensory bandaging for orchitis and epididymitis.

Small hydroceles may benefit from a locally injected sclerosing agent, or surgery may be indicated. To manage elephantiasis, lymphovenous shunt procedures may be useful, combined with removal of excess subcutaneous fatty and fibrous tissue, postural drainage, and physiotherapy.

Prognosis

The prognosis is good with treatment of early and mild cases (including low-grade lymphedema, chyluria, small hydrocele), but in advanced infection the prognosis is poor.

GNATHOSTOMIASIS

Gnathostomiasis, due for the most part to infection by the larval stage of the nematode *Gnathostoma spinigerum*, is rarely caused by other gnathostoma species. Infection is most common in Thailand and Japan but is also reported from Southeast Asia, China, India, Ecuador, Israel, and East Africa. In Mexico, where the gnathostoma species has not been identified, the number of cases is increasing; more than 1000 have been reported in the past 10 years, commonly associated with increased eating of raw fresh-water fish, especially a preparation called ceviche. In the USA, though *G spinigerum* has rarely been seen in minks, it has not been reported in humans. Eggs passed in feces of the definitive hosts, wild and domestic dogs and cats, are infective for copepods (water fleas). Ingestion of copepods by secondary hosts results in encysted larvae in their tissues; humans are infected when these larvae are ingested in raw, marinated, or inadequately cooked freshwater fish, chicken or other fowl, frogs, or pork. Infection has also been attributed to ingestion of infected copepods in water.

Within 24-48 hours, larval migration through the intestinal wall can cause acute epigastric pain, vomiting, urticaria, and eosinophilia. The worm then migrates to subcutaneous and other tissues but is unable to mature. Most common is a pruritic subcutaneous swelling up to 25 cm across, occasionally accompanied by stabbing pain. Over weeks to years, the swelling may remain in one area for days or weeks, or move continuously. Occasionally the worm becomes visible under the skin.

Internal organs and the eye may also be invaded. Spontaneous pneumothorax, leukorrhea, hematemesis, hematuria, hemoptysis, paroxysmal coughing, and edema of the pharynx with dyspnea have been reported as complications. Invasion of the brain can result in an eosinophilic meningoencephalitis or subarachnoid hemorrhage. Spinal cord invasion can lead to myelitis or radiculopathy.

Definitive diagnosis is sometimes possible by surgical removal of the worm when it appears close to the skin. Marked eosinophilia is common, except for parasites in the central nervous system. Serodiagnosis by immunoblot assay or ELISA is promising. Skin and other serologic tests are unsatisfactory.

Treatment is with ivermectin (200 ug/kg daily for 1 or 2 days) or with albendazole (400 mg twice daily for 21 days); larval death appears to occur slowly, and cure rates may reach 95%. Courses of prednisolone have provided temporary relief of symptoms.

HOOKWORM DISEASE

Essentials of Diagnosis

Early findings (not commonly recognized):

- Dermatitis: pruritic, erythematous, papulovesicular eruption at site of larval invasion.
- Pulmonary migration of larvae: transient episodes of coughing, asthma, fever, blood-tinged sputum, marked eosinophilia.

Later findings:

- Intestinal symptoms: anorexia, diarrhea, abdominal discomfort.
- Anemia (iron deficiency): fatigue, pallor, dyspnea on exertion, poikilonychia, heart failure.
- Characteristic eggs and occult blood in the stool.

General Considerations

Hookworm disease, widespread in the moist tropics and subtropics and sporadically in southeastern USA, is caused by *Ancylostoma duodenale* and *Necator americanus*. Probably a quarter of the world's population is infected, and in many areas the infection is a major cause of general debility, retardation of growth and development of children, and increased susceptibility to infection. Prevalence rates can reach 80% in the humid tropics under unsanitary conditions.

In the Western Hemisphere and tropical Africa, *N americanus* was the prevailing species, and in the Far East, India, China, and the Mediterranean area, *A duodenale* was prevalent, but both species have now become widely distributed. Infection is rare in regions with less than 40 inches of rainfall annually. Humans are the only host for both species.

The adult worms are approximately 1 cm long. Eggs produced by females are passed in the stool and must fall on warm, moist soil if hatching followed by larval development is to take place. Larvae remain infective for hours to about a week, depending on environmental conditions. Following skin penetration, the larvae migrate in the bloodstream to the pulmonary capillaries, break into alveoli, and then are carried by ciliary action upward to the bronchi, trachea, and mouth. After being swallowed, they reach and attach to the mucosa of the upper small bowel; maturation and release of eggs occur in 6-8 weeks. *Ancylostoma* infection can also be acquired by ingestion of the larvae in food or water. Adult *ancylostoma* worms survive about a year; *necator*, about 3-5 years.

The worms suck blood at their attachment sites. Blood loss is proportionate to the worm burden. A light infection is approximately 1000 eggs per gram of feces (equivalent to about 11 *ancylostoma* and 32 *necator* adults); a moderate worm load is 2000-8000 eggs per gram of feces. Iron loss with moderate infection is 1.1 mg/d for *N americanus* and 2.3 mg/d for *A duodenale*, which compares with a basal intake requirement of 0.72 for a typical woman. Over years—and depending upon the host's dietary intake of iron—iron reserves can be depleted and severe anemia can result from moderate infections with 30 or more *ancylostoma* or 100 or more *necator* worms.

Clinical Findings

A. Symptoms and Signs

Ground itch, the first manifestation of infection, is a pruritic erythematous dermatitis, either maculopapular or vesicular, that follows skin penetration by the infective larvae. Severity is a function of the number of invading larvae and the sensitivity of the host. Scratching may result in secondary infection. Strongyloidiasis and cutaneous larva migrans must be considered in the differential diagnosis at this stage.

The pulmonary stage, in which there is larval migration through the lungs, may show dry cough, wheezing, blood-tinged sputum, and low-grade fever. The pulmonary migration of *ascaris* and *strongyloides* larvae can produce similar findings.

After 2 or more weeks, maturing worms attach to the mucosa of the duodenum and upper jejunum. In heavy infections, worms may reach the ileum. Patients who have

light infections and adequate iron intake often remain asymptomatic. In heavy infections, however, there may be anorexia, diarrhea, vague abdominal pain, and ulcer-like epigastric symptoms. Severe anemia may result in pallor, deformed nails, pica, and cardiac decompensation. Marked protein loss may also occur, resulting in hypoalbuminemia, with edema and ascites. There are conflicting reports of malabsorption in some severe infections.

Reduction in worm loads and symptoms after the first decade of life suggests that a moderate degree of immunity develops.

B. Laboratory Findings

Diagnosis depends upon demonstration of characteristic eggs in feces; a concentration method may be needed. The two species cannot be differentiated by the appearance of their eggs. The stool usually contains occult blood. Hypochromic microcytic anemia can be severe, with hemoglobin levels as low as 2 g/dL, a low serum iron and a high iron-binding capacity, and low serum ferritin. Eosinophilia (as high as 30-60% of a total white blood count reaching 17,000/uL) is usually present in the pulmonary migratory stage of infection but is not marked in the chronic intestinal stage.

Treatment

A. General Measures

The availability of safe anthelmintics makes it possible to treat all patients initially, irrespective of the intensity of infection; nevertheless, it may not be necessary or beneficial to treat light infections. Re-treatment of heavy infections may be necessary at 2-week intervals until the worm burden is reduced to a low level as estimated by semiquantitative egg counts. Eradication of infection is not essential, since light infections do not injure the well-nourished patient and iron loss is replaced if the patient is receiving adequate dietary iron.

If anemia is present, oral ferrous sulfate and a diet high in protein and vitamins are required for at least 3 months after the anemia has been corrected in order to replace iron stores. A dosage schedule for ferrous sulfate tablets (200 mg) is one tablet three times daily for 2 months followed by one tablet daily for 4 months. Parenteral iron is rarely indicated. Blood transfusion may be necessary if anemia is severe.

B. Specific Measures

Pyrantel, mebendazole, and albendazole are highly effective drugs for treatment of both hookworm species; mebendazole or albendazole can be used to treat concurrent trichuriasis, and all three drugs can be used to treat concurrent ascariasis. The drugs are given before or after meals, without purges. For the three drugs, mild gastrointestinal side effects are rare; none should be used in pregnancy. Albendazole and mebendazole should not be given to children under about 1 year of age.

1. Pyrantel pamoate—In *A duodenale* infections, pyrantel given as a single dose, 10 mg (base)/kg (maximum 1 g), produces cures in 76-98% of cases and a marked reduction in the worm burden in the remainder. For *N americanus* infections, a single dose may give a satisfactory cure rate in light infection, but for moderate or heavy infection a 3-day course is necessary. If the species is unknown, treat as for necatoriasis. Mild and transient drowsiness and headache may occur.

2. Mebendazole—When mebendazole is given at a dosage of 100 mg twice daily for 3 days, reported cure rates for both hookworm species range from 35% to 95%. A single 500-mg dose may be sufficient for light infections.

3. Albendazole—Albendazole given orally once only at a dosage of 400 mg results in the cure of 85-95% of patients with ancylostoma infection and markedly reduces the worm burden in those not cured. Because cure rates for single-dose treatments of necator infection were 33-90%, treatment should be continued for 2-3 days, especially in heavy infections. Albendazole is available in the USA, though it is not FDA-approved for this indication.

Prognosis

If the disease is recognized before serious secondary complications appear, complete recovery is the rule following treatment.

Eosinophilic Enteritis

In Australia, *Ancylostoma caninum*, the dog hookworm, has been found to cause abdominal pain, diarrhea, and peripheral eosinophilia.

LOIASIS

Loiasis is a chronic filarial disease caused by infection with *Loa loa*. The infection occurs in humans and monkeys in rain and swamp forest areas of West Africa from Nigeria to Angola and throughout the Congo river watershed of central Africa eastward to southwestern Sudan and western Uganda. An estimated 3-13 million persons are infected.

The adult worms live in the subcutaneous tissues for up to 12 years. Gravid females release microfilariae into the bloodstream which subsequently are ingested in a blood meal by the vector-intermediate host, female *Chrysops* species, day-biting flies. When the fly feeds again, the larval stage can infect a new host or cause superinfection. The time to worm maturity and detection of new microfilariae is 6 months to several years.

Clinical Findings

A. Symptoms and Signs

Many infected persons are asymptomatic. In symptomatic persons, the worms (females, 4-7 cm × 0.5 mm) are evidenced by their temporary appearance beneath the skin or conjunctiva, by unilateral edema of an extremity, or by Calabar swellings. The latter are subcutaneous edematous reactions, 3-10 cm in diameter, nonpitting and nonerythematous, and at times associated with low-grade fever, local pain, and pruritus. The swellings may migrate a few centimeters for 2-3 days or stay in place before they subside. At irregular intervals, they recur at the same or different sites, but only one appears at a time. When near joints, they may be temporarily disabling. Migration across the eye may be asymptomatic or may produce pain, intense conjunctivitis, and eyelid edema. Dying adult worms may elicit small nodules or local sterile abscesses, and dead worms may result in radiologically detectable calcification.

Microfilariae in the blood do not induce symptoms. Rarely, however, they enter the central nervous system and may cause encephalitis, myelitis, or jacksonian seizures; the larvae can also induce lesions and complications in the retina, heart, lungs, kidneys, and other tissues.

Natives generally have a mild form of the infection or are asymptomatic but are microfilaremic and serologically positive. The disease among visitors, however, is often characterized by more pronounced immunologically mediated symptoms (frequent and debilitating Calabar swellings, elevated leukocyte and eosinophil counts, hypergammaglobulinemia, increased polyclonal IgE) and frequently a positive serologic test but nondetectable microfilaremia.

B. Laboratory Findings

Specific diagnosis is made by finding characteristic microfilariae in daytime (10 AM to 4 PM) blood specimens by concentration methods; in order of increasing sensitivity, they are (1) thick films, (2) Knott's concentration, and (3) Nuclepore filtration. Multiple daily samples may be needed. Presumptive diagnosis that permits treatment is based on Calabar swellings or eye migration, a history of residence in an endemic area, and marked eosinophilia (40% or greater). Serologic tests may be positive, but cross-reactions occur with other filarial diseases and sometimes with nematode infections. A polymerase chain reaction test, highly sensitive and specific, can detect the organism in some amicrofilaremic persons.

Treatment & Prognosis

See specialized sources and references for details on proper use of diethylcarbamazine (drug of choice both as a micro- and macrofilaricide), since side effects to dying microfilariae may be severe, and life-threatening encephalitis can occur rarely. The dosage is 50 mg once (day 1), 50 mg three times daily (day 2), 100 mg three times daily (day 3), and 3 mg/kg three times daily (days 4-21). One course of treatment cures about 50% of patients; three courses, 90%. Reactions are more likely with pretreatment microfilaria counts greater than 25/uL. Cytapheresis has been used to reduce parasite loads before starting diethylcarbamazine. Prednisone is sometimes indicated in heavily infected persons to minimize reactions. When ivermectin was used in treatment of 1.1 million persons with onchocerciasis in the presence of endemic loiasis, 28 neurologic reactions occurred (some severe) from death of *Loa loa* microfilariae. The risk of these reactions was high when the *L loa* microfilaria load exceeded 8/uL and very high above 50/uL; albendazole at a dosage of 200 mg twice daily for 3 weeks is being evaluated as a safe way to reduce the level of *L loa* microfilariae. Surgical removal of adult worms from the eye or skin is not recommended.

In the USA, diethylcarbamazine is available only from the Parasitic Diseases Drug Service, Centers for Disease Control and Prevention, Atlanta, GA 30333, telephone 404-639-3670.

Individual protection is facilitated by daytime use of insect repellent and by wearing light-colored clothing with long sleeves and trousers. Diethylcarbamazine prophylaxis, 300 mg weekly, may be useful if the risk of exposure is high. It is not indicated, however, for the casual traveler or for persons who might previously have acquired any of the filarial infections.

Most infections run a benign course, but some are accompanied by severe and temporarily disabling symptoms. The prognosis is excellent with treatment.

ONCHOCERCIASIS

Onchocerciasis is a chronic filarial disease caused by *Onchocerca volvulus*. The advent of the safe drug ivermectin has led to effective individual treatment and to mass control programs in the developing world. Heavy infection leads to chronic pruritus, disfiguring skin lesions, visual impairment, and debility. An estimated 18 million persons are infected, of whom 3-4 million have skin disease, 0.3 million are blinded, and 0.5 million severely visually impaired. In hyperendemic areas, more than 40% of inhabitants over 40 years of age are blind. The infection, predominant in West Africa, also occurs in many other parts of tropical Africa and in localized areas of the southwestern Arabian peninsula, southern Mexico, Guatemala, Venezuela, Colombia, and northwestern Brazil. The West African savanna strain is especially associated with severe blinding eye lesions. In some areas of Africa where blindness is not a severe problem, cutaneous onchocerciasis can nevertheless be severe and disabling.

Humans are the only important host. The vector and intermediate host are *Simulium* flies, day biters that breed in rivers and fast-flowing streams and become infected by ingesting microfilariae with a human blood meal; at subsequent feedings, they can infect new susceptible hosts.

The skin and eye changes are the result of dead or dying microfilariae. However, recent findings indicate that the predominant corneal changes are due to wolbachia bacteria, which are obligate intracellular organisms in the worms.

Clinical Findings

A. Symptoms and Signs

Adult worms, which can live for up to 14 years, typically are in fibrous subcutaneous nodules that are painless, freely movable, and 0.5-1 cm in diameter. Many nodules, however, are deep in the connective and muscular tissues and nonpalpable. The interval from exposure to onset of symptoms can be as long as 1-3 years. Female worms release motile microfilariae into the skin, subcutaneous tissues, lymphatics, and eyes; microfilariae are occasionally seen in the urine but rarely in blood or cerebrospinal fluid. Skin manifestations are localized or cover large areas. Pruritus may be severe, leading to skin excoriation and lichenification; other findings include pigmentary changes, papules, scaling, atrophy, pendulous skin, and acute inflammation. Pruritus may occur in the absence of skin lesions. There may be marked enlargement of femoral and inguinal nodes and generalized lymph node enlargement. Microfilariae in the eye may lead to visual impairment and blindness; findings include itching, photophobia, anterior segment changes (limbitis, punctate and sclerosing keratitis, iritis, secondary glaucoma, cataract), and posterior segment changes (optic neuritis, optic atrophy, chorioretinitis, and other retinal and choroidal findings). Infected visitors, as compared with indigenous persons, may show a more prominent dermatitis despite a low to nondetectable microfilariderma or eosinophilia and an absence of nodules and eye disease.

B. Laboratory Findings

Diagnosis is by demonstrating microfilariae in skin snips (usually obtained with a punch biopsy instrument), identifying them in the cornea or anterior chamber by slitlamp examination (after the patient has sat with head lowered between knees for 2 minutes) or by nodule aspiration or excision. Skin snips placed in saline are incubated for 2-4 hours before examination, or overnight for low-intensity infections. Adult worms may be recovered in excised nodules, whereas ultrasound has been used to detect nonpalpable onchocercomas and to distinguish them from other lesions (lipomas, fibromas, lymph nodes, foreign body granulomas). Traditional serologic tests are usually positive, but cross-reactions occur with other forms of filariasis, and the tests do not distinguish current from past infection. The immunoblot assay and the ELISA continue under development, but cross-reactions also occur. Where available, polymerase chain reaction can be done on skin snips and urine and is positive only in active infection. Methods to detect circulating antigen are being evaluated. Eosinophilia (15-50%), polyclonal hypergammaglobulinemia, and elevated IgE levels are common. The Mazzotti skin test is no longer recommended because of the potential for dangerous reactions.

Treatment & Prognosis

Drug treatment is with ivermectin (a microfilaricide) as a single oral dose of 150 ug/kg given with water on an empty stomach; the patient should remain fasting for 2 more hours. The number of microfilariae in the skin diminishes markedly within 2-3 days, remains low for about 6 months, and then gradually increases; microfilariae in the anterior chamber of the eye decrease slowly in number over months, eventually disappear, and then gradually return. The optimum frequency of treatment to control symptoms and prevent disease progression remains to be determined. To initiate treatment, three schedules have been proposed: (1) an initial and repeat dose at 6 months, (2) repeated doses at 3-month intervals for a year, or (3) repeated doses at monthly intervals for a total of three doses. Thereafter, treatment is repeated at intervals of 6 months for 2 years and yearly thereafter until the adult worms die, which may take 12-15 years or longer. With the initial treatment only, patients with microfilariae in the cornea or anterior chamber may benefit from several days of prednisone treatment (1 mg/kg/d) to avoid inflammatory eye reactions. Although single-dose ivermectin does not kill the adult worms, with repeated doses, increasing evidence suggests that the drug has a low-level macrofilaricidal action. Adverse reactions, which are more marked with the first dose, are mild in 9% of patients and severe in 0.2%; these include edema (face and limbs), fever, pruritus, lymphadenitis, malaise, and hypotension. Ivermectin does not, however, cause a severe reaction in the eyes or skin as does occur with diethylcarbamazine. Ivermectin should not be used in the presence of concurrent *Loa loa* infections, pregnancy, or in patients with central nervous system diseases in which increased penetration may occur of ivermectin into the central nervous system (eg, meningitis). Safety in children under 15 kg has not been established. For individual and mass treatment in developing countries, the drug is provided free by the manufacturer, Merck & Co. In Latin America only, nodulectomy continues to be used for nodules on or near the head.

In comparison studies, ivermectin was as effective as diethylcarbamazine in reducing the number of microfilariae but did so with significantly fewer systemic and ocular adverse reactions. Diethylcarbamazine is no longer recommended by WHO in onchocerciasis therapy. For selected patients in whom repeated ivermectin treatments do not control symptoms, suramin can be given for its macrofilaricidal action; however, because of suramin's toxicity and complex administration, it should only be administered by experts. Amocarzine is under evaluation for its macro- and microfilaricidal actions. Albendazole does not kill microfilariae but interferes with embryogenesis. Doxycycline may have potential as a chemotherapeutic agent based on the recent finding that 6 weeks of treatment was macrofilaricidal through its action on wolbachia bacteria, obligate intracellular organisms in onchocerca microfilariae and adults.

With treatment, some skin and ocular lesions improve and ocular progression is prevented. The prognosis is unfavorable only for those patients who are seen for the first time with already far-advanced ocular onchocerciasis.

STRONGYLOIDIASIS

Essentials of Diagnosis

- Pruritic dermatitis at sites of larval penetration.
- Diarrhea, epigastric pain, nausea, malaise, weight loss.
- Cough, rales, transient pulmonary infiltrates.
- Eosinophilia; characteristic larvae in stool specimens, duodenal aspirate, or sputum.
- Hyperinfection syndrome: Severe diarrhea, bronchopneumonia, ileus.

General Considerations

Strongyloidiasis is caused by infection with *Strongyloides stercoralis* (2-2.5 mm × 30-50 µm). Major symptoms result from adult parasitism, principally in the duodenum and jejunum, or from larval migration through pulmonary and cutaneous tissues. The primary host is humans, but dogs, cats, and primates have been found infected with strains indistinguishable from those of humans. Human infections with *S. fulleborni* have been encountered in Papua New Guinea and parts of Africa.

Strongyloidiasis is endemic in tropical and subtropical regions; although the prevalence is generally low, in some areas disease rates exceed 25%. An estimate of total world prevalence is 60 million. In temperate areas, the disease occurs sporadically. In the USA, highest infection rates are found in immigrants from endemic areas, in parts of Appalachia (up to 4%), and in southeastern areas; Puerto Rico is also an endemic area. Multiple infections in households are common, and prevalence may be high in institutions, particularly mental institutions (2-4%). The infection is also prevalent among immunosuppressed persons (see below).

The parasite is uniquely capable of maintaining its life cycle both within the human host and in soil. Infection occurs when filariform larvae in soil penetrate the skin, enter the bloodstream, and are carried to the lungs, where they escape from capillaries into alveoli and ascend the bronchial tree to the glottis. The larvae are then swallowed and carried to the duodenum and upper jejunum, where maturation to the adult stage takes place. The parasitic female, generally held to be parthenogenetic, matures and lives embedded in the mucosa, where its eggs are laid and hatch. Rhabditiform larvae, which are noninfective, emerge, and migrate into the intestinal lumen to leave the host via the feces. The life span of the adult worm may be as long as 5 years.

In the soil, the rhabditiform larvae metamorphose into the infective (filariform) larvae. However, the parasite also has a free-living cycle in soil, in which some rhabditiform larvae develop into adults that produce eggs from which rhabditiform larvae emerge to continue the life cycle.

Autoinfection in humans, which probably occurs at a low rate in most infections, is an important factor in determining worm burden and is responsible for the persistence of infections. Internal autoinfection takes place in the lower bowel when some rhabditiform larvae develop into filariform larvae that penetrate the intestinal mucosa, enter the intestinal lymphatic and portal circulation, are carried to the lungs, and return to the small bowel to complete the cycle. This process is accelerated by achlorhydria, constipation, diverticula, and other conditions that reduce bowel motility. In addition, an external autoinfection cycle can occur as a result of fecal contamination of the perianal area.

Recrudescence of a chronic asymptomatic infection may occur with the immunosuppression accompanying severe infections, corticosteroid treatment, metabolic diseases, severe malnutrition, or malignancy; exacerbation may lead to the hyperinfection syndrome. In the hyperinfection syndrome, autoinfection is greatly increased, resulting in a marked increase in the intestinal worm burden and in massive dissemination of filariform larvae to the lungs and most other tissues, where they can cause local inflammatory reactions and granuloma formation. Occasionally, in the lungs and elsewhere, larvae metamorphose into adults. Penetration of the bowel wall by filariform larvae can result in bacterial or fungal sepsis or meningitis. Hyperinfection is generally initiated under conditions of depressed host cellular immunity, especially in debilitated, malnourished persons and in patients with leukemia or lymphoma or those receiving immunosuppressive therapy, particularly chemotherapy or corticosteroids. Although the hyperinfection syndrome is rare in AIDS, these patients do have a protracted course that is difficult to cure.

Clinical Findings

A. Symptoms and Signs

Up to 30% of infected persons are asymptomatic. The time from larval penetration of the skin by filariform larvae until their appearance in the feces is 3-4 weeks. An acute syndrome can sometimes be recognized in which cutaneous symptoms, usually of the feet, are followed by pulmonary and then intestinal symptoms. Patients usually present, however, with chronic symptoms (continuous or with irregular exacerbations) that can persist for years or for life.

1. Cutaneous manifestations—In acute infection in sensitized patients, there may be focal edema, inflammation, petechiae, serpiginous or urticarial tracts, and intense itching. In chronic infections, both stationary urticaria and larva currens occur, the latter characterized by transient eruptions that migrate in serpiginous tracts.

2. Intestinal manifestations—Symptoms range from mild to severe, the most common being diarrhea, abdominal pain, and flatulence. Anorexia, nausea, vomiting, epigastric tenderness, and pruritus ani may be present; with increasing severity, fever and malaise may appear. Diarrhea may alternate with constipation, and in severe cases the feces contain mucus and blood. The pain is often epigastric in location and may mimic a duodenal ulcer. Malabsorption or a protein-losing enteropathy can result from a large intestinal worm burden.

3. Pulmonary manifestations—With migration of larvae through the lungs, bronchi, and trachea, symptoms may be limited to a dry cough and throat irritation, or low-grade fever, dyspnea, wheezing, and hemoptysis may occur; asthma is rare. Bronchopneumonia, bronchitis, pleural effusion, progressive dyspnea, and miliary abscesses can develop; the cough may become productive of an odorless, mucopurulent sputum.

4. Hyperinfection syndrome—Intense dissemination of filariform larvae to the lungs and other tissues can result in additional complications, including pleural effusion, pericarditis and myocarditis, hepatic granulomas, cholecystitis, purpura, ulcerating lesions at all levels of the gastrointestinal tract, central nervous system involvement, paralytic ileus, perforation and peritonitis, gram-negative septicemia and meningitis (due to larval carriage of enterobacteria from the colon), cachexia, shock, and death. Nephrotic syndrome is encountered on rare occasions.

B. Laboratory Findings

1. Detection of eggs and larvae—Eggs are seldom found in feces. Diagnosis, which may be difficult, requires finding the larval stages in feces or duodenal fluid. Rhabditiform larvae may be found in recently passed stool specimens; filariform larvae, however, will be present in specimens held in the laboratory for some hours. Four to six specimens, some unpreserved, should be collected at 2-day intervals or longer (the number of larvae in feces varies from day to day). Since the sensitivity of direct microscopic examination of one specimen is about 30%, it is essential that one-half of the specimens be processed, unpreserved, in the Baermann concentration, Harada-Mori filter paper, or agar plate culture methods, the sensitivities of which are high.

The diagnosis can sometimes be made by finding rhabditiform larvae or ova in mucus obtained by means of the duodenal string test or by duodenal intubation and aspiration. Duodenal biopsy is seldom indicated but will confirm the diagnosis in most patients. Rarely, filariform or rhabditiform larvae can be detected in urine or in sputum or bronchial washings during the pulmonary phase of the disease.

2. Serologic and hematologic findings—For screening, the ELISA is sensitive (84-95%) and specific (97-99%), as apparently is the Western blot, but cross-reactions can occur with filarial and other helminthic infections. A positive test indicates current or past infection. These IgG antibodies remain detectable in immunocompromised patients.

In chronic low-grade intestinal strongyloidiasis, the white blood cell count is often normal, with a slightly elevated percentage of eosinophils. However, with increasing larval migration, eosinophilia may reach 50% and leukocytosis 20,000/µL. In immunocompromised patients, eosinophilia may not be seen. Mild anemia may be present.

3. Hyperinfection—In the hyperinfection syndrome, there may also be findings of hypoproteinemia, malabsorption, abnormal liver function, and extensive pulmonary opacities. Filariform larvae may appear in the urine. Eosinopenia, when present, is thought to be an unfavorable prognostic sign.

C. Imaging

Small bowel x-rays may show inflammation, irritability, and prominent mucosal folds; there may also be bowel dilation, delayed emptying, and ulcerative duodenitis. In chronic infections, the findings can resemble those in nontropical and tropical sprue, or there may be narrowing, rigidity, and diminished peristalsis. During pulmonary migration of larvae, chest films are normal or show fine miliary nodules or irregular changing patches of pneumonitis, abscess, or pleural effusion.

Differential Diagnosis

Because of varied signs and symptoms, the diagnosis of strongyloidiasis is often difficult. Eosinophilia plus one or more of the following factors should further enhance consideration of the diagnosis: endemic area exposure, duodenal ulcer-like pain, persistent or recurrent diarrhea, malabsorption, recurrent coughing or wheezing, and transient pulmonary infiltrates. The duodenitis and jejunitis of strongyloidiasis can also mimic giardiasis, cholecystitis, and pancreatitis. Transient pulmonary infiltrates must be differentiated from tropical pulmonary eosinophilia and Löffler's syndrome. The diagnosis should be considered among the many causes of malabsorption in the tropics and in immunocompromised persons, including HIV-infected patients.

Treatment

Since strongyloides can multiply in humans, treatment should continue until the parasite is eradicated. In follow-up, multiple stool examinations should be done at weekly intervals, preferably by the Baermann concentration method. Patients receiving immunosuppressive therapy should be examined for strongyloidiasis before and at intervals during that treatment. Patients with strongyloidiasis infections who are resistant to treatment should be evaluated for AIDS. In concurrent infection with strongyloidiasis and ascariasis or hookworm (which is common), eradicate the latter infections first.

The drug of choice in treatment is ivermectin, which appears to be equal in effectiveness to thiabendazole but has far fewer side effects.

A. Ivermectin

The dosage is 200 ug/kg; since cure is essential in this disease, a second dose is recommended within several days. Cure rates reported in several studies ranged from 82% to 98%. In the hyperinfection syndrome in immunocompromised patients with or without AIDS, it may be necessary to prolong treatment or change to thiabendazole.

B. Thiabendazole

An oral dose of 25 mg/kg (maximum, 1.5 g per dose) is given after meals twice daily for 2-3 days. Repeat the course in 2 weeks. A 5- to 7-day (or longer) course is needed for disseminated infections. Tablet and liquid formulations are available; tablets should be chewed. Side effects, including headache, weakness, vomiting, vertigo, and decreased mental alertness, occur in as many as 30% of patients and may be severe. These symptoms are lessened if the drug is taken after meals. Other potentially serious side effects occur rarely. Erythema multiforme and the Stevens-Johnson syndrome have been associated with thiabendazole therapy; several fatalities have occurred in children.

C. Albendazole

Albendazole is given at a dosage of 400 mg twice daily for 3-7 days and repeated in 1 week; cure rates in several studies ranged from 38% to 95%. In comparative studies, albendazole is less effective than ivermectin.

Prognosis

The prognosis is favorable except in the hyperinfection syndrome and in infections associated with malnutrition, advanced liver disease, immunologic disorders, or the use of immunosuppressive drugs. In selected instances, to control infections that cannot be eradicated, once-monthly treatments can be tried with a 1-day dose of ivermectin or 2-day course of thiabendazole.

TRICHINOSIS (TRICHINELLOSIS, TRICHINELLOSIS)

Essentials of Diagnosis

- History of ingestion of raw or inadequately cooked pork, boar, or bear.
- First week: diarrhea, cramps, malaise.
- Second week to 1-2 months: muscle pain and tenderness, fever, periorbital and facial edema, conjunctivitis, systemic toxicity.
- Eosinophilia and elevated serum enzymes; positive serologic tests; larvae in muscle biopsy.

General Considerations

Trichinosis is caused worldwide by *Trichinella spiralis*. The disease is present wherever pork is eaten but is a greater problem in many temperate areas than in the tropics. In the USA, there has been a marked reduction in prevalence in pigs (rates in commercial pork are nil to 0.01%) and in incidence in humans (fewer than 35 cases are reported yearly). Four other species of trichinella have been recognized in humans: *T nativa* appears to be restricted to Arctic and sub-Arctic regions and *T nelsoni* to tropical Africa. *T pseudospiralis*, reported rarely worldwide, occurs as a persistent muscular infection accompanied by prolonged myalgia, muscular weakness and swelling, elevated muscle enzymes, and asthenia. *T britovi* occurs in temperate areas of Europe.

Human infections occur sporadically or in outbreaks. Infection is usually acquired by eating viable encysted larvae in raw or uncooked pork or pork products. Ground beef has also been a source of infection when adulterated with pork or inadvertently contaminated in a common meat grinder. In some cases, the source of infection is the flesh of dogs (East Asia), horses (France), or wild animals, particularly bears, walruses, bush pigs, foxes, or cougars (USA).

Gastric juices liberate the encysted larvae. They rapidly mature and mate, and the adult female then burrows into the mucosa of the small intestine. Within 4-5 days, the female begins to discharge viviparous larvae (100 × 6 um) that are disseminated via the lymphatics and bloodstream to most body tissues. Larvae that reach striated muscle encyst and remain viable for months to years; those that reach other tissues are rapidly destroyed. The adult worms (2-3.6 mm × 75-90 um) survive for up to about 6 weeks.

In the natural cycle, larvae develop into adult worms in the intestines when a carnivore or omnivore ingests parasitized muscle. Pigs generally become infected by feeding on uncooked food scraps or, less often, by eating infected rats. Other reservoir hosts include swine, dogs, cats, rats, and many wild animals, including the wolf, bear, and boar; marine animals in the Arctic; and the hyena, jackal, and lion in the tropics.

Clinical Findings

A. Symptoms and Signs

The incubation period is 2-7 days (range: 12 hours to 28 days). Severity depends upon intensity of infection, tissues invaded, immune status and age of the host (children have less severe infections), and perhaps the strain of the parasite. Findings range from asymptomatic to a mild febrile illness with short-lasting symptoms to a severe progressive illness with multiple system involvement that in rare cases is fatal.

1. Intestinal stage—When present, intestinal symptoms persist for 1-7 days: diarrhea, abdominal cramps, and malaise are the major findings; nausea and vomiting occur less frequently; and constipation is uncommon. Fever, eosinophilia, and leukocytosis are rare during the first week.

2. Muscle invasion stage—This begins at the end of the first week and lasts about 6 weeks. Parasitized muscles show an intense inflammatory reaction. Findings include fever (low-grade to marked); muscle pain and tenderness, edema, and spasm; periorbital and facial edema; sweating; photophobia and conjunctivitis; weakness or prostration; pain on swallowing; dyspnea, coughing, and hoarseness; subconjunctival, retinal, and nail splinter hemorrhages; and rashes and formication. The most frequently parasitized muscles and sites of findings are the masseters, tongue, diaphragm, intercostals, extraocular, laryngeal, paravertebral, nuchal, deltoid, pectoral, gluteus, biceps, and gastrocnemius. Inflammatory reactions around larvae that reach tissues other than muscle may result in a broad range of findings, including the development of meningitis, encephalitis, myocarditis, bronchopneumonia, nephritis, and peripheral and cranial nerve disorders.

3. Convalescent stage—This generally begins in the second month but in severe infections may not begin before 3 months or longer. Vague muscle pains and malaise may persist for several more months. Permanent muscular atrophy has been reported.

B. Laboratory Findings

The diagnosis is supported by findings of eosinophilia, elevated serum muscle enzymes (creatinine kinase, lactate dehydrogenase, aspartate aminotransferase), and positive serologic tests. There may be a marked hypergammaglobulinemia with reversal of the albumin-globulin ratio. Absence of an elevated sedimentation rate is a

useful diagnostic clue. Confirmation of the diagnosis is by detection of larvae in muscle biopsy specimens.

Leukocytosis and eosinophilia appear during the second week. The proportion of eosinophils rises to a maximum of 20-90% in the third or fourth week and then slowly declines to normal over the next few months.

Serologic tests can detect most clinically manifest cases but are not sufficiently sensitive to detect low-level infections (ie, a few larvae per gram of ingested muscle). More than one antibody test should be used and then repeated to observe for seroconversion or for a rising titer. Seropositivity may not appear for 3-5 weeks, peak in 2-3 months, and remain detectable for 2-3 years. The ELISA becomes positive in 80-100% of symptomatic persons. The bentonite flocculation (BF) test (positive titer > 1:5) is highly sensitive and specific. The immunofluorescent test (positive titer > 16) may become positive in the second week. IgM and IgE antibodies may also appear but are less sensitive indicators of infection than IgG. Circulating antigen—now being evaluated—can be detected about 2 weeks after infection in heavily infected persons and in 3-4 weeks in light infections. The intradermal test is no longer recommended, as it may remain positive for years and batches of antigen vary in potency.

Adult worms may be looked for in feces, though they are seldom found. In the second week, there are occasional larvae in blood, duodenal washings, and, rarely, in centrifuged spinal fluid. In the third to fourth weeks, biopsy of skeletal muscle (approximately 1 cm³) may be definitive (particularly gastrocnemius and pectoralis), preferably at a site of swelling or tenderness or near tendinous insertions. Portions of the specimen should be examined microscopically by compression between glass slides, by digestion, and by preparation of multiple histologic sections. If the biopsy is done too early, larvae may not be detectable. Myositis even in the absence of larvae is a significant finding.

C. Imaging

Chest films during the acute phase may show disseminated or localized infiltrates. Late calcification of muscle cysts cannot be detected radiologically.

Complications

The more important complications are granulomatous pneumonitis, encephalitis, and cardiac failure.

Differential Diagnosis

Because of its protean manifestations, trichinosis may resemble many other diseases. Eosinophilia, muscle pain and tenderness, and fever should lead the physician to consider collagen vascular disorders such as dermatomyositis or polyarteritis nodosa, which is generally accompanied by an elevated sedimentation rate.

Prevention

The frequency and intensity of infection in the USA and other countries have been significantly reduced by public health measures to prevent feeding of uncooked garbage to hogs and by animal inspection (not in the USA). The chief safeguard against trichinosis is adequate cooking of pork to 77 °C or by freezing meat at -17 °C for 20 days (longer if meat is over 15 cm thick). *T. nativa* in game is often relatively resistant to freezing. Low doses of gamma irradiation are also effective in killing larvae. *Government inspection of pork is not practiced in the USA as it is in some European countries.*

Treatment

Treatment is principally supportive, since in most cases recovery is spontaneous without sequelae.

A. Intestinal Phase

Though supporting evidence for efficacy is limited, albendazole, because of its relatively high absorption and freedom from adverse reactions, is proposed as the drug of choice in a dosage of 400 mg twice daily for 10 days. Mebendazole is an alternative drug at a dosage of 200-300 mg three times daily for 3 days, followed by 400-500 mg three times daily for 10 days. A third alternative drug is thiabendazole at a dosage of 25 mg/kg (maximum, 1.5 g per dose) twice daily after meals for 3-7 days; side effects, sometimes severe, are common (see Strongyloidiasis, above). Corticosteroids are contraindicated in the intestinal phase.

B. Muscle Invasion Phase

In this stage, severe infections require hospitalization and high doses of corticosteroids (40-60 mg/d for 1-2 days), followed by lower doses for several days or weeks to control symptoms. However, because corticosteroids may suppress the inflammatory response to adult worms, they should be used only when symptoms are severe. Although drug treatment has not been shown to be effective in the muscle invasion stage, albendazole, mebendazole, or thiabendazole can be tried.

Prognosis

Death is rare—sometimes within 2-3 weeks in overwhelming infections, more often in 4-8 weeks from a major complication such as cardiac failure or pneumonia.

TRICHURIASIS (TRICHOCEPHALIASIS, WHIPWORM)

Trichuris trichiura is a common intestinal parasite of humans throughout the world, particularly in the subtropics and tropics. Persons of all ages are affected, but infection is heaviest and most frequent in children. The slender worms, 30-50 mm in length, attach by means of their anterior whip-like end to the mucosa of the large intestine, particularly to the cecum. Eggs are passed in the feces but require 2-4 weeks for larval development after reaching the soil before becoming infective; thus, person-to-person transmission is not possible. Infections are acquired by ingestion of the infective egg. The larvae hatch in the small intestine and mature in the large bowel but do not migrate through the tissues.

Clinical Findings

A. Symptoms and Signs

Light (fewer than 10,000 eggs per gram of feces) to moderate infections rarely cause symptoms. Heavy infections (30,000 or more eggs per gram of feces) may be accompanied by abdominal cramps, tenesmus, diarrhea, distention, flatulence, and nausea and vomiting. With persistent dysentery and blood loss into the stool, the trichuris dysentery syndrome can appear—particularly in malnourished young children—which is accompanied by anemia, rectal prolapse, clubbing of fingers, growth stunting, and possibly cognitive defects. Adult worms are sometimes seen in stools. Invasion of the appendix, with resulting appendicitis, is rare.

B. Laboratory Findings

Diagnosis is by identification of characteristic eggs and, sometimes, adult worms in stools. Eosinophilia (5-20%) is common with all but light infections. Charcot-Leyden crystals may be seen in stool. Severe iron deficiency anemia may be present with heavy infections.

Treatment

Patients with asymptomatic light infections do not require treatment. For those with heavier or symptomatic infections, give mebendazole or albendazole. Thiabendazole should *not* be used because it is not effective and because it is potentially toxic. Iron replacement may be needed for anemia.

A. Albendazole

Albendazole, given orally at a single dose of 400 mg, has resulted in cure rates of 33-90%, with marked reduction in egg counts in those not cured. Daily treatment for 3 days improves cure rates. Albendazole should not be used in pregnancy.

B. Mebendazole

A dosage of 100 mg twice daily before or after meals for 3 days results in cure rates of 60-80%, with marked reduction in ovum counts in the remaining patients. It may be therapeutically advantageous for the tablets to be chewed before swallowing. In mild disease, a 500-mg dose may be sufficient, whereas in severe trichuriasis a longer course of treatment (up to 6 days) or a repeat course will often be necessary. Gastrointestinal side effects from the drug are rare. The drug is contraindicated in pregnancy.

VISCERAL LARVA MIGRANS (TOXOCARIASIS)

Most visceral larva migrans cases are due to *Toxocara canis*, an ascarid of dogs and other canids; *Toxocara cati* in domestic cats has occasionally been implicated and rarely *Belascaris procyonis* of raccoons. The adult worms live in the intestinal tracts of their respective hosts and release large numbers of eggs in the stool.

The reservoir mechanism for *T canis* is latent infection in female dogs which is reactivated during pregnancy. Transmission from mother to puppies is via the placenta and milk. Most eggs passed to the environment are from puppies (2 weeks to 6 months) and lactating bitches (up to 6 months after parturition). The life cycle of *T cati* is similar, but transplacental transmission does not occur.

Human infections are sporadic and probably occur worldwide. In the USA, antibody seroprevalence is 5-7%. Infection is generally in dirt-eating young children who ingest *T canis* or *T cati* eggs from soil or sand contaminated with animal feces, most often from puppies. Direct contact with infected animals does not produce infection, as the eggs require a 3- to 4-week extrinsic incubation period to become infective; thereafter, eggs in soil remain infective for months to years.

In humans, hatched larvae are unable to mature but continue to migrate through the tissues for up to 6 months. Eventually they lodge in various organs, particularly the lungs and liver and less often the brain, eyes, and other tissues, where they produce eosinophilic granulomas up to 1 cm in diameter.

Clinical & Laboratory Findings

A. Acute Infection

Migrating larvae may induce fever, cough, wheezing, hepatosplenomegaly, and lymphadenopathy. A variety of other findings may occur when other organs are invaded, including myelitis, encephalitis, and carditis. The acute phase may last 2-3 weeks, but resolution of all physical and laboratory findings may take up to 18 months.

Leukocytosis is marked (may exceed 100,000/uL), with 30-80% due to eosinophils. Hyperglobulinemia occurs when the liver is extensively invaded and is a useful clue in diagnosis. Nonspecific isohemagglutinin titers (anti-A and anti-B) are usually greater than 1:1024. Chest radiographs may show infiltrates. Ultrasonography may detect 1-cm hypoechoic lesions in the liver, each with a thread-like hyperechoic line. With central nervous system involvement, the cerebrospinal fluid may show eosinophils. No parasitic forms can be found by stool examination.

Antibody detection is generally the only way to confirm a clinical diagnosis. The ELISA, the most specific (92%) and sensitive (78%) test, may permit a presumptive diagnosis, though it does not distinguish acute from prior infection. However, rising or falling titers with twofold differences are consistent with acute disease. Definitive diagnosis is by percutaneous liver biopsy or by direct biopsy of a granuloma at laparoscopy (mixed inflammatory infiltrate with numerous eosinophils), but these procedures are seldom justified and may not yield larvae.

B. Ocular Toxocariasis

Most cases occur in children, most commonly 5-10 years old, who present with visual impairment in one eye and sometimes leukocoria, squint, and red eye. The principal pathologic entity is eosinophilic granuloma of the retina that resembles retinoblastoma. Until the recent development of the toxocara ELISA test, this resulted in the enucleation of many eyes. Other common clinical findings are peripheral retinochoroiditis, a diffuse, painless endophthalmitis; posterior pole granuloma; and a peripheral inflammatory mass. Uncommonly seen are an iris nodule, optic nerve granuloma, unioocular pars planitis, and a migrating retinal nematode. Ocular toxocariasis, which is generally recognized years after the acute infection, is generally not associated with peripheral eosinophilia, hypergammaglobulinemia, or isohemagglutinin elevation. Serum ELISA tests may be positive, but a negative test does not rule out the diagnosis. If doubt exists about whether a patient with a positive serum ELISA test has toxocariasis or retinoblastoma, the vitreous humor should be examined for ELISA antibody (specificity has been reported as greater than 90% at a titer of 1:32 or higher) and eosinophils. High-resolution CT scanning of the orbit should be done.

Prevention, Treatment, & Prognosis

Disease in humans is best prevented by periodic treatment of puppies, kittens, and nursing dog and cat mothers, starting at 2 weeks postpartum, repeating at weekly intervals for 3 weeks and then every 6 months.

A. Acute Infection

Treatment of symptomatic persons is primarily supportive. Although there is no proved specific treatment, the following drugs can be tried: albendazole (400 mg twice daily for 21 days), mebendazole (200 mg twice daily for 21 days), thiabendazole (as used in strongyloidiasis), or ivermectin. Theoretically, release of antigens from dying parasites may exacerbate clinical and laboratory findings. Corticosteroids, antibiotics, antihistamines, and analgesics may be needed to provide symptomatic relief. Symptoms may persist for months but generally clear within 1-2 years. The ultimate outcome is usually good, but permanent neuropsychologic deficits have been seen.

B. Ocular Toxocariasis

Treatment includes oral and subconjunctival corticosteroids, an anthelmintic drug, vitrectomy for vitreous traction, and laser photocoagulation. Partial or total permanent visual impairment is rare.

Clinical Presentation	Drug(s) of Choice	Alternative Drug(s)
Asymptomatic intestinal infection	Diloxanide furoate ^{1,2}	Iodoquinol (diiodohydroxyquin) ³ or paromomycin ⁴
Mild to moderate intestinal disease (nondysenteric colitis)	(1) Metronidazole ⁵ or tinidazole ^{1,5} plus (2) Diloxanide furoate, ^{1,2} iodoquinol, ³ or paromomycin ⁴	(1) Diloxanide furoate ^{1,2} or iodoquinol ³ plus (2) A tetracycline ⁶ followed by (3) Chloroquine ⁷ or (1) Paromomycin ⁴ followed by (2) Chloroquine ⁷
Severe intestinal disease (dysentery)	(1) Metronidazole ⁵ or tinidazole ^{1,5} plus (2) Diloxanide furoate ^{1,2} or iodoquinol ³ or, if parenteral therapy is needed initially: (1) Intravenous metronidazole ⁸ until oral therapy can be started; (2) Then give oral metronidazole ⁵ plus diloxanide furoate ^{1,2} or iodoquinol ³	(1) A tetracycline ⁶ plus (2) Diloxanide furoate ^{1,2} or iodoquinol ³ followed by (3) Chloroquine ⁹ or, if parenteral therapy is needed initially: (1) Dehydroemetine ¹⁰ or emetine ^{1,10} followed by (2) A tetracycline ⁶ plus diloxanide furoate ^{1,2} or iodoquinol ³ followed by (3) Chloroquine ⁹
Hepatic abscess	(1) Metronidazole ^{5,8} or tinidazole ^{1,5} plus (2) Diloxanide furoate ^{1,2} or iodoquinol ³ followed by (3) Chloroquine ⁹	(1) Dehydroemetine ¹¹ or emetine ^{1,11} followed by (2) Chloroquine ¹² plus (3) Diloxanide furoate ^{1,2} or iodoquinol ³
Ameboma or extraintestinal disease	As for hepatic abscess, but not including chloroquine	As for hepatic abscess, but not including chloroquine

¹Not available in the USA.

²Diloxanide furoate, 500 mg three times daily with meals for 10 days.

³Iodoquinol (diiodohydroxyquin), 650 mg three times daily for 21 days.

⁴Paromomycin, 25-30 mg/kg (base) (maximum 3 g) in three divided doses after meals daily for 7 days.

⁵Metronidazole, 750 mg three times daily for 10 days. In countries where it is available (not in the USA), tinidazole is preferred over metronidazole as the nitroimidazole component in treatment; although the two drugs are equally effective, tinidazole is given in a shorter course of treatment and is better tolerated. The tinidazole dosage is 800 mg three times daily for 3 days; in severe intestinal disease and hepatic abscess, continue for 5 days.

⁶Tetracycline, 250 mg four times daily for 10 days; in severe dysentery, give 500 mg four times daily for the first 5 days, then 250 mg four times daily for 5 days. Tetracycline should not be used during pregnancy.

⁷Chloroquine, 500 mg (salt) daily for 7 days.

⁸An intravenous metronidazole formulation is available; change to oral medication as soon as possible. See manufacturer's recommendation for dosage and cautions.

⁹Chloroquine, 500 mg (salt) daily for 14 days.

¹⁰Dehydroemetine or emetine, 1 mg/kg subcutaneously (preferred) or intramuscularly daily for the least number of days necessary to control severe symptoms (usually 3-5 days) (maximum daily dose for dehydroemetine is 90 mg; for emetine, 65 mg).

¹¹Use dosage recommended in footnote 10 for 8-10 days.

¹²Chloroquine, 500 mg (salt) orally twice daily for 2 days and then 500 mg orally daily for 19 days.

TABLES
Table 35-1. Treatment of amebiasis.
-

Table 35-2. Prevention of malaria in travelers.¹

TO PREVENT ATTACKS OF ALL FORMS OF MALARIA AND TO ERADICATE *P FALCIPARUM* AND *P MALARIAE* INFECTIONS^{2,3,4}

REGIONS WITH CHLOROQUINE-SENSITIVE *P falciparum* malaria: Central America west of the Panama Canal, the Caribbean, North Africa, and parts of the Middle East

Chloroquine⁵

Dose: Chloroquine phosphate, 500 mg salt (300 mg base) weekly. Give a single dose of chloroquine weekly starting 1 week before entering the endemic area, while there, and for 4 weeks after leaving.

REGIONS WITH CHLOROQUINE-RESISTANT *P falciparum* malaria: All other regions of the world; the frequency and intensity of resistance vary by region.

Mefloquine (preferred method)⁶

Dose: one 250-mg tablet salt (228 mg base) weekly. Give a single dose of mefloquine weekly starting 1 week before entering the endemic area, while there, and for 4 weeks after leaving.

Malarone (atovaquone [250 mg] combined with proguanil [100 mg] [alternative method]⁷

Dose: One tablet daily. Give one tablet the day before entering the endemic area, daily while there, and daily for 1 week after leaving.

Doxycycline (alternative method)⁸

Dose: 100 mg daily. Give the daily dose for 2 days before entering the endemic area, while there, and for 4 weeks after leaving.

TO ERADICATE *P vivax* AND *P ovale* INFECTIONS²

Primaquine⁹

Start primaquine only after returning home, during the last 2 weeks of chemoprophylaxis.

Dose: 26.3 mg salt (15 mg base) daily for 14 days. An alternative regimen in regions where chloroquine is effective in prophylaxis is chloroquine phosphate, 500 mg (salt), plus primaquine phosphate 78.9 mg (salt), weekly for 8 weeks.

¹See text for additional information on drug cautions, contraindications, and side effects. For additional information on prophylaxis for specific countries, see the references or call the Centers for Disease Control and Prevention, Atlanta, GA at 770-488-7788 (for fax response: 888-232-3299). The information is also available on the Internet at <http://www.cdc.gov> (choose the Traveler's Health category).

²The blood schizonticides (chloroquine, mefloquine, Malarone, and doxycycline), when taken for 4 weeks (7 days for Malarone) after leaving the endemic area, are curative for sensitive *P falciparum* and *P malariae* infections; primaquine, however, is needed to eradicate the persistent liver stages of *P vivax* and *P ovale*.

³A test dose of the selected prophylactic drug should be given before departure to allow for changing to an alternative drug in the event of significant side effects: chloroquine (once weekly for 2 weeks), Malarone (daily for 2 days), doxycycline (daily for 2 days), mefloquine (weekly for 3 weeks). Side effects from mefloquine sometimes do not appear until after the third or later doses.

⁴See text for standby drugs for emergency self-treatment of presumptive malaria; such drugs should be used only when a physician is not immediately available. It is imperative, however, that medical follow-up be sought promptly.

⁵Chloroquine and proguanil can be used by pregnant women.

⁶Because of the high frequency of resistance, mefloquine should not be used in Thailand or adjacent countries; it is now the preferred drug for sub-Saharan Africa. Mefloquine is not recommended in the first trimester of pregnancy or under some other conditions (see text).

⁷Malarone recently became available in the USA. It eradicates falciparum infections after 1 week of postexposure treatment; its efficacy against *P malariae*, however, is undetermined. To eradicate *P vivax* and *P ovale* infections, a course of primaquine is needed, which should be started early in the final week of Malarone treatment. Malarone has not been shown to be safe in pregnancy.

⁸Doxycycline is used in Thailand and adjacent countries and in other regions by persons who cannot tolerate mefloquine or Malarone. It is contraindicated in pregnant women. Take with evening meals. See text for side effects.

⁹Primaquine is indicated only for persons who have had a high probability of exposure to *P vivax* or *P ovale* (see text), and who have not taken the drug for daily prophylaxis. The drug should be taken with food and is contraindicated in pregnancy. Before use, patients must be screened for glucose-6-phosphate dehydrogenase deficiency.

Start oral therapy with quinine sulfate plus the second drug as soon as possible to complete 7 days of treatment. or Artemether, ¹³ 3.2 mg/kg IM initially, followed by 1.6 mg/kg daily; followed by mefloquine, ¹¹ 1250 mg (salt) once

¹See text for cautions, contraindications, and side effects of each drug. For advice on management, call the Centers for Disease Control and Prevention (CDC), Atlanta, GA (770-488-7760).

²In falciparum malaria, if the patient has not shown a clinical response to chloroquine (48-72 hours for mild infections, 24 hours for severe ones), parasitic resistance to chloroquine should be considered. Chloroquine should be stopped and treatment started with oral quinine plus doxycycline, or mefloquine, or halofantrine.

³500 mg chloroquine phosphate = 300 mg base; 26.3 mg of primaquine = 15 mg base.

⁴Chloroquine alone is curative for infection with sensitive strains of *P falciparum* and for *P malariae*, but primaquine is needed to eradicate the persistent liver stages of *P vivax* and *P ovale*. Start primaquine after the patient has recovered from the acute illness; continue chloroquine weekly during primaquine therapy. Patients should be screened for glucose-6-phosphate dehydrogenase deficiency before use of primaquine. An alternative mode for primaquine therapy is combined primaquine, 78.9 mg (salt), and chloroquine, 0.5 g (salt), weekly for 8 weeks.

⁵Strains of *P vivax* resistant to chloroquine have appeared in some regions (see text). For their treatment, give quinine (plus doxycycline or Fansidar), mefloquine, or halofantrine as used to treat *P falciparum* resistant to chloroquine.

⁶Quinine dihydrochloride. Give 10 mg/kg (salt) in 500 mL of 5% glucose solution IV slowly over 4 hours; repeat every 8 hours until oral therapy is possible (maximum, 1800 mg/d). Blood pressure and ECG should be monitored constantly to detect arrhythmias or hypotension. As severe hypoglycemia may occur, blood glucose levels should be monitored. A higher initial loading dose of quinine is given (20 mg/kg) to patients who acquired infections in Southeast Asia if it is known with certainty that they have not already taken the medication. Extreme caution is required in treating patients with quinine who previously have been taking mefloquine in prophylaxis. In the USA, quinine dihydrochloride is no longer available.

⁷When parenteral quinine is unavailable (as in the USA), quinidine gluconate can be used, administered as a continuous infusion. A loading dose of 10 mg/kg (salt) (maximum, 600 mg) is diluted in 300 mL of normal saline and administered over 1-2 hours, followed by 0.02 mg/kg/min (maximum, 10 mg/kg every 8 hours) by continuous infusion until oral quinine therapy is possible. If more than 48 hours of parenteral treatment is required, some authorities reduce the quinidine dose by one-third to one-half. Fluid status, glucose, blood pressure, and ECG should be closely monitored; widening of the QRS interval or lengthening of the QT interval requires discontinuation.

⁸Although quinine sulfate is usually given for 3 days, it should be continued for 7 days in patients who acquired infections in Southeast Asia and South America, where diminished responsiveness to quinine has been noted.

⁹Contraindicated in pregnant women.

¹⁰Fansidar should not be used for infections acquired in Southeast Asia, the Amazon Basin, Bangladesh, or Oceania.

¹¹Serious side effects are rare. See text for cautions and contraindications. In the USA, a 250 mg tablet of mefloquine contains 228 mg of base; outside the USA, each 275 mg tablet contains 250 mg of base. Mefloquine is hazardous with quinine, quinidine, or halofantrine.

¹²The dosage is 500 mg (salt) every 6 hours for three doses and repeat in 1 week. A possible contraindication is the presence of cardiac conduction abnormalities. Do not use if mefloquine has been taken in previous 2-3 weeks.

¹³Not available in the USA but available in some other countries.

¹⁴To avoid potential severe toxicity, give parenteral chloroquine by low-dose intramuscular injection (maximum, 3.5 mg/kg [salt] every 6 hours).

36. Infectious Diseases: Mycotic* - *Richard J. Hamill, MD*

INTRODUCTION

*Superficial mycoses are discussed in [Chapter 6](#).

Fungal infections have assumed an increasingly important role as use of broad-spectrum antimicrobial agents has increased and the number of immunodeficient patients has risen. Some pathogens (eg, cryptococcus, candida, pneumocystis, fusarium) rarely cause serious disease in normal hosts. Other endemic fungi (eg, histoplasma, coccidioides, paracoccidioides) commonly cause disease in normal hosts but tend to be more aggressive in immunocompromised ones.

CANDIDIASIS

Essentials of Diagnosis

- Common normal flora but opportunistic pathogen.
- Gastrointestinal mucosal disease, particularly esophagitis, most common; catheter-associated fungemia occurs in hospitalized patients.
- Diagnosis of invasive systemic disease requires tissue biopsy or evidence of retinal disease.

General Considerations

Candida albicans can be cultured from the mouth, vagina, and feces of most people. Cutaneous and oral lesions are discussed in [Chapters 6](#) and [8](#), respectively. The risk factors for invasive candidiasis include prolonged neutropenia, recent surgery, broad-spectrum antibiotic therapy, the presence of intravascular catheters (especially when providing total parenteral nutrition), and intravenous drug use. Cellular immunodeficiency predisposes to mucocutaneous disease. When no other underlying cause is found, persistent oral or vaginal candidiasis should arouse a suspicion of HIV infection.

Clinical Findings & Treatment

A. Mucosal Candidiasis

Esophageal involvement is the most frequent type of invasive mucosal disease. Individuals present with substernal odynophagia, gastroesophageal reflux, or nausea without substernal pain. Oral candidiasis, though often associated, is not invariably present. Diagnosis is best confirmed by endoscopy with biopsy and culture; the condition may be difficult to distinguish from esophagitis caused by infection with cytomegalovirus or herpes simplex virus when barium swallow alone is used for diagnosis. Therapy depends upon the severity of disease. If patients are able to swallow and take adequate amounts of fluid orally, fluconazole, 100 mg/d (or itraconazole solution, 10 mg/mL, 100 mg/d), for 10-14 days will usually suffice. In the individual who is more ill or has developed esophagitis while taking fluconazole, a 10- to 14-day course of amphotericin B at a dose of 0.3 mg/kg/d intravenously usually results in resolution. Caspofungin acetate at a loading dose of 70 mg followed by a daily dosage of 50 mg intravenously has equivalent efficacy and is essentially free of significant toxicity. Relapse is common when there is underlying HIV infection.

Vulvovaginal candidiasis occurs in an estimated 75% of women during their lifetime. Risk factors include pregnancy, uncontrolled diabetes mellitus, broad-spectrum antimicrobial treatment, corticosteroid use, and HIV infection. In women with HIV infection, vaginal candidiasis is usually the first and most common opportunistic infection. Symptoms include acute vulvar pruritus, burning vaginal discharge, and dyspareunia. Various topical azole preparations (eg, clotrimazole, 100-mg vaginal tablet for 7 days, or miconazole, 200-mg vaginal suppository for 3 days) are effective. One 150-mg oral dose of fluconazole has been shown to have equivalent efficacy with better patient acceptance.

B. Candidal Funguria

Candidal funguria frequently resolves with discontinuance of antibiotics or removal of bladder catheters. Clinical benefit from treatment of asymptomatic candiduria has not been demonstrated. When symptomatic funguria persists, oral fluconazole, 200 mg/d for 7-14 days, can be used if renal function is normal. Bladder irrigation with amphotericin B (50-200 mg/mL) is rarely indicated, though it may transiently clear candiduria, especially if colonization is confined to the bladder. However, failure to clear the candiduria in this way suggests the presence of upper urinary tract infection. Rare complications of candidal urinary tract infections are ureteral obstruction and dissemination.

C. Candidal Fungemia

Candidal fungemia may represent a benign, self-limited process, but until proved otherwise it should be considered a sign of serious invasive disease. If fungemia resolves with removal of intravascular catheters, there are often no further complications. The incidence of endophthalmitis may be higher than previously recognized, and a short course of intravenous amphotericin B to a total dose of 200 mg appears to lower this incidence. Such an approach is strongly recommended for patients with candidal fungemia. (See Amphotericin B, [Chapter 37](#).)

If fungemia is documented, if retinal lesions are identified, or if candida is isolated from other sites, the patient is considered to have invasive disease. Important clinical findings in invasive candidiasis are fluffy white retinal infiltrates that extend into the vitreous and raised, erythematous skin lesions that may be painful. Though characteristic, these are seen in less than 50% of cases. Other organ system involvement in invasive disease may include the brain, meninges, and myocardium. Although blood cultures are positive in only about 50% of cases of invasive disease, any positive blood culture for candida should be considered significant. Serologic tests for candida have not proved helpful in differentiating transient fungemia from invasive disease. Detailed funduscopic examination should be performed on fungemic patients. Amphotericin B at a dosage of 0.3-0.5 mg/kg/d is one of the agents of choice. Flucytosine, 150 mg/kg/d orally in four divided doses, is added if central nervous system involvement occurs until clinical improvement results. Individuals who do not tolerate amphotericin B may be given fluconazole, 200-800 mg/d intravenously once daily, or caspofungin acetate, 70 mg as loading dose followed by 50 mg intravenously once daily, with equivalent efficacy. Therapy for fungemia and invasive disease should be continued for 2 weeks after the last positive blood culture and resolution of symptoms and signs of infection. Once patients have become clinically stable, parenteral therapy can be discontinued and oral fluconazole, 200-800 mg orally given as one or two doses daily, used to complete treatment. Removal or exchange of intravascular catheters substantially decreases the duration of candidemia. Mortality of invasive candidiasis approaches 30%.

Another form of invasive disease is hepatosplenic candidiasis. This results from aggressive chemotherapy and prolonged neutropenia in patients with underlying hematologic cancers. Patients typically present with fever and variable abdominal pain weeks after chemotherapy, when neutrophil counts have recovered. Blood cultures are generally negative. Hepatic enzymes reveal an alkaline phosphatase elevation that may be marked. CT scanning of the abdomen shows hepatosplenomegaly, most often with multiple low-density defects in the liver. Diagnosis is established by liver biopsy, histopathology, and culture. Fluconazole, 400 mg daily, or a lipid formulation of amphotericin B is given until clinical and radiographic improvement occurs.

D. Candidal Endocarditis

Candidal endocarditis rarely is a complication of transient fungemia. It usually results from direct inoculation at the time of valvular heart surgery or repeated inoculation with intravenous drug use. Candidal endocarditis occurs with increased frequency on prosthetic valves in the first few months following surgery. Splenomegaly and petechiae are common, and there is a predilection for large-vessel embolization. Non-albicans species such as *Candida parapsilosis* and *Candida tropicalis* are more often important etiologic agents in endocarditis than in fungemia, which is most often due to *C. albicans*. The diagnosis is established definitively by culturing candida from emboli or from vegetations at the time of valve replacement. Valve destruction (usually aortic or mitral) is common, and surgical therapy is necessary in addition to a prolonged course of amphotericin therapy, given in a dosage of 0.5-1 mg/kg/d intravenously, usually to a total dose of 1-1.5 g intravenously.

It is important to note that non-albicans species of candida now account for over 50% of clinical bloodstream isolates and are often resistant to imidazole antibiotics such as fluconazole. The widespread use of these agents for prophylaxis in immunocompromised patients can lead to the emergence of pathogens such as *Candida krusei*. Dissemination of this organism has been reported in patients undergoing bone marrow transplantation for leukemia. Imidazole-resistant *C. albicans* has increased in frequency in immunocompromised patients, particularly in patients with late-stage AIDS receiving chronic suppressive fluconazole.

In all forms of invasive candidiasis, an important element of therapy is reversal of the underlying predisposing factor when possible. In high-risk patients undergoing induction chemotherapy or liver transplant recipients, prophylaxis with fluconazole has been shown to be beneficial.

HISTOPLASMOSIS

Essentials of Diagnosis

- Epidemiologically linked to bird droppings and bat exposure; common along river valleys (especially the Ohio River and the Mississippi River valleys).
- Most patients asymptomatic; respiratory illness most common clinical problem.
- Rare patients with normal immune function develop dissemination, with hepatosplenomegaly, lymphadenopathy, and oral ulcers.
- Widespread disease especially common in AIDS or other immunosuppressed states, with poor prognosis.
- Skin test and serology seldom diagnostic; biopsy of affected organs with culture, or urinary polysaccharide antigen most useful in disseminated disease.

General Considerations

Histoplasmosis is caused by *Histoplasma capsulatum*, a dimorphic fungus that has been isolated from soil contaminated with bird or bat droppings in endemic areas (central and eastern USA, eastern Canada, Mexico, Central America, South America, Africa, and southeast Asia). Infection presumably takes place by inhalation of conidia. These convert into small budding cells that are engulfed by phagocytic cells in the lungs. The organism proliferates and is carried hematogenously to other organs.

Clinical Findings

A. Symptoms and Signs

Most cases of histoplasmosis are asymptomatic or mild and thus go unrecognized. Past infection is recognized by the development of a positive histoplasmin skin test and occasionally by pulmonary and splenic calcification noted on incidental x-rays. Symptoms and signs of pulmonary involvement are usually absent even in patients who subsequently show areas of calcification on chest x-ray. Symptomatic infection may present with mild influenza-like illness, often lasting 1-4 days. Moderately severe infections are frequently diagnosed as atypical pneumonia. These patients have fever, cough, and mild central chest pain lasting 5-15 days. Physical examination is usually negative. Radiographic findings, including chest x-ray and CT scanning, are variable and nonspecific during acute illness.

Clinically evident infections occur in several forms: (1) **Acute histoplasmosis** frequently occurs in epidemics, often when soil containing infected bird or bat droppings is disturbed. It is a severe disease manifested by marked prostration, fever, and relatively few pulmonary complaints even when x-rays show pneumonia. The illness may last from 1 week to 6 months but is almost never fatal. (2) **Progressive disseminated histoplasmosis** is usually fatal within 6 weeks or less. Symptoms usually consist of fever, dyspnea, cough, loss of weight, and prostration. Ulcers of the mucous membranes of the oropharynx may be present. The liver and spleen are nearly always enlarged, and all the organs of the body are involved, particularly the adrenal glands, though this infrequently results in adrenal insufficiency. (3) **Chronic progressive pulmonary histoplasmosis** is usually seen in older patients with chronic obstructive lung disease. The lungs show chronic progressive changes, often with apical cavities. (4) **Disseminated disease in the profoundly immunocompromised host** often represents reactivation of prior infectious foci or may reflect acute infection. This form is commonly seen in patients with underlying HIV infection—with CD4 cell counts usually < 100 cells/uL—and is characterized by fever and multiple organ system involvement. Chest x-rays may show a miliary pattern. Presentation may be fulminant, simulating septic shock, with death ensuing rapidly unless treatment is provided.

B. Laboratory Findings

Most patients with progressive pulmonary disease show anemia of chronic disease. Bone marrow involvement may be prominent in disseminated forms with occurrence of pancytopenia. Alkaline phosphatase and marked LDH and ferritin elevations are also common.

In pulmonary disease, sputum culture is rarely positive except in chronic disease; in contrast, blood or bone marrow cultures from immunocompromised patients with acute disseminated disease are positive more than 80% of the time. A urine antigen assay has a sensitivity of greater than 90% for disseminated disease in AIDS patients and can be used to diagnose relapse. The sensitivity of screening immunodiffusion is 70% in acute pulmonary histoplasmosis, and complement fixation titers are positive in about 80% of cases. A combination of these two methods yields a sensitivity of up to 80% in immunodeficient adults.

Treatment

For progressive localized disease and for mild to moderately severe nonmeningeal disseminated disease in immunocompetent or immunocompromised patients, itraconazole, 200-400 mg/d orally divided into two doses, is the treatment of choice with an overall response rate of approximately 80%. Duration of therapy ranges from weeks to several months depending upon the severity of illness. Amphotericin B is reserved for individuals who cannot take oral medications; for those who have failed itraconazole therapy; for those with meningitis; and for management of severe disseminated disease in an immunocompromised host. Up to 2.5 g total may need to be given in the latter two situations, though this course of treatment can be abbreviated and oral itraconazole instituted once clinical stabilization has occurred. (See Amphotericin B, [Chapter 37](#).) Liposomal amphotericin B in a dosage of 3 mg/kg/d intravenously may be more effective and safer than conventional amphotericin B in seriously ill individuals. Patients with AIDS-related histoplasmosis require lifelong suppressive therapy with itraconazole, 200-400 mg/d orally.

BR>COCCIDIOIDOMYCOSIS

Essentials of Diagnosis

- Influenza-like illness with malaise, fever, backache, headache, and cough.
- Arthralgia and periarticular swelling of knees and ankles.
- Erythema nodosum common.
- Dissemination may result in meningitis, bony lesions, or skin and soft tissue abscesses.
- Chest x-ray findings vary widely from pneumonitis to cavitation.
- Serologic tests useful; spherules containing endospores demonstrable in sputum or tissues.

General Considerations

Coccidioidomycosis should be considered in the diagnosis of any obscure illness in a patient who has lived in or visited an endemic area.

Infection results from the inhalation of arthroconidia of *Coccidioides immitis*, a mold that grows in soil in certain arid regions of the southwestern USA, in Mexico, and in Central and South America.

Fewer than 1% of immunocompetent hosts show dissemination, but among these patients the mortality rate is high.

In HIV-infected people in endemic areas, coccidioidomycosis is a common opportunistic infection. These patients may present with disease manifestations ranging from focal pulmonary infiltrates to widespread miliary disease with multiple organ involvement and meningitis.

Clinical Findings

A. Symptoms and Signs

Symptoms of primary coccidioidomycosis occur in about 40% of infections. Symptom onset (after an incubation period of 10-30 days) is usually that of a respiratory tract illness with fever and occasionally chills. Pleuritic pain is common. Nasopharyngitis may be followed by bronchitis accompanied by a dry or slightly productive cough.

Arthralgia accompanied by periarticular swellings, often of the knees and ankles, is common. Erythema nodosum may appear 2-20 days after onset of symptoms. Persistent pulmonary lesions, varying from cavities and abscesses to parenchymal nodular densities or bronchiectasis, occur in about 5% of diagnosed cases.

Disseminated disease occurs in about 0.1% of white and 1% of nonwhite patients. Filipinos and blacks are especially susceptible, as are pregnant women of all races. Symptoms depend upon the site of dissemination. Any organ may be involved. Pulmonary findings usually become more pronounced, with mediastinal lymph node enlargement, cough, and increased sputum production. Lung abscesses may rupture into the pleural space, producing an empyema. These may also extend to bones and skin, and pericardial and myocardial extension has been occasionally observed. Fungemia may occur and is characterized clinically by a diffuse miliary pattern on chest x-ray and by early death. The course may be particularly rapid in immunosuppressed patients.

Bone lesions most often occur at bony prominences. Meningitis occurs in 30-50% of cases of dissemination. Subcutaneous abscesses and verrucous skin lesions are especially common in fulminating cases. Lymphadenitis may occur and may progress to suppuration. Mediastinal and retroperitoneal abscesses are not uncommon. HIV-infected persons with disseminated disease have a higher incidence of miliary infiltrates, lymphadenopathy, and meningitis, but skin lesions are uncommon.

B. Laboratory Findings

In primary coccidioidomycosis, there may be moderate leukocytosis and eosinophilia. Serologic testing is useful for both diagnosis and prognosis. The tube precipitin test and an immunodiffusion test detect IgM antibodies and are useful for diagnosis early in the disease process. Historically, a persistent rising complement fixation titer (= 1:16) has been considered suggestive of disseminated disease; in addition, complement fixation titers can be used to assess the adequacy of therapy. Serum complement fixation titer may be low when there is meningitis but no other disseminated disease. In patients with HIV-related coccidioidomycosis, the false-negative rate may be as high as 30%.

Demonstrable complement-fixing antibodies in spinal fluid are diagnostic of coccidioidal meningitis. These are found in over 90% of cases. Spinal fluid findings include increased cell count with lymphocytosis and reduced glucose. Spinal fluid culture is positive in approximately 30% of meningitis cases. Spherules filled with endospores may be found in biopsy specimens; though they are not infectious, they convert to the highly contagious arthroconidia when grown in culture media. Blood cultures in appropriate media are only rarely positive in disseminated disease.

C. Imaging

Radiographic findings vary, but patchy, nodular pulmonary infiltrates and thin-walled cavities are most common. Hilar lymphadenopathy may be visible and is seen in localized disease; mediastinal lymphadenopathy suggests dissemination. There may be pleural effusions and lytic lesions in bone.

Treatment

General symptomatic therapy is given as needed for disease limited to the chest with no evidence of progression. For progressive pulmonary or extrapulmonary disease, amphotericin B intravenously has proved effective in some patients (see [Chapter 37](#)). Therapy should be continued, with duration of therapy determined by a declining complement fixation titer and a favorable clinical response. For meningitis, treatment consists of the lumbar or cisternal intrathecal administration of amphotericin B daily in increasing doses up to 1-5 mg/d until the patient is clinically stable. The drug can then be tapered to once every 6 weeks for several years thereafter. Systemic therapy with amphotericin B, 0.6 mg/kg/d intravenously, is generally given concurrently with intrathecal therapy but is not sufficient alone for the treatment of meningeal disease. Once the patient is clinically stable, oral therapy with an azole for an indefinite period is the recommended alternative to intrathecal amphotericin B therapy.

Approximately 75% of patients with mild coccidioidal meningitis who are treated with oral fluconazole at a dosage of 400 mg/d will have a favorable clinical response. Such therapy is suppressive only and must be continued indefinitely, probably lifelong.

Fluconazole, 200-400 mg orally once daily, or itraconazole, 400 mg orally daily divided into 2 doses, may be given for disease in the chest, bones, and soft tissues; however, therapy must be continued for 6 months or longer after the disease is inactive in order to prevent relapse. Response to therapy should be monitored by following the progressive decrease in serum complement fixation titers.

Thoracic surgery is occasionally indicated for giant, infected, or ruptured cavities. Surgical drainage is also useful for soft tissue abscesses and bone disease. Amphotericin B, 1 mg/kg/d intravenously, is advisable following extensive surgical manipulation of infected tissue until the disease is inactive, whereupon therapy may be continued with an azole.

Prognosis

The prognosis for patients with limited disease is good, but persistent pulmonary cavities may cause complications such as hemoptysis or rupture producing pyopneumothorax. Nodules, cavities, and fibrotic residuals may rarely progress after long periods of stability or regression. Serial complement fixation titers should be performed after therapy for patients with coccidioidomycosis; rising titers warrant reinstitution of therapy because relapse is likely. Disseminated and meningeal forms still have mortality rates exceeding 50% in the absence of therapy.

PNEUMOCYSTOSIS (*Pneumocystis jiroveci* Pneumonia)

Essentials of Diagnosis

- Fever, dyspnea, nonproductive cough.
- Bilateral diffuse interstitial disease without hilar adenopathy by chest x-ray.
- Bibasilar crackles on auscultation in many cases; others have no findings.
- Reduced partial pressure of oxygen.
- P jiroveci in sputum, bronchoalveolar lavage fluid, or lung tissue.

General Considerations

Pneumocystis carinii is a fungal organism that has been found in the lungs of a variety of domesticated and wild mammals. *Pneumocystis jiroveci*, the pneumocystis species that affects humans, is distributed worldwide. Although symptomatic *P jiroveci* disease is rare in the general population, serologic evidence indicates that asymptomatic infections have occurred in most persons by a young age. The overt infection is an acute interstitial plasma cell pneumonia that occurs with high frequency among two groups: (1) as epidemics of primary infections among premature or debilitated or marasmic infants on hospital wards in underdeveloped parts of the world, and (2) as sporadic cases among older children and adults who have an abnormal or altered cellular immune status. Cases occur generally in patients with cancer or severe malnutrition and debility, in patients treated with immunosuppressive or cytotoxic drugs or irradiation for the management of organ transplants and cancer, and, most commonly, in patients with AIDS (see [Chapter 31](#)).

The mode of transmission in primary infection is unknown, but the evidence suggests airborne transmission. Following asymptomatic primary infection, latent and presumably inactive organisms are sparsely distributed in the alveoli. Whether acute infection in older children and adults results from de novo infection or from reactivation of latent infection is unknown.

Pneumocystis pneumonia occurs in up to 80% of AIDS patients not receiving prophylaxis and is a major cause of death. Its incidence increases in direct proportion to the fall in CD4 cells, with most cases occurring at CD4 cell counts below 200/uL. Dissemination of the infection to tissues other than the lung is rare, except in those who have received prophylactic aerosolized pentamidine. In non-AIDS patients receiving immunosuppressive therapy, symptoms frequently begin after corticosteroids have been tapered or discontinued.

Clinical Findings

A. Symptoms and Signs

Findings are usually limited to the pulmonary parenchyma; extrapulmonary disease is reported rarely. In the sporadic form of the disease associated with deficient cell-mediated immunity, the onset is abrupt, with fever, tachypnea, shortness of breath, and usually nonproductive cough. Pulmonary physical findings may be slight and disproportionate to the degree of illness and the radiologic findings; many patients have bibasilar crackles, but others do not. Without treatment, the course is usually one of rapid deterioration and death. Adult patients may present with spontaneous pneumothorax, usually in patients with previous episodes or those receiving aerosolized pentamidine prophylaxis. In the infantile form of the disease, the patient is generally free of fever and may show eosinophilia. Patients with AIDS will usually have other evidence of HIV-associated disease, including fever, fatigue, and weight loss, for weeks or months preceding the illness.

B. Laboratory Findings

Chest radiographs most often show diffuse "interstitial" infiltration, which may be heterogeneous, miliary, or patchy early in infection. There may also be diffuse or focal consolidation, cystic changes, nodules, or cavitation within nodules. Pleural effusions are not seen. About 5-10% of patients with pneumocystis pneumonia have normal chest films. Patients who have received prophylaxis with aerosolized pentamidine often have atypical chest x-rays, demonstrating upper lobe infiltrates.

Typically, there is reduction in vital and total lung capacity, and the single-breath diffusing capacity for carbon monoxide shows impaired diffusion. Arterial blood gas determinations usually show hypoxemia with hypocapnia but may be normal; however, rapid desaturation occurs if patients are exercised before samples are drawn. Gallium lung scanning (sensitivity > 95%, specificity 20-40%) shows diffuse uptake; the test should be reserved for those with normal chest films and normal pulmonary function in whom the disease is suspected. Isolated elevation or rising levels of serum LDH are very sensitive but not specific findings for *P jiroveci*. Lymphopenia with depleted CD4 lymphocytes is common. Serologic tests, including tests to detect antigenemia, are not helpful in diagnosis.

Specific diagnosis depends on morphologic demonstration of the organisms in clinical specimens using specific stains. The organism cannot be cultured. Although patients rarely spontaneously produce sufficient sputum for examination, adequate specimens can be obtained with induced sputum by having patients inhale an aerosol of hypertonic saline (3%) produced by an ultrasonic nebulizer. Specimens are then stained with Giemsa's stain or methenamine silver, either of which allows detection of cysts. The use of monoclonal antibody with immunofluorescence has increased the sensitivity of diagnosis. If diagnostic results cannot be achieved with induced sputum specimens and the diagnosis of *P jiroveci* pneumonia is strongly suspected, alternative techniques for obtaining specimens include bronchoalveolar lavage (sensitivity 86-97%) followed if necessary by transbronchial lung biopsy (85-97%). Open lung biopsy and needle lung biopsy are infrequently done. Although conclusions are still preliminary, the polymerase chain reaction (PCR) test for the detection of *P jiroveci* appears to be sensitive but does not provide more rapid diagnosis.

Treatment

(See [Table 31-4](#).)

It is appropriate to start empiric therapy for *P jiroveci* pneumonia if the disease is suspected clinically; however, in both AIDS patients and non-AIDS patients with mild to moderately severe disease, continued treatment should be based on a proved diagnosis because of the toxicity of therapy and the possible coexistence of other infections. Both in AIDS patients and in non-AIDS patients with mild to moderately severe disease, oral TMP-SMZ is the preferred agent because of its low cost and excellent bioavailability. Patients suffering from nausea and vomiting or intractable diarrhea should be given intravenous TMP-SMZ until they can tolerate the oral formulation. Pentamidine is used if fluid must be restricted or if there is a history of sulfonamide drug sensitivity. Therapy should be continued with the selected drug for at least 5-10 days before one considers changing agents, as fever, tachypnea, and pulmonary infiltrates persist for 4-6 days after starting treatment; some patients have a transient worsening of their disease during the first 3-5 days, which may be related to an inflammatory response secondary to the presence of dead or dying organisms. Early addition of corticosteroids may attenuate this response ([Chapter 31](#)). Some clinicians prefer to treat episodes of AIDS-associated pneumocystis pneumonia for 21 days rather than the usual 14 days recommended for non-AIDS cases.

A. Trimethoprim-Sulfamethoxazole

The dosage is TMP 20 mg/kg (12-15 mg/kg may decrease side effects without decreasing efficacy) and SMZ 100 mg/kg given orally or intravenously daily in three or four divided doses for 14-21 days. Adverse reactions are generally those of the sulfonamide component. Patients with AIDS have a high frequency of hypersensitivity reactions (approaching 50%), which may include fever, rashes (sometimes severe), malaise, neutropenia, hepatitis, nephritis, thrombocytopenia, and hyperbilirubinemia.

B. Pentamidine Isethionate

This drug is administered intravenously (preferred) or intramuscularly as a single dose of 3 mg (salt) per kilogram per day for 14-21 days. To avoid injection site pain or sterile abscesses, most workers administer the drug only intravenously by diluting it in 250 mL of 5% dextrose in water and giving it slowly over 1 hour. Pentamidine causes side effects in nearly 50% of patients. Occasional reactions include rash, neutropenia, abnormal liver function tests, serum folate depression, hyperkalemia, and hypocalcemia. Hypoglycemia (often clinically inapparent), hyperglycemia, hyponatremia, and delayed nephrotoxicity with azotemia may occur. Rarely, a variety of other severe adverse reactions may occur, including anemia, thrombocytopenia, ventricular arrhythmias, and fatal pancreatitis. Blood glucose levels should be monitored. Inadvertent rapid intravenous infusion may cause precipitous hypotension.

C. Atovaquone

Atovaquone has been FDA-approved for patients with mild to moderate disease who cannot tolerate TMP-SMZ or pentamidine, but failure is reported in 15-30% of cases. Mild side effects are common, but no serious reactions have been reported. The dosage is 750 mg three times daily for 21 days. Because poor gastrointestinal absorption can lead to low serum concentrations and treatment failure, the drug should be taken with food, especially a fatty meal.

D. Other Drugs

Clindamycin, 600 mg three times daily, plus primaquine, 15 mg/d; and dapsone, 100 mg/d, plus trimethoprim 15 mg/kg/d, in three divided doses daily, are alternative oral regimens for mild to moderate disease or for continuation of therapy after intravenous therapy is no longer needed. Trimetrexate, 45 mg/m²/d intravenously, plus high-dose leucovorin has been approved for salvage use in patients not responding to other therapies, but the success rate is less than 25%.

E. Prednisone

In conjunction with antimicrobials, prednisone is given for moderate to severe pneumonia (when PaO₂ on admission is < 70 mm Hg or oxygen saturation is < 90%); its use during the first 72 hours of therapy for severe pneumocystis pneumonia prevents deterioration in oxygenation and improves survival. The dosage of prednisone is 40 mg twice daily for 5 days, then 40 mg daily for 5 days, and then 20 mg daily until therapy is completed.

F. Supportive Care

Oxygen therapy is indicated to maintain the oxygen saturation over 90% by pulse oximeter.

Prevention

Primary prophylaxis for pneumocystis pneumonia should be given to patients with CD4 counts < 200 cells/uL, a CD4 percentage below 14%, or weight loss or oral candidiasis. Patients with a history of pneumocystis pneumonia should receive secondary prophylaxis until they have had a durable virologic response to HAART for at least 3-6 months and maintain a CD4 count of > 250 cells/uL.

Prognosis

In the absence of early and adequate treatment, the fatality rate for the endemic infantile form of pneumocystis pneumonia is 20-50%; for the sporadic form in immunodeficient persons, the fatality rate is nearly 100%. Early treatment reduces the mortality rate to about 3% in the former and 10-20% in AIDS patients. The mortality rate in other immunodeficient patients is still 30-50%, probably because of failure to make a timely diagnosis. In immunodeficient patients who do not receive prophylaxis, recurrences are common (30% in AIDS).

CRYPTOCOCCOSIS

Essentials of Diagnosis

- Most common cause of fungal meningitis.
- Predisposing factors: Hodgkin's disease, corticosteroid therapy, HIV infection.
- Symptoms of headache, abnormal mental status; meningismus seen occasionally, though rarely in HIV-infected patients.
- Demonstration of capsular polysaccharide antigen in cerebrospinal fluid diagnostic; 95% of HIV-infected patients also have a positive serum antigen.

General Considerations

Cryptococcosis is caused by *Cryptococcus neoformans*, an encapsulated budding yeast that has been found worldwide in soil and on dried pigeon dung.

Infections are acquired by inhalation. In the lung, the infection may remain localized, heal, or disseminate. Immunocompetent hosts rarely develop clinically apparent cryptococcal pneumonia. Progressive lung disease and dissemination most often occur in the setting of cellular immunodeficiency, including underlying hematologic

cancer under treatment, Hodgkin's disease, long-term corticosteroid therapy, or HIV infection.

Clinical Findings

A. Symptoms and Signs

Disseminated disease may involve any organ, but central nervous system disease predominates. Headache is usually the first symptom of meningitis. Confusion and other mental status changes as well as cranial nerve abnormalities, nausea, and vomiting may be seen as the disease progresses. Nuchal rigidity and meningeal signs occur about 50% of the time but are uncommon in HIV-infected patients with this complication. Intracerebral mass lesions (cryptococcomas) are rarely seen. Obstructive hydrocephalus may complicate the course.

B. Laboratory Findings

For suspected meningeal disease, lumbar puncture is the preferred diagnostic procedure. A substantial proportion of individuals who have systemic disease without clinical signs of meningitis will have meningeal involvement necessitating examination of the cerebrospinal fluid. Spinal fluid findings include increased opening pressure, variable pleocytosis, increased protein, and decreased glucose, though as many as 50% of AIDS patients have no pleocytosis. India ink smear or Gram stain of the cerebrospinal fluid usually reveals budding encapsulated fungal cells. Cryptococcal antigen in cerebrospinal fluid and culture together establish the diagnosis over 90% of the time. Patients with AIDS often have the antigen in both cerebrospinal fluid and serum, and extrameningeal disease (lungs, blood, urinary tract) is common. In patients with AIDS, the serum cryptococcal antigen is a sensitive screening test for meningitis, being positive in over 95% of cases. CT or MRI of the head should be performed if focal neurologic signs or papilledema is present to evaluate for mass lesions (eg, cryptococcoma) or hydrocephalus.

Treatment

In AIDS-related cryptococcal meningitis, oral fluconazole, 400 mg/d for a minimum of 10 weeks, has reasonable efficacy as acute therapy in patients with mild disease. Candidates for initial fluconazole therapy are patients with an intact level of consciousness and a spinal fluid cryptococcal antigen titer of less than 1:128. Higher-risk patients should receive amphotericin B initially. A preliminary study in patients with AIDS suggests that fluconazole plus flucytosine is efficacious for mild cases, but this regimen has not been compared with fluconazole alone.

There has been a trend away from regimens based on prolonged amphotericin B therapy, particularly in HIV-infected patients. However, this agent remains important, especially in severe disease. Amphotericin B, 0.7-1 mg/kg/d intravenously for 14 days, followed by an additional 8 weeks of fluconazole, 400 mg/d orally, have been quite effective, achieving clinical responses and cerebrospinal fluid sterilization in about 70% of patients. Adding flucytosine at this early stage does prevent late relapses but does not substantially contribute to improved cure rates. Flucytosine is administered orally at a dose of 100 mg/kg/d divided into four equal doses and given every 6 hours. Repeated lumbar punctures or ventricular shunting should be performed to relieve high cerebrospinal fluid pressures or if hydrocephalus is a complication. The end points for amphotericin B therapy and for switching to oral fluconazole are a favorable clinical response (decrease in temperature; improvement in headache, nausea, vomiting, and mini-mental status scores), declining cerebrospinal fluid cryptococcal antigen titer, and, most importantly, conversion of cerebrospinal fluid culture to negative.

A similar approach is reasonable for patients with cryptococcal meningitis in the absence of AIDS, though the mortality rate is considerably higher. Because of serious underlying illnesses and generally greater age, this group of patients does not tolerate the higher doses of amphotericin B as well as patients with AIDS. Lipid amphotericin B preparations appear to have equivalent efficacy with reduced nephrotoxicity. Therapy is generally continued until cerebrospinal fluid cultures become negative and cerebrospinal fluid antigen titers are below 1:8.

Maintenance antifungal therapy is important after treatment of an acute episode in HIV-related cases, since otherwise the rate of relapse is greater than 50%. Fluconazole, 200 mg/d, is the maintenance therapy of choice, decreasing the relapse rate approximately tenfold compared with placebo and threefold compared with weekly amphotericin B in patients whose cerebrospinal fluid has been sterilized by the induction therapy. After successful therapy of cryptococcal meningitis, it is possible to discontinue secondary prophylaxis with fluconazole in individuals with AIDS who have had a satisfactory response to highly active antiretroviral therapy (eg, CD4 cell count > 100-200 cells/uL for at least 6 months). Among practitioners treating patients without AIDS, there has been a trend in recent years to prescribe a brief course (eg, 3 months) of fluconazole as maintenance therapy following successful therapy for acute illness; recently published guidelines suggest this as an option.

Prognosis

Factors that indicate a poor prognosis include the activity of the predisposing conditions, older age, organ failure, lack of spinal fluid pleocytosis, high initial antigen titer in either serum or cerebrospinal fluid, decreased mental status, increased intracranial pressure, and the presence of disease outside the nervous system.

ASPERGILLOSIS

Aspergillus fumigatus is the usual cause of aspergillosis, though many species of aspergillus may cause a wide spectrum of disease. Burn eschar and debris in the external ear canal are often colonized by these fungi. Clinical illness results either from an aberrant immunologic response or tissue invasion.

Allergic bronchopulmonary aspergillosis occurs in patients with preexisting asthma who develop worsening bronchospasm and fleeting pulmonary infiltrates accompanied by eosinophilia, high levels of IgE, and aspergillus precipitins in the blood. It also may complicate cystic fibrosis. The disease characteristically pursues a waxing and waning course with gradual improvement over time, but it may result in saccular bronchiectasis and end-stage fibrotic lung disease. For acute exacerbations, oral prednisone is begun at a dose of 1 mg/kg/d and then tapered slowly over several months. Itraconazole at a dose of 200 mg daily for 16 weeks appears to improve pulmonary function and decrease steroid requirements in these patients.

Invasive manifestations may be seen in immunocompetent adults. These include chronic **sinusitis** and colonization of preexisting pulmonary cavities (**aspergilloma**). Sinus disease is usually diagnosed histologically after patients with chronic sinus disease undergo surgery. These patients may require protracted courses of antifungals (itraconazole, 200 mg twice daily, for weeks to months) in addition to the surgical debridement. Aspergillomas of the lung may be found by incidental radiographic studies but may also present with significant hemoptysis. Intracavitary instillation of amphotericin B and bronchoscopic removal have been tried with little success; several uncontrolled trials have suggested some benefit from itraconazole. The most effective therapy for symptomatic aspergilloma remains surgical resection.

Life-threatening **invasive aspergillosis** most commonly occurs in profoundly immunodeficient patients, particularly those with prolonged severe neutropenia. Patients with very advanced HIV disease may also be at risk for invasive aspergillosis, particularly if they have other risk factors for the disease. Pulmonary disease is most common, with patchy infiltration leading to a severe necrotizing pneumonia. There is often tissue infarction as the organism grows into blood vessels; clues to this are the development of pleuritic chest pain and elevation of serum LDH. AIDS patients are also predisposed to a unique ulcerative tracheobronchitis that may coexist with parenchymal pulmonary disease. At any time, there may be hematogenous dissemination to the central nervous system, skin, and other organs. Early diagnosis and reversal of any correctable immunosuppression are essential. Blood cultures have very low yield. In contrast to allergic aspergillosis, serologic tests have low sensitivities for invasive disease; detection of galactomannan by ELISA has recently been demonstrated to have a sensitivity of 89% and a specificity of 98% for the diagnosis of invasive disease, though multiple determinations may need to be done. Isolation of aspergillus from pulmonary secretions does not necessarily imply invasive disease. Therefore, the mainstay of diagnosis is demonstration of aspergillus in tissue. Biopsy specimens may show branched septate hyphae. Biopsy specimens will not invariably grow the organism.

When severe invasive aspergillosis is considered clinically likely or is demonstrable by laboratory testing, rapid institution of voriconazole or high doses of amphotericin B may be life-saving (see [Chapter 37](#)). Recently, it has been shown that voriconazole is more effective, improves survival, and is associated with fewer severe side effects than conventional amphotericin B when used as initial therapy in invasive aspergillosis. The dosage of voriconazole is 6 mg/kg intravenously twice on the first day, followed by 4 mg/kg twice daily given either intravenously or by mouth. The total daily dose of amphotericin is rapidly increased to 0.8-1.5 mg/kg/d intravenously as tolerated for the first several weeks of therapy. Thereafter, more traditional doses of 0.6 mg/kg/d are continued until resolution of clinical signs of disease. Itraconazole orally or intravenously at a dosage of 200-400 mg/d has activity against aspergillus, and initial clinical experience is favorable for less severe disease or as a follow-up to amphotericin B therapy. Until more data accumulate, amphotericin B should remain the first-line drug for invasive disease. Some experts believe that lipid preparations of amphotericin B should be used preferentially in this setting because they are better tolerated and can be given at higher doses. Caspofungin acetate, an echinocandin antifungal, has been approved for the treatment of invasive aspergillosis in patients who are refractory to or intolerant of other treatments. The drug is given as a 70-mg intravenous loading dose followed by 50-mg intravenously daily. In critically ill patients who are not responding to conventional antifungal treatment, there may be a role for the addition of caspofungin to amphotericin B therapy. Based on promising results in neutropenic patients with invasive pulmonary aspergillosis,

surgical resection warrants further study. The mortality rate of pulmonary or disseminated disease in the immunocompromised patient remains well above 50%, however.

MUCORMYCOSIS

The term mucormycosis (zygomycosis, phycomycosis) is applied to opportunistic infections caused by members of the genera *Rhizopus*, *Mucor*, *Absidia*, and *Cunninghamella*. Predisposing conditions include diabetic ketoacidosis, chronic renal failure, and treatment with steroids or cytotoxic drugs. These organisms appear in tissues as broad, branching nonseptate hyphae. Biopsy with histologic examination is almost always required for diagnosis; cultures are frequently negative. Invasive disease of the sinuses, orbits, and the lungs may occur. Widely disseminated disease has been more commonly seen recently in patients who have received aggressive chemotherapy. The diagnosis should be considered in acidotic diabetic patients with black necrotic lesions of the nose or sinuses or with new cranial nerve abnormalities. Without treatment, cerebral invasion may ensue. A prolonged course of high-dosage amphotericin B (1-1.5 mg/kg/d intravenously) or a lipid preparation of amphotericin B should be started early. Control of diabetes and other underlying conditions, along with extensive repeated surgical removal of necrotic, nonperfused tissue, are essential. Even when these measures are introduced in a timely fashion, the prognosis is poor, with a 30-50% mortality rate for localized disease and higher rates in disseminated cases.

BLASTOMYCOSIS

Blastomycosis occurs most often in men infected during occupational or recreational activities out of doors and in a geographically limited area of the south central and midwestern USA and Canada. A few cases have been found in Mexico and Africa. Disease usually occurs in immunocompetent individuals.

Pulmonary infection is most common and may be asymptomatic. When dissemination takes place, lesions are most frequently seen in the skin, bones, and urogenital system.

Cough, moderate fever, dyspnea, and chest pain are common. These may resolve or progress, with bloody and purulent sputum production, pleurisy, fever, chills, loss of weight, and prostration. Radiologic studies, either chest x-ray or CT, usually reveal pulmonary infiltrates and enlarged regional lymph nodes, though less commonly than in histoplasmosis or coccidioidomycosis.

Raised, verrucous cutaneous lesions that have an abrupt downward sloping border are usually present in disseminated blastomycosis. The border extends slowly, leaving a central atrophic scar. If left untreated for long periods, they may mimic skin cancer. Bones—often the ribs and vertebrae—are frequently involved. Lesions appear to be both destructive and proliferative on radiography. Epididymitis, prostatitis, and other involvement of the male urogenital system may occur. Central nervous system involvement is uncommon. Although they do not appear to be at greater risk for acquisition of disease, infection in HIV-infected persons may progress rapidly, with dissemination common.

Laboratory findings usually include leukocytosis and anemia, though these are not specific. The organism is found in clinical specimens, such as expectorated sputum or tissue, as a thick-walled cell 5-20 um in diameter that may have a single broad-based bud. It grows readily on culture. Serologic tests are not well standardized.

Itraconazole, 100-200 mg/d orally for at least 2-3 months, is now the therapy of choice for nonmeningeal disease, with a response rate of over 80%. Amphotericin B, 0.3-0.6 mg/kg/d intravenously for a total dose of 1.5-2.5 g, is given for treatment failures or cases with central nervous system involvement.

Clinical follow-up for relapse should be regularly made for several years so that therapy may be resumed or another drug instituted.

Martynowicz MA et al: Pulmonary blastomycosis. An appraisal of diagnostic techniques. Chest 2002;121:768. [\[PMID: 11888958\]](#)

PARACOCCIDIOIDOMYCOSIS (SOUTH AMERICAN BLASTOMYCOSIS)

Paracoccidioides brasiliensis infections have been found only in patients who have resided in South or Central America or Mexico. Long asymptomatic periods enable patients to travel far from the endemic areas before developing clinical problems. Ulceration of the nasopharynx and oropharynx is usually the first symptom. Papules ulcerate and enlarge both peripherally and deeper into the subcutaneous tissue. Differential diagnosis includes mucocutaneous leishmaniasis and syphilis. Extensive coalescent ulcerations may eventually result in destruction of the epiglottis, vocal cords, and uvula. Extension to the lips and face may occur. Eating and drinking are extremely painful. Skin lesions may occur, usually on the face. Variable in appearance, they may have a necrotic central crater with a hard hyperkeratotic border. Lymph node enlargement may follow mucocutaneous lesions, eventually ulcerating and forming draining sinuses; in some patients, it is the presenting symptom. Hepatosplenomegaly may be present as well. Cough, sometimes with sputum, indicates pulmonary involvement, but the symptoms and signs are often mild, even though radiographic findings indicate severe parenchymatous changes in the lungs. The extensive ulceration of the upper gastrointestinal tract may prevent caloric intake and result in cachexia.

Laboratory findings are nonspecific. Serology by immunodiffusion is positive in 98% of cases. Complement fixation titers correlate with progressive disease and fall with effective therapy. The fungus is found in clinical specimens as a spherical cell that may have many buds arising from it. If direct examination does not reveal the organism, biopsy with Gomori staining may be helpful.

Itraconazole, 100-200 mg orally daily, is the treatment of choice and generally results in a clinical response within 1 month and effective control after 2-6 months.

Bethlem EP et al: Paracoccidioidomycosis. Curr Opin Pulm Med 1999;5:319. [\[PMID: 10461538\]](#)

SPOROTRICHOSIS

Sporotrichosis is a chronic fungal infection caused by *Sporothrix schenckii*. It is worldwide in distribution; most patients have had contact with soil, sphagnum moss, or decaying wood. Infection takes place when the organism is inoculated into the skin—usually on the hand, arm, or foot, especially during gardening.

The most common form of sporotrichosis begins with a hard, nontender subcutaneous nodule. This later becomes adherent to the overlying skin and ulcerates. Within a few days to weeks, similar nodules develop along the lymphatics draining this area, and these may ulcerate as well. The lymphatic vessels become indurated and are easily palpable.

Disseminated sporotrichosis is rare in the immunocompetent host but may present with widespread cutaneous, lung, bone, joint, and central nervous system involvement in immunocompromised patients, especially those with AIDS and alcohol abuse.

Cultures are needed to establish diagnosis. Antibody tests may be useful for diagnosis of disseminated disease, especially meningitis.

Itraconazole, 200-400 mg orally daily for several months, is now the treatment of choice for localized disease and some milder cases of disseminated disease. Because it is inconvenient to take and has unpleasant side effects, saturated solution of potassium iodide (5 drops three times daily, increasing to 40-50 drops three times daily) is considered an alternative to itraconazole for localized lymphocutaneous disease. Amphotericin B intravenously, 1-2 g (see [Chapter 37](#)), is used for severe systemic infection. Surgery is usually contraindicated except for simple aspiration of secondary nodules. Joint involvement may require arthrodesis.

The prognosis is good for lymphocutaneous sporotrichosis; pulmonary, joint, and disseminated disease respond less favorably.

Morris-Jones R: Sporotrichosis. Clin Exp Dermatol 2002;27:427. [\[PMID: 12372075\]](#)

PENICILLIUM MARNEFFEI INFECTIONS

Penicillium marneffei is a dimorphic fungus, endemic in southeast Asia, that causes systemic infection in both healthy and compromised hosts. There have been increasing reports of travelers with advanced AIDS returning from southeast Asia with disseminated infection. Clinical manifestations include fever, generalized umbilicated papular rash, lymphadenopathy, cough, and diarrhea. Diagnosis is made by identification of the organism on smears or histopathologic specimens or by culture, where the fungus produces a characteristic red pigment. The best sites for isolation of the fungus include the skin, blood, bone marrow, respiratory tract, and lymph nodes. Patients with mild to moderate infection can be treated with itraconazole, 400 mg divided into two doses daily by mouth for 8 weeks. Amphotericin B, 0.5-0.7 mg/kg/d, is the drug of choice for severe disease and should be continued until patients have had a satisfactory clinical response, at which time they can be switched to itraconazole. Because the relapse rate after successful treatment is 30%, maintenance therapy with itraconazole, 200- 400 mg daily, is indicated indefinitely.

Chariyalertsak S et al: A controlled trial of itraconazole as primary prophylaxis for systemic fungal infections in patients with advanced human immunodeficiency virus infection in Thailand. Clin Infect Dis 2002;34:277. [\[PMID: 11740718\]](#)

Supparatpinyo K et al: A controlled trial of itraconazole to prevent relapse of *Penicillium marneffei* infection in patients infected with the human immunodeficiency virus. N Engl J Med 1998;339:1739. [\[PMID: 9845708\]](#)

CHROMOBLASTOMYCOSIS (CHROMOMYCOSIS)

Chromoblastomycosis is a chronic, principally tropical cutaneous infection usually affecting young men who are agricultural workers and caused by several species of closely related black molds (*Fonsecaea* species and *Phialophora* species).

Lesions are slowly progressive and occur most frequently on a lower extremity. The lesion begins as a papule or ulcer. Over months to years, papules enlarge to become vegetating, papillomatous, verrucous elevated nodules. Satellite lesions may appear along the lymphatics. There may be secondary bacterial infection. Elephantiasis may result.

The fungus is seen as brown, thick-walled, spherical, sometimes septate cells in potassium hydroxide preparations of pus or skin scrapings, which are quite sensitive for diagnosis. The type of reproduction found in culture determines the species. *Fonsecaea pedrosoi* is the responsible pathogen in the vast majority of cases.

Itraconazole, 200-400 mg/d orally for 6-18 months, achieves a response rate of 65%. Response rates may be improved by the addition to itraconazole of flucytosine, 100-150 mg/kg/d by mouth divided into four doses. Cryosurgery alone for smaller lesions or combined with itraconazole for larger lesions is beneficial.

Hussain I et al: Parenteral vitamin D₃ and oral terbinafine for refractory chromoblastomycosis. Br J Dermatol 2002;146: 704. [\[PMID: 11966710\]](#)

MYCETOMA (MADUROMYCOSIS & ACTINOMYCETOMA)

Mycetoma is a chronic local, slowly progressive destructive infection that begins in subcutaneous tissues, frequently after localized trauma, and then spreads to contiguous structures. Maduromycosis is the term used to describe mycetoma caused by the true fungi. Actinomycotic mycetoma is caused by *Nocardia* and *Actinomadura* species. The disease begins as a papule, nodule, or abscess that over months to years progresses slowly to form multiple abscesses and sinus tracts ramifying deep into the tissue. Secondary bacterial infection may result in large open ulcers. Radiographs may show destructive changes in the underlying bone. Tissue Gram stain reveals fine branching hyphae with actinomycotic mycetoma. Larger hyphae are seen with fungal mycetoma; the causative species can often be identified by the color of the characteristic grains within the infected tissues.

The prognosis is good for patients with actinomycetoma, since they usually respond well to sulfonamides and sulfones, especially if treated early. Trimethoprim-sulfamethoxazole, 160/800 mg orally twice a day, or dapsone, 100 mg twice daily after meals, has been reported to be effective. Streptomycin, 14 mg/kg/d intramuscularly, may be useful during the first month of therapy. All oral medications must be taken for months and continued for several months after clinical cure to prevent relapse. Debridement assists healing.

The prognosis for maduromycosis is poor, though surgical debridement along with prolonged ketoconazole or itraconazole therapy may result in a response rate of 70%. Amputation is necessary in far-advanced cases.

OTHER OPPORTUNISTIC MOLD INFECTIONS

Fungi previously considered to be harmless colonizers, including *Pseudallescheria boydii* (*Scedosporium apiospermum*), *Fusarium*, *Paecilomyces*, and *Trichosporon*, are emerging as significant pathogens in immunocompromised patients. This occurs most often in patients being treated for hematopoietic malignancies. Infection may be localized in the skin, lungs, or sinuses, or widespread disease may appear with lesions in multiple organs. Colonization of old cavitory disease may cause minimal symptoms or may precede dissemination with meningitis or brain abscesses. Endocarditis occurs more commonly in intravenous drug abusers. Sinus infection may cause bony erosion. Infection in subcutaneous tissues following traumatic implantation may develop as a well-circumscribed cyst or as an ulcer.

Nonpigmented septate hyphae are seen in tissue and are indistinguishable from those of aspergillus when infections are due to *Scedosporium apiospermum* or species of *Fusarium*, *Paecilomyces*, *Penicillium*, or other hyaline molds. Spores or mycetoma-like granules are rarely present in tissue.

Infection by any of a number of black molds is designated as phaeohyphomycosis. These black molds (eg, *Exophiala*, *Bipolaris*, *Cladophialophora*, *Curvularia*, *Alternaria*) are common in the environment, especially on decaying vegetation. Human disease due to these agents is rarely encountered but may result in soft tissue abscesses due to traumatic inoculation or may occur as a sequela of chronic sinusitis or profound immunosuppression. In tissues of patients with phaeohyphomycosis, the mold is seen as black or faintly brown hyphae, yeast cells, or both. Culture on appropriate medium is needed to identify the agent. Histologic demonstration of these organisms is definitive evidence of invasive infection; positive cultures must be interpreted cautiously and not assumed to be contaminants in immunocompromised hosts. Some isolates are sensitive to antifungal antibiotics. The differentiation of *S apiospermum* and *Aspergillus* is particularly important, since the former is uniformly resistant to amphotericin B but may be sensitive to imidazole antibiotics (eg, voriconazole).

Silveira F et al: Emergence of black moulds in fungal disease: epidemiology and therapy. Curr Opin Infect Dis 2001;14:679. [\[PMID: 11764884\]](#)

ANTIFUNGAL THERAPY

[Table 36-1](#) summarizes the major properties of currently available antifungal agents. A number of lipid-based amphotericin B formulations have recently become available. These agents have shown promise in the treatment of systemic candidiasis, invasive aspergillosis, disseminated histoplasmosis, and cryptococcal meningitis. Their principal advantage appears to be substantially reduced nephrotoxicity, allowing administration of much higher doses. Because of their expense, use of these agents should be reserved for individuals who develop significant nephrotoxicity during amphotericin B therapy. Caspofungin acetate, the first of several agents in the echinocandin class, has recently been approved for use in invasive aspergillosis and invasive candida infections. These drugs are fungicidal for candida and are active also against aspergillus. They have relatively few adverse effects. Their exact role in the treatment of invasive fungal diseases needs to be further defined. A new azole, voriconazole, is now available and has excellent activity against aspergillus species. Cytokine therapy (such as with interferon-?) and use of growth factors such as GM-CSF (sargramostim or molgramostim) have been shown in animal models to increase clearance of fungi and result in better clinical outcomes.

Drug	Renal Dosing	CSF Clearance?	Penetration?	Toxicities	Spectrum of Activity	Daily Cost of Therapy (65 kg patient)
Amphotericin B	0.3-1.5 mg/kg/d IV	No	Poor	Rigors, fever, azotemia, hypokalemia, hypo-magnesemia, renal tubular acidosis, anemia	All major pathogens except scedosporium	\$23.28
Amphotericin B cholesteryl sulfate complex (Amphotec)	3-6 mg/kg/d IV	No	Poor	Fevers, rigors, nausea, hypotension, azotemia, hypomagnesemia, anemia, tachypnea, thrombophlebitis	Same as amphotericin B, above	\$64.00
Amphotericin B lipid complex (Abelcet)	5 mg/kg/d IV	No	Poor	Fever, rigors, nausea, hypotension, anemia, azotemia, tachypnea	Same as amphotericin B, above	\$757.33
Liposomal amphotericin B (Am Bisome)	3-6 mg/kg/d IV	No	Poor	Fever, rigors, nausea, hypotension, azotemia, anemia, tachypnea, chest tightness	Same as amphotericin B, above	\$1469.52
Caspofungin acetate (Cancidas)	70 mg IV loading dose, followed by 50 mg/d IV in one dose	<50% ²	Poor	Transient neutropenia; hepatic enzyme elevations when used with cyclosporine	Aspergillosis, candidiasis	\$360.00
Fluconazole (Diflucan)	100-400 mg/d in one or two doses IV or orally	Yes	Yes	Nausea, rash, alopecia, headache, hepatic enzyme elevations	Mucosal candidiasis (including urinary tract), cryptococcosis, histoplasmosis, coccidioidomycosis	\$360.00
Flucytosine (Ancobon)	100-150 mg/kg/d orally in four divided doses	Yes	Yes	Leukopenia, ³ rash, diarrhea, hepatitis, nausea, vomiting	Cryptococcosis, ⁴ candidiasis, ⁴ chromomycosis	\$160.00
Intraconazole (Sporanox)	100-400 mg/d orally in one or two doses; 200-400 mg/d IV in one or two doses	No	Variable	Nausea, hypokalemia, edema, hypertension	Histoplasmosis, coccidioidomycosis, blastomycosis, paracoccidioidomycosis, mucosal candidiasis (except urinary), sporotrichosis, aspergillosis, chromomycosis	\$295.80 IV \$34.32 PO
Ketoconazole (Nizoral)	200-800 mg/d orally in one or two doses	No	Poor	Anorexia, nausea, suppression of testosterone and cortisol, rash, headache, hepatic enzyme elevations, hepatic failure	Nonmeningeal histoplasmosis and coccidioidomycosis, blastomycosis, paracoccidioidomycosis, mucosal candidiasis (except urinary)	\$12.64
Terbinafine (Lamisil)	250 mg/d orally in one dose	Yes	Poor	Nausea, abdominal pain, taste disturbance, rash, diarrhea and hepatic enzyme elevations	Dermatophytes, sporotrichosis	\$9.12
Voriconazole (V Fend)	200-400 mg/d orally in two doses or 12 mg/kg IV as loading dose for 2 days followed by 6 mg/kg/d IV in two doses	Yes	Yes	Transient visual disturbances, rash, hepatic enzyme elevations ⁵	All major pathogens except zygomycetes and sporotrix	\$425.00 IV loading dose \$212.50 IV maintenance \$62.50 PO

¹Average wholesale price (AWP, for AB-rated generic when available) for quantity listed. Source: *Drug Topics Red Book*, May 2003: Vol. 22, No. 5. AWP may not accurately represent actual prices because wide contractual variations exist among institutions.

²No dosage adjustment required for renal insufficiency; dosage adjustment necessary with moderate to severe hepatic dysfunction.

³Use should be monitored with blood levels to prevent this or the dose adjusted according to creatinine clearance.

⁴In combination with amphotericin B.

⁵Administration with drugs that are metabolized by the cytochrome P450 system is contraindicated or requires careful monitoring.

Some Principles of Antimicrobial Therapy

The following steps are required in each patient considered for antibiotic therapy. Drugs of first choice and alternative drugs are presented in [Table 37-1](#).

A. Etiologic Diagnosis

Based on the organ system involved, the organism causing infection can usually be predicted. See [Tables 37-2](#) and [37-3](#).

B. "Best Guess"

One selects an empirical regimen that is likely to be effective against the suspected pathogens.

C. Laboratory Control

Specimens for laboratory examination are commonly obtained before institution of therapy to determine susceptibility.

D. Clinical Response

Based on clinical response, one evaluates the laboratory reports and considers the desirability of changing the regimen. If the specimen was obtained from a normally sterile site (eg, blood, cerebrospinal fluid, pleural fluid, joint fluid), the recovery of a microorganism in significant amounts is meaningful even if the organism recovered is different from the clinically suspected agent, and this may force a change in treatment. Isolation of unexpected microorganisms from the respiratory tract, gastrointestinal tract, or surface lesions (sites that have a complex flora) may represent colonization or contamination, and cultures must be critically evaluated before drugs are abandoned that were judiciously selected on a "best guess" basis.

E. Drug Susceptibility Tests

Some microorganisms are predictably responsive to certain drugs; if such organisms are isolated, they need not be tested for drug susceptibility. For example, most group A hemolytic streptococci and clostridia respond well to penicillin. Other organisms (eg, enteric gram-negative rods) are variably susceptible and require sensitivity testing whenever they are isolated. Organisms that once had predictable susceptibility patterns have now become resistant and require testing. Examples include the pneumococci, which may be resistant to multiple agents, including penicillin, macrolides, and trimethoprim-sulfamethoxazole (TMP-SMZ) and the enterococci, which may be resistant to penicillin, aminoglycosides, and vancomycin.

Antimicrobial drug susceptibility tests may be performed on solid media as "disk tests," in broth in tubes, in wells of microdilution plates, or as E-tests. The latter three methods yield results expressed as MIC (minimal inhibitory concentration), and the technique can be modified to give MBC (minimal bactericidal concentration) results. In most infections, the MIC is the appropriate in vitro test to guide selection of an antibacterial agent. When there appear to be marked discrepancies between susceptibility testing and clinical response, the following possibilities must be considered:

1. Selection of an inappropriate drug, drug dosage, or route of administration.
2. Failure to drain a collection of pus or to remove a foreign body.
3. Failure of a poorly diffusing drug to reach the site of infection (eg, central nervous system) or to reach intracellular phagocytosed bacteria.
4. Superinfection in the course of prolonged chemotherapy.
5. Emergence of drug-resistant or tolerant organisms.
6. Participation of two or more microorganisms in the infectious process, of which only one was originally detected and used for drug selection.
7. Inadequate host defenses, including immunodeficiencies and diabetes.
8. Noninfectious causes, including drug fever, malignancy, and autoimmune disease.

F. Promptness of Response

Response depends on a number of factors, including the host (immunocompromised patients respond slower than immunocompetent patients), the site of infection (deep-seated infections such as osteomyelitis and endocarditis respond more slowly than superficial infections such as cystitis or cellulitis), the pathogen (virulent organisms such as *Staphylococcus aureus* respond more slowly than viridans streptococci; mycobacterial and fungal infections respond slower than bacterial infections), and the duration of illness (in general, the longer the symptoms are present, the longer it takes to respond). Thus, depending on the clinical situation, persistent fever and leukocytosis several days after initiation of therapy may not indicate improper choice of antibiotics but may be due to the natural history of the disease being treated. In most infections, either a bacteriostatic or a bactericidal agent can be used. In some infections (eg, infective endocarditis and meningitis), one must kill the infecting organism to achieve a cure. When potentially toxic drugs (eg, aminoglycosides, flucytosine) are used, serum levels of the drug are measured to avoid toxicity and ensure appropriate dosage. In patients with altered clearance of drugs, the dosage or frequency of administration must be adjusted. Especially in elderly, morbidly obese patients or those with altered renal function, it is best to measure levels directly and adjust therapy accordingly.

In renal or hepatic failure, the dosage is adjusted as shown in [Table 37-4](#).

G. Duration of Antimicrobial Therapy

Generally, effective antimicrobial treatment results in reversal of the clinical and laboratory parameters of active infection and marked clinical improvement. However, varying periods of treatment may be required for cure. Key factors include (1) the type of infecting organism (bacterial infections can be cured more rapidly than fungal or mycobacterial ones), (2) the location of the process (eg, endocarditis and osteomyelitis require prolonged therapy), and (3) the immunocompetence of the patient. Recommendations about duration of therapy are often given based on clinical experience, not prospective controlled studies of large numbers of patients.

H. Adverse Reactions and Toxicity

These include (1) hypersensitivity reactions, (2) direct toxicity, (3) superinfection by drug-resistant microorganisms, and (4) drug interactions. If the infection is life-threatening and treatment cannot be stopped, the reactions are managed symptomatically or another drug is chosen that does not cross-react with the offending one ([Table 37-1](#)). If the infection is less serious, it may be possible to stop all antimicrobials and follow the patient closely.

I. Route of Administration

Parenteral therapy is preferred for acutely ill patients with serious infections (eg, endocarditis, meningitis, sepsis, severe pneumonia) when dependable levels of antibiotics are required for successful therapy. Certain drugs (eg, fluconazole, rifampin, metronidazole, trimethoprim-sulfamethoxazole, and fluoroquinolones) are so well absorbed that they can be administered orally in seriously ill patients.

Food does not significantly influence the bioavailability of oral antimicrobial agents save the tetracyclines and the quinolones, which are chelated by heavy metals. Azithromycin capsules are associated with decreased bioavailability when taken with food and should be given 1 hour before or 2 hours after meals.

A major complication of intravenous antibiotic therapy is catheter infections. Peripheral Teflon catheters are changed every 48-72 hours to prevent phlebitis, and antimicrobial-coated central venous catheters (minocycline and rifampin, chlorhexidine and sulfadiazine) have been associated with a decreased incidence of catheter-related infections. Most of these infections present with local signs of infection (erythema, tenderness) at the insertion site. In a patient with fever who is receiving intravenous therapy, the catheter must always be considered a potential source. Small-gauge (20-23F) peripherally inserted silicone or polyurethane catheters (Per Q Cath, A-Cath, Ven-A-Cath, and others) are associated with a low infection rate and can be maintained for 3-6 months without replacement. Such catheters are ideal for long-term outpatient antibiotic therapy.

J. Cost of Antibiotics

The cost of these agents can be substantial. In addition to the direct cost of purchasing a drug, one must consider the costs of monitoring for toxicity (drug levels, liver function tests, electrolytes, etc); the cost of treating adverse reactions; the cost of treatment failure; and the costs associated with the time required for administering drugs that must be given at frequent intervals. [Table 37-5](#) lists the costs of commonly used antibiotics.

PENICILLINS

The penicillins share a common chemical nucleus (6-aminopenicillanic acid) that contains a β -lactam ring essential to their biologic activity.

Antimicrobial Action & Resistance

The initial step in penicillin action is the binding of the drug to receptors—penicillin-binding proteins. The proteins of different organisms vary in number and in affinity for a given drug. After penicillins have attached to receptors, peptidoglycan synthesis is inhibited because the activity of transpeptidation enzymes is blocked. The final bactericidal action is the removal of an inhibitor of the autolytic enzymes in the cell wall, which activates the enzymes and results in cell lysis. Organisms defective in autolysin function are inhibited but not killed by β -lactam antibiotics ("tolerance"). Organisms that produce β -lactamases (penicillinases) are resistant to some penicillins because the β -lactam ring is broken and the drug is inactivated. Only organisms actively synthesizing peptidoglycan (in the process of multiplication) are susceptible to β -lactam antibiotics. Nonmultiplying organisms or those lacking cell walls are not susceptible.

Microbial resistance to penicillins is caused by four factors: (1) Production of β -lactamases, eg, by staphylococci, gonococci, haemophilus species, and coliform organisms; (2) lack of penicillin-binding proteins or decreased affinity of penicillin-binding protein for β -lactam antibiotic receptors (eg, resistant pneumococci, methicillin-resistant staphylococci, enterococci) or impermeability of cell envelope; (3) failure of activation of autolytic enzymes in the cell wall—"tolerance," eg, in staphylococci, group B streptococci; and (4) cell wall-deficient (L) forms or mycoplasmas, which do not synthesize peptidoglycans.

1. Natural Penicillins

The natural penicillins include penicillin G for parenteral administration (aqueous crystalline, procaine, and benzathine penicillin G) or for oral administration (penicillin G and phenoxymethyl penicillin [penicillin V]). They are most active against gram-positive organisms and are susceptible to hydrolysis by β -lactamases. They are used (1) for infections caused by susceptible and moderately susceptible pneumococci, depending upon the site of infection (however, up to 30-35% of strains now demonstrate intermediate- or high-level resistance to penicillin); (2) streptococci (including anaerobic streptococci); (3) meningococci; (4) non- β -lactamase-producing staphylococci; (5) *Treponema pallidum* and other spirochetes; (6) *Bacillus anthracis* and other gram-positive rods; (7) clostridia; (8) actinomyces; and (9) most anaerobes except β -lactamase-producing strains, eg, *Bacteroides fragilis*. See (Table 37-1).

Pharmacokinetics & Administration

After parenteral administration, penicillin is widely distributed in tissues. Lower levels are present in the eye, prostate, and central nervous system. However, with inflammation of the meninges and with appropriate dosing, adequate penetration into the cerebrospinal fluid takes place.

Special dosage forms of penicillin permit delayed absorption to yield low blood and tissue levels for long periods, eg, benzathine penicillin G and procaine penicillin G.

Phenoxymethyl penicillin (penicillin V) is the oral penicillin of choice. It is more acid-stable than oral penicillin G, is better absorbed, and gives higher serum levels. Most absorbed penicillin is rapidly excreted by the kidneys into the urine. Ten percent of renal excretion occurs by glomerular filtration and 90% by tubular secretion. Tubular secretion can be partially blocked by probenecid to achieve higher systemic levels. The dose should be reduced in moderate to severe renal failure. One commonly used formula for calculating the maximum daily dose of penicillin in millions of units in patients with a creatinine clearance of less than 40 mL/min is as follows (see also Table 37-4):

$$\text{Dosage (millions of units/d)} = 3.2 + \frac{\text{Creatinine clearance (mL/min)}}{7}$$

Clinical Uses

Most infections caused by organisms sensitive to penicillin will respond to aqueous penicillin G in daily doses of 1-2 million units administered intravenously every 4-6 hours. For life-threatening infections (meningitis, endocarditis), much larger daily doses (18-24 million units) should be given by intermittent intravenous infusion every 4-6 hours in equally divided doses.

Penicillin V is indicated in minor infections such as streptococcal pharyngitis and cellulitis. The usual dose is 1-2 g/d in four equally divided doses.

A single injection of 1.2 million units of benzathine penicillin intramuscularly is satisfactory for treatment of β -hemolytic streptococcal pharyngitis. Syphilis is usually treated with benzathine penicillin, 2.4 million units intramuscularly weekly for 1-3 weeks, depending on the stage of the disease (see Table 37-3).

Procaine penicillin is rarely used except as an alternative drug for neurosyphilis (Table 37-3).

2. Extended-Spectrum Penicillins

The extended-spectrum group of penicillins includes the aminopenicillins: ampicillin and amoxicillin; the carboxypenicillins: ticarcillin; and the ureidopenicillins: piperacillin and mezlocillin. These drugs are all susceptible to destruction by staphylococcal (and other) β -lactamases. They tend to be active against many gram-negative rods and have the same activity as natural penicillins against gram-positive bacteria.

Antimicrobial Activity

Ampicillin and amoxicillin are active against most strains of *Proteus mirabilis*, listeria, and non- β -lactamase-producing strains of *Haemophilus influenzae* but are inactive against most gram-negative pathogens. Both drugs are effective against the pneumococcus, and both are more active than penicillin against *Enterococcus faecalis*.

Ticarcillin extends the activity of ampicillin to include many strains of pseudomonas, serratia, and indole-positive proteus, but it has poor activity against most strains of klebsiella and enterococci and is less active than ampicillin against pneumococci.

The ureidopenicillins are similar to ticarcillin but exhibit slight differences in activity against gram-negative organisms. Piperacillin and mezlocillin are more active than ticarcillin against *Pseudomonas aeruginosa* and klebsiella, but otherwise their gram-negative spectrum of activity is similar to that of ticarcillin. Similar to ampicillin, mezlocillin and piperacillin are active against *E faecalis*. Piperacillin works better than ticarcillin against pneumococci. The extended-spectrum penicillins kill most anaerobes. Ampicillin and amoxicillin are not active against β -lactamase-producing strains of *B fragilis*—in contrast to the other drugs in this class which are active against most (not all) isolates at high concentrations.

Pharmacokinetics & Administration

Ampicillin can be given orally or parenterally. Amoxicillin is absorbed better than ampicillin, resulting in serum levels twice as high as those achieved with ampicillin.

The carboxy- and ureidopenicillins are given intravenously. Increased doses (200-300 mg/kg/d) are required for treatment of infections due to *P aeruginosa*.

Dosage adjustments are required in renal failure and are summarized in Table 37-4.

Clinical Uses

Amoxicillin is given orally for minor infections, such as exacerbations of chronic bronchitis, sinusitis, or otitis. Ampicillin is administered intravenously for pneumonia, meningitis, bacteremia, or endocarditis.

Amoxicillin is also used as prophylaxis for endocarditis. Because of the increased serum and respiratory secretion levels, this agent is valuable in the treatment of moderately penicillin-susceptible pneumococcus. In general, if amoxicillin levels remain above the MIC of the pneumococcus for more than 40% of the dosing interval, bacteriologic cure rates approach 85-100%. Although ticarcillin, mezlocillin, and piperacillin have been used as monotherapy, they are more commonly administered in combination with other agents as empirical therapy in the febrile neutropenic patient.

3. Penicillins Combined With β -Lactamase Inhibitors

The addition of β -lactamase inhibitors (clavulanic acid, sulbactam, tazobactam) prevents inactivation of the parent penicillin by bacterial β -lactamases. Products available are Augmentin (amoxicillin, 250 mg, 500 mg, or 875 mg, plus 125 mg of clavulanic acid); Augmentin XR (amoxicillin 1 g plus 62.5 mg of clavulanic acid); Timentin (ticarcillin 3 g plus 100 mg of clavulanic acid); Unasyn (ampicillin 1 g plus sulbactam 0.5 g, and ampicillin 3 g plus sulbactam 1 g); and Zosyn (piperacillin 3 g plus tazobactam 0.375 g, and piperacillin 4 g plus tazobactam 0.5 g). Augmentin is given orally and the others intravenously. In general, the β -lactamase inhibitors effectively inactivate β -lactamases produced by *S aureus*, *H influenzae*, *Moraxella catarrhalis*, and *Bacteroides fragilis*, thus making Augmentin, Timentin, Unasyn, and Zosyn effective agents for infections with these organisms. In contrast, the β -lactamase inhibitors are variably and unpredictably effective against certain β -lactamases produced by certain aerobic gram-negative bacilli, such as enterobacter, and thus cannot be relied upon to treat these organisms unless specific sensitivity testing is done. Of the available parenteral drugs, Zosyn has the broadest spectrum of activity. Like Unasyn (but not Timentin) it is active against ampicillin-susceptible enterococci. It has greater in vitro activity against *P aeruginosa* than Timentin and is more active than either Timentin or Unasyn against *serratia* and *klebsiella* species.

Augmentin, because of its high cost and gastrointestinal intolerance, is limited to the treatment of refractory cases of sinusitis and otitis that have not responded to less costly agents and is used for therapy and prophylaxis of infections resulting from animal and human bites. The roles of Timentin, Unasyn, and Zosyn include the treatment of polymicrobial infections such as peritonitis from a ruptured viscus, osteomyelitis in a diabetic patient, or traumatic osteomyelitis.

The dosage regimens of these drugs are the same as those of the parent drugs. When Timentin or Zosyn is used to treat pseudomonas infections, dosages of 200-300 mg/kg/d of the penicillin component are used. Nonpseudomonal infection can be treated with lower doses (100-200 mg/kg/d).

4. Penicillinase-Resistant Penicillins

Methicillin, oxacillin, cloxacillin, dicloxacillin, nafcillin, and others are relatively resistant to destruction by β -lactamases produced by staphylococci and are limited to the treatment of infections with such organisms. They are less active than natural penicillins against nonstaphylococcal gram-positives; however, they are still adequate in certain streptococcal infections, including those due to group A streptococci in skin and soft tissue infections.

With the exception of methicillin, the primary route of clearance of the above agents is nonrenal—thus, no dosage adjustment is needed in renal insufficiency.

5. Adverse Effects of Penicillins

Allergy

All penicillins are cross-sensitizing and cross-reacting. The responsible antigenic determinants appear to be degradation products of penicillins, particularly penicilloic acid and products of alkaline hydrolysis (minor antigenic determinants) bound to host protein. Skin tests with penicilloyl-polylysine, with minor antigenic determinants, and with undegraded penicillin can identify most individuals with IgE-mediated reactions (hives, bronchospasm). Among positive reactors to skin tests, the incidence of subsequent immediate severe penicillin reactions is high. Although many persons develop IgG antibodies to antigenic determinants of penicillin, the presence of such antibodies is not correlated with allergic reactivity (except for rare instances of hemolytic anemia), and serologic tests have little predictive value. A history of a penicillin reaction in the past is not reliable. Only 15-20% of patients with a history of penicillin allergy have an adverse reaction when challenged with the drug. The decision to administer penicillin or related drugs (other β -lactams) to patients with an allergic history depends upon the severity of the reported reaction, the severity of the infection being treated, and the availability of alternative drugs. For patients with a history of severe reaction (anaphylaxis), alternative drugs should be used. In the rare situations when there is a strong indication for using penicillin (eg, syphilis in pregnancy) despite a history of severe reaction, desensitization can be performed. If the reaction is mild (rash), the patient may be rechallenged with penicillin or may be given another β -lactam antibiotic. (See [Chapter 30](#) for discussion and methods of desensitization.)

Allergic reactions include anaphylaxis, serum sickness (urticaria, fever, joint swelling, angioneurotic edema 7-12 days after exposure), and a variety of skin rashes, oral lesions, fever, interstitial nephritis, eosinophilia, hemolytic anemia, other hematologic disturbances, and vasculitis. The incidence of hypersensitivity to penicillin is estimated to be 1-5% among adults in the USA. Life-threatening anaphylactic reactions are very rare (0.05%). Ampicillin produces maculopapular skin rashes more frequently than other penicillins, but some ampicillin rashes are not allergic in origin. The nonallergic ampicillin rash usually occurs after 3-4 days of therapy, is maculopapular, is more common in patients with coexisting viral illness (especially Epstein-Barr infection), and resolves with continued therapy. Penicillins can induce nephritis with primary tubular lesions associated with anti-basement membrane antibodies.

Toxicity

All penicillins are irritating to the central nervous system, and excessive doses, particularly in renal insufficiency, have been associated with seizures.

Of the oral penicillins, Augmentin is most commonly associated with diarrhea. Nafcillin administered at high doses is associated with a modest leukopenia. Oxacillin may cause a higher incidence of liver and skin toxicity than other agents in this class. High doses of penicillins, particularly ticarcillin, mezlocillin, or piperacillin can inhibit platelet aggregation and produce hypokalemia due to binding of potassium in the kidney.

CEPHALOSPORINS (TABLES 37-6 AND 37-7)

The cephalosporins are structurally related to the penicillins. They consist of a β -lactam ring attached to a dihydrothiazoline ring. Substitutions of chemical groups at various positions on the basic structure have resulted in a proliferation of drugs with varying pharmacologic properties and antimicrobial activities.

The mechanism of action of cephalosporins is analogous to that of the penicillins: (1) binding to specific penicillin-binding proteins, (2) inhibition of cell wall synthesis, and (3) activation of autolytic enzymes in the cell wall. Resistance to cephalosporins may be due to poor permeability of the drug into bacteria, lack of penicillin-binding proteins, or degradation by β -lactamases.

Cephalosporins have been divided into four major groups or "generations" ([Table 37-6](#)) based mainly on their antibacterial activity: First-generation cephalosporins have good activity against aerobic gram-positive organisms and some community-acquired gram-negative organisms (*P mirabilis*, *E coli*, *klebsiella* species); second-generation drugs have a slightly extended spectrum against gram-negative bacteria, and some are active against gram-negative anaerobes; and third-generation cephalosporins are active against most gram-negative bacteria (except enterobacter and citrobacter). Not all cephalosporins fit neatly into this grouping, and there are exceptions to the general characterization of the drugs in the individual classes; however, the generational classification of cephalosporins is useful for discussion purposes. Cefepime is considered a fourth-generation agent because it is more stable against plasmid-mediated β -lactamase and has little or no β -lactamase-inducing capacity. Cefepime compares favorably with ceftazidime with respect to its gram-negative activity; however, its stability versus plasmid-mediated β -lactamase results in improved coverage against enterobacter and citrobacter species. The gram-positive coverage of cefepime approaches that of cefotaxime or ceftriaxone.

1. First-Generation Cephalosporins

Antimicrobial Activity

These drugs are very active against gram-positive cocci, including penicillin-sensitive pneumococci, viridans streptococci, group A hemolytic streptococci, and *S aureus*. Like all cephalosporins, they are inactive against enterococci and methicillin-resistant staphylococci. Activity against *H influenzae* is poor, and many strains of penicillin-resistant streptococci (both intermediately and highly resistant) are resistant also to first-generation cephalosporins. Among gram-negative bacteria, *E coli*, *K pneumoniae*, and *P mirabilis* are usually susceptible except for some hospital-acquired strains. There is very little activity against most nosocomial gram-negative rods. Anaerobic cocci are usually susceptible, but *B fragilis* is not.

Pharmacokinetics & Administration

A. Oral

Cephalexin, cephradine, and cefadroxil are variably absorbed. Cefadroxil, because of its longer half-life, can be given twice daily. Dosage adjustment is required in renal insufficiency.

B. Intravenous

Cefazolin is preferred because it has a longer half-life, resulting in less frequent dosing. In renal insufficiency, all of these agents require dosage adjustments.

C. Intramuscular

Both cephapirin and cefazolin can be given intramuscularly, but pain on injection is less with cefazolin.

Clinical Uses

Oral drugs are sometimes used for treatment of urinary tract infections, and they can be used for minor staphylococcal infections. Oral cephalosporins may also be preferred for minor polymicrobial infections (eg, cellulitis, soft tissue abscess).

Intravenous first-generation cephalosporins are the drugs of choice for surgical prophylaxis in many cases. More expensive second- and third-generation cephalosporins offer no advantage for surgical prophylaxis except where anaerobes play an important role, such as for colorectal surgery or for hysterectomy.

First-generation cephalosporins do not adequately penetrate the cerebrospinal fluid and cannot be used to treat meningitis.

2. Second-Generation Cephalosporins

Second-generation cephalosporins are a heterogeneous group with marked individual differences in activity, pharmacokinetics, and toxicity. In general, all are active against gram-negative organisms also covered by first-generation drugs, but they have an extended gram-negative coverage. Indole-positive proteus and klebsiella (including first-generation cephalosporin-resistant strains) as well as *Moraxella catarrhalis* and neisseria species are usually sensitive. Cefuroxime and cefprozil are active against *H influenzae*, including β -lactamase-producing strains, but have little activity against serratia and *B fragilis*. In contrast, cefoxitin and cefotetan are active against many strains of *B fragilis* and some strains of serratia. Against gram-positive organisms, these drugs are generally less active than the first-generation cephalosporins (cefuroxime is an exception). Second-generation agents have no activity against *P aeruginosa* or enterococci.

Pharmacokinetics & Administration

A. Oral

Only cefaclor, cefuroxime axetil, and cefprozil can be given orally. Cefuroxime axetil is deesterified to cefuroxime after absorption. Its longer half-life permits twice-daily dosing, and absorption is enhanced when it is taken with food (as is not the case with many other oral antibiotics).

B. Intravenous and Intramuscular

Because of differences in drug half-life and protein binding, peak serum levels achieved and dosing intervals vary greatly for this group of drugs ([Table 37-7](#)). Drugs with shorter half-lives (cefoxitin) require higher doses and more frequent dosing than drugs with longer half-lives (cefuroxime, cefotetan). Dosage adjustments are required with renal impairment.

Clinical Uses

Because of their activity against β -lactamase-producing *H influenzae* and *M catarrhalis*, cefprozil and cefuroxime axetil can be used to treat sinusitis and otitis media in patients with mild allergy to ampicillin or amoxicillin or have not responded to treatment with those drugs.

Because of their activity against *B fragilis*, cefoxitin, cefmetazole, and cefotetan can be used to treat mixed anaerobic infections, eg, peritonitis and diverticulitis. However, since many *B fragilis* and enteric gram-negative organisms are resistant to these drugs, alternative agents are preferred for life-threatening intra-abdominal infections. Cefoxitin and cefotetan are useful as prophylaxis in colorectal surgery, vaginal or abdominal hysterectomy, and appendectomy because of their activity against *B fragilis*.

3. Third- & Fourth-Generation Cephalosporins

Antimicrobial Activity

Most of these drugs are active against staphylococci (not methicillin-resistant strains) but less so than first-generation cephalosporins. Ceftazidime, however, has notably weak activity against *S aureus* and pneumococci. They have no activity against enterococci but do inhibit most streptococci. Ceftriaxone and cefotaxime offer the most reliable antipneumococcal coverage. A major advantage of these cephalosporins is their expanded gram-negative coverage. In addition to organisms inhibited by other cephalosporins, they are consistently active against *S marcescens*, providencia, haemophilus, and neisseria, including β -lactamase-producing strains. Ceftazidime is effective against *P aeruginosa*. Acinetobacter, citrobacter, enterobacter, and non-aeruginosa strains of pseudomonas are variably sensitive to third-generation cephalosporins, and listeria is uniformly resistant. Activity against *B fragilis* is variable. In contrast to the third-generation agents, cefepime—the only currently available fourth-generation cephalosporin—is active against enterobacter and citrobacter, has activity comparable to that of ceftazidime against *P aeruginosa*, and has gram-positive activity similar to that of ceftriaxone.

Cefpodoxime proxetil, cefdinir, cefditoren pivoxil, and ceftibuten, the only oral agents in this group, are more active than cefuroxime axetil but are not as active as parenteral third-generation cephalosporins against gram-negative organisms such as pseudomonas, enterobacter, morganella, and *S marcescens*. The major difference in these drugs is activity against gram-positive bacteria. All are active against *Streptococcus pyogenes* (group A streptococcus). Cefpodoxime proxetil, cefditoren pivoxil, and cefdinir are active against methicillin-sensitive *S aureus*, whereas ceftibuten has little activity (none are active against methicillin-resistant strains). Cefdinir, cefditoren pivoxil, and cefpodoxime proxetil are active against penicillin-sensitive strains of *Streptococcus pneumoniae* (the pneumococcus), but ceftibuten has marginal activity. None of the oral cephalosporins are reliable against intermediately susceptible or penicillin-resistant *S pneumoniae*. Like other members of this class, these drugs are ineffective against enterococci and *Listeria monocytogenes*.

Pharmacokinetics & Administration

The intravenous agents penetrate well into body fluids and tissues and reach levels in the cerebrospinal fluid that exceed those needed to inhibit most pathogens, including gram-negative rods. The half-lives of these drugs are variable, which accounts for the differences in dosing intervals ([Table 37-7](#)). Ceftriaxone is eliminated primarily by biliary excretion, and no dosage adjustment is required in renal insufficiency. The other drugs are eliminated primarily by the kidney and thus require dosage adjustments in renal insufficiency.

Clinical Uses

Because of their penetration into the cerebrospinal fluid, intravenous third-generation cephalosporins can be used to treat meningitis. Meningitis due to susceptible pneumococci—meningococci, *H influenzae*, and susceptible enteric gram-negative rods has been successfully treated. Strains resistant to penicillin may have high MICs to third-generation cephalosporins and should not be used to treat meningitis caused by highly penicillin-resistant pneumococci. In meningitis in older patients, third-generation cephalosporins should be combined with ampicillin or trimethoprim-sulfamethoxazole until *L monocytogenes* has been excluded as the etiologic agent. Ceftazidime has been used to treat pseudomonas meningitis. The dosage for meningitis should be at the upper limits of the recommended range, because cerebrospinal fluid levels of these drugs are only 10-20% of serum levels. Ceftazidime or cefepime is frequently administered empirically in the febrile neutropenic patient. Ceftriaxone is indicated for gonorrhea, chancroid, and more serious forms of Lyme disease (see [Chapter 34](#)). Because of its long half-life and once-daily dosing requirement, ceftriaxone is an attractive option for the outpatient parenteral therapy of infections due to susceptible organisms.

Cefepime is useful for third-generation cephalosporin-resistant isolates such as enterobacter and citrobacter.

Cefdinir, cefditoren pivoxil, and cefpodoxime proxetil are the best third-generation oral agents against pneumococci and *S aureus*. Single-dose cefpodoxime proxetil is probably as effective as ceftriaxone for the therapy of genital, rectal, and pharyngeal gonorrhea.

4. Adverse Effects of Cephalosporins

Allergy

Cephalosporins are sensitizing, and a variety of hypersensitivity reactions occur, including anaphylaxis, fever, skin rashes, nephritis, granulocytopenia, and hemolytic anemia. The frequency of IgE cross-allergy between cephalosporins and penicillins approximates 5-10%. Persons with a history of anaphylaxis to penicillins should not receive cephalosporins.

Toxicity

Local pain can occur after intramuscular injection, or thrombophlebitis after intravenous injection. Hypoprothrombinemia is a frequent adverse effect (40-68%) of

cephalosporins that have a methylthiotetrazole group (eg, cefamandole, cefmetazole, cefotetan). Prophylactic administration of vitamin K, 10 mg twice weekly, can prevent this complication. Drugs containing the methylthiotetrazole ring can also cause severe disulfiram-like reactions, and use of alcohol or medications containing alcohol (eg, theophylline elixir) must be avoided. Ceftriaxone has been associated with a dose-dependent biliary sludging syndrome and cholelithiasis due to precipitation of drug when its solubility in bile is exceeded. Long-term administration of 2 g/d or more is a risk factor for this complication.

Marshall WF et al: The cephalosporins. Mayo Clin Proc 1999; 74:187. [PMID: 10069359]

OTHER β -LACTAM DRUGS

Monobactams

These are drugs with a monocyclic β -lactam ring that are resistant to β -lactamases and active against gram-negative organisms (including pseudomonas) but have no activity against gram-positive organisms or anaerobes. Aztreonam resembles ceftazidime in its gram-negative activity. Clinical uses of aztreonam are limited because of the availability of third-generation cephalosporins with a broader spectrum of activity and minimal toxicity. Despite the structural similarity of aztreonam to penicillin, cross-reactivity is limited, and it can therefore be used in most patients with penicillin allergy.

Carbapenems

This class of drugs is structurally related to β -lactam antibiotics. Imipenem, the first drug of this type, has a wide spectrum of activity that includes most gram-negative rods (including *P aeruginosa*) and gram-positive organisms and anaerobes, with the exception of *Burkholderia cepacia*, *Stenotrophomonas maltophilia*, *E faecium*, and most methicillin-resistant *S aureus* and *S epidermidis*. The half-life of imipenem is 1 hour. Dosage adjustment is required in renal insufficiency.

Meropenem is similar to imipenem in spectrum of activity and pharmacology. It is less likely to cause seizures than imipenem, though the risk of seizures is low with imipenem if dosage is appropriately adjusted for renal insufficiency. Meropenem is associated with less nausea and vomiting than imipenem, a feature of importance when high doses must be used, as in the treatment of pseudomonas infection in patients with cystic fibrosis. The usual dose is 1-2 g every 8 hours. Dosage adjustment in renal insufficiency is required.

Ertapenem is similar to imipenem and meropenem in its activity against aerobic gram-positive and anaerobic organisms but is less active against pseudomonas and acinetobacter. Because of its long half-life (4 hours), it can be administered once daily. The usual dose is 1 g, and adjustments are needed for renal insufficiency.

The carbapenems should not be routinely used as first-line therapy unless the pathogen is multidrug-resistant and is known to be sensitive to these agents. In patients hospitalized for a prolonged period who may have infection with a multidrug-resistant organism, empirical use of carbapenems while awaiting culture results is reasonable. (Ertapenem should not be used if pseudomonas and enterobacter are common nosocomial pathogens.) Pseudomonas may rapidly develop resistance to imipenem and meropenem. The use of imipenem or meropenem alone appears to be as effective as combination therapy in the febrile neutropenic patient and all of the carbapenems are as effective as combination therapy in certain polymicrobial infections such as peritonitis and obstetric pelvic infections.

The most common adverse effects of imipenem and meropenem are nausea, vomiting, diarrhea, reactions at the infusion site, and skin rashes. Seizures are more commonly observed with imipenem. Patients allergic to penicillins may be allergic to imipenem and meropenem as well. BR>

ERYTHROMYCIN GROUP (MACROLIDES)

The erythromycins are a group of closely related compounds characterized by a macrocyclic lactone ring to which various sugars are attached.

Antimicrobial Activity

Erythromycins inhibit protein synthesis by binding to the 50S subunit of bacterial ribosomes. They generally are bacteriostatic and sometimes bactericidal for gram-positive organisms, including most streptococci and corynebacteria in a concentration of 0.02-2 ug/mL. Similar to penicillin, macrolide-resistant *S pneumoniae* is being reported with increased frequency (15-50%), and recent reports demonstrate increased resistance in group A streptococci. Erythromycin-resistant pneumococci are azalide-resistant as well (azithromycin, clarithromycin). Chlamydiae, mycoplasmas, legionella, and campylobacter are susceptible.

Pharmacokinetics & Administration

Preparations for oral use include erythromycin base, erythromycin stearate, estolate, and ethyl succinate. None of the oral preparations have any advantage over others. Erythromycins are excreted primarily nonrenally; no adjustment is therefore required in renal failure.

Erythromycin and azithromycin are available for intravenous use, particularly in the treatment of Legionnaires' disease.

Clinical Uses

Macrolides are drugs of choice for infections caused by legionella, mycoplasma, ureaplasma, corynebacterium (including diphtheria), and chlamydia (including ocular and respiratory infections). They are effective in streptococcal and pneumococcal disease in penicillin-allergic patients, though resistance is increasing. They can also be used with neomycin in prophylaxis for bowel surgery. When administered early, erythromycin may shorten the course of campylobacter enteritis. Erythromycins are effective against certain bartonella species (bacillary angiomatosis) and rhodococcus species. In vitro data suggest that macrolides have a direct effect on neutrophil function and the production of cytokines associated with inflammation. Thus, these agents are being evaluated for their anti-inflammatory effects in infectious diseases as well. Recent reports demonstrate a lack of benefit in the prevention of cardiac events.

Adverse Effects

Nausea, vomiting, and diarrhea may occur after oral or intravenous intake. Erythromycins—particularly the estolate—can produce acute cholestatic hepatitis (fever, jaundice, impaired liver function), probably as a hypersensitivity reaction. Hepatitis recurs if the drug is readministered. Reversible auditory impairment occurs with large doses (4 g/d or more), particularly in patients with impaired renal or hepatic function. Ototoxicity has been reported with high doses of all agents. Intravenous erythromycin has been associated with prolongation of the QT interval and torsade de pointes—more commonly in women. Erythromycins (and clarithromycin) can increase the effects of oral anticoagulants, digoxin, theophylline, and cyclosporine by inhibiting cytochrome P450.

AZALIDES

Azalides (azithromycin, clarithromycin, dirythromycin, and others) are a group of antibiotics closely related structurally to the macrolides. They are similar to erythromycin in activity against *Streptococcus pneumoniae*, group A streptococcus, viridans streptococci, *M catarrhalis*, legionella, *Mycoplasma pneumoniae*, and *Chlamydia pneumoniae* and are slightly more active in vitro than erythromycin against *H influenzae* (with azithromycin having better activity than clarithromycin and dirythromycin having activity equivalent to that of erythromycin). They are also active against *Chlamydia trachomatis*, *N gonorrhoeae*, *Ureaplasma urealyticum*, and *Haemophilus ducreyi*. In addition, these drugs have in vitro activity against a number of unusual pathogens, including atypical mycobacteria (*Mycobacterium avium-intracellulare*, *Mycobacterium chelonae*, *Mycobacterium fortuitum*, *Mycobacterium marinum*), *Toxoplasma gondii*, *Campylobacter jejuni*, *Helicobacter pylori*, and *Borrelia burgdorferi*.

The azalides are more acid-stable than erythromycin, penetrate tissues well, and have a long terminal half-life, with high tissue concentrations that persist for days. The elevated tissue levels associated with azithromycin and clarithromycin could overcome the high incidence of in vitro resistance seen with pneumococci (30%), but clinical observations suggest that the reported resistance translates to clinical failure. Azithromycin, clarithromycin, and dirythromycin are approved for treatment of streptococcal pharyngitis, uncomplicated skin infections, and acute bacterial exacerbations of chronic bronchitis. Because of the long half-life, outpatient treatment with azithromycin is with once-daily dosing for a total of 5 days (500 mg on day 1 and then 250 mg on days 2-5). Clarithromycin is usually administered in a dosage of 250-500 mg twice daily, though an extended-release formulation that is given as a single daily 1000-mg dose has been approved for acute sinusitis and acute exacerbation of chronic bronchitis. Dirythromycin is given as a single daily dose of 500 mg. The azalides are more expensive than erythromycin. However, the less frequent dosing and better tolerability make them superior choices in certain patients.

Azithromycin has also been approved as single-dose therapy (1 g) for chlamydial genital infections. This is more expensive than 7 days of treatment with doxycycline ([Table 37-5](#)), but the assurance of adequate supervised therapy for this infection makes azithromycin preferred therapy in many patients. Azithromycin can also be used as single-dose therapy (1 g) for chancroid, and a single dose of 1 g is as efficacious as 7 days of doxycycline for nongonococcal urethritis in men and is effective also for incubating syphilis. While a 2-g dose of azithromycin is used for the treatment of gonorrhea, its efficacy is less than that observed with quinolones or ceftriaxone. Furthermore, the incidence of upper gastrointestinal side effects is increased with this dose. The spectrum of activity of the macrolides—particularly their atypical coverage—results in their utility in mild to moderate cases of community-acquired pneumonia; however, penicillin-resistant strains are often resistant to these agents as well. Weekly 1200-mg doses of azithromycin are effective in preventing *Mycobacterium avium* complex infections in HIV-positive patients, and doses of 500 mg daily may be effective in *M avium* complex pulmonary infections in non-HIV-positive patients. Azithromycin may be considered for therapy of dysentery caused by multidrug-resistant shigella. Used as prophylaxis, azithromycin (500 mg weekly) is as effective as benzathine penicillin in preventing upper respiratory tract infections in military recruits, and at a dose of 250 mg daily it is adequate as prophylaxis for malaria (though inferior to doxycycline for multidrug-resistant *P falciparum*). Clarithromycin has been used for the therapy of *M avium* complex infections, usually in combination with other drugs (eg, rifabutin and ethambutol), and can be given daily (500 mg twice daily) or three times weekly (1000 mg) as intermittent therapy. Clarithromycin (500 mg twice daily for 6 months) is effective therapy for disseminated *Mycobacterium chelonae* infections and may be the drug of choice for use against this pathogen. Clarithromycin has also been used in combination regimens for the therapy of *Helicobacter pylori* infections. When clarithromycin is given with omeprazole and amoxicillin or metronidazole, cure rates in excess of 80-90% have been achieved.

Adverse effects of these agents are similar to those of erythromycin, but upper gastrointestinal upset, the major side effect, occurs less often with the azalides. Hepatic enzyme elevations, interstitial nephritis, headache, and dizziness have been reported rarely. Similar to erythromycin, azithromycin and clarithromycin have been associated with dose-dependent ototoxicity. Clarithromycin is similar to erythromycin in its effect on the cytochrome P450 system. Azithromycin appears to affect metabolism of other drugs only minimally.

McConnell SA et al: Review and comparison of advanced-generation macrolides clarithromycin and dirithromycin. Pharmacotherapy 1999;18:404. [\[PMID: 10212011\]](#)

KETOLIDES

Ketolides (such as telithromycin) are similar in structure to macrolides, but they have a broader spectrum of activity and may offer additional benefit in the treatment of community-acquired respiratory infections. They are active against both penicillin-resistant and macrolide-resistant pneumococci and equal to azithromycin therapeutically against atypical pathogens and *H influenzae*. Upper gastrointestinal adverse events are the complications most commonly associated with these drugs. The dose is 100 mg/d, and no adjustment is needed for renal or hepatic insufficiency. Cytochrome P450 inhibition with telithromycin approximates that of erythromycin, and increased serum levels of warfarin and other agents would be expected with concomitant administration of telithromycin.

TETRACYCLINE GROUP

The tetracyclines are a large group of drugs with common basic chemical structures, antimicrobial activity, and pharmacologic properties.

Antimicrobial Activity

Tetracyclines are inhibitors of protein synthesis and are bacteriostatic for many gram-positive and gram-negative bacteria. They are strongly inhibitory for the growth of mycoplasmas, rickettsiae, chlamydiae, spirochetes, and some protozoa (eg, amebas). Their antipneumococcal activity approaches that of the macrolides; almost all *H influenzae* are inhibited. Tetracyclines also have moderate activity against some vancomycin-resistant enterococci. Doxycycline and minocycline are potential options for therapy of staphylococcal infections, including infections with many methicillin-resistant strains. There are marked differences in the susceptibility of different strains of a given species of microorganism. Because of the emergence of resistant strains, tetracyclines have lost much of their former usefulness in the treatment of gram-negative aerobic organisms.

Pharmacokinetics & Administration

Oral bioavailability varies depending upon the drug. Absorption is impaired by dairy products, aluminum hydroxide gels (antacids), and chelation with divalent cations, eg, Ca^{2+} or Fe^{2+} . Consequently, doses of tetracyclines should be staggered at least 2 hours before or after receipt of multivalent cations. Oral bioavailability is moderate with tetracycline and highest with doxycycline and minocycline (95% or more). Lipid solubility of minocycline and doxycycline accounts for their penetration into the cerebrospinal fluid, prostate, tears, and saliva.

Tetracyclines are primarily metabolized in the liver and excreted in bile. All tetracyclines except doxycycline accumulate in renal insufficiency. Thus, doxycycline requires no dosage adjustment in renal failure; in contrast other tetracyclines should be avoided or given in reduced dosage.

For patients unable to take oral medication, some tetracyclines (doxycycline, minocycline) are formulated for parenteral administration in doses similar to the oral ones.

Clinical Uses

Tetracyclines are drugs of choice for infections with chlamydiae, mycoplasmas, rickettsiae, ehrlichia, and vibrio and for some spirochetal infections. Sexually transmitted diseases in which chlamydiae often play a role—endocervicitis, urethritis, proctitis, and epididymitis—should be treated with doxycycline for 7-14 days. Pelvic inflammatory disease is often treated with doxycycline plus cefoxitin or cefotetan. Other chlamydial infections (psittacosis, lymphogranuloma venereum, trachoma) and sexually transmitted diseases (granuloma inguinale) also respond to doxycycline. Other uses include treatment of acne, respiratory infections, Lyme disease and relapsing fever, brucellosis, glanders, tularemia (often in combination with streptomycin), cholera, mycoplasmal pneumonia, actinomycosis, nocardiosis, malaria, infections caused by *M marinum* and *Pasteurella multocida* (typically after an animal bite), and as malaria prophylaxis (including multidrug-resistant *P falciparum*). They also have been used in combination with other drugs for amebiasis, falciparum malaria, and recurrent ulcers due to *H pylori*. Because of generally good activity against pneumococci, *Haemophilus influenzae*, chlamydia, legionella, and mycoplasma, doxycycline should be considered as empirical therapy for outpatient pneumonia.

Minocycline is equally as efficacious as doxycycline for the therapy of nongonococcal urethritis and cervicitis.

Adverse Effects

A. Allergy

Hypersensitivity reactions with fever or skin rashes are uncommon.

B. Gastrointestinal Side Effects

Diarrhea, nausea, and anorexia are common.

C. Bones and Teeth

Tetracyclines are bound to calcium deposited in growing bones and teeth, causing fluorescence, discoloration, enamel dysplasia, deformity, or growth inhibition. Therefore, tetracyclines should not be given to pregnant women or children under 6 years of age.

D. Liver Damage

Tetracyclines can impair hepatic function or even cause liver necrosis, particularly during pregnancy or in the presence of preexisting liver damage.

E. Kidney Effects

Demeclocycline can cause nephrogenic diabetes insipidus and has been used therapeutically to treat inappropriate antidiuretic hormone secretion. Tetracyclines may increase blood urea nitrogen when diuretics are administered.

F. Other

Tetracyclines—principally demeclocycline—may induce photosensitization, especially in fair-skinned individuals. Minocycline induces vestibular reactions (dizziness, vertigo, nausea, vomiting), with a frequency of 35-70% after doses of 200 mg daily and has also been implicated as a cause of hypersensitivity pneumonitis.

Smilack JD: The tetracyclines. Mayo Clin Proc 1999;74:727. [\[PMID: 10405705\]](#)

CHLORAMPHENICOL

Antimicrobial Activity

Chloramphenicol is active against certain rickettsiae. It binds to the 50S subunit of ribosomes and inhibits protein synthesis. It is bacteriostatic for most organisms but is often bactericidal for *S pneumoniae*, *H influenzae*, and *Neisseria meningitidis*. The drug is used minimally because of its toxicity and the availability of alternative agents.

Pharmacokinetics & Administration

Chloramphenicol is widely distributed in tissues, including the eye and central nervous system. Cerebrospinal fluid levels are 70-80% of peak serum levels, and the levels in brain tissue may even exceed those in serum.

Chloramphenicol is metabolized in the liver, and less than 10% is excreted unchanged in the urine. Thus, no dosage adjustment is needed in renal insufficiency. Patients with liver disease may accumulate the drug, and levels should be monitored.

Clinical Uses

Chloramphenicol is a possible choice in the following circumstances: (1) Meningococcal, *H influenzae*, or pneumococcal infections of the central nervous system in patients with a history of anaphylaxis to β -lactam drugs. (2) Anaerobic or mixed infections in the central nervous system, eg, brain abscess. (3) As an alternative to tetracyclines in rickettsial infections, especially in pregnant women, in whom tetracycline is contraindicated.

Adverse Effects

Nausea, vomiting, and diarrhea are uncommon. The most serious adverse effects are hematologic. Chloramphenicol in excess of 50 mg/kg/d regularly causes disturbances in red cell maturation within 1-2 weeks. There is anemia, hyperferremia, reticulocytopenia, and the appearance of vacuolated nucleated red cells in the bone marrow. These changes regress when the drug is stopped and are not related to aplastic anemia. The latter is an irreversible consequence of chloramphenicol administration and represents a specific, probably genetically determined individual defect. It occurs in 1:40,000-1:25,000 courses of chloramphenicol treatment.

Kasten MJ: Clindamycin, metronidazole and chloramphenicol. Mayo Clin Proc 1999;74:825. [\[PMID: 10473362\]](#)

AMINOGLYCOSIDES

Aminoglycosides are a group of bactericidal drugs sharing chemical, antimicrobial, pharmacologic, and toxic characteristics. At present, the group includes streptomycin, neomycin, kanamycin, amikacin, gentamicin, tobramycin, sisomicin, netilmicin, paromomycin, and spectinomycin. All these agents inhibit protein synthesis in bacteria by attaching to and inhibiting the function of the 30S subunit of the bacterial ribosome. Resistance is based on (1) a deficiency of the ribosomal receptor (chromosomal mutant); (2) the enzymatic destruction of the drug (plasmid-mediated transmissible resistance of clinical importance) by acetylation, phosphorylation, or adenylation; or (3) a lack of permeability to the drug molecule or failure of active transport across cell membranes. (This can be chromosomal, eg, streptococci are relatively impermeable to aminoglycosides; or plasmid-mediated, eg, in gram-negative enteric bacteria.) Anaerobic bacteria are resistant to aminoglycosides because transport across the cell membrane is an oxygen-dependent energy-requiring process.

All aminoglycosides are more active at alkaline than at acid pH. All are potentially ototoxic and nephrotoxic, though to different degrees. All can accumulate in renal insufficiency; therefore, dosage adjustments must be made in patients with renal dysfunction (see [Table 37-8](#)).

Because of their considerable toxicity and the availability of other antibiotics with broad spectrums of activity and fewer adverse effects (eg, cephalosporins, quinolones, carbapenems, β -lactamase inhibitor combinations), aminoglycosides have been used less often in recent years. They are most commonly used to treat resistant gram-negative organisms that are sensitive only to aminoglycosides, or in low doses in combination with β -lactam drugs or vancomycin for their synergistic effect (eg, enterococci, penicillin-resistant viridans streptococci, right-sided *S aureus* endocarditis, *S aureus* and *S epidermidis* prosthetic valve infection). Although aminoglycosides demonstrate in vitro activity against many gram-positive bacteria, they should never be used alone to treat infections caused by these organisms—both because there is no clinical experience with the treatment of such infections and because less toxic alternatives are available.

General Properties of Aminoglycosides

Because of the similarities of the aminoglycosides, a summary of properties is presented briefly.

A. Absorption, Distribution, Metabolism, and Excretion

Aminoglycosides are not absorbed from the gastrointestinal tract. They diffuse poorly into the eye, prostate, bile, central nervous system, and spinal fluid after parenteral injection.

There is no significant metabolic breakdown of aminoglycosides. The serum half-life is 2-3 hours in patients with normal renal function. Excretion is almost entirely by glomerular filtration. Aminoglycosides are removed fairly effectively by hemodialysis. Continuous hemofiltration is associated with significant aminoglycoside clearance.

B. Dosage and Effect of Impaired Renal Function

In persons with normal renal function who have gram-negative infections, the dosage of amikacin is 15 mg/kg/d in a single daily dose; that for gentamicin, tobramycin, or netilmicin is 5 mg/kg injected once daily. A single large daily dose of gentamicin, tobramycin, netilmicin, or amikacin is just as efficacious as—and no more nephrotoxic than—traditional dosing every 8-12 hours. Trough aminoglycoside levels should be undetectable in patients with normal body composition and renal function receiving once-daily dosing. Some clinicians recommend serum level monitoring 12-18 hours after the dose and extending the interval to every 48-72 hours for patients with elevated aminoglycoside levels. Others have suggested maintaining the dosage interval but decreasing the dose. Patients with renal failure, volume overload, or obesity have altered antibiotic clearance or volume of distribution. In patients with abnormal renal function or body composition, once-daily dosing is not recommended and aminoglycoside levels are recommended to guide dosing. For more traditional dosing, peak levels greater than 6 ug/mL are necessary for optimal outcome in the treatment of serious gram-negative infection, including pneumonia. Trough levels of more than 2 ug/mL have been associated with an increased incidence of nephrotoxicity. In patients with normal body composition, once-daily dosing regimens as set forth in [Table 37-8](#) should be followed. Reduced gentamicin doses (1 mg/kg every 8 hours) are recommended when used synergistically with β -lactams or vancomycin in the treatment of serious gram-positive infection (eg, enterococcal endocarditis).

C. Adverse Effects

All aminoglycosides can cause ototoxicity and nephrotoxicity. Ototoxicity can be irreversible and is cumulative, presenting as hearing loss (cochlear damage), noted first with high-frequency tones, or as vestibular damage, manifested by vertigo and ataxia. Amikacin appears to be more cochlear toxic than gentamicin, tobramycin, or netilmicin. Nephrotoxicity, which is more common than ototoxicity, is accompanied by rising serum creatinine levels or reduced creatinine clearance. Nephrotoxicity is usually reversible and occurs with similar frequency with gentamicin, tobramycin, amikacin, and netilmicin.

In very high doses, particularly with irrigation of an inflamed peritoneum, aminoglycosides can be neurotoxic, producing a curare-like effect with neuromuscular blockade that results in respiratory paralysis.

1. Streptomycin

The usual dosage of streptomycin is 15-25 mg/kg/d (about 1 g/d) injected in one or two divided doses intramuscularly. If administered over 30-60 minutes, it can also be given intravenously. Streptomycin exhibits all the adverse effects typically associated with the aminoglycosides; however, it has greater vestibular toxicity and probably less nephrotoxicity when compared with gentamicin.

Resistance emerges so rapidly and has become so widespread that only a few specific indications for this drug remain: plague and tularemia; endocarditis caused by *Enterococcus faecalis* or viridans streptococci (use in conjunction with penicillin or vancomycin) in strains that are susceptible to high levels of streptomycin (ie, ≥ 2000 ug/mL)—gentamicin may be substituted for streptomycin in this setting; active tuberculosis when other less toxic drugs cannot be used; and acute brucellosis (in combination with tetracycline).

2. Neomycin, Kanamycin, & Paromomycin

These aminoglycosides are closely related, with similar activity and complete cross-resistance. Systemic use has been abandoned because of oto- and nephrotoxicity.

Ointments containing neomycin, often combined with bacitracin and polymyxin, can be applied to infected superficial skin lesions. While the drug mixture covers most staphylococci, streptococci, and gram-negative bacteria likely to be present, the efficacy of topical application is questionable.

In preparation for elective bowel surgery, 1 g of neomycin is given orally every 6-8 hours for 1-2 days (combined with erythromycin, 1 g) to reduce aerobic bowel flora. Action on gram-negative anaerobes is negligible. In hepatic encephalopathy, the coliform bacteria can be suppressed for prolonged periods by oral neomycin, 1 g every 6-8 hours, during reduced protein intake, resulting in diminished ammonia production. Lactulose is more widely used for this indication.

Neomycin or kanamycin can give rise to allergic reactions when applied topically to skin or eye.

Paromomycin, closely related to neomycin and kanamycin, is poorly absorbed after oral administration and has been used mainly to treat asymptomatic intestinal amebiasis and in doses of 25-30 mg/kg/d in three divided doses for 7 days to treat giardiasis in pregnancy. A dosage of 500 mg orally three or four times daily is marginally effective for cryptosporidiosis in AIDS.

3. Amikacin

Amikacin is a semisynthetic derivative of kanamycin. It is relatively resistant to several of the enzymes that inactivate gentamicin and tobramycin. Many gram-negative enteric bacteria—including many gentamicin-resistant strains of proteus, pseudomonas, enterobacter, and serratia—are inhibited. After injection of 500 mg of amikacin every 12 hours (15 mg/kg/d), peak levels in serum are 10-30 ug/mL. In addition to therapy for serious gram-negative infections, amikacin is sometimes included with other drugs for therapy of *M avium* complex and *Mycobacterium fortuitum* complex.

Like all aminoglycosides, amikacin is nephrotoxic and ototoxic (particularly for the auditory portion of the eighth nerve). Its levels should be monitored in patients with renal failure.

4. Gentamicin

With doses of 5 mg/kg/d of this aminoglycoside, serum levels are sufficient for bactericidal effect against most gram-negative organisms. Enterococci are resistant unless a penicillin or vancomycin is also given. Gentamicin may be synergistic with penicillins active against pseudomonas, proteus, enterobacter, klebsiella, and other gram-negatives.

Indications, Dosages, & Routes of Administration

Gentamicin is used in serious infections caused by gram-negative bacteria. The usual dosage is 5 mg/kg/d intravenously administered once daily. In endocarditis due to viridans streptococci or *E faecalis*, gentamicin in lower synergistic doses (3 mg/kg/d) is combined with penicillin or ampicillin. A single daily dose of 3 mg/kg is just as effective as divided daily doses in the synergistic treatment of endocarditis due to viridans streptococci. In renal insufficiency, the dose should be adjusted as noted above.

5. Tobramycin

Tobramycin closely resembles gentamicin in antibacterial activity, toxicity, and pharmacologic properties and exhibits partial cross-resistance. It may be effective against some gentamicin-resistant pseudomonads but is not used synergistically with penicillin for enterococcal endocarditis. Dosing is the same as for gentamicin. Tobramycin is also given by aerosol (300 mg twice daily) to patients with cystic fibrosis and improves pulmonary function and decreases colonization with pseudomonas without toxicity and without selecting for resistant strains.

Netilmicin shares many characteristics with gentamicin and tobramycin and can be given in a similar dosage. It may be less ototoxic and less nephrotoxic than the other aminoglycosides.

6. Spectinomycin

Spectinomycin is an aminocyclitol antibiotic (related to aminoglycosides) for intramuscular administration. Its sole application is in the treatment of uncomplicated urogenital and anorectal gonorrhea in persons who are hypersensitive to penicillin and who cannot tolerate fluoroquinolones. It is not effective for pharyngeal gonorrhea.

Mulheran M et al: Occurrence and risk of cochleotoxicity in cystic fibrosis patients receiving repeated high dose aminoglycoside therapy. Antimicrob Agents Chemother 2001;45: 2502. [\[PMID: 11502521\]](#)

POLYMYXINS

The polymyxins are basic polypeptides that are bactericidal for most gram-negative aerobic rods, including pseudomonas. Because of poor distribution into tissues and substantial toxicity (primarily nephrotoxicity and neurotoxicity), systemic use of these agents is limited to infections caused by multidrug-resistant gram-negative organisms that are sensitive only to the polymyxins. Despite the toxicity of the polymyxins, the increased incidence of resistant pseudomonas has resulted in their increased use, particularly in patients with cystic fibrosis. Polymyxins B and E (colistin) are the only parenteral agents available. Dosage adjustments are required with renal insufficiency.

Li J et al: In vitro pharmacodynamic properties of colistin and colistin methanesulfonate against *Pseudomonas aeruginosa* isolates from patients with cystic fibrosis. Antimicrob Agents Chemother 2001;45:781. [\[PMID: 11181360\]](#)

ANTITUBERCULOUS DRUGS

Singular problems exist in the treatment of tuberculosis and other mycobacterial infections. The organisms are intracellular, have long periods of metabolic inactivity, and tend to develop resistance to any one drug. Therefore, combined drug therapy is employed to delay the emergence of this resistance. First-line drugs, increasingly used together in all tuberculosis, are isoniazid, ethambutol, rifampin, and pyrazinamide.

See [Chapter 9](#) for a discussion of these medications.

ALTERNATIVE DRUGS IN TUBERCULOSIS TREATMENT

The drugs listed alphabetically below are usually considered only in cases of drug resistance (clinical or laboratory) to first-line drugs.

Clofazimine is a phenazine dye used in the treatment of leprosy and is active in vitro against *M avium* complex and *M tuberculosis*. It is given orally as a single daily dose of 100 mg for treatment of *M avium* complex disease. Its clinical efficacy for the therapy of tuberculosis has not been established. Adverse effects include nausea, vomiting, abdominal pain, and skin discoloration from red-brown to black.

Capreomycin is an injectable agent given intramuscularly in doses of 15-30 mg/kg/d (maximal dose 1 g). Major toxicities include ototoxicity (both vestibular and cochlear) and nephrotoxicity. If the drug must be used in older patients, the dose should not exceed 750 mg.

Cycloserine, a bacteriostatic agent, is given in doses of 15-20 mg/kg (not to exceed 1 g) orally and has been used in re-treatment regimens and for primary therapy of highly resistant *M tuberculosis*. It can induce a variety of central nervous system dysfunctions and psychotic reactions. These may be controlled by phenytoin, 100 mg/d orally, or pyridoxine, 50-100 mg daily.

Ethionamide, like cycloserine, is bacteriostatic and is given orally in a dose of 15-20 mg/kg (maximal dose 1 g). It has been used in combination therapy but produces marked gastric irritation and is the least well tolerated antimycobacterial agent.

The **fluoroquinolones** ofloxacin, levofloxacin, ciprofloxacin, and moxifloxacin are active in vitro against *M tuberculosis*, with MICs of 0.25-2 ug/mL. Limited data suggest that these drugs are efficacious in therapy of tuberculosis, particularly in re-treatment regimens. In re-treatment schedules or for infection with resistant

organisms, high doses should be used (ciprofloxacin, 750 mg orally twice daily; ofloxacin, 400 mg orally twice daily; levofloxacin, 750 mg orally once daily).

SULFONAMIDES & ANTIFOLATE DRUGS

Antimicrobial Activity

Sulfonamides are structural analogs of *p*-aminobenzoic acid (PABA) and compete with PABA to block its conversion to dihydrofolic acid. Organisms that utilize PABA in the synthesis of folates and pyrimidines are inhibited. Animal cells and some resistant microorganisms (eg, enterococci) use exogenous folate and thus are not affected by sulfonamides.

Trimethoprim, pyrimethamine, and trimetrexate are compounds that inhibit the conversion of dihydrofolic acid to tetrahydrofolic acid by blocking the enzyme dihydrofolate reductase. These agents are generally used in combination with other drugs (usually sulfonamides) to prevent or treat a number of bacterial and parasitic infections. At high doses, all can inhibit mammalian dihydrofolate reductase, but clinically this is a problem only with pyrimethamine and trimetrexate. Folinic acid (leucovorin) is given concurrently with pyrimethamine and trimetrexate to prevent bone marrow suppression.

Sulfonamides alone are rarely used in the treatment of bacterial infection. When used in combination with other drugs, sulfonamides are useful in the treatment of toxoplasmosis and pneumocystosis.

The combination of trimethoprim (TMP) (one part) plus sulfamethoxazole (SMZ) (five parts) is bactericidal for such gram-negative organisms as *E coli*, klebsiella, enterobacter, salmonella, and shigella, though resistance has emerged. It is also active against many strains of serratia, providencia, *Stenotrophomonas maltophilia*, *Burkholderia cepacia* (formerly *Pseudomonas cepacia*), and *Burkholderia pseudomallei*, but not against *P aeruginosa*. It is inactive against anaerobes and enterococci but inhibits most nocardia and *S aureus* and about 50% *S epidermidis*. *M catarrhalis*, *H influenzae*, *H ducreyi*, *L monocytogenes*, and some atypical mycobacteria are also inhibited by this combination.

Pharmacokinetics & Administration

Trimethoprim-sulfamethoxazole is well absorbed from the gastrointestinal tract and widely distributed in tissues and fluids, including cerebrospinal fluid. For patients who are unable to take oral drugs, intravenous trimethoprim-sulfamethoxazole is available. Dosage adjustment is required for significant renal impairment (creatinine clearance = 50 mL/min).

Clinical Uses

Present indications for sulfonamides include the following.

A. Urinary Tract Infections

Coliform bacteria, the most common cause of urinary tract infections, generally remain susceptible to sulfonamides, though resistance of *E coli* has emerged. Short-course therapy (3 days) with double-strength TMP-SMZ (160 mg TMP + 800 mg SMZ) given twice daily is effective therapy for lower urinary tract infections in women who are symptomatic for less than a week. Since TMP is concentrated in the prostate, TMP-SMZ, one double-strength tablet twice daily for 14-21 days, is effective in acute prostatitis. In chronic prostatitis, treatment for 6-12 weeks is indicated. Considering the above resistance trend, the routine use of TMP-SMZ for empirical therapy of urinary tract infections has been questioned. In those areas where resistance of *E coli* is greater than 10-20%, alternative agents should be used as empirical therapy.

B. Parasitic Infections

TMP-SMZ is effective for prophylaxis and treatment of pneumocystis pneumonia, cyclospora infection, and *Isospora belli* infection. For therapy of pneumocystis pneumonia, 15-20 mg/kg/d of trimethoprim and 75-100 mg/kg/d of sulfamethoxazole in three or four divided doses is administered intravenously or orally—depending upon the severity of disease—for 3 weeks. The dose for prophylaxis is 160 mg TMP + 800 mg SMZ daily or three times per week. (When given daily, it is also effective prophylaxis against toxoplasmal encephalitis.) *I belli* infection in AIDS has been successfully treated with 160 mg TMP + 800 mg SMZ orally four times daily for 10 days followed by twice-daily administration for 3 weeks. Treatment with 160 mg TMP + 800 mg SMZ three times a week or 500 mg sulfadoxine with 25 mg pyrimethamine once a week has prevented recurrences. Cyclosporiasis is successfully treated with 160 mg TMP and 800 mg SMZ twice daily for 7-10 days. Sulfadiazine with pyrimethamine is also used to treat and prevent recurrence of toxoplasmosis, and sulfadoxine plus pyrimethamine is used to treat chloroquine-resistant falciparum malaria.

C. Bacterial Infections

Sulfonamides are the drugs of choice for nocardia infections. TMP-SMZ is widely distributed in tissues, penetrates into the cerebrospinal fluid and has been used to treat meningitis caused by gram-negative rods, though third-generation cephalosporins are now preferred. While it still is used for outpatient respiratory tract infections, the increasing pattern of resistance associated with *S pneumoniae* has decreased its utility. The usual dose for adults is 160 mg TMP + 800 mg SMZ twice daily for 10 days.

TMP-SMZ is effective also for infections with enterobacter, *B pseudomallei* (melioidosis), *Stenotrophomonas maltophilia*, or *Burkholderia cepacia*; in combination with rifampin, for eradication of nasopharyngeal carriage of staphylococci; for prophylaxis against meningococcal disease when susceptible strains predominate; for antibacterial prophylaxis in organ transplant recipients or patients with chronic granulomatous disease; for treatment of *Listeria monocytogenes* meningitis; and perhaps also for management of pulmonary Wegener's granulomatosis.

D. Leprosy

Certain sulfones are widely used (see below).

Adverse Effects

Adverse reactions to sulfonamides occur in 10-15% of non-AIDS patients (usually a minor rash or gastrointestinal disturbance) and in up to 50% of patients with AIDS (predominantly rash, fever, neutropenia, and thrombocytopenia, often severe enough to require discontinuation of therapy). These drugs have many side effects—due partly to hypersensitivity, partly to direct toxicity—that must be considered whenever unexplained symptoms or signs occur in a patient who may have received these drugs.

A. Systemic Side Effects

Fever, skin rashes, urticaria; nausea, vomiting, or diarrhea; stomatitis, conjunctivitis, arthritis, aseptic meningitis, exfoliative dermatitis; bone marrow depression, thrombocytopenia, hemolytic (in G6PD deficiency) or aplastic anemia, granulocytopenia, leukemoid reactions; hepatitis, polyarteritis nodosa, vasculitis, Stevens-Johnson syndrome; reversible hyperkalemia; and many others have been reported. Because of the risk of Stevens-Johnson syndrome, patients with a previous rash after TMP-SMZ should not receive the drug again.

HIV-positive patients intolerant to TMP-SMZ can often be desensitized. A 70% success rate has been reported after giving 0.004 mg TMP/0.02 mg SMZ as oral suspension and increasing the dose tenfold each hour to achieve a final dose of 160 mg TMP/500 mg SMZ.

B. Urinary Tract Disturbances

Older sulfonamides were relatively insoluble and would precipitate in urine. The most commonly used sulfonamides presently (sulfisoxazole and sulfamethoxazole) are quite soluble, and the old admonition to force fluids is no longer warranted. Sulfonamides have been implicated in interstitial nephritis. HIV-positive patients receiving high-dose sulfadiazine therapy are predisposed to crystalluria.

SULFONES USED IN THE TREATMENT OF LEPROSY

A number of drugs closely related to the sulfonamides (eg, dapsone) have been used effectively in the long-term treatment of leprosy. The clinical manifestations of both lepromatous and tuberculoid leprosy can often be suppressed by treatment extending over several years. At least 5-30% of *Mycobacterium leprae* organisms are resistant to dapsone, so initial combined treatment with rifampin is advocated. Dapsone, 100 mg daily, is effective therapy for mild to moderate pneumocystis pneumonia in AIDS when combined with trimethoprim, 20 mg/kg/d in four divided doses. At a dose of 50-100 mg daily or 100 mg two or three times a week, it is

effective prophylaxis for *P jiroveci* (formerly *P carinii*) infection and, when combined with pyrimethamine, 50 mg per week, also prevents toxoplasma encephalitis in HIV-infected patients.

Absorption, Metabolism, & Excretion

All sulfones are well absorbed from the intestinal tract, are distributed widely in all tissues, and tend to be retained in skin, muscle, liver, and kidney. Skin involved by leprosy contains ten times more drug than normal skin. Sulfones are excreted into the bile and reabsorbed by the intestine, prolonging therapeutic blood levels. Excretion into the urine is variable, and the drug occurs in urine mostly as a glucuronic acid conjugate. Some persons acetylate sulfones slowly and others rapidly; this requires dosage adjustment.

Dosages & Routes of Administration

See Leprosy, [Chapter 33](#), for recommendations.

Adverse Effects

The sulfones may cause any of the side effects listed above for sulfonamides. Anorexia, nausea, and vomiting are common. Hemolysis, methemoglobinemia, or agranulocytosis may occur. G6PD levels should be determined prior to initiation of dapsone therapy. If sulfones are not tolerated, clofazimine can be substituted.

SPECIALIZED DRUGS USED AGAINST BACTERIA

1. Bacitracin

This polypeptide is selectively active against gram-positive bacteria. Because of severe nephrotoxicity upon systemic administration, its use has been limited to topical application on surface lesions, usually in combination with polymyxin or neomycin.

2. Mupirocin

Mupirocin (formerly pseudomonic acid) is a naturally occurring antibiotic produced by *Pseudomonas fluorescens* active against most gram-positive cocci, including methicillin-sensitive and methicillin-resistant *S aureus* and most streptococci (but not enterococci). It is used topically. It is effective in eliminating staphylococcal nasal carriage in the majority of patients for up to 3 months after application to the anterior nares twice daily for 5 days. However, recurrent colonization occurs (50% at the end of 1 year) and when mupirocin is used chronically over months, resistant organisms can emerge. Monthly application for 5 days each month for up to a year decreases staphylococcal colonization, which in turn lowers the risk of recurrent staphylococcal skin infections. Recent studies demonstrate an associated reduction in postoperative staphylococcal lung infections in colonized patients treated with mupirocin. Whether it is more effective than trimethoprim-sulfamethoxazole or dicloxacillin plus rifampin for eradication of staphylococcal nasal carriage is unknown. The other major use of mupirocin is for therapy of impetigo; it is useful in mild disease.

3. Clindamycin

Clindamycin resembles erythromycin (though different in structure) and is active against gram-positive organisms including *S pneumoniae*, viridans streptococci, group A streptococci, and *S aureus*, though resistance has been described in all of these organisms. Pneumococci with an efflux-based mechanism of resistance can be effectively treated with clindamycin. However, isolates with ribosomal methylase resistance (about 10% of isolates) are also resistant to clindamycin. Enterococci, methicillin-resistant *S aureus*, and most *S epidermidis* also are resistant. A dosage of 0.15-0.3 g orally every 6 hours generally is used. It is widely distributed in tissues but not in cerebrospinal fluid. Excretion is primarily nonrenal. Clindamycin is an alternative to erythromycin as a substitute for penicillin. Clindamycin is currently recommended as an alternative drug for prophylaxis against endocarditis following oral procedures in patients allergic to amoxicillin. Clindamycin, 300 mg orally twice daily for 7 days, can be used as an alternative to metronidazole for the therapy of bacterial vaginosis. Topical application of a 2% vaginal cream once or twice daily for 7 days is also effective. Clindamycin is active against most anaerobes, including bacteroides, prevotella, clostridium, peptococcus, peptostreptococcus, and fusobacterium. However, 10-20% of bacteroides isolates are resistant, and alternative agents should be considered for life-threatening anaerobic infections due to these organisms. It is frequently used to treat less severe infections in which anaerobes are significant pathogens (eg, aspiration pneumonia, pelvic and abdominal infections), often in combination with other drugs (aminoglycosides, cephalosporins, fluoroquinolones). In patients with necrotizing pneumonia or lung abscess following aspiration, clindamycin appears to be superior to penicillin. Seriously ill patients are given clindamycin, 600-900 mg (20-30 mg/kg/d) intravenously every 8 hours. It has also been of use in staphylococcal osteomyelitis. Because tissue models document that clindamycin significantly decreases toxin production of a number of organisms, the addition of clindamycin to penicillin for therapy of group A streptococcus toxic shock syndrome has been suggested. In the sulfonamide-allergic patient, high-dose clindamycin therapy (600-1200 mg intravenously every 6 hours or 600 mg orally every 6 hours) in conjunction with pyrimethamine has been used to treat toxoplasmosis of the central nervous system and appears to be as effective as pyrimethamine and sulfadiazine. Clindamycin in combination with primaquine is effective in pneumocystis pneumonia, and clindamycin with quinine is of value for falciparum malaria. While useful in brain abscess, clindamycin is ineffective in meningitis.

Common side effects are diarrhea, nausea, and skin rashes. Bloody diarrhea with pseudomembranous colitis has been associated with the administration of clindamycin and other antibiotics. This antibiotic-associated colitis is due to a necrotizing toxin produced by *C difficile*. The organism is resistant to the antimicrobial, is selected out by its presence, and is favored in its growth and toxin production. *C difficile* is usually susceptible to—and can be treated with—vancomycin or metronidazole given orally, though metronidazole is the drug of choice (see below).

4. Metronidazole

Metronidazole is an antiprotozoal drug (see [Chapter 35](#)) that also has striking antibacterial effects against most anaerobic gram-negative bacilli (bacteroides, prevotella, fusobacterium) and clostridium species but has minimal activity against other anaerobic gram-positive and microaerophilic organisms. It is well absorbed after oral administration, is widely distributed in tissues. It penetrates well into the cerebrospinal fluid, yielding levels similar to those in serum. The drug is metabolized in the liver, and dosage reduction is required in severe hepatic insufficiency or biliary dysfunction.

Metronidazole is employed in amebiasis and giardiasis (see [Chapter 35](#)) and in the following circumstances:

(1) Trichomonas vaginitis responds to either a single dose (2 g) or to 250 mg orally three times daily for 7-10 days. Bacterial vaginosis responds to a single 2-g dose or to 500 mg twice daily for 7 days. Metronidazole vaginal cream (0.75%) applied twice daily for 5 days is also effective.

(2) In anaerobic infections, metronidazole can be given orally or intravenously, 500 mg three times daily (30 mg/kg/d). It is more predictable against *B fragilis* than clindamycin or second-generation cephalosporins with anaerobic activity.

(3) Metronidazole is less expensive and equally as efficacious as oral vancomycin for the therapy of *C difficile* colitis and is the drug of choice for the disease. A dosage of 500 mg orally three times daily is recommended. If oral medication cannot be tolerated, intravenous metronidazole can be tried at the same dose; however, this route is unproved and usually less effective than the oral one. Because of the emergence of vancomycin-resistant enterococci as a major pathogen and the role of oral vancomycin in selecting for these resistant organisms, metronidazole should be used as first-line therapy for *C difficile* disease.

(4) Preparation of the colon before bowel surgery.

(5) Therapy of brain abscess, often in combination with penicillin or a third-generation cephalosporin.

(6) In combination with clarithromycin and omeprazole for therapy of *H pylori* infections.

Adverse effects include stomatitis, nausea, and diarrhea. Ingestion of alcohol while taking metronidazole can result in a disulfiram reaction. With prolonged use at high doses, reversible peripheral neuropathy can develop. Metronidazole can decrease the metabolism of warfarin and increase the prothrombin time, necessitating monitoring of the prothrombin time and dosage adjustment of warfarin when both drugs are used together. Metronidazole is carcinogenic in certain animal models and mutagenic for certain bacteria, but to date an increased incidence of malignancy has not been confirmed in humans.

Kasten MJ: Clindamycin, metronidazole, and chloramphenicol. Mayo Clin Proc 1999;74:825. [\[PMID: 10473362\]](#)

Raz R et al: Empiric use of trimethoprim-sulfamethoxazole (TMP-SMX) in the treatment of women with uncomplicated urinary tract infections, in a geographic area with a high prevalence of TMP-SMX-resistant uropathogens. Clin Infect Dis 2002;34:1165. [\[PMID: 11941541\]](#)

5. Vancomycin

This drug is bactericidal for most gram-positive organisms, particularly staphylococci and streptococci, and is bacteriostatic for most enterococci. While active against staphylococci, vancomycin kills more slowly when compared with nafcillin. Although vancomycin has retained activity against staphylococci and streptococci, vancomycin-resistant strains of enterococci (particularly *Enterococcus faecium*) have become a major problem. *Staphylococcus aureus* both intermediately sensitive and highly vancomycin-resistant has been observed in patients receiving long-term vancomycin therapy. Vancomycin is not absorbed from the gastrointestinal tract. It is given orally only for the treatment of antibiotic-associated enterocolitis. For systemic effect the drug must be administered intravenously (20-30 mg/kg/d in two or three divided doses). Vancomycin is excreted mainly via the kidneys. In renal insufficiency, the half-life may be up to 8 days. Thus, only one dose of 0.5-1 g may be given every 4-8 days to a uremic individual undergoing standard chronic hemodialysis. However, vancomycin is cleared via high-flux hemodialysis, necessitating postdialysis dosing. Patients receiving continuous arteriovenous hemofiltration (CAVH) generally required daily dosing. In patients with impaired renal function, the dosing interval is determined by measuring serum levels. When levels decline to 5-15 ug/mL, repeat dosing is required.

Indications for parenteral vancomycin include the following: (1) Severe staphylococcal infections in penicillin-allergic patients; it is the drug of choice for methicillin-resistant *S aureus* and *S epidermidis* infections and for serious infections (pneumonia, meningitis) due to highly resistant *S pneumoniae*. (2) Severe enterococcal infections in the penicillin-allergic patient, usually in combination with an aminoglycoside. (3) Other gram-positive infections in penicillin-allergic patients, eg, viridans streptococcal endocarditis. (4) Surgical prophylaxis in penicillin-allergic patients. (5) For gram-positive infections due to organisms that are multidrug-resistant, ie, *Corynebacterium jeikeium*. (6) Endocarditis prophylaxis in the penicillin-allergic patient undergoing certain genitourinary and gastrointestinal procedures (in combination with an aminoglycoside). (See [Table 33-3](#).)

In antibiotic-associated enterocolitis, vancomycin, 0.125 g, is given orally four times daily.

Vancomycin is irritating to tissues; thrombophlebitis sometimes follows intravenous injection. The drug is infrequently ototoxic when given concomitantly with aminoglycosides or high-dose intravenous erythromycins; it is potentially nephrotoxic when administered with aminoglycosides. Rapid infusion or high doses (1 g or more) may induce diffuse hyperemia ("red man syndrome") and can be avoided by extending infusions over 1-2 hours, by reducing the dose, or by pretreating with a histamine antagonist such as hydroxyzine.

Wilhelm MP et al: Vancomycin. Mayo Clin Proc 1999;74:928. [\[PMID: 10488798\]](#)

STREPTOGRAMINS

Streptogramins are structurally similar to macrolides but do not share cross-resistance with that class. **Pristinamycin** is an oral streptogramin marketed in France for treatment of gram-positive infections. **Synercid** is a combination of two synthetic derivatives of pristinamycin—quinupristin and dalbapristin—in a 30:70 ratio that is administered intravenously. It is bactericidal and inhibits protein synthesis by binding to bacterial ribosomes. In vitro, it has activity against *Moraxella catarrhalis*, *Haemophilus influenzae*, clostridium, peptostreptococcus, mycoplasma, legionella, and chlamydia. It has no activity against enteric gram-negative bacilli. However, its major clinical use is in the therapy of gram-positive infections, including those due to streptococci (including penicillin-resistant pneumococci) staphylococci (including methicillin-sensitive and methicillin-resistant *S aureus* and *S epidermidis*) and enterococci, including vancomycin-resistant *Enterococcus faecium*. The combination is not reliably active against *E faecalis*. The drug is generally bacteriostatic against the enterococci. The recommended dose is 7.5 mg/kg intravenously every 8 hours. In addition to phlebitis with peripheral administration, the major adverse effect is arthralgias and myalgias that resolve with discontinuation of the drug. It is primarily cleared via the liver; streptogramins inhibit the cytochrome P450 system, resulting in increased levels of cyclosporine and other agents.

Delgado G Jr et al: Quinupristin-dalbapristin: an overview. Pharmacotherapy 2000;20:1469. [\[PMID: 11130220\]](#)

OXAZOLIDINONES

Oxazolidinones represent a new class of antibacterials of which linezolid is the first released. Linezolid is primarily active against aerobic gram-positive pathogens, including penicillin-resistant pneumococci, methicillin-resistant staphylococci and enterococci (both *E faecalis* and vancomycin-sensitive and vancomycin-resistant *E faecium*). Linezolid is bacteriostatic against all of these pathogens. Linezolid-resistant and vancomycin-resistant enterococci and linezolid-resistant *S aureus* may be encountered, however. The oral bioavailability of linezolid is complete, with serum levels approaching those observed with intravenous administration. The drug is eliminated primarily by nonrenal mechanisms. The primary toxicity is bone marrow suppression with long-term therapy, particularly the platelet line. Other adverse effects include tongue discoloration and mild MAO inhibition.

Eliopoulos GM: Quinupristin-dalbapristin and linezolid: evidence and opinion. Clin Infect Dis 2003;36:473. [\[PMID: 12567306\]](#)

QUINOLONES

The quinolones are synthetic analogs of nalidixic acid that have an exceedingly broad spectrum of activity against many bacteria. The mode of action of all quinolones involves inhibition of bacterial DNA synthesis by blocking the enzyme DNA gyrase.

The earlier quinolones (nalidixic acid, oxolinic acid, cinoxacin) did not achieve systemic antibacterial levels after oral intake and thus were useful only as urinary antiseptics. The newer fluorinated derivatives (norfloxacin, ciprofloxacin, ofloxacin, levofloxacin, gatifloxacin, and moxifloxacin) have more potent antibacterial activity, achieve clinically useful levels in blood and tissues, and have low toxicity.

Antimicrobial Activity

A number of fluoroquinolones are in use. Most have quite similar spectrums of activity. In general, these drugs have excellent activity against Enterobacteriaceae but are also active against other gram-negative bacteria such as haemophilus, neisseria, moraxella, brucella, legionella, salmonella, shigella, campylobacter, yersinia, vibrio, and aeromonas. Ciprofloxacin has slightly better activity against *P aeruginosa* than the other fluoroquinolones, but the increasing resistance of *P aeruginosa* to ciprofloxacin limits its utility for infections caused by that organism. None of these agents have reliable activity against *S maltophilia* or *B cepacia*—though the newer drugs are more active against *S maltophilia*—as they are for treating genital tract pathogens such as *Mycoplasma hominis*, *Ureaplasma urealyticum*, and *C pneumoniae*. *M tuberculosis* is sensitive to the quinolones, as is *M fortuitum* and *Mycobacterium kansasii*. Although most *M avium* complex organisms are resistant to fluoroquinolones when combined with other antibiotics (ethambutol, rifabutin, and amikacin), ciprofloxacin is effective in treating infections caused by this organism.

In general, the fluoroquinolones are less potent against gram-positive than against gram-negative organisms, with norfloxacin having less activity than ciprofloxacin. Levofloxacin, gatifloxacin, and moxifloxacin have the best gram-positive activity, including pneumococci and strains of *S aureus* and *S epidermidis*, including some methicillin-resistant strains. However, the emergence of resistant strains of staphylococci has limited the use of these drugs as monotherapy of infections caused by these organisms. Enterococci, including *E faecalis*, *S pneumoniae*, group A, B, and D streptococci, and viridans streptococci, are only moderately sensitive to the older quinolones. Anaerobic bacteria, *T pallidum*, and nocardia are resistant to the earlier fluoroquinolones.

Moxifloxacin demonstrates activity against many of the significant anaerobic pathogens, including *Bacteroides fragilis* and mouth anaerobes.

Pharmacokinetics & Administration (Table 37-9)

After oral administration, the fluoroquinolones are well absorbed and widely distributed in body fluids and tissues and are concentrated intracellularly. Fluoroquinolones are bound by some heavy metals, and absorption is inhibited when they are given with iron, calcium, and other multivalent cations. Optimal oral bioavailability is achieved if they are given about 1 hour before or 2 hours after meals. The serum half-life ranges from 4 hours (ciprofloxacin) to 12 hours (moxifloxacin). After ingestion of 500 mg, the peak serum level of ciprofloxacin is 2.5 ug/mL and is lower than that of the other quinolones (4-6 ug/mL), but this is offset by ciprofloxacin's slightly greater in vitro activity against most gram-negative organisms. A number of the fluoroquinolones can be administered intravenously, resulting in peak serum levels ranging from 4 to 9 ug/mL. Most are eliminated via mixed renal and nonrenal pathways. As a result, only modest accumulation takes place in the presence of renal insufficiency. Exceptions are ofloxacin, levofloxacin, and gatifloxacin, which are primarily dependent upon the kidney for elimination.

Clinical Uses

Because of their broad spectrum of activity and a tendency for some organisms (eg, *P aeruginosa*, staphylococcal species) to develop resistance, these drugs should not be routinely used as first-line therapy when less expensive agents with narrower spectrums are available.

Urinary tract infections caused by trimethoprim-sulfamethoxazole-resistant gram-negative organisms have resulted in quinolones being recognized as one of the drugs of choice in areas with > 10-20% resistance of *E coli* to trimethoprim-sulfamethoxazole.

Because of good penetration into prostatic tissue, quinolones are effective in treating bacterial prostatitis and are alternatives to trimethoprim-sulfamethoxazole (doses for prostatitis are the same as for urinary tract infection, but the duration should be 6-12 weeks).

Quinolones have been approved for use in therapy of certain sexually transmitted diseases. Ofloxacin, 300 mg twice daily for 7 days, is as effective as doxycycline, 100 mg twice daily for 7 days, for the therapy of *C trachomatis* cervicitis, urethritis, and proctitis. It is also effective for nongonococcal urethritis caused by *U urealyticum*. Ciprofloxacin is not effective for the therapy of chlamydial infections or nongonococcal urethritis. In general, the use of quinolones for the therapy of any sexually transmitted disease will be limited by their lack of efficacy in concomitant syphilis. Gonococcal urethritis, cervicitis, pharyngitis, and proctitis can be treated with a single dose of 500 mg of ciprofloxacin or 400 mg of ofloxacin. However, the increased prevalence of quinolone-resistant gonococci in California and Hawaii has resulted in the use of ceftriaxone as the primary drug choice in those regions.

Pelvic inflammatory disease is usually caused by *Chlamydia trachomatis*, *N gonorrhoeae*, Enterobacteriaceae, or anaerobes. Oral outpatient treatment with ofloxacin, 400 mg twice daily for 14 days, in addition to clindamycin, 450 mg orally four times daily for 14 days, or metronidazole, 500 mg orally twice daily for 14 days, can be used. Epididymitis in young men (< 35 years of age) is caused most commonly by chlamydia and the gonococcus, and outpatient therapy with single-dose ciprofloxacin (500 mg) or ofloxacin (400 mg) followed by doxycycline, 100 mg twice daily for 10 days, is adequate therapy. Alternatively, ofloxacin, 300 mg twice daily for 10 days, can be used. *H ducreyi*, the agent that causes chancroid, is sensitive to quinolones, and ciprofloxacin, 500 mg twice daily, or enoxacin, 400 mg daily for 3 days, can be used as an alternative to erythromycin, azithromycin, or ceftriaxone as therapy for this disease.

Ciprofloxacin and ofloxacin have been successfully used to treat complicated skin and soft tissue infections and osteomyelitis caused by gram-negative organisms. Ciprofloxacin, 500-750 mg twice daily for at least 6 weeks, has been effective therapy for malignant otitis externa.

Because quinolones are among the few oral agents active against campylobacter despite increasing resistance, in addition to the other major bacterial pathogens associated with diarrhea (salmonella, shigella, toxigenic *E coli*), they have been used for the therapy of traveler's diarrhea as well as domestically acquired acute diarrhea. Norfloxacin, ciprofloxacin, and ofloxacin may be effective in eradicating the chronic carrier state of salmonella when therapy is continued for 4-6 weeks.

Ciprofloxacin has been used to eradicate meningococci from the nasopharynx of carriers.

Fluoroquinolones are effective for prophylaxis against gram-negative infections in the neutropenic patient, and intravenous ciprofloxacin in combination with β -lactam antibiotics has been used successfully to treat the febrile neutropenic patient.

Although some clinical studies have suggested that ciprofloxacin is efficacious in the therapy of community-acquired pneumonia, caution should be exercised since the drug has only marginal activity against *S pneumoniae* and *M pneumoniae*, and failures in treating pneumococcal pneumonia have been reported. Newer agents such as levofloxacin, gatifloxacin, and moxifloxacin are more active against the pneumococci, including penicillin resistant strains, and are useful in the treatment of infections due to these organisms. However, their broad spectrum of activity against resistant aerobic gram-negative pathogens suggests that they should be reserved for the treatment of refractory infections. One setting in which ciprofloxacin is indicated for the therapy of lower respiratory tract infections is in cystic fibrosis, where *P aeruginosa* is the predominant pathogen. However, the increasing rate of resistance to ciprofloxacin has impacted upon use of the drug for this indication.

Ciprofloxacin in combination with other agents has been used to treat *M avium* complex infections, and ciprofloxacin, ofloxacin, and moxifloxacin may be efficacious in the therapy of multidrug-resistant tuberculosis.

Adverse Effects

The most prominent adverse effects of the quinolones are nausea, vomiting, and diarrhea. Occasionally, headache, dizziness, seizures, insomnia, impaired liver function, and skin rashes have been observed as well as more serious reactions such as acute renal failure, hypoglycemia (especially with gatifloxacin), and anaphylaxis. Severe hepatotoxicity, including liver failure and the need for liver transplantation, has occurred with trovafloxacin use. Although the drug has not been withdrawn, a warning by the FDA has been issued, and trovafloxacin should not be used unless there are no other alternatives. Fluoroquinolones as a class prolong the QT interval; grepafloxacin has been withdrawn from the market as a result of this effect. Quinolones should be used cautiously in patients receiving antiarrhythmics such as amiodarone or in persons with a history of prolonged QT. Ciprofloxacin appears least likely to prolong the QT. Prolongation of the prothrombin time has been observed in some patients receiving stable doses of warfarin after ciprofloxacin has been given, but this interaction is unpredictable and modest. Tendonitis and tendon rupture have been reported with quinolone agents, especially pefloxacin. Risk factors include concomitant glucocorticoid use and hepatic and renal failure. Patients experiencing musculoskeletal symptoms while receiving fluoroquinolones should discontinue therapy.

PENTAMIDINE & ATOVAQUONE

Pentamidine and atovaquone are antiprotozoal agents that are primarily used to treat pneumocystis pneumonia. Pentamidine is discussed in [Chapters 31](#) and [35](#). Atovaquone inhibits mitochondrial electron transport and probably also folate metabolism. It is poorly absorbed and should be given with food to maximize bioavailability. The suspension is significantly better absorbed than the tablet formulation and thus should be used preferentially, especially in high-risk patients (those with diarrhea, malabsorption). It has moderate activity against *P jiroveci*. In comparative trials with trimethoprim-sulfamethoxazole and pentamidine in the therapy of pneumocystis pneumonia in AIDS, atovaquone, 750 mg orally three times daily for 3 weeks, is less effective than both agents but better tolerated. It has also been used as prophylaxis in AIDS patients at a dosage of 1500 mg daily. Major adverse effects include rash, nausea, vomiting, diarrhea, fever, and abnormal liver function tests. The use of atovaquone is limited to patients with mild to moderate pneumocystis infections who have failed or cannot tolerate other therapies.

URINARY ANTISEPTICS

These drugs exert antimicrobial activity in the urine but have little or no systemic antibacterial effect. Their usefulness is limited to therapy and prevention of urinary tract infections.

1. Nitrofurantoin

Nitrofurantoin is active against the common gram-positive urinary pathogens *Enterococcus faecalis* and *Staphylococcus saprophyticus*, but the drug inhibits only about 50% of *Enterococcus faecium*. It is also used against *E coli* and citrobacter, but activity against proteus, serratia, and pseudomonas is poor. Following oral administration, about 50% of the drug is absorbed, but serum concentrations are very low and tissue levels are undetectable. Levels in the urine reach concentrations of 200-400 ug/mL, which are well above the MICs of susceptible organisms. Because clearance is primarily renal, the amounts of these drugs in the urine are proportionate to the creatinine clearance, and with severe renal insufficiency subtherapeutic levels are present. Given low serum levels, poor tissue penetration, and renal elimination, the use of nitrofurantoin is limited to therapy or prophylaxis of cystitis in patients with normal renal function. Nitrofurantoin should not be used to treat pyelonephritis or prostatitis.

The average daily dose in urinary tract infections is 100 mg orally four times daily, taken with food. The macrocrystal preparation can be given at a dosage of 100 mg twice daily. A single daily dose of 50-100 mg can prevent recurrent urinary tract infections in women.

Oral nitrofurantoin often causes nausea and vomiting. The crystalline formulation is better tolerated than previous preparations. Hemolytic anemia may occur in G6PD deficiency. Other side effects are skin rashes and, uncommonly, peripheral neuropathy. Acute and chronic pulmonary hypersensitivity reactions may occur, and pulmonary fibrosis has occurred with prolonged use.

2. Fosfomycin

Fosfomycin tromethamine is a phosphonic acid derivative useful in the treatment of uncomplicated urinary tract infection. The spectrum of activity includes *E coli*, *E faecalis*, and other gram-negative aerobic urinary pathogens, but not *P aeruginosa*. Available as a 3- g sachet, fosfomycin may be useful for the single-dose treatment of the above organisms. Like nitrofurantoin, fosfomycin should not be used for systemic infection. However, the increased concentrations in urine allow for its use in uncomplicated bacteriuria. The most frequently reported adverse effects include diarrhea, headache, and nausea.

Nicolle LE et al (editors): Progress in the management of urinary tract infections. J Antimicrob Chemother 2000;46(Suppl 1).

ANTIFUNGAL DRUGS

Empirical antifungal therapy is rarely instituted except for febrile neutropenic patients. Therapy is reserved for situations in which yeast or mold is seen on KOH preparation or when isolated organisms are thought to be pathogenic. Antifungal sensitivity testing recently has been standardized for yeasts and azoles. However, standardization for other agents and fungi is still in progress. Thus, therapy generally is based on experience and clinical trials and not on susceptibility tests.

1. Amphotericin B

Amphotericin B in vitro inhibits several organisms producing systemic mycotic disease in humans, including aspergillus, histoplasma, cryptococcus, coccidioides, candida, blastomyces, sporothrix, and others. This drug can be used for treatment of these systemic fungal infections. *Pseudallescheria boydii* and fusarium are often resistant to amphotericin B.

There is no consensus on how amphotericin B should be administered or on the dosage and the duration of therapy. Most centers no longer use a test dose, since anaphylaxis is extremely rare. The daily dose of amphotericin B for most fungal infections varies from 0.3 mg/kg to 0.7 mg/kg, though infections caused by aspergillus and mucor are often treated with 1-1.5 mg/kg daily.

In meningitis due to fungi other than *Coccidioides immitis*, long-term therapy beyond the initial 8-10 weeks is rarely needed. Combined treatment with flucytosine is beneficial in cryptococcal meningitis and possibly systemic candidiasis. Amphotericin B may have some benefit in naegleria meningoencephalitis.

Amphotericin B in low (0.1-0.25 mg/kg/d) and moderate doses (0.5 mg/kg/d) has been used prophylactically to prevent invasive fungal infections in bone marrow transplant recipients; however, its efficacy is unproved. Whether prophylactic administration is better than early empirical therapy in febrile patients who have not responded to broad-spectrum antibiotics has not been determined.

In patients with Foley catheters in place who have candiduria, amphotericin B bladder irrigations have been used to decrease colony counts. Although the procedure is widely used, the efficacy of amphotericin B bladder irrigation is marginal, and long-term eradication of candiduria following amphotericin B bladder irrigation rarely occurs.

In impaired renal function, the dose of amphotericin B need not be reduced initially. However, if the serum creatinine reaches 2.5-3 mg/dL, either a less nephrotoxic agent can be used (see below) or the dose can be temporarily lowered (or even stopped for a few days) until renal function recovers. Amphotericin B is then resumed at about one-half the previous dosage and increased in increments as tolerated. The drug is not removed by hemodialysis, so that no additional drug is needed after dialysis.

The intravenous administration of amphotericin B often produces chills, fever, vomiting, and headache. As a rule, infusions given over 1-2 hours are as well tolerated as those given over 4-6 hours. However, patients who experience infusion-related adverse effects may benefit from slowing the rate of administration. Tolerability may be enhanced by temporary lowering of the dose or premedication with acetaminophen and diphenhydramine. Addition of 25 mg of hydrocortisone to the infusion decreases the incidence of rigors, and meperidine, 25-50 mg, is effective in arresting rigors once they start. Central intravenous administration eliminates the likelihood of thrombophlebitis. Amphotericin B is associated with anemia and is due to impaired iron utilization. Electrolyte disturbances (hypokalemia, hypomagnesemia, distal renal tubular acidosis) also occur. Renal insufficiency can be prevented with salt supplementation. As a result, administration of 0.5-1 L of 0.9% saline prior to infusion of amphotericin B may prevent nephrotoxicity.

The nephrotoxicity of amphotericin has resulted in the development of lipid-based amphotericin B products. Three such products are available: amphotericin B lipid complex (ABLC; Abelcet), amphotericin B colloidal dispersion (ABCD; Amphotec), and liposomal amphotericin B (L-AmB; AmBisome). Complexing amphotericin B with lipid allows larger doses to be administered (1-6 mg/kg, depending on the preparation and the fungal species). All three preparations are associated with less nephrotoxicity than conventional amphotericin B and thus offer benefit for patients who develop renal insufficiency while receiving amphotericin B. Liposomal amphotericin is less nephrotoxic than ABLC. Infusion-related adverse effects are variable, with liposomal amphotericin being associated with the lowest incidence of fevers and chills even when infused over 30-60 minutes. ABCD is associated with the highest rate of infusion toxicity and requires administration over 2.5-3 hours. ABLC is comparable to conventional amphotericin B. All three have significant differences in serum levels, half-life, and tissue penetration. Most of the information on efficacy is gleaned from open-label trials in patients who failed or were intolerant of conventional amphotericin B and who were infected with aspergillus or candida. Most clinical experience has been with L-Am B, as it has been licensed in Europe for several years. L-Am B is approved for therapy in the febrile neutropenic patient, with efficacy equal to or better than that of conventional amphotericin B in success of therapy and prevention of emergent fungal infections. Direct comparative trials between lipid-based preparations are limited.

Drug acquisition costs for all three products are much higher than for conventional amphotericin B. Whether decreased toxicity and the decreased need to monitor for adverse effects offset these cost differences is not known. A prudent approach is to reserve lipid-based preparations for patients who fail conventional amphotericin B or those who develop renal insufficiency (serum creatinine 2.5-3 mg/dL). The availability of echinocandins and new azoles has resulted in additional choices for patients with renal dysfunction who require antifungal therapy. The lipid formulations are particularly effective for therapy of visceral leishmaniasis. Short courses (5-10 days) with low doses (2-24 mg/kg depending on which preparation is used) are very effective in eradicating the parasite, probably because of distribution of the drug to the reticuloendothelial system, the major site of parasite invasion.

2. Nystatin

Nystatin has a wide spectrum of antifungal activity but is used almost exclusively to treat superficial candidal infections. It is too toxic for systemic administration, and the drug is not absorbed from mucous membranes or the gastrointestinal tract. Several preparations are available, including oral suspension (100,000 units/mL) and ointments, gels, and creams (100,000 units/g). For oral candidiasis, 500,000 units of suspension is used to rinse the mouth and is retained in the mouth as long as possible before it is swallowed. This is repeated four times a day for at least 2 days after resolution of the infection. Infections of skin are treated with cream or ointment, 100,000 units applied to the affected area twice daily until resolution of the infection. Nystatin is less effective than azoles for therapy of vaginal candidiasis.

3. Flucytosine

Flucytosine inhibits some strains of candida, cryptococcus, aspergillus, and other fungi. Dosages of 3-8 g daily (100-150 mg/kg/d) orally produce good levels in serum and cerebrospinal fluid. Clinical remissions of meningitis or sepsis due to yeasts have occurred. However, resistant organisms are selected out rapidly, and flucytosine is therefore not employed as a single drug except in urinary tract infections.

In renal insufficiency, flucytosine may accumulate to toxic levels, and dosage adjustments are needed. Because patients with HIV infection and normal renal function do not tolerate the normal doses of flucytosine (150 mg/kg/d in four divided doses), 75-100 mg/kg/d is recommended. The drug is effectively removed by hemodialysis. Toxic effects include bone marrow depression, abnormal liver function, loss of hair, and others. Bone marrow suppression is caused by conversion of flucytosine to fluorouracil. Combined use of flucytosine and amphotericin B in cryptococcal meningitis and possibly systemic candidiasis has been shown to be of value.

4. Natamycin

Natamycin is a polyene antifungal drug effective against many different fungi in vitro. When it is combined with appropriate surgical measures, topical application of 5% ophthalmic suspension may be beneficial in the treatment of keratitis caused by fusarium, acremonium (cephalosporium), or other fungi. The drug may also be effective in the treatment of oral or vaginal candidiasis. The toxicity after topical application appears to be low.

5. Terbinafine

Terbinafine, an allylamine, inhibits fungal cell membrane function by blocking ergosterol synthesis. Terbinafine is now available topically as well as in 250-mg tablets for oral administration. The recommended dosage is 250 mg daily for 12 weeks for toenail infections and 250 mg daily for 6 weeks for fingernail infections (success rate about 70%). The drug also is active against many strains of candida and aspergillus and has been used in combination with other antifungals for therapy of severe cutaneous infections with these agents. Terbinafine is well tolerated. Most adverse effects are minor (diarrhea, dyspepsia) or transient (taste disturbance). Rare cases

of severe hepatic injury have occurred.

6. Antifungal Imidazoles & Triazoles

These antifungal drugs also inhibit synthesis of ergosterol, resulting in inhibition of membrane-associated enzyme activity, cell wall growth, and replication.

Clotrimazole, taken orally in the form of 10-mg troches five times daily, can prevent and treat oral candidiasis. Vaginal tablets inserted daily for 3-7 days are effective for vaginal candidiasis. Topical preparations for treatment of cutaneous dermatophytes are also available. Toxicity precludes systemic use.

Ketoconazole, an imidazole, can be given orally as a single daily dose of 200-600 mg, preferably with food. The dosage remains the same in renal or hepatic failure. Absorption is impaired by antacids and H₂-blockers; coadministration of phenytoin or rifampin can cause enhanced metabolism of ketoconazole and lower plasma levels. The reduction in achievable serum levels in achlorhydria patients has been associated with decreased efficacy in the treatment of HIV-positive patients with esophageal candidiasis.

While ketoconazole previously was used in the treatment of a variety of fungal infections, the improved spectrum of activity, reduced toxicity, and superior pharmacokinetics of newer azoles have reduced ketoconazole to a secondary role.

Adverse effects include nausea, vomiting, skin rashes, and occasional elevations in aminotransferase levels. Although most elevations of liver enzymes are asymptomatic, on rare occasions symptomatic and even fatal hepatitis can occur. Ketoconazole blocks the synthesis of adrenal steroids and testosterone and can cause gynecomastia and impotence. Ketoconazole can also cause increased levels of cyclosporine (and other agents) when administered with this drug, and careful monitoring of serum levels is needed to avoid toxicity.

Fluconazole, a bis-triazole with activity similar to that of ketoconazole, is water-soluble and can be given both orally and intravenously. Absorption of the drug after oral administration is not pH-dependent, in contrast to ketoconazole, and therapeutic serum levels are obtained even when H₂ receptor antagonists are given simultaneously. It penetrates well into the cerebrospinal fluid and eye. The drug has been shown to be effective primarily in therapy of infections with candida, cryptococcus, and blastomyces. *Candida albicans*, *C tropicalis*, and *C parapsilosis* are usually sensitive to fluconazole, but many other species of candida (*C krusei*, *C glabrata*, etc) are often resistant. Fluconazole-resistant strains of *C albicans* have been reported and are usually seen in HIV-positive patients on long-term fluconazole therapy. With the advent of highly active antiretroviral therapy, the rate of fluconazole resistance in *C albicans* has decreased. The drug is inactive against aspergillus, mucor, and pseudallescheria. Fluconazole is effective in oropharyngeal candidiasis and candidal esophagitis in immunosuppressed patients. It is also valuable in vaginal candidiasis, where a single oral dose of 150 mg is 80-90% effective. Response to fluconazole in leukemic patients with hepatosplenic candidiasis has also been observed, as it has in other invasive infections such as peritonitis, wound infection, and pyelonephritis. Fluconazole, 400 mg daily, is as effective as amphotericin B, 0.5-0.6 mg/kg/d, for candidemia in both neutropenic and nonneutropenic patients. Most of these infections are intravenous line-related, and removal of the line is critical to successful therapy. Fluconazole (200 mg/d) is effective as chronic suppressive therapy of cryptococcal meningitis in patients with AIDS and is the drug of choice in this setting. At a dose of 200 mg/d, response rates and overall mortality rates are the same in patients treated with oral fluconazole and with amphotericin B. However, the mortality rate in the first 2 weeks is higher—and it takes longer to sterilize the cerebrospinal fluid—among patients treated with fluconazole than among patients treated with amphotericin. Most clinicians would initiate therapy with amphotericin B for 2 weeks and then switch to oral fluconazole. A dosage of 400 mg of fluconazole daily is effective therapy for coccidioidal meningitis (80% response), but improvement is slow, taking as long as 4-8 months; efficacy has been observed in both non-HIV-infected and HIV-infected individuals. Higher doses (800-1200 mg/d) have been used; however, it is unclear whether they are superior to usual doses. Fluconazole, 400 mg daily, is effective prophylaxis against superficial and invasive fungal infections in bone marrow and liver transplant recipients, but concern has been raised about superinfection with resistant organisms (*Candida krusei*, *C glabrata*, aspergillus). The same dose of fluconazole has not reduced the incidence of invasive fungal disease in leukemic patients undergoing intensive chemotherapy and has not reduced the need for amphotericin B. Thus, the use of fluconazole as prophylaxis in the neutropenic patient remains controversial. Because the overall incidence of invasive fungal disease in HIV infection is low, universal prophylaxis to prevent disease in a few should be discouraged, especially with the advent of more potent antiretroviral therapy. Fluconazole is also effective for the therapy of cutaneous leishmaniasis due to *Leishmania major* in a dose of 200 mg/d for 6 weeks.

Fluconazole is well absorbed after oral administration (80% bioavailability), and serum levels approach those seen after administering the same dose intravenously. In addition, the intravenous preparation is about ten times more expensive than the oral medication. Thus, unless the patient cannot take medication by mouth or has an overwhelming infection, the preferred route of administration is by mouth.

Itraconazole is an oral triazole with antifungal and pharmacologic properties similar to those of ketoconazole. It is moderately well absorbed from the gastrointestinal tract (food increases absorption from 30% to 60%; antacids and H₂ receptor antagonists decrease absorption) and widely distributed in tissues with the notable exception of the central nervous system, where levels in spinal fluid are undetectable. Itraconazole solution is more predictably absorbed than the tablets. While the tablet formulation should be administered with food, the solution is best absorbed on an empty stomach. A parenteral formulation is available, but it is not approved for patients with renal insufficiency (creatinine clearance < 30 mL/min) because of the theoretic risk of pancreatic adenocarcinoma. The drug is metabolized by the liver, and no dosage adjustment is needed in renal insufficiency. Itraconazole is very active against most strains of *Histoplasma capsulatum*, *Blastomyces dermatitidis*, *Cryptococcus neoformans*, *Sporotrichum schenckii*, and various dermatophytes. It is also active against some fluconazole-resistant strains of candida, especially *C albicans*, and aspergillus species but inactive against fusarium and zygomycetes. Itraconazole in doses of 200-400 mg/d is effective and approved therapy for localized or disseminated histoplasmosis and is more effective than ketoconazole in AIDS patients with histoplasmosis. It is also effective prophylaxis against recurrent histoplasmosis in these patients and is also effective as secondary prophylaxis against *P marneffei* infection in AIDS patients. Itraconazole is preferred over ketoconazole for therapy of blastomycosis because it is more efficacious and better tolerated. It is also effective in sporotrichosis, dermatophytic infections (including those of the nails), and oral and esophageal candidiasis. Noncomparative clinical trials indicate efficacy in therapy of invasive aspergillosis (55-80%) and coccidioidomycosis (57- 94%). In the absence of comparative trials with other agents active against *C immitis* and aspergillus, it is difficult to know if itraconazole should be used as a first-line drug against these organisms, but the oral route of administration makes the drug attractive, particularly in patients who are not critically ill. At doses of 200 mg twice daily, itraconazole increases exercise tolerance and decreases steroid requirements in patients with allergic bronchopulmonary aspergillosis. Itraconazole has been shown to decrease superficial and invasive fungal infections compared with placebo when used as prophylaxis in neutropenic patients. Itraconazole has been approved for onychomycosis. Pulse therapy with 200 mg twice daily for 1 week each month, repeated for 4 consecutive months, is effective in 70% of cases.

Adverse effects are similar to those of ketoconazole and fluconazole, with anorexia, nausea, vomiting, and abdominal pain occurring most commonly. Skin rash has been reported in up to 8% of patients. Hepatitis and hypokalemia occur uncommonly. Exacerbation of heart failure occasionally occurs with itraconazole. Drugs that increase hepatic drug-metabolizing enzymes (isoniazid, rifampin, phenytoin, phenobarbital) may increase itraconazole metabolism, and higher doses may be needed when these drugs are administered concurrently with itraconazole. Itraconazole also impairs the metabolism of cyclosporine and can result in toxic levels unless the dosage is adjusted. Like ketoconazole, itraconazole increases blood levels of digoxin and warfarin.

The usual dosage is 200 mg once or twice daily with meals. Higher dosages (400-600 mg/d) may be required in patients who are immunocompromised and those with severe disease, especially that due to aspergillus. In patients with life-threatening infections, a 600-mg loading dose is given for 3 or 4 days.

Voriconazole is a new triazole antifungal with broad in vitro activity against a number of pathogens, including most species of candida and molds, aspergillus, fusarium, pseudallescheria, and others. It is as efficacious as liposomal amphotericin in the therapy of documented and suspected fungal infections in febrile neutropenic patients, and it is superior to liposomal amphotericin in preventing breakthrough fungemias. Voriconazole has been found to be superior to conventional amphotericin in the treatment of disseminated aspergillosis. Voriconazole is the drug of choice in the treatment of fusarium infections. Similar to fluconazole, oral administration leads to predictable absorption. The primary toxicity associated with voriconazole is infusion-related but transient alteration in light perception. This usually resolves with subsequent administrations. Visual hallucinations may occur in patients receiving voriconazole.

7. Candins

The echinocandins and pneumocandins represent a new class of antifungals active by inhibition of fungal wall synthesis. They are active against candida, including nonalbicans species, as well as aspergillus species. Candins are not active against cryptococcus or fusarium. Their long pharmacologic half-life confers the advantage of once-daily dosing. Candins are associated with minimal toxicity or adverse effects, and they are not implicated in significant drug interactions. Clinical data in the treatment of aspergillus infections suggest caspofungin, the first candin clinically available, to be associated with success similar to that of other agents active against aspergillus. Caspofungin is indicated for treatment of aspergillus infections in those who fail to respond to or are intolerant of amphotericin and itraconazole. Caspofungin is superior to conventional amphotericin B in the treatment of candidemia, primarily on the basis of greater patient tolerability. Its primary role is in the treatment of infections due to *C glabrata* and *C krusei*. Caspofungin may be additive to voriconazole in the treatment of disseminated aspergillosis.

ANTIVIRAL CHEMOTHERAPY

Several compounds can influence viral replication and the development of viral disease.

Amantadine is active against influenza A (but not influenza B) and has efficacy both in prophylaxis and therapy of this infection. Yearly immunization against influenza is recommended (see [Chapter 30](#)) for disease prevention, but in certain select situations amantadine can be used for this purpose. Amantadine prophylaxis is 70-90% effective and is suggested for the influenza season (6-8 weeks) in patients who cannot be immunized who are at increased risk of developing complications of influenza (those with chronic pulmonary and cardiac diseases, persons over 65 years of age, persons with chronic metabolic diseases such as diabetes mellitus, and chronic renal failure); in medical personnel who cannot receive vaccine but are capable of transmitting influenza to high-risk patients; if vaccine is not available; and if vaccine strains differ from the strain causing an epidemic. Short-term prophylaxis (2 weeks) is indicated if an outbreak occurs before vaccination has been given. In this setting, amantadine will protect against disease while antibody production is induced and will not interfere with antibody production. Because of its modest therapeutic benefit, high-risk patients and others with influenza A may benefit from treatment with amantadine if it is instituted within 48 hours after the onset of symptoms and continued for 1 week. The usual adult dosage is 200 mg orally per day (in persons over 65 years of age, 100 mg). Emergence of influenza A resistant to amantadine and rimantadine has been observed in patients receiving therapy. Considering this resistance, neuraminidase inhibitors such as zanamivir or oseltamivir may be preferable in an outbreak situation. The most marked untoward effects are insomnia, nightmares, and ataxia, especially in the elderly. Amantadine may accumulate and be more toxic in patients with renal insufficiency, and the dosage should be reduced.

Rimantadine, an analog of amantadine, is as effective as amantadine and is associated with fewer central nervous system adverse effects. It is considerably more expensive than amantadine and thus should be considered only in the elderly, in whom central nervous system side effects occur more commonly.

Neuraminidase inhibitors, including zanamivir inhalation and oseltamivir tablets, are available for prevention and treatment of influenza A and B. Like amantadine and rimantadine, they must be administered soon (within 48 hours) after the onset of symptoms to be effective. Zanamivir inhalers are difficult to use for some patients, especially those with asthma and chronic obstructive pulmonary disease, in whom bronchospasm has been reported. Oseltamivir has limited application because of its gastrointestinal side effects. Both drugs are administered twice daily for 5 days when used for therapy. Both agents are significantly more expensive than amantadine and reduce the duration of symptoms by only 1 day and viral shedding by 2 days. The major advantages of neuraminidase inhibitors over amantadine or rimantadine include activity against influenza A and B and a low likelihood of development of resistance, resulting in their preferential use in outbreak settings. Both agents also effectively prevent disease in household contacts when administered prophylactically for 10 days.

Acyclovir is useful in infections due to herpes simplex and in herpes zoster-varicella infections. In herpes-infected cells, it is selectively active against viral DNA polymerase and thus inhibits virus proliferation. Given intravenously (15 mg/kg/d in three divided doses), it can promote healing of mucocutaneous herpes simplex in immunocompromised patients. It can reduce pain, accelerate healing, and prevent dissemination of herpes zoster and varicella in immunocompromised patients. The usual dosage for varicella-zoster infections is 30 mg/kg/d intravenously in three equal doses. The drug has no effect on establishment of latency, frequency of recurrence, or incidence of postherpetic neuralgia. Acyclovir (30 mg/kg/d intravenously in three equal doses) is the drug of choice for herpes encephalitis. Intravenous or oral acyclovir is effective prophylaxis against recurrent mucocutaneous and visceral herpes infections in transplant and other severely immunosuppressed patients. Investigation of the role of intravenous acyclovir in the prevention of cytomegalovirus disease in transplant recipients has yielded conflicting data. Acyclovir appears to be effective in some transplant settings (renal and perhaps bone marrow) but not in others (liver).

Oral acyclovir, 400 mg three times daily for 7-10 days, is effective in primary genital herpes simplex infections. Oral acyclovir at a dose of 800 mg three times a day for 2 days for recurrent genital herpes reduces viral shedding and symptoms. Suppressive therapy (400 mg twice daily) for 4-6 months reduces the frequency and severity of recurrent genital herpetic lesions. Acyclovir minimally affects symptoms or viral shedding in recurrent herpes labialis and is not generally used for this disease. However, in a dose of 400 mg twice daily, it is effective in preventing recurrent herpes labialis in those with frequent relapses and in preventing sun-induced relapses.

Other uses of oral acyclovir include (1) therapy of acute herpetic keratitis and prevention of recurrences, (2) prevention and treatment of herpetic whitlow, (3) acceleration of healing of herpes zoster in immunocompetent patients if initiated within 48 hours after onset (800 mg five times daily for 7 days), (4) more rapid healing of rash and lessened clinical symptoms of primary varicella in adults and children if instituted within 24 hours after onset of rash and continued for 5-7 days, (5) therapy of herpes proctitis (400 mg five times daily for 10 days), (6) prevention of herpes simplex and cytomegalovirus infections in transplant recipients (in doses of 800 mg four or five times daily), (7) prevention of erythema multiforme that is herpes simplex-related, and (8) prophylaxis against varicella in susceptible household contacts.

Topical 5% acyclovir ointment can shorten the period of pain and viral shedding in herpes simplex mucocutaneous oral lesions in immunosuppressed patients but not in patients with normal immunity. In contrast, acyclovir cream or penciclovir ointment (see famciclovir, below) appears to reduce the duration of pain and viral shedding by approximately 1 day in immunocompetent patients. Oral acyclovir is significantly more efficacious than topical therapy.

The absolute oral bioavailability of acyclovir is 10-30%. Newer agents (famciclovir, valacyclovir; see below) are significantly better absorbed than oral acyclovir and generally can be administered less frequently. Dosage reduction in renal insufficiency is required. For most herpes simplex infections except encephalitis, the intravenous dose is 5 mg/kg per dose. Since hemodialysis reduces serum levels significantly, the daily dose should be given after hemodialysis.

Acyclovir is relatively nontoxic. Precipitation of drug in renal tubules has been described with intravenous acyclovir and can best be avoided by maintaining adequate hydration and urine flow. Central nervous system toxicity manifested by confusion, agitation, tremors, and hallucinations has been reported. Resistance has been described, usually in immunosuppressed patients who have received multiple courses of therapy.

Famciclovir is a prodrug of penciclovir. After oral administration, 75-80% is absorbed and deacetylated in the intestinal wall to the active drug, penciclovir. Penciclovir, like acyclovir, inhibits viral replication by interfering with viral DNA polymerase. Acyclovir-resistant strains of herpes simplex and varicella-zoster virus are also resistant to famciclovir. Famciclovir in a dose of 500 mg three times daily for 7 days accelerates healing of lesions in acute herpes zoster if started within 72 hours after the onset of rash. At a dose of 125 mg twice daily for 5 days, famciclovir is effective therapy of recurrent genital herpes; at a dose of 500 mg twice daily, it is effective as chronic suppressive therapy.

Valacyclovir is a prodrug of acyclovir that has significantly increased oral bioavailability when compared with acyclovir. After absorption, it is converted to acyclovir and serum levels are three to five times higher than those achieved with acyclovir. Valacyclovir at a dosage of 1 g three times daily for 7-10 days is effective therapy for herpes zoster when started within 72 hours after onset of rash and is slightly more effective than acyclovir in relieving zoster-associated pain. It shortens the course of initial episodes of genital herpes (1 g twice daily for 7-10 days), can be used to treat recurrent genital herpes (500 mg twice daily for three days), and is effective prophylaxis for recurrent genital herpes when given as a single 1-g daily dose. At doses of 2 g four times daily, valacyclovir is more effective than placebo in preventing cytomegalovirus infections in seronegative recipients of a kidney from a seropositive donor. The adverse effect profile of valacyclovir is comparable to that of acyclovir. However, HIV-positive patients receiving long-term valacyclovir (8 g/d) for prevention of cytomegalovirus disease have been found to have an increased incidence of thrombocytopenic purpura-hemolytic anemic syndrome.

Foscarnet (trisodium phosphonoformate) is a pyrophosphate analog that inhibits viral DNA polymerase of human herpesviruses (CMV, herpes simplex, varicella-zoster) and the reverse transcriptase of human immunodeficiency virus. The drug is more expensive than ganciclovir, less well tolerated, and more difficult to administer. Therefore, its use is limited to patients who do not respond to ganciclovir or cannot tolerate it. Isolates of CMV resistant to ganciclovir and herpes simplex and varicella-zoster resistant to acyclovir usually are sensitive to foscarnet. Foscarnet appears to be effective for CMV retinitis and has been used successfully in patients who have failed to respond to ganciclovir. Once therapy is stopped, recurrences develop, and lifelong suppressive therapy is required for AIDS patients not receiving highly active antiretroviral therapy. Combination therapy with ganciclovir and foscarnet has been associated with improved efficacy over monotherapy in the treatment of CMV retinitis. While combination therapy reduced progression of disease (eg, retinal changes), no improvement of visual acuity was observed over either drug used alone. Foscarnet has also been used to treat acyclovir-resistant mucocutaneous herpes simplex in AIDS patients as well as varicella cutaneous lesions in AIDS patients who failed to respond to acyclovir. There may be efficacy in CMV gastrointestinal disease, therapy of CMV infection following bone marrow and renal transplantation, and prevention of CMV disease when the drug is given prophylactically to seropositive bone marrow transplant recipients. Oral absorption is poor, and the drug must be given intravenously. The half-life is 3-5 hours, and this is prolonged with renal insufficiency. The usual induction dose is 60 mg/kg every 8 hours, and the dose for maintenance therapy is 120 mg/kg once daily. Adjustments are required for even minimal impairment in renal function (see package insert).

Toxicity is a major drawback. The drug can cause severe phlebitis and must be diluted to a concentration of 12 mg/mL to be given peripherally. At higher concentrations, it is given centrally. Nephrotoxicity, dose-dependent and reversible, is its major toxicity. Prehydration with 2.5 L of 0.9% saline may protect against nephrotoxicity. Foscarnet binds divalent cations, and hypocalcemia with peripheral neuropathy, seizures and arrhythmias, hypomagnesemia, and hypophosphatemia can occur. Monitoring of electrolytes and renal function is required during therapy. Anemia (20-50%) and nausea and vomiting (20-30%) are other common adverse effects.

Resistance of herpes simplex virus to foscarnet has been described in HIV infection and in association with bone marrow transplantation. It is usually seen in patients who are infected with HIV and either have received foscarnet previously or were receiving suppressive therapy.

Cidofovir is a nucleotide analog that is active against all human herpesviruses. The drug has a prolonged pharmacokinetic intracellular half-life, allowing for administration every 1-2 weeks. Phosphorylation of cidofovir to its active form does not depend on viral enzymes. Thus, strains of cytomegalovirus, herpes simplex virus, and herpes zoster virus that are resistant to ganciclovir or acyclovir often are sensitive to cidofovir. Cidofovir delays progression of CMV retinitis in newly diagnosed disease (5 mg/kg weekly for 2 weeks, followed by maintenance of 3-5 mg/kg every other week) and is effective therapy in relapsed disease or in patients who are intolerant of traditional therapy (5 mg/kg every other day). Limited data suggest that direct intravitreal injection (20 ug every 5-6 weeks) of cidofovir is also effective for initial and maintenance therapy. Cidofovir gel (as 3% or 1%) topically applied to mucocutaneous herpetic lesions in AIDS patients unresponsive to oral or intravenous acyclovir provides benefit in healing. The drug is ineffective or only marginally effective in the treatment of AIDS-associated progressive multifocal leukoencephalopathy. Cidofovir is associated with a high incidence of nephrotoxicity, sometimes severe. To avoid this complication, probenecid and intravenous saline are administered with each dose. Ocular toxicity, including uveitis and iritis, is another complication reported with cidofovir.

Ribavirin aerosol is potentially useful in the treatment of respiratory syncytial virus infections in bone marrow transplant patients. It is not known whether the addition of immune globulin provides additional benefit. Intravenous ribavirin can significantly lower the fatality rate of Lassa fever and has been used as a therapeutic agent for hantavirus pneumonia. However, the benefit in hantavirus infection is unclear. The drug is teratogenic in animals, and pregnant women should not take care of patients receiving the aerosol. Oral ribavirin is used in combination with interferons to treat chronic hepatitis C infections (see [Chapter 15](#)).

Ganciclovir is an analog of acyclovir that has broad antiviral activity, including activity against CMV. The drug is efficacious in the therapy of CMV retinitis in AIDS patients, but once therapy is stopped, the relapse rate is high, and long-term maintenance suppressive therapy is required in patients not receiving HAART. CMV pneumonitis therapy with this agent has been disappointing. It has been suggested that the addition of intravenous immunoglobulin or CMV immune globulin to ganciclovir may improve CMV pneumonitis. CMV viremia and hepatitis are often self-limited diseases, and the role of ganciclovir in treating these syndromes awaits clarification. However, because CMV viremia often predicts the presence of invasive disease, it is usually treated when it occurs. Ganciclovir is frequently used in solid and bone marrow transplant patients to treat documented infection and for prophylaxis. However, there is no uniformity of opinion about the duration of therapy or the route of administration. Before the availability of oral valganciclovir (see below), which results in serum levels equivalent to those achieved with intravenous drug, ganciclovir was frequently administered intravenously and in the immediate posttransplant period for 1-2 weeks. Depending on the type of transplant (bone marrow transplant patients are at greater risk of developing cytomegalovirus disease than solid organ transplant patients) and the serologic status of the donor and recipient (seronegative recipients who receive transplants from seropositive donors are at greatest risk of developing disease), various antiviral agents were used to prevent infection. High-dose acyclovir (800 mg four or five times daily), valacyclovir, oral ganciclovir (1 g three times daily), and even intravenous ganciclovir (5 mg/kg three times weekly for 100-120 days posttransplant) in bone marrow transplant patients have all been all used. With the availability of oral valganciclovir, many transplant patients—especially those with the greatest risk of developing CMV infection—are placed on this drug as prophylaxis. In addition, because tests to detect early infection with CMV are very sensitive, the strategy for prevention has shifted from one of universal prophylaxis to one of preemptive therapy. At many institutions, high-risk patients are routinely screened for CMV DNA in blood by antigen detection or PCR. If the test is positive, only then are patients treated with either intravenous ganciclovir or oral valganciclovir.

The major adverse effect is neutropenia, which is reversible but requires dosage reduction. Thrombocytopenia, disorientation, nausea, rash, and phlebitis occur less commonly.

Oral ganciclovir has poor bioavailability, with maximum absorption of only 6-9% when taken with food. After a dose of 1 g, peak serum levels are about 1 ug/mL (clinical isolates of CMV are inhibited by 0.02-3.5 ug/mL). Controlled clinical studies indicate that the oral drug in a dose of 1 g three times a day is slightly less effective than intravenous ganciclovir, 5 mg/kg daily as maintenance therapy for CMV retinitis (time to progression is 5-12 days shorter in those treated with the oral drug). Thus, in selected populations with peripheral non-sight-threatening lesions, oral ganciclovir maintenance may be convenient and effective therapy compared with long-term intravenous therapy. Because of its poor bioavailability, oral ganciclovir is unlikely to be effective as primary therapy for active CMV infection. The role of oral ganciclovir in prevention of CMV infection following bone marrow or solid organ transplantation has not been well studied, but liver transplant recipients receiving oral ganciclovir, 1 g three times daily for 3 months, appear to have less CMV disease than those receiving placebo. Oral ganciclovir is also effective as preemptive therapy (ie, for patients with CMV antigenemia) for CMV disease in liver transplant patients.

Oral ganciclovir generally has been replaced by **valganciclovir**, an esterification product of ganciclovir with significantly better oral bioavailability. Administration of 900 mg of valganciclovir results in serum ganciclovir levels equal to that achieved with an intravenous 5-mg/kg dose of ganciclovir. In cytomegalovirus retinitis in AIDS patients, the drug is as efficacious as intravenous therapy. Although valganciclovir is now widely used as prophylaxis in transplant patients, few studies have established its effectiveness.

Lamivudine (3TC), a well-tolerated oral antiviral nucleoside analog used in treatment of HIV infection, is effective against hepatitis B. Once-daily therapy (100 mg) for a year results in clinical, serologic, and histologic improvement in approximately 50% of patients. While lamivudine is useful, development of resistance is common with long-term therapy. Therapy post-liver transplantation is associated with a reduced risk of reinfection with hepatitis B.

Adefovir is an antiviral agent with activity against hepatitis B. It appears to be as effective against lamivudine-susceptible as against lamivudine-resistant isolates. While higher doses previously used have been associated with substantial nephrotoxicity, this complication is rare with the lower doses used to treat hepatitis B. Twenty-five to 35 percent of patients experience marked increases in liver function tests associated with discontinuation of adefovir, presumably secondary to viral replication. The drug is primarily eliminated by the kidney.

Human interferons have been prepared from stimulated lymphocytes and by DNA recombinant technology. These agents have antiviral, antitumor, and immunoregulatory properties. The most common uses of these agents include therapy of chronic hepatitis due to hepatitis B, C, and D (see [Chapter 15](#)). A long-acting preparation of interferon, peginterferon, has been determined to be superior to conventional interferon. Oral ribavirin in combination with interferon is more effective than interferon monotherapy in the treatment of chronic hepatitis C infection. The optimal therapy for chronic hepatitis C is probably a peginterferon product in combination with oral ribavirin. Interferons are also efficacious in condyloma acuminatum, as prophylaxis against infection in patients with chronic granulomatous disease, and for therapy of a number of malignancies such as hairy cell leukemia, Kaposi's sarcoma in AIDS, chronic myelogenous leukemia, multiple myeloma, renal cell carcinoma, and others, as well as in therapy for relapsing multiple sclerosis. Other potential uses are for therapy of certain intracellular pathogens such as leprosy, atypical mycobacterial infection, toxoplasmosis, and leishmaniasis. Relapse of the underlying disease after cessation of therapy is common but usually responds to reinstitution of drug. Adverse effects are common and include an influenza-like illness with fever, chills, nausea, vomiting, headache, arthralgia, and myalgias. Bone marrow suppression, especially with high-dose therapy, also occurs. Considering the poor tolerability of interferon, only a minority of patients infected with hepatitis C are actually candidates for therapy.

Table 37-1. Drugs of choice for suspected or proved microbial pathogens, 2001.¹
(± = alone or combined with)

Suspected or Proved Etiologic Agent	Drug(s) of First Choice	Alternative Drug(s)
Gram-negative cocci		
<i>Moraxella catarrhalis</i>	TMP-SMZ ²	Cefuroxime, cefotaxime, ceftizoxime, ceftriaxone, cefepime, cefuroxime axetil, an erythromycin, ³ a tetracycline, ⁴ azithromycin, amoxicillin-clavulanic acid, clarithromycin, a fluoroquinolone ⁵
<i>Neisseria gonorrhoeae</i> (gonococcus)	Cefixime, ciprofloxacin, or ofloxacin	Ceftriaxone, spectinomycin, cefpodoxime proxetil
<i>Neisseria meningitidis</i> (meningococcus)	Penicillin ⁶	Cefotaxime, ceftizoxime, ceftriaxone, ampicillin, chloramphenicol
Gram-positive cocci		
<i>Streptococcus pneumoniae</i> ⁸ (pneumococcus)	Penicillin ⁶	An erythromycin, ³ a cephalosporin, ⁷ vancomycin, TMP-SMZ, chloramphenicol, clindamycin, azithromycin, clarithromycin, a tetracycline, ⁴ imipenem, meropenem, quinupristin-dalfopristin, certain fluoroquinolones, ⁵ linezolid
Streptococcus, hemolytic, groups A, B, C, G	Penicillin ⁶	An erythromycin, ³ a cephalosporin, ⁷ vancomycin, clindamycin, azithromycin, clarithromycin
Viridans streptococci	Penicillin ⁶ ± gentamicin	Cephalosporin, ⁷ vancomycin
Staphylococcus, methicillin-resistant	Vancomycin ± gentamicin ± rifampin	TMP-SMZ, ² minocycline, a fluoroquinolone ⁵
Staphylococcus, non-penicillinase-producing	Penicillin ⁶	A cephalosporin, ⁸ vancomycin, imipenem, meropenem, a fluoroquinolone, ⁵ clindamycin
Staphylococcus, penicillinase-producing	Penicillinase-resistant penicillin ⁹	Vancomycin, a cephalosporin, ⁷ clindamycin, amoxicillin-clavulanic acid, ticarcillin-clavulanic acid, ampicillin-sulbactam, piperacillin- tazobactam, imipenem, meropenem, a fluoroquinolone, ⁵ TMP-SMZ ²
<i>Enterococcus faecalis</i>	Ampicillin + gentamicin ¹⁰	Vancomycin + gentamicin
<i>Enterococcus faecium</i>	Vancomycin + gentamicin ¹⁰	Quinupristin-dalfopristin, linezolid
Gram-negative rods		
Acinetobacter	Imipenem or meropenem	Minocycline, TMP-SMZ, ² doxycycline, aminoglycosides, ¹¹ piperacillin, ceftazidime, a fluoroquinolone ⁵
Prevotella, oropharyngeal strains	Clindamycin	Penicillin, ⁶ metronidazole, cefoxitin, cefotetan
Bacteroides, gastrointestinal strains	Metronidazole	Cefoxitin, chloramphenicol, clindamycin, cefotetan, cefmetazole, imipenem, meropenem, ticarcillin-clavulanic acid, ampicillin-sulbactam, piperacillin-tazobactam
Brucella	Tetracycline, rifampin ⁴	TMP-SMZ ² ± gentamicin; chloramphenicol ± gentamicin; doxycycline + gentamicin
<i>Campylobacter jejuni</i>	A fluoroquinolone ⁵	Tetracycline, ⁴ erythromycin ³ or azithromycin
Enterobacter	TMP-SMZ, ² imipenem, meropenem	Aminoglycoside, a fluoroquinolone, ⁵ cefepime
<i>Escherichia coli</i> (sepsis)	Cefotaxime, ceftizoxime, ceftriaxone, ceftazidime, cefepime	Imipenem or meropenem, aminoglycosides, ¹¹ a fluoroquinolone ⁵
<i>Escherichia coli</i> (uncomplicated urinary infection)	Fluoroquinolones, nitrofurantoin	TMP-SMZ, ² oral cephalosporin, fosfomycin
Haemophilus (meningitis and other serious infections)	Cefotaxime, ceftizoxime, ceftriaxone, ceftazidime	Chloramphenicol, meropenem
Haemophilus (respiratory infections, otitis)	TMP-SMZ ²	Ampicillin, amoxicillin, doxycycline, azithromycin, clarithromycin, cefotaxime, ceftizoxime, ceftriaxone, cefepime, cefuroxime, cefuroxime axetil, ampicillin-clavulanate
<i>Helicobacter pylori</i>	Amoxicillin + clarithromycin + omeprazole	Clarithromycin + omeprazole or bismuth subsalicylate (Pepto-Bismol) + metronidazole + tetracycline
Klebsiella	A cephalosporin	TMP-SMZ, ² aminoglycoside, ¹¹ imipenem or meropenem, a fluoroquinolone, ⁵ piperacillin, mezlocillin, aztreonam
Legionella species (pneumonia)	Erythromycin ³ or clarithromycin or azithromycin, a fluoroquinone, or fluoroquinolones ⁵ ± rifampin	TMP-SMZ, ² doxycycline ± rifampin
<i>Proteus mirabilis</i>	Ampicillin	An aminoglycoside, ¹¹ TMP-SMZ, ² a fluoroquinolone, ⁵ a cephalosporin ⁷
<i>Proteus vulgaris</i> and other species (morganella, providencia)	Cefotaxime, ceftizoxime, ceftriaxone, ceftazidime, cefepime	Aminoglycoside, ¹¹ imipenem, TMP-SMZ, ² a fluoroquinolone ⁵
<i>Pseudomonas aeruginosa</i>	Aminoglycoside ¹¹ + antipseudomonal penicillin ¹²	Ceftazidime ± aminoglycoside; imipenem or meropenem ± aminoglycoside; aztreonam ± aminoglycoside; ciprofloxacin ± piperacillin; ciprofloxacin ± ceftazidime; ciprofloxacin ± cefepime
<i>Burkholderia pseudomallei</i> (melioidosis)	Ceftazidime	Chloramphenicol, tetracycline, ⁴ TMP-SMZ, ² amoxicillin-clavulanic acid, imipenem or meropenem
<i>Burkholderia mallei</i> (glanders)	Streptomycin + tetracycline ⁴	Chloramphenicol + streptomycin
Salmonella (bacteremia)	Ceftriaxone, a fluoroquinolone ⁵	TMP-SMZ, ² ampicillin, chloramphenicol
Serratia	Cefotaxime, ceftizoxime, ceftriaxone, ceftazidime, cefepime	TMP-SMZ, ² aminoglycosides, ¹¹ imipenem or meropenem, a fluoroquinolone ⁵
Shigella	A fluoroquinolone ⁵	Ampicillin, TMP-SMZ, ² ceftriaxone
Vibrio (cholera, sepsis)	Tetracycline ⁴	TMP-SMZ, ² a fluoroquinolone ⁵
<i>Yersinia pestis</i> (plague, tularemia)	Streptomycin ± a tetracycline ⁴	Chloramphenicol, TMP-SMZ ²

Gram-positive rods

Actinomyces	Penicillin ⁶	Tetracycline, ⁴ clindamycin
Bacillus (eg, anthrax)	Penicillin ⁶	Erythromycin, ³ tetracycline, ⁴ a fluoroquinolone ⁵
Clostridium (eg, gas gangrene, tetanus)	Penicillin ⁶	Metronidazole, chloramphenicol, clindamycin, imipenem or meropenem
Corynebacterium diphtheriae	Erythromycin ³	Penicillin ⁶
Corynebacterium jeikeium	Vancomycin	Ciprofloxacin, penicillin + gentamicin
Listeria	Ampicillin ± aminoglycoside ¹¹	TMP-SMZ ²

Acid-fast rods

Mycobacterium tuberculosis ¹³	INH + rifampin + pyrazinamide ± ethambutol or streptomycin	Other antituberculous drugs
Mycobacterium leprae	Dapsone + rifampin ± clofazimine	Minocycline, ofloxacin, clarithromycin
Mycobacterium kansasii	INH + rifampin ± ethambutol	Ethionamide, cycloserine
Mycobacterium avium complex	Clarithromycin or azithromycin + one or more of the following: ethambutol, rifampin or rifabutin, ciprofloxacin	Other antituberculous drugs
Mycobacterium fortuitumcheilonei	Amikacin + clarithromycin	Cefoxitin, sulfonamide, doxycycline
Nocardia	TMP-SMZ ²	Minocycline, imipenem or meropenem, sulfisoxazole

Spirochetes

Borrelia burgdorferi (Lyme disease)	Doxycycline	Amoxicillin, ceftriaxone, cefuroxime axetil, penicillin
Borrelia recurrentis (relapsing fever)	Tetracycline ⁴	Penicillin ⁶
Leptospira	Penicillin ⁶	Tetracycline ⁴
Treponema pallidum (syphilis)	Penicillin ⁶	Tetracycline, ⁴ ceftriaxone
Treponema pertenue (yaws)	Penicillin ⁶	Tetracycline ⁴

Mycoplasmas

	Erythromycin ³ or tetracycline ⁴	Clarithromycin, azithromycin, a fluoroquinolone ⁵

Chlamydiae

C psittaci	Tetracycline ⁴	Chloramphenicol
C trachomatis (urethritis or pelvic inflammatory disease)	Doxycycline or azithromycin	Ofloxacin
C pneumoniae	Tetracycline ⁴	Erythromycin, ³ clarithromycin, azithromycin, a fluoroquinolone

Rickettsiae

	Tetracycline ⁴	Chloramphenicol, a fluoroquinolone ^{5,14}

¹Adapted from Med Lett Drugs Ther 2001;43:69.

²TMP-SMZ is a mixture of 1 part trimethoprim and 5 parts sulfamethoxazole.

³Erythromycin estolate is best absorbed orally but carries the highest risk of hepatitis; erythromycin stearate and erythromycin ethylsuccinate are also available.

⁴All tetracyclines have similar activity against most microorganisms. Minocycline and doxycycline have increased activity against *S aureus*. Dosage is determined by rates of absorption and excretion of various preparations.

⁵Fluoroquinolones include ciprofloxacin, ofloxacin, levofloxacin, sparfloxacin, moxifloxacin, gatifloxacin, and others (see text). Levofloxacin and sparfloxacin have the best activity against gram-positive organisms, including penicillin-resistant *S pneumoniae* and methicillin-sensitive *S aureus*. Activity against enterococci and *S epidermidis* variable. Ciprofloxacin has the best activity against *P aeruginosa*.

⁶Penicillin G is preferred for parenteral injection; penicillin V for oral administrationto be used only in treating infections due to highly sensitive organisms.

⁷Most intravenous cephalosporins (with the exception of ceftazidime) have good activity against gram-positive cocci.

⁸Intermediate and high-level resistance to penicillin has been described. Infections caused by strains with intermediate resistance may respond to high doses of penicillin, cefotaxime, or ceftriaxone. Infections caused by highly resistant strains should be treated with vancomycin ± rifampin. Many strains of penicillin-resistant pneumococci are resistant to erythromycin, macrolides, TMP-SMZ, and chloramphenicol.

⁹Parenteral nafcillin or oxacillin; oral dicloxacillin, cloxacillin, or oxacillin.

¹⁰Addition of gentamicin indicated only for severe enterococcal infections (eg, endocarditis, meningitis).

¹¹Aminoglycosidesgentamicin, tobramycin, amikacin, netilmicinshould be chosen on the basis of local patterns of susceptibility.

¹²Antipseudomonal penicillins: ticarcillin, mezlocillin, piperacillin.

¹³Resistance may be a problem, and susceptibility testing should be done.

¹⁴Ciprofloxacin has inferior antichlamydial activity compared with newer fluoroquinolones.

Table 37-2. Examples of initial antimicrobial therapy for acutely ill adults pending identification of causative organism.

Suspected Clinical Diagnosis	Likely Etiologic Diagnosis	Drugs of Choice
(A) Meningitis, bacterial	Pneumococcus, ¹ meningococcus	Cefotaxime, ² 2-3 g IV every 6 hours, or ceftriaxone, 2 g IV every 12 hours plus vancomycin,10 mg/kg every 8 hours
(B) Meningitis, bacterial, age > 50	Pneumococcus, meningococcus, <i>Listeria monocytogenes</i> , ³ gram-negative bacilli	Ampicillin, 2 g IV every 4 hours, plus cefotaxime or ceftriaxone and vancomycin as in (A)
(C) Meningitis, postoperative (or posttraumatic)	<i>S aureus</i> , gram-negative bacilli (pneumococcus, posttraumatic)	Vancomycin, 10 mg/kg every 8 hours, plus ceftazidime, 3 g IV every 8 hours
(D) Brain abscess	Mixed anaerobes, pneumococci, streptococci	Penicillin G, 4 million units IV every 4 hours, or metronidazole, 500 mg IV every 8 hours, plus cefotaxime or ceftriaxone as in (A)
(E) Pneumonia, acute, community-acquired, severe	Pneumococci, <i>M pneumoniae</i> , legionella, <i>C pneumoniae</i>	Erythromycin, ⁴ 0.5 g orally or IV four times daily, or doxycycline, 100 mg IV or orally every 12 hours, plus cefotaxime, 2 g IV every 8 hours (or ceftriaxone, 1 g IV every 24 hours) or a fluoroquinolone ⁶
(F) Pneumonia, postoperative or nosocomial	<i>S aureus</i> ,mixed anaerobes, gram-negative bacilli	Cefotaxime or ceftriaxone or cefipime, 2 g IV every 8 hours, or piperacillintazobactam, 4-5 g IV every 6 hours, with or without tobramycin or ciprofloxacin
(G) Endocarditis, acute (including IV drug user)	<i>S aureus</i> , <i>E faecalis</i> , gram-negative aerobic bacteria, viridans streptococci	Vancomycin, 15 mg/kg every 12 hours, plus gentamicin, 2 mg/kg every 8 hours
(H) Septic thrombophlebitis (eg, IV tubing, IV shunts)	<i>S aureus</i> , gram-negative aerobic bacteria	Nafcillin, 2 g IV every 4 hours, plus gentamicin, ⁵ 2 mg/kg every 8 hours
(I) Osteomyelitis	<i>S aureus</i>	Nafcillin, 2 g IV every 4 hours, or cefazolin, 2 g IV every 8 hours
(J) Septic arthritis	<i>S aureus</i> , <i>N gonorrhoeae</i>	Ceftriaxone, 1-2 g IV every 24 hours
(K) Pyelonephritis with flank pain and fever (recurrent UTI)	<i>E coli</i> ,klebsiella, enterobacter, pseudomonas	Ciprofloxacin, 400 mg IV every 12 hours, or levofloxacin, 500 mg IV once daily
(L) Suspected sepsis in neutropenic patient receiving cancer chemotherapy	<i>S aureus</i> , pseudomonas, klebsiella, <i>E coli</i>	Ceftazidime, 2 g IV every 8 hours, or cefepime, 2 g IV every 8 hours
(M) Intra-abdominal sepsis (eg, post-operative, peritonitis, cholecystitis)	Gram-negative bacteria, bacteroides, anaerobic bacteria, streptococci, clostridia	Ampicillin, 1-2 g every 6 hours, plus gentamicin, 2 mg/kg every 8 hours, plus metronidazole, 500 mg IV every 8 hours, or piperacillin-tazobactam as in (F) or ticarcillin-clavulanate, 3.1 g IV every 6 hours

¹Some strains may be resistant to penicillin. Vancomycin should be used with or without rifampin.

²Cefotaxime, ceftriaxone, ceftazidime, or ceftizoxime can be used. Most studies on meningitis have been done with cefotaxime or ceftriaxone (see text).

³TMP-SMZ can be used to treat *Listeria monocytogenes* in patients allergic to penicillin in a dosage of 15-20 mg/kg of TMP in three or four divided doses.

⁴Other macrolides such as azithromycin or clarithromycin can be used.

⁵Depending on local drug susceptibility pattern, use tobramycin, 5 mg/kg/d, or amikacin, 15 mg/kg/d, in place of gentamicin.

⁶Gatifloxacin, levofloxacin, moxifloxacin.

 - TABLES
 - Table 37-2. Examples of initial antimicrobial therapy for acutely ill adults pending identification of causative organism.

Table 37-3. Examples of empirical choices of antimicrobials for adult outpatient infections.

Suspected Clinical Diagnosis	Likely Etiologic Agents	Drugs of Choice	Alternative Drugs
Erysipelas, impetigo, cellulitis, ascending lymphangitis	Group A streptococcus	Phenoxymethyl penicillin, 0.5 g orally four times daily.	Erythromycin, 0.5 g orally four times daily, or cephalexin, 0.5 g orally four times daily for 7-10 days; azithromycin, 500 mg on day 1, and 250 mg on days 2-5.
Furuncle with surrounding cellulitis	<i>Staphylococcus aureus</i>	Dicloxacillin, 0.5 g orally four times daily for 7-10 days.	Cephalexin, 0.5 g orally four times daily for 7-10 days.
Pharyngitis	Group A streptococcus	Phenoxymethyl penicillin, 0.5 g orally four times daily for 10 days.	Erythromycin, 0.5 g orally four times daily for 10 days; azithromycin, 500 mg on day 1 and 250 mg on days 2-5, or clarithromycin, 500 mg twice daily daily for 10 days.
Otitis media	<i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Moraxellacatarrhalis</i>	Amoxicillin, 0.5 g orally three times daily for 10 days.	Augmentin, ² 0.5 g orally three timesdaily; cefuroxime, 0.5 g orally twice daily; or cefpodoxime, 0.2-0.4 g daily, or doxycycline, 100 mg twice daily or TMP-SMZ, one double-strength tablet twice daily for 10 days.
Acute sinusitis	<i>S pneumoniae</i> , <i>H influenzae</i> , <i>M catarrhalis</i>	Amoxicillin, 0.5 g orally three times daily; or TMP-SMZ, one double-strength tablet twice daily for 10 days.	Augmentin, ² 0.5 g orally three timesdaily; cefuroxime, 0.5 g orally twice daily; or cefpodoxime, 0.2-0.4 g daily, or doxycycline, 100 mg twice daily for 10 days.
Aspiration pneumonia	Mixed oropharyngeal flora, including anaerobes	Clindamycin, 0.3 g orally four times daily for 10-14 days.	Phenoxymethyl penicillin, 0.5 g orally four times daily for 10-14 days.
Pneumonia	<i>S pneumoniae</i> , <i>Mycoplasma pneumoniae</i> , <i>Legionella pneumophila</i> , <i>Chlamydia pneumoniae</i>	Doxycycline, 100 mg twice daily, or erythromycin, 0.5 g four times daily, or clarithromycin, 0.5 g twice daily, for 10-14 days; or azithromycin, 0.5 g on day 1 and 0.25 g on days 2-5.	Amoxicillin, 0.5 g four times daily, or a fluoroquinolone ⁵ for 10-14 days.
Cystitis	<i>Escherichia coli</i> , <i>Klebsiella pneumoniae</i> ,proteus species, <i>Staphylococcus saprophyticus</i>	Fluoroquinolones, ⁴ nitrofurantoin.	TMP-SMZ, ¹ one double-strength tablet twice daily for 3 days; cephalexin, 0.5 g orally four times daily for 7 days.
Pyelonephritis	<i>E coli</i> , <i>K pneumoniae</i> ,proteus species, <i>S saprophyticus</i>	Fluoroquinolones. ⁴ for 7-14 days	TMP-SMZ, ¹ one double-strength tablet twice daily for 7-14 days
Gastroenteritis	Salmonella, shigella, campylobacter, <i>Entamoeba histolytica</i>	See Note 3.	
Urethritis, epididymitis	<i>Neisseria gonorrhoeae</i> , <i>Chlamydia trachomatis</i>	Cefixime, 400 mg orally once, or ciprofloxacin, 500 mg orally once, for <i>N gonorrhoeae</i> ; plus doxycycline, 100 mg twice daily for 10 days, or ofloxacin, 300 mg orally twice daily for 10 days.	Ceftriaxone, 250 mg IM once, for <i>N gonorrhoeae</i> ; plus doxycycline, 100 mg twice daily for 10 days, for <i>C trachomatis</i> .
Pelvic inflammatory disease	<i>N gonorrhoeae</i> , <i>C trachomatis</i> , anaerobes, gram-negative rods	Ofloxacin, 400 mg orally twice daily, for 14 days, plus metronidazole, 500 mg orally twice daily, for 14 days.	Cefoxitin, 2 g IM, with probenecid, 1 g orally, followed by doxycycline, 100 mg orally twice daily for 14 days; or ceftriaxone, 250 mg IM once, followed by doxycycline, 100 mg orally twice daily for 14 days.
Syphilis			
Early syphilis (primary, secondary, or latent of < 1 year's duration)	<i>Treponema pallidum</i>	Benzathine penicillin G, 2.4 million units IM once.	Doxycycline, 100 mg orally twice daily for 2 weeks.
Latent syphilis of > 1 year's duration or cardiovascular syphilis	<i>Treponema pallidum</i>	Benzathine penicillin G, 2.4 million units IM once a week for 3 weeks (total: 7.2 million units).	Doxycycline, 100 mg orally twice daily, for 4 weeks.
Neurosyphilis	<i>Treponema pallidum</i>	Aqueous penicillin G, 12-24 million units/d IV for 10-14 days.	Procaine penicillin G, 2-4 million units/d IM, plus probenecid, 500 mg orally four times daily, both for 10-14 days.

¹TMP-SMZ is a fixed combination of 1 part trimethoprim and 5 parts sulfamethoxazole. Single-strength tablets: 80 mg TMP, 400 mg SMZ; double-strength tablets: 160 mg TMP, 800 mg SMZ.

²Augmentin is a combination of amoxicillin, 250 mg, 500 mg, or 875 mg, plus 125 mg of clavulanic acid.

³The diagnosis should be confirmed by culture before therapy. Salmonella gastroenteritis does not require therapy. For sensitive shigella, give TMP-SMZ double-strength tablets twice daily for 5 days; or ampicillin, 0.5 g orally four times daily for 5 days; or ciprofloxacin, 0.5 g orally twice daily for 5 days. For campylobacter, give erythromycin, 0.5 g orally four times daily for 5 days; or ciprofloxacin, 0.5 g orally twice daily for 5 days. For *E histolytica*, give metronidazole, 750 mg orally three times daily for 5-10 days, followed by diiodohydroxyquin, 600 mg three times daily for 3 weeks.

⁴Fluoroquinolones and dosages include ciprofloxacin, 500 mg orally twice daily; ofloxacin, 400 mg orally twice daily; levofloxacin, 500 mg daily; and sparfloxacin, 500 mg as loading dose and then 200 mg once daily. For others see text.

⁵Fluoroquinolones with activity against *S pneumoniae*, including penicillin-resistant isolates, include levofloxacin (500 mg once daily), gatifloxacin (400 mg once daily), sparfloxacin (400 mg on day 1 and then 200 mg once daily), and moxifloxacin (400 mg once daily).

Table 37-4. Use of antimicrobials in patients with renal failure¹ and hepatic failure.

Drug	Principal Mode of Excretion or Detoxification	Approximate Half-Life in Serum		Proposed Dosage Regimen in End-Stage Renal Failure		Removal of Drug by Hemodialysis
		Normal	Renal Failure ²	Initial Dose ³	Maintenance Dose	
Acyclovir	Renal	2.5-3.5 hours	20 hours	2.5 mg/kg	2.5 mg/kg q24h	Yes
Ampicillin-sulbactam	Renal	0.5-1 hour	8-12 hours	3 g	1.5 g q8-12h	Yes
Amphotericin B	Unknown	360 hours	360 hours	No change	No change	No
Ampicillin	Tubular secretion	0.5-1 hour	8-12 hours	1 g	1 g q8-12h	Yes
Azithromycin	Renal 20%; hepatic 35%	3-4 hours	Not known	500 mg	250 mg q24h	No
Aztreonam	Renal	1.7 hours	6 hours	1-2 g	0.5-1 g q6-8h	Yes
Chloramphenicol	Mainly liver	3 hours	4 hours	0.5 g	0.5 g q6h	Yes
Clarithromycin	Renal 30%; hepatic > 50%	3-4 hours	15 hours	500 mg	250 mg q12h	No
Clindamycin	Liver	2-4 hours	2-4 hours	0.6 g IV	0.6 g q8h	No
Doxycycline	Renal	15-24 hours	15-24 hours	100 mg	100 mg q12h	No
Erythromycin	Mainly liver	1.5 hours	1.5 hours	0.5-1 g	0.5-1 g q6h	No
Famciclovir ⁵	Renal	2.5 hours	13-20 hours	500 mg	500 mg q24h	Yes
Fluconazole	Renal	30 hours	98 hours	0.2 g	0.1 g q24h	Yes
Flucytosine	Renal	3-6 hours	30-250 hours	37.5 mg/kg	25 mg/kg q24h	Yes
Foscarnet	Renal	3-8 hours	Not known	90-120 mg	Not known ⁶	No
Fosfomycin	Renal	6 hours	11-50 hours	NA	NA	NA
Ganciclovir ⁷	Renal	3 hours	11-28 hours	1.25 mg/kg	1.25 mg/kg q24h	Yes
Imipenem	Glomerular filtration	1 hour	3 hours	0.5 g	0.25-0.5 g q12h	Yes
Isoniazid	Renal	1-5 hours	2.5 hours	300 mg	300 mg q24h	Yes
Itraconazole	Hepatic	21 hours	25 hours	50-200 mg	50-200 mg q24h	No
Ketoconazole	Hepatic	8 hours	8 hours	200 mg	200-400 mg q24h	No
Meropenem	Renal	1 hour	5-10 hours	1 g	.5-1 g q24h	Yes
Metronidazole	Liver	6-10 hours	6-10 hours	0.5 g IV	0.5 g q8h	Yes
Mezlocillin	Renal 50-70%; biliary 20-30%	1 hour	3-6 hours	3 g	2 g q6-8h	Yes
Nafcillin	Liver 80%; kidney 20%	0.75 hours	1.5 hours	1.5 g	1.5 g q4h	No
Penicillin G	Tubular secretion	0.5 hours	7-10 hours	1-2 million units	1 million units q8h	Yes
Pentamidine	Not known	6-9 hours	6-9 hours	4 mg/kg	4 mg/kg q24h	No
Piperacillin and piperacillin + tazobactam	Renal 50-70%; biliary 20-30%	1 hour	3-6 hours	3 g	2 g q6-8h	Yes
Rifampin	Hepatic	2-3 hours	3-5 hours	600 mg	600 mg q24h	No
Ticarcillin	Tubular secretion	1.1 hour	15-20 hours	3 g	2 g q6-8h	Yes
Trimethoprim-sulfamethoxazole	Some liver	TMP 10-12 hours; SMZ 8-10 hours	TMP 24-48 hours; SMZ 18-24 hours	320 mg TMP + 1600 mg SMZ	80 mg TMP + 400 mg SMZ q 12 h	Yes
Trimetrexate	Hepatic	15 hours	Not known	45 mg/m ² 40 mg/m ² q24h	No	None
Vancomycin on serum levels ⁸	Glomerular filtration	6 hours	6-10 days	1 g	1 g q6-10d based on serum levels ⁸	No
Voriconazole	Hepatic	6-24 hours; dose-dependent	6-24 hours	200 mg orally; avoid IV in renal failure	200 mg orally twice daily; avoid IV in renal failure	No

¹For cephalosporins, see text and Table 37-7; for aminoglycosides, see Table 37-8.

²Considered here to be marked by creatinine clearance of 10 mL/min or less.

³For a 70-kg adult with a serious systemic infection.

⁴Dose adjustment in hepatic failure has not been studied, but because clearance of the drug is principally hepatic, dose reduction may be required.

⁵Pharmacokinetics and dosing are in reference to the active agent, penciclovir.

⁶When creatinine clearance is 30 mL/min, a dose of 60 mg/kg is given once daily. For clearances less than 30 mL/min, the dose has not been established.

⁷Oral ganciclovir is same as IV ganciclovir except that the initial dose is 1000 mg, maintenance dose is 500 mg daily, and dose after hemolysis is 500 mg.

⁸When serum levels reach 5-10 µg/mL, another dose should be given.

Table 37-5. Approximate costs of antimicrobials.

Drug	Dose per Day ¹	Cost per Unit ²	Daily Cost of Therapy ³
INTRAVENOUS PREPARATIONS			
Acyclovir	15 mg/kg (mucocutaneous herpes)	\$32.70/1 g	\$32.70
Acyclovir	30 mg/kg (CNS herpes)	\$32.70/1 g	\$65.40
Amikacin (Amikin, others)	15 mg/kg	\$18.70/0.5 g	\$37.40
Ampicillin	100 mg/kg	\$2.45/2 g	\$9.80
Ampicillin plus sulbactam (Unasyn)	3 g q8h	\$15.35/3 g (IV)	\$46.05
Aztreonam (Azactam)	50 mg/kg	\$18.90/1 g	\$75.60
Caspofungin (Cancuas)	50 mg	\$360.00	\$360.00
Cefazolin (Ancef, others)	50 mg/kg	\$2.00/1 g (IV)	\$6.00
Cefepime (Maxipime)	500 mg/kg	\$16.00/1 g	\$48.00
Cefoxitin (Mefoxin)	80 mg/kg	\$12.00/1 g	\$36.00
Ceftazidime (Fortaz, others)	50 mg/kg	\$14.25/1 g	\$42.75
Ceftizoxime (Cefizox)	50 mg/kg	\$11.40/1 g	\$34.20
Ceftriaxone (Rocephin)	30 mg/kg	\$50.25/1 g	\$50.25
Cefuroxime (Zinacef, others)	60 mg/kg	\$13.45/1.5 g	\$40.35
Ciprofloxacin (Cipro IV)	0.8 g	\$30.00/0.4 g	\$60.00
Clindamycin (Cleocin, others)	2400 mg	\$4.30/0.6 g	\$17.20
Fluconazole (Diflucan IV)	0.2-0.4 g	\$95.65/0.2 g \$139.80/0.4 g	\$95.65-139.80
Foscarnet (Foscavir)	180 mg/kg (induction) 90-120 mg/kg (maintenance)	\$76.60 (24 mg/mL × 250 mL = 6000 mg)	\$153.20 \$76.60-107.00
Ganciclovir (Cytovene IV)	10 mg/kg	\$37.10/0.5 g	\$74.20
Gatifloxacin (Tequin)	400 mg	\$38.20/400 mg	\$38.20
Gentamicin	5 mg/kg	\$2.50/80 mg	\$12.50
Imipenem (Primaxin IV)	50 mg/kg	\$31.45/0.5 g	\$125.80
Meropenem (Merrem IV)	500 mg/kg	\$27.40/0.5 g	\$82.20-109.60
Metronidazole (Flagyl, others)	1500 mg	\$15.35/0.5 g	\$46.05
Nafcillin	100 mg/kg	\$4.60/2 g	\$18.40
Penicillin	12 million units	\$0.60/1 million units	\$7.20
Piperacillin (Pipracil)	250 mg/kg	\$22.70/3 g	\$90.80
Piperacillin plus tazobactam (Zosyn)	3.75 g q6-8h	\$16.20/3.375 g	\$64.80
Ticarcillin (Ticar)	250 mg/kg	\$13.50/3 g	\$54.00
Ticarcillin-potassium clavulanic acid (Timentin)	3.1 g q6h	\$15.10/3.1 g	\$60.40
Tobramycin	5 mg/kg	\$3.80/80 mg	\$19.00
Trimethoprim-sulfamethoxazole (Bactrim, Septra)	15 mg/kg TMP	\$19.25 (0.48 g TMP in 30 mL)	\$38.50
Vancomycin	20-30 mg/kg	\$17.70/1 g	\$35.40
Voriconazole (VFend)	200 mg q12h	\$106.25	\$212.50
ORAL PREPARATIONS			
Acyclovir	1000 mg (therapy of herpes)	\$1.10/0.2 g	\$5.50
Acyclovir	800 mg three times daily (herpes suppression for immunocompromised patient)	\$4.20/0.8 g	\$12.60
Amoxicillin	20-30 mg/kg	\$0.43/0.5 g	\$1.00-2.50
Ampicillin	20-30 mg/kg	\$0.40/0.5 g	\$1.60
Augmentin (0.5 g amoxicillin plus 0.125 g clavulanic acid)	30 mg/kg	\$4.00/0.5 g	\$8.00
Azithromycin (Zithromax)	500 mg as loading dose, then 250 mg/d for 4 days	\$7.60/0.25 g	\$15.20 load, then \$7.60
Azithromycin (Zithromax)	1 g as single dose for <i>C trachomatis</i> infection	\$23.50/1 g packet	\$23.50/1 g packet
Cefaclor (Ceclor)	20-30 mg/kg	\$3.80/0.5 g	\$11.40
Cefditoren (Spectracef)	400 mg twice daily	\$1.57/200 mg	\$6.28
Cefpodoxime proxetil (Vantin)	400 mg	\$5.20/0.2 g	\$10.40
Cefprozil (0.5 g) (Cefzil)	15 mg/kg	\$8.25/0.5 g	\$16.50
Cefuroxime (0.5 g) (Ceftin)	0.5 g twice daily	\$9.40/0.5 g	\$18.80
Cephalexin (0.5 g) (Keflex, others)	30 mg/kg	\$1.40/0.5 g	\$5.60
Ciprofloxacin (0.5 g) (Cipro)	0.5-0.75 g twice daily	\$5.40/0.5 g	\$10.80
Ciprofloxacin (0.75 g) (Cipro)		\$5.60/0.75 g	\$11.20

38. Disorders Due to Physical Agents - *Richard Cohen, MD, MPH, & Brent R.W. Moelleken, MD, FACS*

■ DISORDERS DUE TO COLD

Cold tolerance varies considerably among individuals. Factors that increase the likelihood of injury from exposure to cold include poor general physical conditioning, nonacclimatization, advanced age, systemic illness, poor tissue oxygenation, wet or insufficient clothing, previous cold weather injury, and the use of alcohol or other sedative drugs. High wind velocity ("windchill factor") increases the severity of cold injury at low temperatures.

Cold Urticaria

Some persons have a familial or acquired hypersensitivity to cold and may develop urticaria upon even limited exposure to a cold (eg, wind, freezer compartments). The urticaria usually occurs only on exposed areas, but in markedly sensitive individuals the response can be generalized and fatal. Immersion in cold water may result in severe systemic reactions, including shock; histamine release occurs. Familial cold urticaria is an autosomal dominant inflammatory disorder, manifested as a burning sensation of the skin occurring about 30 minutes after exposure to cold. Acquired cold urticaria may be associated with medication (eg, griseofulvin) or with infection. Cold urticaria may occur secondarily to cryoglobulinemia or as a complication of syphilis. Most cases of acquired cold urticaria are idiopathic. For diagnosis, an ice cube is usually applied to the skin of the forearm for 4-5 minutes, then removed, and the area is observed for 10 minutes. As the skin rewarms, an urticarial wheal appears at the site and may be accompanied by itching. Cyproheptadine, 16-32 mg/d in divided doses, is the drug of choice for cold urticaria. As an alternative, a combination of terbutaline, 5 mg three times daily, and aminophylline, 150 mg three times daily, has been recommended.

Raynaud's Phenomenon

See [Chapter 12](#).

ACCIDENTAL SYSTEMIC HYPOTHERMIA

Systemic hypothermia may result from exposure (atmospheric or immersion) to prolonged or extreme cold. The condition may arise in healthy individuals in the course of occupational or recreational exposure or in victims of accidents.

Systemic hypothermia may follow exposure to cool but not cold temperatures when there is altered homeostasis due to debility or disease. In colder climates, elderly and inactive individuals living in inadequately heated housing are particularly susceptible. Patients with cardiovascular or cerebrovascular disease, mental retardation, acute alcoholism, malnutrition, myxedema, hypopituitarism, or use of sedating or tranquilizing drugs are more vulnerable to accidental hypothermia. Prolonged postoperative hypothermia or administration of large amounts of refrigerated stored blood (without rewarming) can cause systemic hypothermia.

Pathogenesis

Systemic hypothermia is a reduction of core (rectal) body temperature below 35 °C. It causes reduced physiologic function—with decreased oxygen consumption and slowed myocardial repolarization, peripheral nerve conduction, gastrointestinal motility, and respirations—as well as hemoconcentration and pancreatitis. Defenses against cold exposure are superficial blood vessel constriction and increased metabolic heat production.

Clinical Findings

Early manifestations of hypothermia include weakness, drowsiness, lethargy, irritability, confusion, shivering, and impaired coordination. A lowered body temperature may be the sole finding; the skin may appear blue or puffy.

The internal (core) body temperature in accidental hypothermia may range from 25 to 35 °C. Oral temperatures are inaccurate; an esophageal or rectal probe that reads as low as 25 °C is required. At core temperatures below 35 °C, the patient may become delirious, drowsy, or comatose and may stop breathing. The pulse and blood pressure may be unobtainable, leading clinicians to believe the patient is dead. Metabolic acidosis, hyperkalemia, pneumonia, pancreatitis, ventricular fibrillation, hypoglycemia or hyperglycemia, coagulopathy, and renal failure may occur. Atrial and ventricular dysrhythmias; prolongation of the PR, QRS, and QT intervals; and the J wave (positive deflection in the terminal portion of the QRS complex, most notable in leads II, V₅, and V₆) are directly related to the lowering of core temperature; cardiac arrhythmias may occur, especially during the rewarming process. Progression of electrocardiographic abnormalities can also occur, including the pathognomonic J wave of Osborn—prominent in lead II ([Figure 38-1](#)). Death in systemic hypothermia usually results from cardiac asystole or ventricular fibrillation.

Treatment ([Figure 38-2](#))

Patients with mild hypothermia (rectal temperature > 33 °C) who have been otherwise healthy usually respond well to a warm bed or to rapid passive rewarming with a warm bath or warm packs and blankets. A conservative approach is also usually employed in treating elderly or debilitated patients, using an electric blanket kept at 37 °C. Gentle handling and movement of the patient are essential to avoid triggering arrhythmias.

Patients with moderate or severe hypothermia (core temperatures of < 33 °C) do not have the thermoregulatory shivering mechanism and require active rewarming with supportive care. Cardiovascular support, acid-base balance, arterial oxygenation, and adequate intravascular volume should be established prior to rewarming to minimize the risk of organ infarction and "afterdrop" (recurrent hypothermia). The methods and rate of active rewarming are controversial. Successful treatment usually includes a combination of active external and internal methods (see below). Aggressive rewarming should be attempted only by those experienced in the methods. *Once begun, CPR should be continued until the patient has been rewarmed to at least 32 °C.* The need for oxygen therapy, endotracheal intubation, controlled ventilation, warmed intravenous fluids, and treatment of metabolic acidosis should be dictated by clinical and laboratory monitoring during the rapid rewarming process. Essential laboratory tests include complete blood count, prothrombin time, partial thromboplastin time, electrolytes, blood urea nitrogen, serum creatinine, liver function tests, amylase, glucose, pH, blood gases, urinalysis, and urine volume. Cardiac rhythm should be monitored, and cardiac, central vascular, or chest trauma or stimulation (catheter, cannulas, etc) should be avoided unless essential because of the risk of inducing ventricular fibrillation. However, patients who are comatose or in respiratory failure should be tracheally intubated. The patient should be evaluated for trauma and peripheral cold injury (eg, frostbite). Antibiotics are not routinely given and should be used only if indicated (neonate, elderly, or immunocompromised patient). Core temperature (esophageal preferred over rectal) should be monitored frequently during and after initial rewarming because of reports of recurrent hypothermia.

A. Active External Rewarming Methods

Heated blankets, forced hot air, radiant heat cradles, or warm baths may be used for active external rewarming. Rewarming by a warm bath is best done in a tub of moving water at 40-42 °C, with a rate of rewarming of about 1-2 °C/h. It is easier, however, to monitor the patient and to perform diagnostic and therapeutic procedures when heated blankets are used for active rewarming. Although relatively simple and generally available, active external warming methods may cause marked peripheral dilation that predisposes to ventricular fibrillation and hypovolemic shock and should be accompanied by core rewarming in moderate to severe hypothermia.

Forced air rewarming (38-43 °C) is recommended for clinic or field use when extracorporeal blood rewarming is not available.

B. Active Internal (Core) Rewarming Methods

Internal rewarming is essential for patients with severe hypothermia; extracorporeal blood rewarming (cardiopulmonary, venovenous, or femorofemoral bypass) is the treatment of choice, especially in the presence of cardiac arrest. In the absence of equipment necessary for extracorporeal rewarming, left-sided thoracotomy followed by pericardial cavity irrigation with warmed saline and cardiac massage has been effective in systemic hypothermia < 28 °C. Repeated peritoneal dialysis may be employed with 2 L of warm (43 °C) potassium-free dialysate solution exchanged at intervals of 10-12 minutes until the core temperature is raised to about 35 °C. Parenteral fluids (D₅ normal saline) should be warmed to 43 °C prior to administration. Heated, humidified air warmed to 42 °C through a face mask or endotracheal tube may be administered. Warm colonic and gastrointestinal irrigations are of less value.

Prognosis

With proper early care, more than 75% of otherwise healthy patients may survive moderate or severe systemic hypothermia. Prognosis is directly related to the severity of metabolic acidosis; if the pH is 6.6 or less, the prognosis is poor. The risk of aspiration pneumonia is great in comatose patients. The prognosis is grave if there are underlying predisposing causes or if treatment is delayed.

HYPOTHERMIA OF THE EXTREMITIES

Exposure of the extremities to cold produces immediate localized vasoconstriction followed by generalized vasoconstriction. When the skin temperature falls to 25 °C,

tissue metabolism is slowed, but the demand for oxygen is greater than the slowed circulation can supply, and the area becomes cyanotic. At 15 °C, tissue metabolism is markedly decreased and the dissociation of oxyhemoglobin is reduced; this gives a deceptive pink, well-oxygenated appearance to the skin. Tissue damage occurs at this temperature. Tissue death may be caused by ischemia and thromboses in the smaller vessels or by actual freezing. Freezing (frostbite) does not occur until the skin temperature drops to -4 to -10 °C or even lower, depending on such factors as wind, mobility, venous stasis, malnutrition, and occlusive arterial disease. Neuropathic sequelae such as pain, numbness, tingling, hyperhidrosis, cold sensitivity of the extremities, and nerve conduction abnormalities may persist for many years after the cold injury.

Prevention

"Keep warm, keep moving, and keep dry." Individuals should wear warm, dry clothing, preferably several layers, with a windproof outer garment. Wet clothing, socks, and shoes should be replaced with dry ones. Extra socks, mittens, and insoles should always be carried in a pack in cold or icy areas. Cramped positions, constricting clothing, and prolonged dependency of the feet are to be avoided. Arms, legs, fingers, and toes should be exercised to maintain circulation. Wet and muddy ground and exposure to wind should be avoided. Tobacco and alcohol should be avoided when the danger of frostbite is present.

CHILBLAIN (ERYTHEMA PERNIO)

Chilblains are red, itching skin lesions, usually on the extremities, caused by exposure to cold without actual freezing of the tissues. They may be associated with edema or blistering and are aggravated by warmth. With continued exposure, ulcerative or hemorrhagic lesions may appear and progress to scarring, fibrosis, and atrophy. Chilblain lupus erythematosus, while clinically similar to ordinary chilblain, can be differentiated by an association with other lupus manifestations or by biopsy.

Treatment consists of elevating the affected part slightly and allowing it to warm gradually at room temperature. Do not rub or massage injured tissues or apply ice or heat. Protect the area from trauma and secondary infection. Prazosin, 1 mg daily, has been recommended for treatment and prevention of recurrence.

FROSTBITE

Frostbite is injury due to freezing and formation of ice crystals within tissues. In mild cases, only the skin and subcutaneous tissues are involved; the symptoms are numbness, prickling, and itching. With increasing severity, deep frostbite involves deeper structures, and there may be paresthesia and stiffness. Thawing causes tenderness and burning pain. The skin is white or yellow, loses its elasticity, and becomes immobile. Edema, blisters, necrosis, and gangrene may appear. MRI with magnetic resonance angiography and triple-phase bone scanning have been used to assess the degree of involvement in severe frostbite and to distinguish viable from nonviable tissue.

Treatment

A. Immediate Treatment

Treat the patient for associated systemic hypothermia.

1. Rewarming—Superficial frostbite (frostnip) of extremities in the field can be treated by firm steady pressure with the warm hand (without rubbing), by placing fingers in the armpits, and, in the case of the toes or heels, by removing footwear, drying feet, rewarming, and covering with adequate dry socks or other protective footwear.

For deep frostbite, rapid thawing at temperatures slightly above body heat may significantly decrease tissue necrosis. If there is any possibility of refreezing, the frostbitten part should not be thawed, even if this might mean prolonged walking on frozen feet. Refreezing results in increased tissue necrosis. Rewarming is best accomplished by immersing the frozen extremity for several minutes in a moving water bath heated to 40-42 °C until the distal tip of the part being thawed flushes. Water in this temperature range feels warm but not hot to the normal hand. Dry heat (eg, stove or open fire) is more difficult to regulate and is not recommended. After thawing has occurred and the part has returned to normal temperature (usually in about 30 minutes), discontinue external heat. Victims and rescue workers should be cautioned not to attempt rewarming by exercise or thawing of frozen tissues by rubbing with snow or ice water.

2. Protection of the part—Pressure or friction is avoided and physical therapy contraindicated in the early stage. The patient is kept at bed rest with the affected parts elevated and uncovered at room temperature. Casts, dressings, or bandages are not applied. A combination of ibuprofen, 200 mg four times daily, and aloe vera has been used to prevent dermal ischemia.

3. Anti-infective measures—Consider tetanus prophylaxis; frostbite increases susceptibility. Protect skin blebs from physical contact. Local infections may be treated with mild soaks of soapy water or povidone-iodine. Whirlpool therapy at 37-40 °C twice daily for 15-20 minutes for a period of 3 or more weeks helps cleanse the skin and debrides superficial sloughing tissue. Antibiotics may be required for deep infections.

4. Other therapy—Other treatments used with varying results include platelet aggregation inhibition, hemodilution, peripheral vasodilation, fibrinolysis, and hyperbaric oxygen.

B. Follow-Up Care

Gentle, progressive physical therapy to promote circulation should be instituted as tolerated.

C. Surgery

Early regional sympathetic blockade can reduce symptoms; sympathectomy (within 36-72 hours) is controversial. In general, other operative procedures are to be avoided. *Amputation should not be considered until it is definitely established that the tissues are dead.* Tissue necrosis (even with black eschar formation) may be quite superficial, and *the underlying skin may sometimes heal spontaneously even after a period of months.*

Prognosis

Recovery from frostbite is most often complete, but there may be increased susceptibility to discomfort in the involved extremity upon reexposure to cold.

IMMERSION SYNDROME (IMMERSION FOOT OR TRENCH FOOT)

Immersion foot (or hand) is caused by prolonged immersion in cool or cold water or mud, usually less than 10 °C. The affected parts are first cold and anesthetic (prehyperemic stage). They become hot with intense burning and shooting pains during the hyperemic stage and pale or cyanotic with diminished pulsations during the vasospastic period (posthyperemic stage); blistering, swelling, redness, heat, ecchymoses, hemorrhage, necrosis, peripheral nerve injury, or gangrene and secondary complications such as lymphangitis, cellulitis, and thrombophlebitis can occur later.

Treatment is best instituted during the stage of reactive hyperemia. Treatment consists of air drying, protecting the extremities from trauma and secondary infection, and gradual rewarming by exposure to air at room temperature (not ice or heat) without massaging or moistening the skin or immersing it in water. Bed rest is required until all ulcers have healed. Affected parts are elevated to aid in removal of edema fluid, and pressure sites (eg, heels) are protected with pillows. Later treatment is as for Buerger's disease (see [Chapter 12](#)).

■ DISORDERS DUE TO HEAT

Four medical disorders (listed here in order of increasing severity) comprise a spectrum of illness that can result from excessive exposure to hot environments: heat syncope, heat cramps, heat exhaustion, and heat stroke. A stable internal temperature requires a balance between heat production and heat loss, which the hypothalamus regulates by initiating changes in muscle tone, vascular tone, and sweat gland function.

Etiology

Conduction (convection)—the direct transfer of heat from the skin to the surrounding air—occurs with diminishing efficiency as ambient temperature rises. The passive transfer of heat from a warmer to a cooler object by radiation accounts for 65% of body heat loss under normal conditions. Radiant heat loss decreases as the temperature of the surrounding environment increases up to 37.2 °C, the point at which heat transfer reverses direction. At normal temperatures, evaporation accounts for approximately 20% of the body's heat loss, but at high temperatures it becomes the major mechanism for dissipation of heat; with vigorous exertion, sweat loss can be as much as 2.5 L/h. This mechanism diminishes as humidity rises.

Health conditions that inhibit sweat production or evaporation and increase susceptibility to heat disorders include obesity, skin disorders (miliaria), reduced cutaneous blood flow, dehydration, malnutrition, hypotension, and reduced cardiac output. Medications that impair sweating include anticholinergics, antihistamines, phenothiazines, tricyclic antidepressants, monoamine oxidase inhibitors, and diuretics; reduced cutaneous blood flow results from use of vasoconstrictors and β -adrenergic blocking agents; and dehydration results from use of alcohol. Illicit drugs—eg, phencyclidine, LSD, amphetamines, and cocaine—can cause increased muscle activity and thus generate increased body heat. Drug withdrawal syndromes or prolonged seizures may have the same effect.

The risk of heat disorder increases with age, impaired cognition, concurrent illness, reduced physical fitness, and insufficient acclimatization.

Prevention

Medical evaluation and monitoring should be used to identify individuals at increased risk of heat disorders. The public should be made aware of the early symptoms and signs of heat disorders. It is not recommended to make salt tablets available for use without medical supervision; close monitoring of fluid and electrolyte intake may be necessary in situations necessitating activity in hot environments. Athletic events should be organized and managed with attention to thermoregulation: the WBGT (wet bulb globe temperature) index should be monitored, fluid consumption should be encouraged, and medical support should be immediately accessible. Competition is not recommended when the WBGT exceeds 28 °C. Workers should not begin work in hot temperatures without proper acclimatization and should be encouraged to drink water or balanced electrolyte fluids frequently.

Protective cooled suits have been used successfully in industry for prolonged work in environments up to 60 °C.

Acclimatization is achieved by scheduled regulated exposure to hot environments and by gradually increasing the duration of exposure and the work load until the body adjusts by producing sweat of lower salt content in greater amounts at lower ambient temperatures. Acclimatization is accompanied by increased plasma volume, cardiac output, and cardiac stroke volume and a slower heart rate.

SPECIFIC SYNDROMES DUE TO HEAT EXPOSURE

1. Heat Syncope

Sudden unconsciousness can result from cutaneous vasodilation with consequent systemic and cerebral hypotension. Systolic blood pressure is usually less than 100 mm Hg, and there is typically a history of vigorous physical activity for 2 hours or more just preceding the episode. The skin is typically cool and moist, and the pulse is weak.

Treatment consists of rest and recumbency in a cool place, with fluids by mouth (or intravenously if necessary).

2. Heat Cramps

Fluid and electrolyte depletion can result in slow, painful skeletal muscle contractions ("cramps") and severe muscle spasms lasting 1-3 minutes, usually of the muscles most heavily used. Cramping results from salt depletion as sweat losses are replaced with water alone. The skin is moist and cool, and the muscles are tender. There may be muscle twitching. The victim is alert, with stable vital signs, but may be agitated and complaining of pain. The body temperature may be normal or slightly increased. Involved muscle groups are hard and lumpy. There is almost always a history of vigorous activity just preceding the onset of symptoms. Laboratory evaluation may show low serum sodium, hemoconcentration, and elevated urea and creatinine.

The patient should be moved to a cool environment and given oral saline solution (4 tsp of salt per gallon of water) to replace both salt and water. *Because of their slower absorption, salt tablets are not recommended.* The victim may have to rest for 1-3 days with continued dietary salt supplementation before returning to work or resuming strenuous activity in the heat.

3. Heat Exhaustion

Heat exhaustion results from prolonged strenuous activity with inadequate salt intake in a hot environment and is characterized by dehydration, sodium depletion, or isotonic fluid loss with accompanying cardiovascular changes.

The diagnosis is based on prolonged symptoms and a rectal temperature over 37.8 °C, increased pulse (> 150% of the patient's normal) and moist skin. Symptoms associated with heat syncope and heat cramps may be present. The patient may be quite thirsty and weak, with central nervous system symptoms such as headache, fatigue, and, in cases due chiefly to water depletion, anxiety, paresthesias, impaired judgment, hysteria, and occasionally psychosis. Hyperventilation secondary to heat exhaustion can lead to respiratory alkalosis. Heat exhaustion may progress to heat stroke if sweating ceases.

Treatment consists of patient location in a shaded, cool environment, providing adequate hydration (1-2 L over 2-4 hours), salt replenishment—orally, if possible—and active cooling (fans, ice packs, etc) if necessary. Physiologic saline or isotonic glucose solution should be administered intravenously when oral administration is not appropriate. Intravenous 3% (hypertonic) saline may be necessary if sodium depletion is severe. At least 24 hours of rest is recommended.

4. Heat Stroke

Heat stroke is a life-threatening medical emergency resulting from failure of the thermoregulatory mechanism. Heat stroke is imminent when the core (rectal) temperature approaches 41 °C. It presents in one of two forms: Classic heat stroke occurs in patients with compromised homeostatic mechanisms; exertional heat stroke occurs in healthy persons undergoing strenuous exertion in a thermally stressful environment. Morbidity or even death can result from cerebral, cardiovascular, hepatic, or renal damage.

The hallmarks of heat stroke are cerebral dysfunction with impaired consciousness, high fever, and absence of sweating. Persons at greatest risk are the very young, the elderly (age > 65), chronically infirm, and patients receiving medications (eg, anticholinergics, antihistamines, phenothiazines) that interfere with heat-dissipating mechanisms.

Exertional heat stroke and exertion-related disorders such as rhabdomyolysis are appearing more frequently as complications of participation by unconditioned amateurs in strenuous athletic activities such as marathon and triathlon competition.

Clinical Findings

A. Symptoms and Signs

Heat stroke may present with dizziness, weakness, emotional lability, nausea and vomiting, diarrhea, confusion, delirium, blurred vision, convulsions, collapse, and unconsciousness. The skin is hot and initially covered with perspiration. Later it dries. The pulse is strong initially. Blood pressure may be slightly elevated at first, but hypotension develops later. The core temperature is usually over 41 °C. Hyperventilation can occur, leading to respiratory alkalosis.

Exertional heat stroke may present with sudden collapse and loss of consciousness followed by irrational behavior. Anhidrosis may not be present. Twenty-five percent of heat stroke victims have prodromal symptoms for minutes to hours that may include dizziness, weakness, nausea, confusion, disorientation, drowsiness, and irrational behavior.

B. Laboratory Findings

Laboratory evaluation may reveal dehydration, leukocytosis, elevated BUN, hyperuricemia, hemoconcentration, acid-base abnormalities (eg, lactic acidosis), and decreased serum potassium, sodium, calcium, and phosphorus; urine is concentrated, with elevated protein, tubular casts, and myoglobinuria. Thrombocytopenia, increased bleeding and clotting times, fibrinolysis, and coagulopathy (DIC) may occur. Rhabdomyolysis and myocardial, hepatic, or renal damage may be identified by elevated serum creatine kinase and aminotransferase levels and BUN and by the presence of anuria, proteinuria, and hematuria. Electrocardiographic findings may include ST-T changes consistent with myocardial ischemia.

Treatment

Treatment is aimed at reducing the core temperature rapidly (within 1 hour) and controlling the secondary effects. Evaporative cooling is rapid and effective and is

easily performed in most emergency settings. The patient's clothing should be removed and the entire body sprayed with water (15 °C) while cooled or ambient air is passed across the patient's body with large fans or other means at high velocity (100 ft/min). The patient should be in the lateral recumbent position or supported in a hands-and-knees position to expose as much skin surface as possible to the air. Other alternatives include use of cold wet sheets accompanied by fanning or immersion in chilled water. Cardiopulmonary bypass provides rapid cooling but is often not practical.

Immersion in an ice-water bath as initial treatment is no longer preferred because of its patient access limitations and potential for complications of hypotension and shivering. However, it should be considered if core temperature is not decreased rapidly in response to other treatment. Alternatives include hand and forearm immersion in cold water, ice packs (groin, axillas, neck), and iced gastric lavage, though these are much less effective than evaporative cooling.

Treatment should be continued until the rectal temperature drops to 39 °C. The temperature remains stable in most cases, but it should continue to be monitored for 24 hours. Chlorpromazine (25-50 mg intravenously) or diazepam (5-10 mg intravenously) can be given initially and then every 4 hours to control shivering. Antipyretics (aspirin, acetaminophen) have no effect on environmentally induced hyperthermia and are contraindicated.

Hypovolemic and cardiogenic shock must be carefully distinguished, as either or both may occur. Central venous or pulmonary artery wedge pressure should be monitored. Five percent dextrose in half-normal or normal saline should be administered for fluid replacement.

The patient should also be observed for renal failure due to rhabdomyolysis, hypokalemia, cardiac arrhythmias, disseminated intravascular coagulation, and hepatic failure. Hypokalemia frequently accompanies heat stroke but may not appear until rehydration. Maintenance of extracellular hydration and electrolyte balance should reduce the risk of renal failure due to rhabdomyolysis. Fluid administration to ensure a high urine output (> 50 mL/h), mannitol administration (0.25 mg/kg), and alkalinizing the urine (intravenous bicarbonate administration, 250 mL of 4%) are recommended. Fluid output should be monitored through the use of an indwelling urinary catheter.

Because sensitivity to high environmental temperature may persist for prolonged periods following an episode of heat stroke, immediate reexposure should be avoided.

■ BURNS

The incidence and severity of burn injuries has been declining, with both deaths and acute hospitalizations attributable to burns down about 50%. Over three-fourths of burns involve less than 10% of total body surface area. Aggressive, early excision (24-72 hours postburn) of deeply burned tissues and skin grafting, early enteral feeding—and improved infection control—have contributed to significantly lower mortality rates and shorter hospitalizations. Nonetheless, an estimated 1.25 million burn injuries and 51,000 acute hospitalizations of burn victims occur each year in the United States. Severe burns cause problems in the initial phase from hemodynamic compromise, related injuries such as smoke inhalation or fractures, and associated multiorgan failure and sepsis. Later, secondary scarring and constrictive wounds occur.

Significant quality of life and social functionality can be expected even for severely burned patients.

CLASSIFICATION

Burns are classified by extent, depth, patient age, and associated illness or injury.

Extent

The "rule of nines" ([Figure 38-3](#)) is useful for rapidly assessing the extent of a burn. More detailed charts based on age are available when the patient reaches the burn unit. Therefore, it is important to view the entire patient after cleaning soot to make an accurate assessment, both initially and on subsequent examinations. Only second- and third-degree burns are included in calculating the total burn surface area (TBSA), since first-degree burns usually do not represent significant injury in terms of prognosis or fluid and electrolyte management. However, first- or second-degree burns may convert to deeper burns, especially if treatment is delayed or bacterial colonization or superinfection occurs.

Depth

Judgment of depth of injury is difficult. The **first-degree burn** may be red or gray but will demonstrate excellent capillary refill. First-degree burns are not blistered initially. If the wound is blistered, this represents a partial-thickness injury to the dermis, or a **second-degree burn**. As the degree of burn is progressively deeper, there is a progressive loss of adnexal structures. Hairs can be easily extracted or are absent, sweat glands become less visible, and the skin appears smoother.

The distinction between second- and third-degree burns is unclear and in a sense artificial. Deep second-degree burns are generally treated as full-thickness (third-degree) burns and excised and grafted earlier because of the long time necessary for reepithelialization and the thin, poor quality of the resultant skin. More accurate depth measurement is possible with immunohistochemical analysis.

Survival After Burn Injury

The survival from major burn injury has dramatically increased in the last 20 years. Consistently, the three major risk factors for mortality were age greater than 60 years, burn area greater than 40% of total body surface area, and inhalation injury. The most accurate rule of thumb for predicting mortality after severe burn injury is still the Baux Score (age + percent burn, eg, age 50 years + 20% burn = 70% mortality), though this is obviously quite variable depending on associated medical factors. Another study indicates that burn size, age, and male sex as well as duration of stay in the ICU and the presence of mechanical ventilation presage a poorer outcome. Likewise, a base deficit during resuscitation of greater than -6 mmol/L predicts a far higher incidence of multiple organ dysfunction and death.

Associated Injuries or Illnesses

An injury commonly associated with burns is smoke inhalation (see [Chapter 9](#)). Suspicion of inhalation injury is aroused when the nasal hairs are singed, the mechanism of burn involves closed spaces, the sputum is carbonaceous, or the carboxyhemoglobin level exceeds 5% in nonsmokers. This suspicion should lead the clinician to institute early intubation before airway edema supervenes. The products of combustion, not heat, are responsible for lower airway injury. Electrical injury that causes burns may also produce cardiac arrhythmias that require immediate attention. Pancreatitis occurs in severe burns. Development of hyperamylasemia or hyperlipasemia may signal the development of pancreatic inflammation and subsequent pseudocyst or abscess formation. Prior alcohol exposure may exacerbate the pulmonary components of burn injury.

Toxic epidermal necrolysis (TEN) occasionally occurs following sulfonamide or phenytoin administration (see [Chapter 6](#)). If TEN is severe, patients are best transferred to a burn unit and treated as having severe burn injury. Corticosteroid therapy should be avoided.

SYSTEMIC REACTIONS TO BURN INJURY

The actual burn injury is only the incipient event in a cascade of deleterious local tissue and systemic inflammatory reactions leading to multiorgan system failure in the severely burned patient. Locally, substance P, serotonin, prostaglandins E₂ and F_{2a}, histamine, platelet-activating factor, nitric oxide, bradykinin, and leukotrienes B₄ and D₄ play a role in the increased local capillary permeability and initiation of the systemic inflammatory cascade. Systemically, levels of interleukin-2, -4, -6, and interferon-gamma (IFN- γ) are elevated in proportion to the severity of the burn injury, perhaps as part of a generalized systemic release of inflammatory mediators and generalized macrophage dysfunction. There is often an altered CD4/ CD8 (T helper/T suppressor) cell ratio. In addition, in the first 24 hours following a significant burn, there is production of tumor necrosis factor (TNF) and IFN- γ , which in turn stimulate production of the enzyme nitric oxide synthetase in hepatocytes. After 24 hours, lipopolysaccharide (LPS) plays a dominant role in its production. Nitric oxide has been proposed as a mediator of the acute inflammation. Transforming growth factor beta and IL-10 and a markedly elevated level of IL-6 serve as harbingers of a declining clinical course in severely burned patients.

INITIAL MANAGEMENT

Airway

The physician or emergency medical technician should proceed as with any other trauma using standard Advanced Trauma Life Support (ATLS) guidelines. The priorities are first to establish an airway, recognizing the frequent necessity to intubate a patient who may appear to be breathing normally but who has sustained an inhalation injury; next, to evaluate the cervical spine and head injuries; and finally, to stabilize fractures. Fluid resuscitation by the Parkland formula (see below) may be

instituted simultaneously with initial resuscitation. Endotracheal intubation should be considered for major burn cases regardless of the area of the body involved, because as fluid resuscitation proceeds generalized edema develops, including edema of the soft tissues of the upper airway and perhaps the lungs as well. Chest radiographs are typically normal initially but may develop an acute respiratory distress syndrome picture in 24-48 hours with severe inhalation injury. Supplemental oxygen should be administered. Inhalation injuries should be followed by serial blood gas determination and bronchoscopy. The use of corticosteroids is contraindicated because of the potential for immunosuppression.

Vascular Access

All clothing and jewelry should be removed and an expedient physical examination performed to assess the extent of burn and associated injuries. Simultaneously with the above procedures, venous access must be sought, since the victim of a major burn may develop hypovolemic shock. A percutaneous large-bore (14- or 16-gauge) intravenous line through nonburned skin is preferred. Subclavian lines are avoided in the emergency setting because of the risk of pneumothorax and subclavian vein laceration when such a line is placed in a volume-depleted patient. Femoral lines provide good temporary access during resuscitation. *All lines—without exception—placed in the emergency department should be changed within 24 hours because of the high risk of nonsterile placement.* Distal saphenous cutdown is occasionally necessary. An arterial line is useful for monitoring mean arterial pressure and drawing blood.

FLUID RESUSCITATION

Crystalloids

Generalized capillary leak results from burn injury over more than 25% of total body surface area. This often necessitates replacement of a large volume of fluid.

There are many guidelines for fluid resuscitation. The **Parkland formula** relies upon the use of lactated Ringer's injection. The fluid requirement in the first 24 hours is estimated as 4 mL/kg body weight per percent of body surface area burned. Deep electrical burns and inhalation injury increase the fluid requirement. Adequacy of resuscitation is determined by clinical parameters, including urine output and specific gravity, blood pressure, and central venous catheter or, if necessary, Swan-Ganz catheter readings.

Half the calculated fluid is given in the first 8-hour period. The remaining fluid, divided into two equal parts, is delivered over the next 16 hours. An extremely large volume of fluid may be required. For example, an injury over 40% of the total body surface area in a 70-kg victim may require 13 L *in the first 24 hours*. The first 8-hour period is measured from the hour of injury.

Beta Blockade

Routine beta blockade (propranolol, adjusting dose to decrease resting heart rate by 20%, for up to 4 weeks) may reverse some of the catecholamine-mediated hypermetabolic response after severe burns.

Colloids

Overly aggressive crystalloid administration must be avoided in patients with pulmonary injury, since significant pulmonary edema can develop in patients with normal pulmonary capillary wedge and central venous pressures. In addition, routine colloid administration, commonplace 10 years ago, must now be considered suspect in routine burn resuscitation in view of its deleterious effect on glomerular filtration and its association with pulmonary edema.

Monitoring Fluid Resuscitation

A Foley catheter is essential for monitoring urinary output. Diuretics have no role in this phase of patient management unless fluid overload has occurred or mannitol diuresis is performed in the case of rhabdomyolysis.

Abdominal Compartment Syndrome

Abdominal compartment syndrome is emerging as a complication in severely burned patients. Increased intra-abdominal pressures can cause excessively high peak inspiratory pressures and increase fluid requirements considerably. Only 40% of patients with this severe form of increased intra-abdominal pressure survive. Bladder pressures over 30 mm Hg establish the diagnosis in at-risk patients. Surgical abdominal decompression may be indicated.

Escharotomy

As edema fluid accumulates, ischemia may develop under any constricting eschar of an extremity, neck, or trunk if the full-thickness burn is circumferential. Escharotomy incisions through the anesthetic eschar can save life and limb and can be performed in the emergency department or operating room.

Fasciotomy in Electrical Burns & Associated Crush Injuries

When high-voltage electrical injury occurs, extensive deep tissue necrosis is almost invariably present. Deep tissue necrosis leads to profound tissue swelling. Because deep tissue compartments in the arms and legs are contained by unyielding fascia, these compartments must be opened by surgical fasciotomy to prevent further soft tissue, vascular, and nerve death.

Electrical burn injuries remain the most devastating and underrecognized burn injuries, causing amputations (often because of unrecognized compartment syndromes) and acute renal failure, resulting in part from rhabdomyolysis. Prompt recognition of the severity of electrical burns, with early fasciotomy and debridement, may reduce the incidence of such complications.

THE BURN WOUND

Treatment of the burn wound is based on several principles: (1) Protection from desiccation and further injury of those burned areas that will spontaneously reepithelialize in 7-10 days by application of topical antibiotic such as silver sulfadiazine or mafenide acetate. Silver sulfadiazine is currently the most popular topical agent. It is painless, easy to apply, and effective against most strains of pseudomonas. (2) Regular and thorough cleansing of burned areas is a critically important intervention in burn units. Early excision and grafting of burned areas as soon as 24 hours after burn injury or when the patient will hemodynamically tolerate the excision and grafting procedure. The tumescent technique (injection under the burn scar of dilute epinephrine and lidocaine prior to surgery) may reduce blood loss, though lidocaine toxicity must be considered.

Systemic infection remains a leading cause of morbidity among patients with major burn injuries, with nearly all severely burned patients having one or more septicemic episodes during the hospital course. Methicillin-resistant *Staphylococcus aureus*, pseudomonas species, klebsiella species, proteus species, methicillin-resistant *S epidermidis*, and acinetobacter are commonly cultured microorganisms. Methicillin-resistant *S epidermidis*, *Pseudomonas aeruginosa*, and acinetobacter infections are more likely to occur in more severely burned patients. Typically, gram-positive organisms predominate early in the clinical course, followed later by gram-negative organisms. Continuous microbiologic surveillance is necessary. There is an increasing trend toward use of prophylactic antibiotics in burn patients. Prophylactic administration of trimethoprim-sulfamethoxazole may help to prevent methicillin-resistant *S aureus* infection in ventilator-dependent burn patients. Systemic infections are manifestations of a globally suppressed immune system. Nitric oxide has been implicated in the depressed lymphoproliferative state in experimental animals. Increasingly, sterile multiple organ failure is regarded as a leading cause of death among severely burned patients.

Wound Closure

The goal of therapy after fluid resuscitation is closure of the wound. Nature's own blister is the best cover to protect wounds that spontaneously epithelialize in 7-10 days (ie, superficial second-degree burns). Where the blister has been disrupted, silver sulfadiazine or skin substitutes can be used. In patients with scald burns, cadaver homografts can also be used.

Wounds that will not heal spontaneously in 7-10 days (ie, deep second-degree or third-degree burns) are best treated by excision and autograft; otherwise, granulation and infection may develop, and the quality of the skin in regenerated deep partial thickness burns is marginal because of the very thin dermis that emerges.

Cultured keratinocytes remain an option for wound coverage; however, their primary use (lacking a formal dermis) continues to be as a temporary skin substitute establishing the skin barrier.

In burn centers, dermal substitutes are achieving some clinical success in management of severely burned patients—particularly Integra Dermal Regeneration Template. Integra is applied to freshly excised burn wounds, and a 76% take rate has been documented (versus 88% for epidermal autografting).

PATIENT SUPPORT

Burn patients require extensive support. An attempt must be made to maintain normal core body temperature in patients with burns over more than 20% of total body surface area, since the hypermetabolic state of burns is exacerbated by subnormal temperatures. Respiratory injury, sepsis, and multiorgan failure are common. Enteral feedings may be started once the ileus of the resuscitation period has resolved, usually the day after the injury. There is often a markedly increased metabolic rate after burn injury, due in large part to whole body synthesis and increased fatty acid substrate cycles. If the patient does not tolerate low-residue tube feedings, TPN should be started without delay through a central venous catheter. As much as 4000-6000 kcal/d may be required in the postburn period. The metabolic demands are immense. A useful guide is to provide 25 kcal/kg body weight plus 40 kcal per percent of burn surface area. Fat emulsions (Intralipid) given intravenously are useful during the resuscitation period to span the period of ileus. Early experimental data from animal models support the administration of low-fat solutions. Early aggressive enteral nutrition reduces infections, noninfectious complications, length of hospital stay, and mortality. Occasionally, burn patients may develop acute respiratory distress syndrome or respiratory failure unresponsive to maximal ventilatory support. Heroic resuscitative measures are sometimes successfully employed, with use of extracorporeal life support (ECLS), in children who would otherwise die of ARDS, inhalation injury, or pneumonia in the postburn period. Early pulmonary dysfunction after severe burn injury is widely recognized. It is now apparent in children that late and permanent pulmonary dysfunction with later obstructive and restrictive lung disease can result from major burn injury.

Prevention of long-term scars remains a formidable problem in seriously burned patients. The tunable pulse-dye or, more recently, the V-beam laser is emerging as adjunctive treatment to the usual regimen of steroid injections, silicone patches, compression, and scar revision. Permanent sequelae can be avoided by prevention of infection, early aggressive rehabilitation, compressive garments and early psychologic support.

Early burn care and grafting, splinting, and hand therapy are the result of coordinated care by general, hand, and plastic surgeons, therapists, and nurses. Late burn reconstruction is best dealt with by a plastic and reconstructive surgeon. Recent advances in reconstructive burn surgery include the use of microsurgery to perform muscle and fasciocutaneous flaps and tissue expansion. However, complex reconstructive options such as free tissue transfer involve much higher than normal complication rates when performed in the acutely burned patient. In late reconstruction of burns involving the head and neck, tissue expansion is sometimes used instead of conventional skin grafting, since this technique provides skin most similar to that lost because of the burn. After severe hand burns, function may be aided by expedient splinting or axial pin fixation to prevent flexion contractures and facilitate prompt skin grafting and physical therapy. Aggressive microsurgical reconstructions of hand injuries facilitate early motion and improved function of burn injuries to the hand.

Patients who have suffered severe burn injuries can recover to a general health status slightly lower than that of the general population but still have very significant vocational and psychologic problems.

There is research interest in a possible role of antioxidants in early fluid resuscitation in order to prevent free radical-induced tissue damage. Monoclonal antibodies against offending pathogens and growth factors continue to be investigated. Dermal matrix substitutes continue to improve but remain plagued by the lack of a substantial dermis.

■ ELECTRIC SHOCK

The extent of injury from electroshock is determined by the amount and type of current, the duration and area of exposure, and the pathway of the current through the body. If the current passes through the heart or brain stem, death may occur immediately owing to ventricular fibrillation or apnea. Current passing through skeletal muscle can cause muscle necrosis and contractions severe enough to result in bone fracture. Current traversing peripheral nerves can cause acute or delayed neuropathy. Delayed effects can include damage to the eye, spinal cord, peripheral nerves, bone, kidneys, and gastrointestinal tract.

With alternating currents (AC) of 25-300 Hz, low voltages (< 220 V) tend to produce ventricular fibrillation; high voltages (> 1000 V), respiratory failure; intermediate voltages (220-1000 V), both. More than 100 mA of domestic house current (AC) of 110 volts at 60 Hz is, accordingly, dangerous to the heart, since it can cause ventricular fibrillation. DC current contact is more likely to cause asystole.

Lightning injuries differ from high-voltage electric shock injuries; lightning usually involves higher voltage, briefer duration of contact, asystole, nervous system injury, and multisystem pathologic involvement.

Electrical burns are of three distinct types: flash (arcing) burns, flame (clothing) burns, and the direct heating effect of tissues by the electric current. The latter lesions are usually sharply demarcated, round or oval, painless yellow-brown areas (Joule burn) with inflammatory reaction. Significant subcutaneous damage can be accompanied by little skin injury, particularly with larger skin surface area electrical contact.

Electric shock may produce loss of consciousness. With recovery there may be muscular pain, fatigue, headache, and nervous irritability. The physical signs vary according to the action of the current. Ventricular fibrillation or respiratory failure—or both—can occur; the patient may be unconscious, pulseless, hypotensive, cold and cyanotic, and without respirations.

Treatment

A. Emergency Measures

The victim must be separated from the electric current prior to initiation of CPR or other treatment; the rescuer must be protected. Turn off the power, sever the wire with a dry wooden-handled ax, make a proper ground to divert the current, or separate the victim using nonconductive implements such as dry clothing.

B. Hospital Measures

Lightning or unstable electric shock victims should be hospitalized when revived and observed for shock, arrhythmia, thrombosis, infarction, sudden cardiac dilation, hemorrhage, and myoglobinuria. A urinalysis, serum CK and CK-MB, and an electrocardiogram should be obtained immediately. Victims should also be evaluated for blunt trauma, dehydration, skin burns, hypertension, posttraumatic stress, acid-base disturbances, and neurologic damage. Indications for hospitalization include significant arrhythmia or electrocardiographic changes, large burn, loss of consciousness, pulmonary or cardiac symptoms, or evidence of significant deep tissue or organ damage. Extra caution is indicated when the electroshock current has followed a transthoracic route (hand to hand or hand to foot) and in patients with a cardiac history.

To counteract fluid losses and myoglobinuria due to electric shock (not lightning) burns, aggressive hydration with Ringer's lactate should seek to achieve a urine output of 50-100 mL/h.

Prognosis

Complications may occur in almost any part of the body but most commonly include sepsis, gangrene requiring limb amputation, or neurologic, cardiac, cognitive, or psychiatric dysfunction.

■ IONIZING RADIATION REACTIONS

The extent of damage due to radiation exposure depends on the quantity of radiation delivered to the body, the dose rate, the organs exposed, the type of radiation (x-rays, neutrons, gamma rays, alpha or beta particles), the duration of exposure, and the energy transfer from the radioactive wave or particle to the exposed tissue. The Chernobyl experience suggests that the best biologic indicators of dose are the duration of the asymptomatic latent period (particularly for nausea or emesis), the severity of early symptoms, the rate of decline of the lymphocyte count, and the number and distribution of dicentric chromosomes in peripheral lymphocytes.

The National Committee on Radiation Protection has established the maximum permissible radiation exposure for occupationally exposed workers over age 18 as 0.1 rem* per week for the whole body (but not to exceed 5 rem per year) and 1.5 rem per week for the hands. (For purposes of comparison, routine chest x-rays deliver from 0.1-0.2 rem.) The FDA has recommended 1 Gy as a threshold for skin-absorbed dose from medical fluoroscopy.

Death after whole body acute lethal radiation exposure is usually due to hematopoietic failure, gastrointestinal mucosal damage, central nervous system damage, widespread vascular injury, or secondary infection. The acute radiation syndrome may be dominated by central nervous system, gastrointestinal, or hematologic manifestations depending on dose and survival. Fatigue, weakness, and anorexia can occur following exposures exceeding 50 cGy. Hematopoietic effects consisting of anemia, platelet loss, and bone marrow suppression can occur 1-3 weeks after exposures exceeding 100 cGy. Exposure to 400-600 cGy may be fatal within 60 days; death is usually due to hemorrhage, anemia, and infection secondary to hematopoietic injury. Whole body exposure levels of 1000-3000 cGy destroy gastrointestinal mucosa; this leads to toxemia and death within 2 weeks. Total body doses above 3000 cGy cause widespread vascular damage, cerebral anoxia, hypotensive shock, and death within 48 hours.

*In radiation terminology, a rad is the unit of absorbed dose and a rem is the unit of any radiation dose to body tissue in terms of its estimated biologic effect. Roentgen (R) refers to the amount of radiation dose delivered to the body. For x-ray or gamma ray radiation, rems, rads, and roentgens are virtually the same. For particulate radiation from radioactive materials, these terms may differ greatly (eg, for neutrons, 1 rad equals 10 rems). In the Systeme International (SI) nomenclature, the rad has been replaced by the gray (Gy), and 1 rad equals 0.01 Gy = 1 cGy. The SI replacement for the rem is the Sievert (Sv), and 1 rem equals 0.01 Sv.

ACUTE (IMMEDIATE) IONIZING RADIATION EFFECTS ON NORMAL TISSUES

Clinical Findings

A. Injury to Skin and Mucous Membranes

Irradiation may cause erythema, epilation, destruction of fingernails, or epidermolysis. Ionizing radiation burns appear similar to thermal burns but usually have a slower onset and course.

B. Injury to Deep Structures

1. Hematopoietic tissues—Injury to the bone marrow may cause diminished production of blood elements. Lymphocytes are most sensitive, polymorphonuclear leukocytes next most sensitive, and erythrocytes least sensitive. Damage to the blood-forming organs may vary from transient depression of one or more blood elements to complete destruction.

2. Cardiovascular system—Pericarditis with effusion or constrictive pericarditis may occur after a period of months or even years. Myocarditis is less common. Smaller vessels (the capillaries and arterioles) are more readily damaged than larger blood vessels.

3. Reproductive effects—In males, small single doses of radiation (200-300 cGy) cause temporary aspermatogenesis, and larger doses (600-800 cGy) may cause permanent sterility. In females, single doses of 200 cGy may cause temporary cessation of menses, and 500-800 cGy may cause permanent castration. Moderate to heavy irradiation of the embryo in utero results in injury to the fetus (eg, mental retardation) or in embryonic death and abortion.

4. Respiratory tract—High or repeated moderate doses of radiation may cause pneumonitis, often delayed for weeks or months.

5. Mouth, pharynx, esophagus, and stomach—Mucositis with edema and painful swallowing of food may occur within hours or days after exposure. Gastric secretion may be inhibited by high doses of radiation.

6. Intestines—Inflammation and ulceration may follow moderately large doses of radiation.

7. Endocrine glands and viscera—Hepatitis and nephritis may be delayed effects of therapeutic radiation. The normal thyroid, pituitary, pancreas, adrenals, and bladder are relatively resistant to low or moderate doses of radiation; parathyroid glands are especially resistant.

8. Nervous system—The brain and spinal cord are much more sensitive to acute exposures than the peripheral nerves.

C. Systemic Reaction (Radiation Sickness)

The basic mechanisms of radiation sickness are not known. Anorexia, nausea, vomiting, weakness, exhaustion, lassitude, and in some cases prostration may occur, singly or in combination. Dehydration, anemia, and infection may follow. Radiation sickness associated with x-ray therapy is most likely to occur when the therapy is given in large dosage to large areas over the abdomen, less often when given over the thorax, and rarely when therapy is given over the extremities.

Prevention

Persons handling radiation sources can minimize exposure to radiation by recognizing the importance of time, distance, and shielding. Areas housing x-ray and nuclear materials must be properly shielded. X-ray equipment should be periodically checked for reliability of output, and proper filters should be employed. When feasible, it is advisable to shield the gonads, especially of young persons. Fluoroscopic procedures should be performed as rapidly as possible, using an optimal combination of beam characteristics and filtration, and the beam size should be kept to a minimum required by the examination. Special protective clothing may be necessary to protect against contamination with radioisotopes. In the event of accidental contamination, all clothing should be removed and the body vigorously bathed with soap and water. This should be followed by careful instrument (Geiger counter) check to localize the ionizing radiation.

Nuclear Terrorism & Emergency Treatment for Radiation Accident Victims

The proliferation of radiation equipment and nuclear energy plants, terrorism, and the increasing need for transportation of radioactive materials have made necessary hospital plans for managing patients who are accidentally exposed to ionizing radiation or are contaminated with radioisotopes. The plans should provide for effective emergency care and disposition of victims and materials with the least possible risk of spreading radioactive contamination to health care personnel and facilities.

The threat of nuclear terrorism is raising the level of awareness about medical aspects of ionizing radiation exposure. The Gusev and Mettler references (see below) provide detailed guidance regarding decontamination, diagnosis, treatment, and isotope-specific postexposure prophylaxis. The Radiation Assistance Center provides 24-hour access to expert guidance regarding medical and safety aspects of ionizing radiation exposures and incidents (865-576-1005).

Treatment

The success of treatment of local radiation effects depends upon the extent, degree, and location of tissue injury. Particulate or radioisotope exposures should be decontaminated in designated confined areas. Serial lymphocyte counts are useful for dose estimation and monitoring of the clinical impact of exposure. For many radioisotopes, chelation, blocking, or dilution therapy is indicated. Treatment of systemic reactions is symptomatic and supportive. Ondansetron, 8 mg orally twice or three times daily, has been recommended for nausea and vomiting. Alternatives include chlorpromazine, 25-50 mg given deeply intramuscularly every 4-6 hours as necessary or 10-25 mg orally every 4-6 hours as necessary; and dimenhydrinate, 50-100 mg, or perphenazine, 4-8 mg, 1 hour before and 1 and 4 hours after radiation therapy has been recommended.

Blood and platelet transfusions, blood stem cell transplantation, bone marrow transplants, antibiotics, fluid and electrolyte maintenance, and other supportive measures may be useful. Recombinant hematopoietic growth factors (filgrastim and sargramostim or molgramostim) have been effective in accelerating hematopoietic recovery.

DELAYED EFFECTS OF EXCESSIVE DOSES OF IONIZING RADIATION

These disorders may occur following excessive ionizing radiation exposure: skin scarring, atrophy, and telangiectasis; cataract, dry eye syndrome, retinopathy; neuropathy, myelopathy, cerebral injury; obliterative endarteritis, coronary artery disease, pericarditis; thyroid disease; pulmonary fibrosis, hepatitis, intestinal stenosis,

nephritis, and chromosomal aberrations. Neoplastic disease, including leukemia and cancers of the skin, breast, lung, and thyroid, is increased in persons exposed to radiation at relatively low doses (< 0.2 Gy). High-dose radon exposure is associated with an increased risk of lung cancer. Association of ionizing radiation with several other cancers has been reported but not well quantified (salivary glands, skin, stomach, colon, bladder, ovary, and central nervous system). Prenatal irradiation may increase the risk of childhood cancer.

Microcephaly and other congenital abnormalities may occur in children exposed in utero, especially if the fetus was exposed during early pregnancy. Carcinogenesis from low-dose (< 10 rem) exposure to adults has not been demonstrated. However, because of age-related differences in sensitivity to radiation, carcinogenesis following childhood exposures has been observed (eg, Chernobyl and childhood thyroid cancer).

■ DROWNING

The asphyxia of drowning is usually due to aspiration of fluid, but it may result from airway obstruction caused by laryngeal spasm while the victim is gasping under water. About 10% of victims develop laryngospasm after the first gulp and never aspirate water ("dry drowning"). The rapid sequence of events after submersion—hypoxemia, laryngospasm, fluid aspiration, ineffective circulation, brain injury, and brain death—may take place within 5-10 minutes. This sequence may be delayed for longer periods if the victim, especially a child, has been submerged in very cold water or if the victim has ingested significant amounts of barbiturates. Immersion in cold water can also cause a rapid fall in the victim's core temperature, so that systemic hypothermia and death may occur before actual drowning.

The primary effect is hypoxia due to perfusion of poorly ventilated alveoli, intrapulmonary shunting, and decreased compliance. *The first requirement of rescue is immediate cardiopulmonary resuscitation.*

A number of circumstances or primary events may precede near drowning and must be taken into consideration in management: (1) use of alcohol or other drugs (a contributing factor in an estimated 25% of adult drownings), (2) extreme fatigue, (3) intentional hyperventilation, (4) sudden acute illness (eg, epilepsy, myocardial infarction), (5) head or spinal cord injury sustained in diving, (6) venomous stings by aquatic animals, and (7) decompression sickness in deep water diving.

Spontaneous return of consciousness often occurs in otherwise healthy individuals when submersion is very brief. Many other patients respond promptly to immediate ventilation. Other patients, with more severe degrees of near drowning, may have frank respiratory failure, pulmonary edema, shock, anoxic encephalopathy, cerebral edema, and cardiac arrest. A few patients may be deceptively asymptomatic during the recovery period—only to deteriorate or die as a result of acute respiratory failure within the following 12-24 hours.

Clinical Findings

A. Symptoms and Signs

The patient may be unconscious, semiconscious, or awake but apprehensive, restless, and complaining of headaches or chest pain. Vomiting is common. Examination may reveal cyanosis, trismus, apnea, tachypnea, and wheezing. A pink froth from the mouth and nose indicates pulmonary edema. Cardiovascular manifestations may include tachycardia, arrhythmias, hypotension, cardiac arrest, and circulatory shock. With prolonged or cold water immersion, hypothermia is likely.

B. Laboratory Findings

Urinalysis shows proteinuria, hemoglobinuria, and acetonuria. Leukocytosis is usually present. The PaO₂ is usually decreased and the PaCO₂ increased or decreased. The blood pH is decreased as a result of metabolic acidosis. Chest x-rays may show pneumonitis or pulmonary edema.

Prevention

Prevention consists of avoidance of alcohol during recreational swimming or boating, close supervision of toddlers, swimming lessons early in life, and use of personal flotation devices when boating. All swimming pools should be fenced.

Treatment

A. First Aid

Immediate measures to combat hypoxemia at the scene of the incident—sustained ventilation, oxygenation, and circulatory support—are critical to survival with complete recovery. Hypothermia and cervical spine injury should always be suspected.

1. Standard CPR is initiated if pulse and respirations are absent.
2. *Do not* attempt to drain water from the victim's lungs. The Heimlich maneuver (subdiaphragmatic pressure) should be used only if airway obstruction by a foreign body is suspected. The cervical spine should be immobilized if neck injury is possible.
3. *Do not* discontinue basic life support for seemingly "hopeless" patients until core temperature reaches 32 °C. Complete recovery has been reported after prolonged resuscitation of hypothermic patients.

B. Hospital Care

Careful observation of the patient; continuous monitoring of cardiorespiratory function; serial determination of arterial blood gases, pH, renal function (serum creatinine), and electrolytes; and measurement of urinary output are required. Pulmonary edema may not appear for 24 hours.

1. Ensure optimal ventilation and oxygenation—The danger of hypoxemia exists even in the alert, conscious patient who appears to be breathing normally. Oxygen should be administered immediately at the highest available concentration. Endotracheal intubation and mechanical ventilation are necessary for patients unable to maintain an open airway or normal blood gases and pH. Nasogastric intubation will allow removal of swallowed water and prevention of aspiration. If the victim does not have spontaneous respirations, intubation is required. Oxygen saturation should be maintained at 90% or higher. Continuous positive airway pressure (CPAP) is the most effective means of reversing hypoxia in patients with spontaneous respirations and patent airways. Positive end-expiratory pressure (PEEP) is also effective for treating respiratory insufficiency. Assisted ventilation may be necessary with pulmonary edema, respiratory failure, aspiration, pneumonia, or severe central nervous system injury. Serial physical examinations and chest x-rays should be carried out to detect possible pneumonitis, atelectasis, and pulmonary edema. Bronchospasm due to aspirated material may require use of bronchodilators. Antibiotics should be given only when there is clinical evidence of infection—not prophylactically.

2. Cardiovascular support—Central venous pressure (or, preferably, pulmonary artery wedge pressure) may be monitored as a guide to determining whether vascular fluid replacement and pressors or diuretics are needed. If low cardiac output persists after adequate intravascular volume is achieved, pressors should be given. Otherwise, standard therapy for pulmonary edema is administered.

3. Correction of blood pH and electrolyte abnormalities—Metabolic acidosis is present in 70% of near-drowning victims, but it is usually of minor importance and corrected through adequate ventilation and oxygenation. While controversial, bicarbonate administration (1 meq/kg) has been recommended for comatose patients (see [Chapter 21](#)).

4. Cerebral injury—Some near-drowning patients may progress to irreversible central nervous system damage despite apparently adequate treatment of hypoxia and shock. Mild hyperventilation to achieve a PaCO₂ of approximately 30 mm Hg is recommended to lower intracranial pressure.

5. Hypothermia—Core temperature should be measured and managed as appropriate (see Systemic Hypothermia, above).

Course & Prognosis

Victims of near drowning who have had prolonged hypoxemia should remain under close hospital observation for 2-3 days after all supportive measures have been withdrawn and clinical and laboratory findings have been stable. Residual complications of near drowning may include intellectual impairment, convulsive disorders, and pulmonary or cardiac disease.

■ OTHER DISORDERS DUE TO PHYSICAL AGENTS

DECOMPRESSION SICKNESS & DYSBARIC ILLNESS

Decompression sickness and other disorders related to rapid changes in environmental pressure are hazards for fliers and divers who are involved in recreational diving (eg, scuba diving), deep-water exploration, rescue or salvage operations, or construction.

At low depths the greatly increased pressure (eg, at 30 meters [100 feet] the pressure is four times greater than at the surface) compresses the respiratory gases into the blood and other tissues. During ascent from depths greater than 9 meters (30 feet), gases dissolved in the blood and other tissues escape as the external pressure decreases. The appearance of symptoms depends on the depth and duration of submersion; the degree of physical exertion; the age, weight, and physical condition of the diver; and the rate of ascent. The size and number of gas bubbles (notably nitrogen) escaping from the tissues depend on the difference between the atmospheric pressure and the partial pressure of the gas dissolved in the tissues. The release of gas bubbles and (particularly) the location of their release determine the symptoms.

Decompression sickness also occurs among fliers during rapid ascent from sea level to high altitudes when there is no adequate pressurizing protection. Deep-sea and scuba divers may be vulnerable to air embolism if airplane travel is attempted too soon (within a few hours) after diving.

The range of clinical manifestations includes gas bubble formation in the joints ("bends"), cerebral or pulmonary decompression sickness, arterial gas embolism (cerebral, pulmonary), ear and sinus barotrauma, and dysbaric osteonecrosis.

Predisposing factors include exercise, injury, patent foramen ovale, obesity, dehydration, alcoholic excess, hypoxia, some medications (eg, narcotics, antihistamines), and cold. Reported sequelae include hemiparesis, neurologic dysfunction, and bone damage. Asthma, pneumothorax, reduced pulmonary function, lung cysts, or thoracic trauma may be contraindications to diving.

The onset of acute decompression symptoms occurs within 30 minutes in half of cases and almost invariably within 6 hours. Symptoms, which are highly variable, include pain (largely in the joints), headache, fatigue, numbness, confusion, pruritic rash, visual disturbances, nausea, vomiting, loss of hearing, weakness, paralysis, dizziness, vertigo, dyspnea, paresthesias, aphasia, and coma.

Pulmonary decompression sickness ("chokes") presents with burning, pleuritic substernal pain, cough, and dyspnea.

Early recognition and prompt treatment are extremely important. Continuous administration of oxygen is indicated as a first aid measure whether or not cyanosis is present. Aspirin may be given for pain, but narcotics should be used very cautiously, since they may obscure the patient's response to recompression. Rapid transportation to a treatment facility for recompression, hyperbaric oxygen, hydration treatment of plasma deficits, and supportive measures is necessary not only to relieve symptoms but also to prevent permanent impairment. It has been recommended, however, that decompression symptoms be treated whenever they are seen—even up to 2 weeks postinjury—since it is still possible to completely alleviate symptoms. The clinician should be familiar with the nearest compression center. The local public health department or nearest naval facility should be able to provide such information. The National Divers Alert Network at Duke University (DAN; 919-684-2948) provides assistance in the management of underwater diving accidents.

MOUNTAIN SICKNESS

Lack of sufficient time for acclimatization, increased physical activity, and varying degrees of health may be responsible for the acute, subacute, and chronic disturbances that result from hypoxia at altitudes greater than 2000 meters (6560 feet). Marked individual differences in tolerance to hypoxia exist. Patients with sickle cell disease are at high risk of painful crises from altitude-induced hypoxemia.

Acute Mountain Sickness

The severity of acute mountain sickness correlates with altitude and rate of ascent. Initial manifestations include headache (most severe and persistent symptom), lassitude, drowsiness, dizziness, chilliness, nausea and vomiting, facial pallor, dyspnea, and cyanosis. Later, there is facial flushing, irritability, difficulty in concentrating, vertigo, tinnitus, visual disturbances, auditory disturbances, anorexia, insomnia, increased dyspnea and weakness on exertion, increased headaches (due to cerebral edema), palpitations, tachycardia, Cheyne-Stokes breathing, and weight loss. More severe manifestations include pulmonary edema and encephalopathy (see below). Voluntary periodic hyperventilation may relieve symptoms. In most individuals, symptoms clear within 24-48 hours, but in some instances, if the symptoms are sufficiently persistent or severe, the patient must be returned to lower altitudes. Definitive treatment is immediate descent, which is essential if reduced consciousness, ataxia, or pulmonary edema occurs. Administration of oxygen, 1-2 L/min, will often relieve acute symptoms. If immediate descent is not possible, portable hyperbaric chambers can provide symptomatic relief depending on altitude and severity. Acetazolamide, 125-250 mg every 12 hours, or dexamethasone, 8 mg initially followed by 4 mg every 6 hours, for as long as symptoms persist, is recommended therapy; they may be used together in severe cases.

Preventive measures include slow ascent—300 meters (984 feet) per day—adequate rest and sleep the day before travel, reduced food intake, and avoidance of alcohol, tobacco, and unnecessary physical activity during travel. Acetazolamide, 125-250 mg every 12 hours, beginning the day before ascent and continuing for 48-72 hours at altitude, may be used as prophylaxis. Dexamethasone, 4 mg every 12 hours beginning on the day of ascent, continuing for 3 days at the higher altitude, and then tapering over 5 days, is an alternative.

Acute High-Altitude Pulmonary Edema (HAPE)

This serious complication usually occurs at levels above 3000 meters (9840 feet). Early symptoms may appear within 6-36 hours after arrival at a high-altitude area: incessant dry cough, shortness of breath disproportionate to exertion, headache, decreased exercise performance, fatigue, dyspnea at rest, and chest tightness. Later, wheezing, orthopnea, and hemoptysis may occur. Recognition of the early symptoms may enable the patient to descend before incapacitating pulmonary edema develops, but strenuous exertion should be avoided. An early descent of even 500 or 1000 meters may result in improvement of symptoms. Physical findings include tachycardia, mild fever, tachypnea, cyanosis, prolonged respiration, and rales and rhonchi. The patient may become confused or comatose, and the clinical picture may resemble severe pneumonia. The white count is often slightly elevated, but the erythrocyte sedimentation rate is usually normal. Chest x-ray findings vary from irregular patchy infiltration in one lung to nodular densities bilaterally or with transient prominence of the central pulmonary arteries. Transient nonspecific electrocardiographic changes, occasionally showing right ventricular strain, may occur. Pulmonary arterial blood pressure is elevated, whereas wedge pressure is normal.

Treatment, which must often be given under field conditions, consists of rest in the semi-Fowler position (head raised) and administration of 100% oxygen by mask at a rate of 4-6 L/min for 15-30 minutes. *Immediate descent (at least 610 meters [2000 feet]) is essential.* Recompression in a portable hyperbaric bag will temporarily reduce symptoms if rapid or immediate descent is not possible. To conserve oxygen, lower flow rates (2-4 L/min) may be used until the victim recovers or can be evacuated to a lower altitude. Treatment for acute respiratory distress syndrome (see [Chapter 9](#)) may be required for some patients who have a prolonged course of pulmonary edema. Nifedipine, 10 mg every 4 hours, may provide symptomatic relief. Dexamethasone, 4 mg every 6 hours, has been recommended if central nervous system symptoms are present. Acetazolamide, 125-250 mg every 12 hours, should be administered if acute mountain sickness is suspected. If bacterial pneumonia occurs, appropriate antibiotic therapy should be given.

Preventive measures include education of prospective mountaineers regarding the possibility of serious pulmonary edema, optimal physical conditioning before travel, gradual ascent to permit acclimatization, and a period of rest and inactivity for 1-2 days after arrival at high altitudes. Salmeterol, 125 ug by inhaler every 12 hours beginning 24 hours prior to ascent, has been shown to reduce the incidence of HAPE in susceptible patients. Prompt medical attention with rest and high-flow oxygen if respiratory symptoms develop may prevent progression to frank pulmonary edema. Persons with a history of high-altitude pulmonary edema should be hospitalized for further observation if possible. Pulmonary embolism and high-altitude bronchitis can also occur. Mountaineering parties at levels of 3000 meters (9840 feet) or higher should carry a supply of oxygen and equipment sufficient for several days. Persons with symptomatic cardiac or pulmonary disease should avoid high altitudes.

Acute High-Altitude Encephalopathy

High-altitude encephalopathy appears to be an extension of the central nervous system symptoms of acute mountain sickness (see above). It usually occurs at elevations above 2500 meters (8250 feet) and is more common in unacclimatized individuals. Clinical findings are due largely to hypoxemia and cerebral edema.

Severe headaches, confusion, truncal ataxia, staggering gait, focal deficits, nausea and vomiting, and seizures may progress to obtundation and coma. High-altitude retinopathy is a separate but related effect of altitude. It can include dilated vessels, retinal hemorrhage, vitreous hemorrhage, and papilledema.

Treatment is immediate descent for at least 610 meters (2000 feet), continuing until symptoms improve. Oxygen (2-4 L/min) should be administered by mask. Dexamethasone, 4-8 mg every 6 hours, is recommended thereafter. If immediate descent is impossible, a portable hyperbaric chamber should be used until symptomatic improvement occurs.

Subacute Mountain Sickness

This occurs most frequently in unacclimatized individuals and at altitudes above 4500 meters (14,764 feet). Symptoms—dyspnea and cough—are probably due to pulmonary hypertension and secondary congestive heart failure. There are additional problems of dehydration, skin dryness, and pruritus. The hematocrit may be elevated, and there may be electrocardiographic and chest x-ray evidence of right ventricular hypertrophy. Treatment consists of rest, oxygen administration, diuretics, and return to lower altitudes.

Chronic Mountain Sickness (Monge's Disease)

This uncommon condition, consisting of chronic hypoxia and polycythemia in residents of high-altitude communities who have lost their acclimatization to such an environment, is difficult to differentiate from chronic pulmonary disease. The disorder is characterized by somnolence, mental depression, hypoxemia, cyanosis, clubbing of fingers, hemoglobin > 22 g/dL, polycythemia (hematocrit often > 75%), signs of right ventricular failure, electrocardiographic evidence of right axis deviation and right atrial and ventricular hypertrophy, and x-ray evidence of right heart enlargement and central pulmonary vessel prominence. There is no x-ray evidence of structural pulmonary disease. Pulmonary function tests usually disclose alveolar hypoventilation and elevated PCO₂ but fail to reveal defective oxygen transport. There is a diminished respiratory response to CO₂. ACE inhibition therapy (enalapril, 5 mg daily) has been shown to reduce polycythemia and proteinuria. Almost complete disappearance of all abnormalities eventually occurs when the patient returns to sea level.

MEDICAL EFFECTS OF AIR TRAVEL & SELECTION OF PATIENTS FOR AIR TRAVEL

The medical safety of air travel depends not only upon the nature and severity of the illness but also upon such factors as the duration of flight, pressurization, the availability of supplementary oxygen and other medical supplies, the presence of health care professionals, and other special considerations. Airline policies, charges, and other details regarding on-board oxygen and medical supplies must be checked with each carrier. The medical hazard most likely to be realized is hypoxia. The most common in-flight emergencies are cardiovascular, syncopal, neuropsychiatric, and abdominal. The Air Transport Association of America defines an incapacitated passenger as "one who is suffering from a physical or mental disability and who, because of such disability or the effect of the flight on the disability, is incapable of self-care; would endanger the health or safety of such person or other passengers or airline employees; or would cause discomfort or annoyance of other passengers."

Pretravel clinician evaluation is advisable for patients with hospitalization, surgery, chronic disease, emergency care, or medication change within the past 4 weeks.

Patients subject to motion sickness can be given sedatives or antihistamines (eg, dimenhydrinate, 50 mg every 4-6 hours; promethazine, 25 mg every 6 hours; or meclizine, 25-50 mg every 24 hours) before and during the flight. Small meals of easily digested food before and during the flight may reduce the tendency to nausea and vomiting. [Table 38-1](#) lists the more common contraindications to air travel.

Pregnancy

Pregnant women may be permitted to fly during the first 8 months of pregnancy unless there is a history of complications of pregnancy or premature birth. During the ninth month of pregnancy, air travel is not recommended; if travel is essential, a physician's authorization is required. Infants less than 1 week old should not be flown at high altitudes or for long distances.

 - DISORDERS DUE TO COLD
 -
-

Table 38-1. Contraindications to air travel.

- Congestive heart failure¹
- Compensated valvular or other heart disease above 2400 m (7874 ft) unless cabin is pressurized and oxygen is available
- Acute myocardial infarction with less than 3 weeks convalescence
- Unstable postinfarction
- Post CABG with less than 2 weeks convalescence
- Severe or poorly controlled hypertension
- Ventricular ectopy
- New or unstable angina
- Deep venous thrombosis unless the person is stable, receiving anticoagulant therapy, and has no pulmonary complications²
- Nasal congestion unresponsive to therapy
- Pulmonary cysts
- Pneumothorax
- Active communicable tuberculosis or other communicable virulent infection (eg, measles, chickenpox)
- Breathlessness or hypoxemia
- Anemia (hemoglobin <8.5 g/dL), sickle cell disease
- Postsurgery (eye, thorax, abdomen) unless 2-3 weeks of convalescence and surgeon's approval
- Emotionally unstable, agitated, or psychotic
- Pregnancy unless low risk, without complications, and less than 8 months

¹Oxygen should be made available for persons with cardiovascular, respiratory, or hematologic illness

²Susceptible patients should wear support hose, perform leg exercises and walk during flight. Preflight low molecular weight heparin may also be indicated.

39. Poisoning - Kent R. Olson, MD

■ INITIAL EVALUATION OF THE PATIENT WITH POISONING OR DRUG OVERDOSE

Patients with drug overdoses or poisoning may initially present with no symptoms or with varying degrees of overt intoxication. The asymptomatic patient may have been exposed to or may have ingested a lethal dose of a poison but not yet have any manifestations of toxicity. It is always important to (1) quickly assess the potential danger, (2) perform gut decontamination to prevent absorption, and (3) observe the patient for an appropriate interval.

Assess the Danger

If the toxin is known, the danger can be assessed by consulting a text or computerized information resource (eg, Poisindex) or by calling a regional poison control center. (Dialing 800-222-1222 will direct the call to the appropriate United States regional poison control center.) Assessment will usually take into account the dose ingested (in milligrams per kilogram of body weight), the time interval since ingestion, the presence of any clinical signs, preexisting cardiac, respiratory, renal, or liver disease, and, occasionally, specific serum drug or toxin levels. Be aware that the history given by the patient or family may be incomplete or unreliable.

The manufacturer or its local representative may be able to provide information over the phone concerning the toxic ingredients in question and can be contacted directly or via the regional poison control center (800-222-1222).

Gut Decontamination

The choice of gut decontamination procedure depends on the toxin and the circumstances. (See below for more discussion of methods.)

Observation of the Patient

Asymptomatic or mildly symptomatic patients should be observed for at least 4-6 hours. Longer observation is indicated if the ingested substance is a sustained-release preparation or is known to slow gastrointestinal motility or if there may have been exposure to a poison with delayed onset of symptoms (such as acetaminophen, colchicine, or hepatotoxic mushrooms). After that time, the patient may be discharged if no symptoms have developed and adequate gastric decontamination has been provided. Before discharge, psychiatric evaluation should be performed to assess suicidal risk. Intentional ingestions in adolescents should raise the possibility of unwanted pregnancy or sexual abuse.

■ THE SYMPTOMATIC PATIENT

In symptomatic patients, treatment of life-threatening complications takes precedence over in-depth diagnostic evaluation. Patients with mild symptoms may deteriorate rapidly, which is why all potentially significant exposures should be observed in an acute care facility. The following complications may occur, depending on the type of poisoning.

COMA

Assessment & Complications

Coma is commonly associated with ingestion of large doses of antihistamines, barbiturates, benzodiazepines and other sedative-hypnotic drugs, γ -hydroxybutyrate (GHB), ethanol, opioids, phenothiazines, or antidepressants. The most common cause of death in comatose patients is respiratory failure, which may occur abruptly. Aspiration of gastric contents may also occur, especially in victims who are deeply obtunded or convulsing. Hypoxia and hypoventilation may cause or aggravate hypotension, arrhythmias and seizures. Thus, protection of the airway and assisted ventilation are the most important treatment measures for any poisoned patient.

Treatment

A. Emergency Management

The initial emergency management of coma can be remembered by the mnemonic *ABCD*, for *A*irway, *B*reathing, *C*irculation, and *D*rugs (dextrose, thiamine, and naloxone or flumazenil), respectively ([Table 39-1](#)).

1. Airway—Establish a patent airway by positioning, suction, or insertion of an artificial nasal or oropharyngeal airway. If the patient is deeply comatose or if there is no gag or cough reflex, perform endotracheal intubation. These airway interventions may not be necessary if the patient is intoxicated by an opioid or a benzodiazepine and responds rapidly to intravenous naloxone or flumazenil (see below).

2. Breathing—Clinically assess the quality and depth of respiration, and provide assistance if necessary with a bag-valve-mask device or mechanical ventilator. Provide supplemental oxygen. The arterial blood CO₂ tension is useful in determining the adequacy of ventilation. The arterial blood PO₂ determination may reveal hypoxemia, which may be caused by respiratory arrest, bronchospasm, pulmonary aspiration, or noncardiogenic pulmonary edema. Pulse oximetry provides an assessment of oxygenation but is not reliable in patients with methemoglobinemia or carbon monoxide poisoning.

3. Circulation—Measure the pulse and blood pressure, and estimate tissue perfusion (eg, by measurement of urinary output, skin signs, arterial blood pH). Place the patient on continuous electrocardiographic monitoring. Insert an intravenous line, and draw blood for complete blood count, glucose, electrolytes, serum creatinine and liver tests, and possible quantitative toxicologic testing.

4. Drugs—

a. Dextrose and thiamine—Unless promptly treated, severe hypoglycemia can cause irreversible brain damage. Therefore, in all comatose or convulsing patients, give 50% dextrose, 50-100 mL by intravenous bolus, unless a rapid bedside blood sugar test is available and rules out hypoglycemia. In alcoholic or very malnourished patients who may have marginal thiamin stores, give thiamine, 100 mg intramuscularly or over 2-3 minutes intravenously.

b. Narcotic antagonists—Naloxone, 0.4-2 mg intravenously, may reverse opioid-induced respiratory depression and coma. If opioid overdose is strongly suspected, give additional doses of naloxone (up to 5-10 mg may be required to reverse potent opioids). **Caution:** Naloxone has a much shorter duration of action (2-3 hours) than most common opioids; repeated doses may be required, and continuous observation for at least 3-4 hours after the last dose is mandatory. Nalmefene, a newer opioid antagonist, has a duration of effect longer than that of naloxone but still shorter than that of the opioid methadone.

c. Flumazenil—Flumazenil, 0.2-0.5 mg intravenously, repeated every 30 seconds as needed up to a maximum of 3 mg, may reverse benzodiazepine-induced coma. **Caution:** Flumazenil has a short duration of effect (2-3 hours), and resedation requiring additional doses is common. Furthermore, flumazenil should not be given if the patient has coingested a tricyclic antidepressant, is a user of high-dose benzodiazepines, or has a seizure disorder—because its use in these circumstances may precipitate seizures. In most circumstances, flumazenil is not advised as the potential risks outweigh its benefits.

HYPOTHERMIA

Assessment & Complications

Hypothermia commonly accompanies coma due to opioids, ethanol, hypoglycemic agents, phenothiazines, barbiturates, benzodiazepines, and other sedative-hypnotics and depressants. Hypothermic patients may have a barely perceptible pulse and blood pressure and often appear to be dead. Hypothermia may cause or aggravate hypotension, which will not reverse until the temperature is normalized.

Treatment

Hypothermia treatment is discussed in [Chapter 38](#). Gradual rewarming is preferred unless the patient is in cardiac arrest.

HYPOTENSION

Assessment & Complications

Hypotension may be due to poisoning by many different drugs and poisons. The most common drugs causing hypotension are antihypertensive drugs, beta-blockers, calcium channel blockers, iron, theophylline, phenothiazines, barbiturates, and tricyclic antidepressants. Poisons causing hypotension include cyanide, carbon monoxide, hydrogen sulfide, arsenic, and certain mushrooms.

Hypotension in the poisoned or drug-overdosed patient may be caused by venous or arteriolar vasodilation, hypovolemia, depressed cardiac contractility, or a combination of these effects. The only certain way to determine the cause of hypotension in any individual patient is to insert a pulmonary artery catheter and calculate the cardiac output and peripheral vascular resistance. Alternatively, a central venous pressure (CVP) monitor may indicate a need for further fluid therapy.

Treatment

Most patients respond to empirical treatment (200 mL intravenous boluses of 0.9% saline or other isotonic crystalloid up to a total of 1-2 L. If fluid therapy is not successful, give dopamine, 5-15 ug/kg/min by intravenous infusion in a large peripheral or central line. Consider pulmonary artery catheterization if hypotension persists.

Hypotension caused by certain toxins may respond to specific treatment. For hypotension caused by overdoses of tricyclic antidepressants or related drugs, administer sodium bicarbonate, 50-100 meq by intravenous bolus injection. Norepinephrine is more effective than dopamine in some patients with overdoses of tricyclic antidepressants or of drugs with predominantly vasodilating effects. For beta-blocker overdose, glucagon (5-10 mg intravenously) may be of value. For calcium channel blocker overdose, administer calcium chloride, 1-2 g intravenously (repeated doses may be necessary; doses of 5-10 g and more have been given in some cases).

HYPERTENSION

Assessment & Complications

Hypertension may be due to poisoning with amphetamines, anticholinergics, cocaine, ephedrine-containing performance-enhancing products, monoamine oxidase inhibitors, and other drugs.

Severe hypertension (eg, diastolic blood pressure > 105-110 mm Hg in a person who does not have chronic hypertension) can result in acute intracranial hemorrhage, myocardial infarction, or aortic dissection. Patients often present with headache, chest pain, or encephalopathy.

Treatment

Treat hypertension if the patient is symptomatic or if the diastolic pressure is greater than 105-110 mm Hg—especially if there is no prior history of hypertension.

Hypertensive patients who are agitated or anxious may benefit from a sedative such as lorazepam, 2-3 mg intravenously. For persistent hypertension, administer phentolamine, 2-5 mg intravenously, or nitroprusside sodium, 0.25-8 µg/kg/min intravenously. If excessive tachycardia is present, add propranolol, 1-5 mg intravenously, or esmolol 25-100 ug/kg/ min intravenously. **Caution:** Do not give beta-blockers alone, since doing so may paradoxically worsen hypertension.

ARRHYTHMIAS

Assessment & Complications

Arrhythmias may occur with a variety of drugs or toxins ([Table 39-2](#)). They may also occur as a result of hypoxia, metabolic acidosis, or electrolyte imbalance (eg, hyper- or hypokalemia, hypocalcemia), or following exposure to chlorinated solvents or chloral hydrate overdose.

Treatment

Arrhythmias are often caused by hypoxia or electrolyte imbalance, and these conditions should be sought and treated. If ventricular arrhythmias persist, administer lidocaine at usual antiarrhythmic doses. **Caution:** Avoid class Ia agents (quinidine, procainamide, disopyramide), which may aggravate arrhythmias caused by tricyclic antidepressants, calcium channel blockers, or beta-blockers. Wide QRS complex tachycardia in the setting of tricyclic antidepressant overdose (or quinidine and other class Ia drugs) should be treated with sodium bicarbonate, 50-100 meq intravenously by bolus injection. (See discussion of tricyclic antidepressant poisoning.)

For tachyarrhythmias induced by chlorinated solvents, chloral hydrate, or sympathomimetic agents, use propranolol or esmolol (see doses given above in hypertension section).

SEIZURES

Assessment & Complications

Seizures may be due to poisoning with many drugs and poisons, including amphetamines, antidepressants (especially tricyclic antidepressants and buspirone), antihistamines, antipsychotics, camphor, cocaine, isoniazid, phencyclidine (PCP), and theophylline.

Seizures may also be caused by hypoxia, hypoglycemia, hypocalcemia, hyponatremia, withdrawal from alcohol or sedative-hypnotics, head trauma, central nervous system infection, or idiopathic epilepsy.

Prolonged or repeated seizures commonly lead to hypoxia, metabolic acidosis, hyperthermia, and rhabdomyolysis.

Treatment

Administer lorazepam, 2-3 mg intravenously over 1-2 minutes, or—if intravenous access is not immediately available—midazolam, 5-10 mg intramuscularly. If convulsions continue, administer phenobarbital, 15- 20 mg/kg slowly intravenously over no less than 30 minutes; or phenytoin, 15 mg/kg intravenously over no less than 30 minutes (maximum infusion rate, 50 mg/min). For drug-induced seizures, phenobarbital is preferred over phenytoin. The drugs may be used together if necessary. Maintenance doses may be required if drug toxicity is expected to last more than 18-24 hours.

Seizures due to a few drugs and toxins may require antidotes or other specific therapies (as listed in [Table 39-3](#)).

HYPERTHERMIA

Assessment & Complications

Hyperthermia may be associated with poisoning by amphetamines (especially ecstasy), atropine and other anticholinergic drugs, cocaine, dinitrophenol and pentachlorophenol, phencyclidine (PCP), salicylates, strychnine, tricyclic antidepressants, and various other medications. Overdoses of serotonin reuptake inhibitors (eg, fluoxetine, paroxetine, sertraline) or use in a patient taking a monoamine oxidase inhibitor may cause agitation, hyperactivity, and hyperthermia ("serotonin syndrome"). Haloperidol and other antipsychotic agents can cause rigidity and hyperthermia (neuroleptic malignant syndrome [NMS]). (See section on schizophrenia and other psychotic disorders in [Chapter 25](#).) Malignant hyperthermia is a rare disorder associated with general anesthetic agents.

Hyperthermia is a rapidly life-threatening complication. Severe hyperthermia (temperature > 40-41 °C) may rapidly cause brain damage and multiorgan failure, including rhabdomyolysis, renal failure, and coagulopathy (see [Chapter 38](#)).

Treatment

Treat hyperthermia aggressively by removing all clothing, spraying with tepid water, and fanning the patient. If this is not rapidly effective, as shown by a normal rectal temperature within 30-60 minutes, or if there is significant muscle rigidity or hyperactivity, induce neuromuscular paralysis with a nondepolarizing neuromuscular blocker (eg, pancuronium, vecuronium). Once paralyzed, the patient must be intubated and mechanically ventilated. In patients with seizures, absence of visible muscular convulsive movements may give the false impression that brain seizure activity has ceased; however, this must be confirmed by electroencephalography.

Dantrolene (2-5 mg/kg intravenously) may be effective for hyperthermia associated with muscle rigidity that does not respond to neuromuscular blockade (ie, malignant hyperthermia). Bromocriptine, 2.5-7.5 mg orally daily, has been recommended for neuroleptic malignant syndrome. Cyproheptadine, 4 mg orally every hour for three or four doses, has been used to treat serotonin syndrome.

■ ANTIDOTES & OTHER TREATMENT

ANTIDOTES

Give an antidote (if available) when there is reasonable certainty of a specific diagnosis ([Table 39-4](#)). Antidotes themselves may have serious side effects. The indications and dosages for specific antidotes are discussed in the respective sections for specific toxins.

DECONTAMINATION OF THE SKIN

Corrosive agents rapidly injure the skin and eyes and must be removed immediately. In addition, many toxins are readily absorbed through the skin, and systemic absorption can be prevented only by rapid action.

Wash the affected areas with copious quantities of lukewarm water or saline. Wash carefully behind the ears, under the nails, and in skin folds. For oily substances (eg, pesticides), wash the skin at least twice with plain soap and shampoo the hair. Specific decontaminating solutions or solvents (eg, alcohol) are rarely indicated and in some cases may paradoxically enhance absorption. For exposure to chemical warfare poisons such as nerve agents or vesicants, some authorities recommend use of a dilute hypochlorite solution (household bleach diluted 1:10 with water).

DECONTAMINATION OF THE EYES

Act quickly to prevent serious damage. Flush the eyes with copious amounts of saline (preferred) or water. (If available, instill local anesthetic drops in the eye before beginning irrigation.) Remove contact lenses if present. Direct the irrigating stream so that it will flow across both eyes after running off the nasal bridge. Lift the tarsal conjunctiva to look for undissolved particles and to facilitate irrigation. Continue irrigation for 15 minutes or until each eye has been irrigated with at least 1 L of solution. If the toxin is an acid or a base, check the pH of the tears after irrigation, and continue irrigation until the pH is between 6.5 and 7.5.

After irrigation is complete, perform a careful examination of the eye, using fluorescein and a slit lamp or Wood's lamp to identify areas of corneal injury. Patients with serious conjunctival or corneal injury should be immediately referred to an ophthalmologist.

GASTROINTESTINAL DECONTAMINATION

Removal of ingested poisons is a traditional part of emergency treatment. However, studies indicate that if more than 60 minutes has passed, induced emesis and gastric lavage are relatively ineffective. For small or moderate ingestions of most substances, toxicologists generally recommend oral activated charcoal alone without prior gastric emptying. Exceptions are large ingestions of anticholinergic compounds and salicylates, which often delay gastric emptying, and ingestion of sustained-release or enteric-coated tablets, which may remain intact for several hours.

Gastric emptying is not generally used for ingestion of corrosive agents or petroleum distillates, because further esophageal injury or pulmonary aspiration may result. However, in certain cases, removal of the toxin may be more important than concern over possible complications. Consult a medical toxicologist or regional poison control center (800-222-1222) for advice.

Emesis

Emesis using syrup of ipecac is a convenient way to partially evacuate gastric contents if given very soon after ingestion (eg, at work or at home). However, it may delay or prevent use of oral activated charcoal and is no longer used in the hospital management of ingestions.

A. Indications

Induced vomiting may find rare indications in prehospital use but has been virtually replaced by oral activated charcoal.

B. Contraindications

Induced emesis is contraindicated for drowsy, unconscious, or convulsing patients and for patients who have ingested kerosene or other hydrocarbons (danger of aspiration of stomach contents), corrosive poisons, or rapidly acting convulsants (eg, tricyclic antidepressants, strychnine, camphor).

C. Technique

Give syrup of ipecac, 30 mL, followed by an 8-oz glass of water. Repeat in 20 minutes if necessary.

Gastric Lavage

Gastric lavage is more effective for liquid poisons or small pill fragments than for intact tablets or pieces of mushroom. It is most effective when started within 60 minutes after ingestion. However, the lavage procedure may delay administration of activated charcoal and may hasten passage of pills and other toxic material into the small intestine. It is no longer used in the routine management of overdose.

A. Indications

Gastric lavage is sometimes used after very large ingestions (eg, massive aspirin overdose); for collection and examination of gastric contents for identification of poison; and for convenient administration of charcoal and antidotes.

B. Contraindications

Do *not* use lavage for stuporous or comatose patients with absent gag reflexes unless they are endotracheally intubated beforehand. Some authorities advise against lavage when caustic material has been ingested; others regard it as essential to remove liquid corrosives from the stomach.

C. Technique

In obtunded or comatose patients, the danger of aspiration pneumonia is reduced by placing the patient in a head down, left lateral decubitus position and, if necessary, protecting the airway with endotracheal intubation. Gently insert a lubricated, soft but noncollapsible stomach tube (at least 37-40F) through the mouth or nose into the stomach. Aspirate and save the contents, and then lavage repeatedly with 50-100 mL of fluid until the return fluid is clear. Use lukewarm tap water or saline.

Activated Charcoal

Activated charcoal effectively adsorbs almost all drugs and poisons. Poorly adsorbed substances include iron, lithium, potassium, sodium, cyanide, mineral acids, and alcohols.

A. Indications

Activated charcoal should be used for prompt adsorption of drugs or toxins in the stomach and intestine. Studies show that activated charcoal given alone may be as effective as or more effective than ipecac-induced emesis or gastric lavage.

B. Contraindications

Activated charcoal should not be used for comatose or convulsing patients unless it can be given by gastric tube and the airway is first protected by a cuffed endotracheal tube. This substance is contraindicated also for patients with ileus or intestinal obstruction or those who have ingested corrosives for whom endoscopy is planned.

C. Technique

Administer activated charcoal, 60-100 g orally or via gastric tube, mixed in aqueous slurry. Repeated doses may be given to ensure gastrointestinal adsorption or to enhance elimination of some drugs (see below).

Catharsis

A. Indications

Cathartics are used by some toxicologists for stimulation of peristalsis to hasten the elimination of unabsorbed drugs and poisons and the activated charcoal slurry.

B. Contraindications and Cautions

Do not use mineral oil or other oil-based cathartics. Avoid sodium-based cathartics in patients with hypertension, renal failure, and congestive heart failure and magnesium-based cathartics in those with renal failure.

C. Technique

Magnesium sulfate 10%, 2-3 mL/kg; or sorbitol 70%, 1-2 mL/kg. Sorbitol is commonly used in prepackaged charcoal slurry products.

Whole Bowel Irrigation

Whole bowel irrigation utilizes large volumes of balanced polyethylene glycol-electrolyte solution to mechanically cleanse the entire intestinal tract. Because of the composition of the irrigating solution, there is no significant gain or loss of systemic fluids or electrolytes.

A. Indications

Whole bowel irrigation is particularly effective for massive iron ingestion in which intact tablets are visible on abdominal x-ray. It has also been used for ingestions of sustained-release and enteric-coated tablets as well as swallowed drug-filled packets.

B. Contraindications

Same as for cathartics.

C. Technique

Administer the balanced polyethylene glycol-electrolyte solution (CoLyte, GoLYTELY) into the stomach via gastric tube at a rate of 1-2 L/h until the rectal effluent is clear. This may take several hours. It is most effective when patients are able to sit on a commode to pass the intestinal contents.

Increased Drug Removal

A. Urinary Manipulation

Forced diuresis is hazardous; the risk of complications (pulmonary edema, electrolyte imbalance) usually outweighs its benefits. Acidic drugs (eg, salicylates, phenobarbital) are more rapidly excreted with an alkaline urine. Acidification (sometimes promoted for amphetamines, phencyclidine) is *not* very effective and is contraindicated in the presence of rhabdomyolysis or myoglobinuria.

B. Dialysis (Hemodialysis or Hemoperfusion)

The indications for dialysis are as follows: (1) Known or suspected potentially lethal amounts of a dialyzable drug ([Table 39-5](#)). (2) Poisoning with deep coma, apnea, severe hypotension, fluid and electrolyte or acid-base disturbance, or extreme body temperature changes that cannot be corrected by conventional measures. (3) Poisoning in patients with severe renal, cardiac, pulmonary, or hepatic disease who will not be able to eliminate the toxin by usual mechanisms.

Many of the substances that cannot be removed effectively by aqueous dialysis can be removed by hemoperfusion through specially designed coated charcoal columns. Indications are the same as for dialysis. Peritoneal dialysis may occasionally be employed for acute poisonings when hemodialysis is not available, but it is very inefficient. Dialysis should usually augment rather than replace well-established emergency and supportive measures. Continuous arteriovenous and venovenous hemodiafiltration is of uncertain benefit for elimination of poisons.

C. Repeat-Dose Charcoal

Repeated doses of activated charcoal, 20-30 g every 3-4 hours, may hasten elimination of some drugs (eg, digitoxin, theophylline, phenobarbital) by adsorbing drug excreted into the gut lumen ("gut dialysis"). However, no clinical studies have documented improved outcome using multiple-dose charcoal. Sorbitol or other cathartics should *not* be used with each dose, or resulting large stool volumes may lead to dehydration or hypernatremia.

■ DIAGNOSIS OF POISONING

The identity of the ingested substance or substances is usually known, but occasionally a comatose patient is found with an unlabeled container or refuses or otherwise fails to give a coherent history. By performing a directed physical examination and ordering common clinical laboratory tests, the clinician can often make a tentative diagnosis that may allow empirical interventions or may suggest specific toxicologic tests.

PHYSICAL EXAMINATION

Important diagnostic variables in the physical examination include blood pressure, pulse rate, temperature, pupil size, sweating, and the presence or absence of peristaltic activity. Poisonings with many drugs fit into one of four common syndromes.

Sympathomimetic Syndrome

The blood pressure and pulse rate are elevated, though with severe hypertension reflex bradycardia may occur. The temperature is often elevated, pupils are dilated, and the skin is sweaty, though mucous membranes are dry. Patients are usually agitated, anxious, or frankly psychotic.

Examples: Amphetamines, cocaine, ephedrine and pseudoephedrine, phencyclidine (pupils normal or small), phenylpropanolamine (bradycardia common).

Sympatholytic Syndrome

The blood pressure and pulse rate are decreased and body temperature is low. The pupils are small or even pinpoint. Peristalsis is usually decreased. Patients are usually obtunded or comatose.

Examples: Barbiturates, benzodiazepines and other sedative hypnotics, γ -hydroxybutyrate (GHB), clonidine and related antihypertensives, ethanol, opioids.

Cholinergic Syndrome

Stimulation of muscarinic receptors causes bradycardia, miosis, sweating, and hyperperistalsis as well as bronchorrhea, wheezing, excessive salivation, and urinary incontinence. Nicotinic receptor stimulation may produce initial hypertension and tachycardia as well as fasciculations and muscle weakness. Patients are usually agitated and anxious.

Examples: Carbamates, nicotine, organophosphates (including nerve agents), physostigmine.

Anticholinergic Syndrome

Tachycardia with mild hypertension is common, and the body temperature is often elevated. Pupils are widely dilated. The skin is flushed, hot and dry. Peristalsis is decreased, and urinary retention is common. Patients may have myoclonic jerking or choreoathetoid movements. Agitated delirium is frequently seen, and severe hyperthermia may occur.

Examples: Atropine, scopolamine, other naturally occurring and pharmaceutical anticholinergics, amantadine, antihistamines, phenothiazines (hypotension, small pupils), tricyclic antidepressants.

■ CLINICAL LABORATORY TESTS IN MANAGEMENT OF POISONING

The following clinical laboratory tests are recommended for screening of the overdosed patient: measured serum osmolality and osmolar gap, electrolytes, glucose, creatinine, BUN, urinalysis (eg, oxalate crystals with ethylene glycol poisoning, myoglobinuria with rhabdomyolysis), and electrocardiography. Serum acetaminophen and ethanol levels should be determined in all patients with drug overdoses.

OSMOLAR GAP

The osmolar gap is defined and calculation of the gap is described in [Table 39-6](#). It is increased in the presence of large quantities of low-molecular-weight substances, most commonly ethanol. Common poisons associated with increased osmolar gap are acetone, ethanol, ethylene glycol, isopropyl alcohol, methanol, and propylene glycol. **Note:** Severe alcoholic ketoacidosis and diabetic ketoacidosis can also cause an elevated osmolar gap resulting from the production of ketones and other low-molecular-weight substances.

ANION GAP

Metabolic acidosis associated with an elevated anion gap is usually due to an accumulation of lactic acid or other acids (see [Chapter 21](#)). Common causes of elevated anion gap in poisoning include carbon monoxide, cyanide, ethylene glycol, medicinal iron, isoniazid, methanol, phenformin, and salicylates.

One should also check the osmolar gap; combined elevated anion and osmolar gap suggests poisoning by methanol or ethylene glycol, though this may also occur in patients with diabetic ketoacidosis and alcoholic ketoacidosis.

TOXICOLOGY LABORATORY EXAMINATION

A comprehensive toxicology screen ([Table 39-7](#)) is of little value in the initial care of the poisoned patient—on the contrary, it is time-consuming, expensive, and frequently erroneous. Specific quantitative levels of certain drugs may be extremely helpful ([Table 39-8](#)), however, especially if specific antidotes or interventions (eg, dialysis) would be indicated based upon the results.

If a toxicology screen is required, urine is the best specimen. Many hospitals can perform a quick but limited screen for "drugs of abuse" (typically these screens include only opioids, amphetamines, and cocaine, and some add benzodiazepines, barbiturates, phencyclidine, and tetrahydrocannabinol). Blood samples may be saved for possible quantitative testing, but blood is not generally used for screening purposes since it is relatively insensitive for many common drugs, including psychotropic agents, opioids, and stimulants.

ABDOMINAL X-RAYS

A plain film of the abdomen may reveal radiopaque iron tablets, drug-filled condoms, or other toxic material. Studies suggest that few tablets are predictably visible (eg, ferrous sulfate, sodium chloride, calcium carbonate, and potassium chloride). Thus, the x-ray is useful only if positive.

■ TREATMENT OF COMMON SPECIFIC POISONINGS (Alphabetical Order)

ACETAMINOPHEN

Acetaminophen (paracetamol) is a common analgesic found in many nonprescription and prescription products. After absorption, it is metabolized mainly by glucuronidation and sulfation, with a small fraction metabolized via the P450 mixed-function oxidase system to a highly toxic reactive intermediate. This toxic intermediate is normally detoxified by cellular glutathione. With acute acetaminophen overdose (> 140 mg/kg, or 7 g in an average adult), hepatocellular glutathione is rapidly depleted and the reactive intermediate attacks other cell proteins, causing necrosis. Patients with enhanced P450 activity, such as chronic alcoholics and patients taking anticonvulsants, are at increased risk of developing hepatotoxicity. Hepatic toxicity may also occur after chronic accidental overuse of acetaminophen—eg, as a result of taking two or three acetaminophen-containing products concurrently or intentionally exceeding the recommended maximum dose of 4 g/d.

Clinical Findings

Shortly after ingestion, patients may have nausea or vomiting, but there are usually no other signs of toxicity until 24-48 hours after ingestion, when hepatic aminotransferase levels begin to increase. With severe poisoning, fulminant hepatic necrosis may occur, resulting in jaundice, hepatic encephalopathy, renal failure, and death. Rarely, massive ingestion can cause acute coma, hypotension, and metabolic acidosis before there is any evidence of hepatic injury.

The diagnosis of severe poisoning after acute overdose is based on measurement of the serum acetaminophen level. Plot the serum level versus the time since ingestion on the acetaminophen nomogram shown in [Figure 39-1](#). Ingestion of sustained-release products or coingestion of an anticholinergic agent, salicylate, or opioid drug may cause delayed elevation of serum levels and may render the nomogram useless. The nomogram is not useful after chronic overdose.

Treatment

A. Emergency and Supportive Measures

Administer activated charcoal (see p 1551). Although charcoal may interfere with absorption of the oral antidote acetylcysteine, this is not considered clinically significant.

B. Specific Treatment

If the serum acetaminophen level is above the toxic line on the nomogram ([Figure 39-1](#)), begin treatment with a loading dose of acetylcysteine, 140 mg/kg orally, followed by 70 mg/kg every 4 hours. Dilute the solution to 5% with water, juice, or soda. If vomiting interferes with oral acetylcysteine administration, give the dose by gastric tube and use metoclopramide, 1-2 mg/kg intravenously, or consider giving the antidote intravenously (see below). The most widely used protocol in the USA continues treatment for 72 hours. However, other regimens have demonstrated equivalent success with 20-48 hours of treatment. Treatment with acetylcysteine is most effective if started within 8-10 hours after ingestion. If the precise time of ingestion is unknown or if the patient is at higher risk of hepatotoxicity (eg, alcoholic, liver disease, chronic use of P450-inducing drugs), then use a lower threshold for initiation of N-acetylcysteine (ie, the lower nomogram line; in some case reports, a level of 100 mg/L at 4 hours was suggested in very high-risk patients).

Acetylcysteine may also be given intravenously; this is the preferred method in Europe and Canada, but there is no approved parenteral formulation or dosing schedule in the United States. If the patient cannot tolerate oral acetylcysteine despite antiemetics and administration via a gastric tube, the United States formulation may be given intravenously using a micropore filter and a slow rate of infusion. Call a regional poison control center or medical toxicologist for assistance.

Buckley NA et al: Oral or intravenous *N*-acetylcysteine: which is the treatment of choice for acetaminophen (paracetamol) poisoning? *J Toxicol Clin Toxicol* 1999;37:759. [\[PMID: 10584588\]](#)

Dargan PI et al: Acetaminophen poisoning: an update for the intensivist. *Crit Care* 2002;6:108. [\[PMID: 11983032\]](#)

ACIDS, CORROSIVE ([TABLE 39-9](#))

The strong mineral acids exert primarily a local corrosive effect on the skin and mucous membranes. Symptoms include severe pain in the throat and upper gastrointestinal tract; bloody vomitus; difficulty in swallowing, breathing, and speaking; discoloration and destruction of skin and mucous membranes in and around the mouth; and shock. Severe systemic metabolic acidosis may occur both as a result of cellular injury and from systemic absorption of the acid.

Severe deep destructive tissue damage may occur after exposure to hydrofluoric acid because of the penetrating and highly toxic fluoride ion. Systemic hypocalcemia and hyperkalemia also may occur after fluoride absorption, even following skin exposure.

Inhalation of volatile acids, fumes, or gases such as chlorine, fluorine, bromine, or iodine causes severe irritation of the throat and larynx and may cause upper airway obstruction and noncardiogenic pulmonary edema.

Treatment

A. Ingestion

Do *not* induce emesis. Dilute immediately by giving a glass (4-8 oz) of milk or water to drink. Do *not* give bicarbonate or other neutralizing agents. Some experts recommend immediate gastric lavage, particularly if the corrosive is a liquid or has important systemic toxicity.

Perform flexible endoscopic esophagoscopy promptly to determine the presence and extent of injury. X-rays of the chest and abdomen may reveal the presence of free air in patients with esophageal or gastric perforation. Perforation, peritonitis, and major bleeding are indications for surgery.

B. Skin Contact

Flood with water for 15 minutes. Use no chemical antidotes; the heat of the reaction may cause additional injury.

For hydrofluoric acid burns, soak the affected area in magnesium sulfate solution or apply 2.5% calcium gluconate gel (prepared by adding 3.5 g calcium gluconate to 5 oz of water-soluble surgical lubricant, eg, K-Y Jelly); then arrange immediate consultation with a plastic surgeon or other specialist. Binding of the fluoride ion may be achieved by injecting 0.5 mL of 5% calcium gluconate per square centimeter under the burned area. (**Caution:** *Do not use calcium chloride.*) Intra-arterial infusion of calcium is sometimes required for extensive burns or those involving the nail bed; consult with a hand surgeon.

C. Eye Contact

Anesthetize the conjunctiva and corneal surfaces with topical local anesthetic drops (eg, proparacaine). Flood with water for 15 minutes, holding the eyelids open. Check pH with pH 6.0-8.0 test paper, and repeat irrigation, using 0.9% saline, until pH is near 7.0. Check for corneal damage with fluorescein and slit lamp examination; consult an ophthalmologist about further treatment.

D. Inhalation

Remove from further exposure to fumes or gas. Check skin and clothing. Treat pulmonary edema.

ALKALIES (TABLE 39-9)

The strong alkalis are common ingredients of some household cleaning compounds and may be suspected by their "soapy" texture. Those with alkalinity above pH 12.0 are particularly corrosive. Clinitest tablets and disk batteries are also a source. Alkalis cause liquefactive necrosis, which is deeply penetrating. Symptoms include burning pain in the upper gastrointestinal tract, nausea, vomiting, and difficulty in swallowing and breathing. Examination reveals destruction and edema of the affected skin and mucous membranes and bloody vomitus and stools. X-ray may reveal the presence of disk batteries in the esophagus or lower gastrointestinal tract.

Treatment

A. Ingestion

Do *not* induce emesis. Dilute immediately with a glass of water. Some gastroenterologists recommend immediate gastric lavage after ingestion of liquid caustic substances to remove residual material.

Immediate endoscopy is recommended to evaluate the extent of damage. If x-ray reveals the location of ingested disk batteries in the esophagus, immediate endoscopic removal is mandatory.

The use of corticosteroids to prevent stricture formation is of no proved benefit and is definitely contraindicated if there is evidence of esophageal perforation.

B. Skin Contact

Wash with running water until the skin no longer feels soapy. Relieve pain and treat shock.

C. Eye Contact

Anesthetize the conjunctival and corneal surfaces with topical anesthetic (eg, proparacaine). Irrigate with water or saline continuously for 20-30 minutes, holding the lids open. Check pH with pH test paper, and repeat irrigation, using 0.9% saline, for additional 30-minute periods until the pH is near 7.0. Check for corneal damage with fluorescein and slitlamp examination; consult an ophthalmologist for further treatment.

Schier JG et al: Desiccant-induced gastrointestinal burns in a child. Vet Hum Toxicol 2002;44:343. [\[PMID: 2458637\]](#)

AMPHETAMINES & COCAINE

Amphetamines and cocaine are widely abused for their euphorigenic and stimulant properties. Both drugs may be smoked, snorted, ingested, or injected. Amphetamines and cocaine produce central nervous system stimulation and a generalized increase in central and peripheral sympathetic activity. The toxic dose of each drug is highly variable and depends on the route of administration and individual tolerance. The onset of effects is most rapid after intravenous injection or smoking. Amphetamine derivatives and related drugs include methamphetamine ("crystal meth," "crank"), methylenedioxymethamphetamine (MDMA, "ecstasy"), ephedrine ("herbal ecstasy"), and methcathinone ("cat"). Nonprescription medications and nutritional supplements may contain stimulant or sympathomimetic drugs such as ephedrine or caffeine (see Theophylline, below): Phenylpropanolamine was recently withdrawn from the market because of an increased incidence of hypertensive intracerebral hemorrhage in young women.

Clinical Findings

Patients may present with anxiety, tremulousness, tachycardia, hypertension, diaphoresis, dilated pupils, agitation, muscular hyperactivity, and psychosis. Metabolic acidosis may occur. In severe intoxication, seizures and hyperthermia may occur. Sustained or severe hypertension may result in intracranial hemorrhage, aortic dissection, or myocardial infarction. Hyponatremia has been reported after MDMA use; the mechanism is not known but may involve excessive water intake, SIADH, or both.

The diagnosis is supported by finding amphetamines, cocaine, or the cocaine metabolite benzoylecgonine in the urine. Blood screening is not sensitive enough to detect these drugs.

Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist ventilation, if necessary. Treat coma or seizures as described at the beginning of this chapter. Rapidly lower the body temperature (see hyperthermia, above) in patients who are hyperthermic (40 °C). Treat agitation or psychosis with a benzodiazepine such as diazepam, 5-10 mg intravenously (repeated as needed up to 20 mg), or midazolam, 0.1-0.2 mg/kg intramuscularly.

For poisoning by ingestion, perform gastric lavage and administer activated charcoal, or administer activated charcoal alone without prior gut emptying (see p 1551). Do *not* induce emesis, because of the risk of seizures.

B. Specific Treatment

Treat agitation with a sedative such as lorazepam, 2-3 mg intravenously. Treat hypertension with a vasodilator drug such as phentolamine (1-5 mg intravenously) or nifedipine (10-20 mg orally) or a combined α - and β -adrenergic blocker such as labetalol (10-20 mg intravenously). Do *not* administer a pure beta-blocker such as propranolol alone, as this may result in paradoxical worsening of the hypertension as a result of unopposed α -adrenergic effects.

Treat tachycardia or tachyarrhythmias with a short-acting beta-blocker such as esmolol (25-100 ug/kg/min by intravenous infusion). Treat hyponatremia as outlined in [Chapter 21](#).

Parrott AC: Recreational Ecstasy/MDMA, the serotonin syndrome, and serotonergic neurotoxicity. Pharmacol Biochem Behav 2002;71:837. [\[PMID: 11888574\]](#)

ANTICOAGULANTS

Warfarin and related compounds (including ingredients of many commercial rodenticides) inhibit the clotting mechanism by blocking hepatic synthesis of vitamin K-dependent clotting factors.

Anticoagulants may cause hemoptysis, gross hematuria, bloody stools, hemorrhages into organs, widespread bruising, and bleeding into joint spaces. The prothrombin time is increased within 12-24 hours (peak 36-48 hours) after a single overdose. After ingestion of brodifacoum and indanedione rodenticides (so-called superwarfarins), inhibition of clotting factor synthesis may persist for several weeks or even months after a single dose.

Treatment

A. Emergency and Supportive Measures

Discontinue the drug at the first sign of gross bleeding, and determine the prothrombin time. If the patient has ingested an acute overdose, administer activated charcoal (see p 1551).

B. Specific Treatment

Do not treat prophylactically—wait for the evidence of anticoagulation (elevated prothrombin time). If the prothrombin time is elevated, give phytonadione (vitamin K₁), 10-25 mg orally, and additional doses as needed to restore the prothrombin time to normal. Doses as high as 200 mg/d have been required after ingestion of "superwarfarins." Give fresh-frozen plasma as needed to rapidly correct the coagulation factor deficit if there is serious bleeding. If the patient is chronically anticoagulated and has strong medical indications for being maintained in that status (eg, prosthetic heart valve), give much smaller doses of vitamin K (1 mg) and fresh-frozen plasma (or both) to titrate to the desired prothrombin time.

If the patient has ingested brodifacoum or a related superwarfarin, prolonged observation (over weeks) and repeated administration of large doses of vitamin K may be required.

Ingels M et al: A prospective study of acute, unintentional, pediatric superwarfarin ingestions managed without decontamination. *Ann Emerg Med* 2002;40:73. [PMID: 12085076]

ANTICONSULSANTS (CARBAMAZEPINE, PHENYTOIN, VALPROIC ACID)

These drugs are widely used in the management of seizure disorders. In addition, carbamazepine and valproic acid are increasingly used for treatment of mood disorders.

Phenytoin can be given orally or intravenously. Rapid intravenous injection of phenytoin can cause acute myocardial depression and cardiac arrest owing to the solvent propylene glycol; a newer form of phenytoin (fosphenytoin) is available that does not contain this diluent. Chronic phenytoin intoxication can occur following only slightly increased doses because of zero-order kinetics and a small toxic-therapeutic window. Phenytoin intoxication can also occur following acute intentional or accidental overdose. The overdose syndrome is usually mild even with high serum levels. The most common manifestations are ataxia, nystagmus, and drowsiness. Choreoathetoid movements have been described.

Carbamazepine was first used for the treatment of trigeminal neuralgia. It has since become a first-line agent for temporal lobe epilepsy and other seizure disorders. Intoxication causes drowsiness, stupor, and, with high levels, coma and seizures. Dilated pupils and tachycardia are common. Toxicity may be seen with serum levels greater than 20 mg/L, though severe poisoning is usually associated with concentrations greater than 30-40 mg/L. Because of erratic and slow absorption, intoxication may progress over several hours to days.

Valproic acid intoxication produces a unique syndrome consisting of hypernatremia (from the sodium component of the salt), metabolic acidosis, hypocalcemia, elevated serum ammonia, and mild liver aminotransferase elevation. Hypoglycemia may occur as a result of hepatic metabolic dysfunction. Coma with small pupils may be seen and can mimic opioid poisoning. Encephalopathy and cerebral edema can occur.

Treatment

A. Emergency and Supportive Measures

For recent ingestions, give activated charcoal orally or by gastric tube. For large ingestions of carbamazepine or valproic acid—especially of sustained-release formulations—consider whole bowel irrigation (see p 1551). Multiple-dose activated charcoal may be beneficial in ensuring gut decontamination for large ingestions and might enhance elimination of absorbed drugs.

B. Specific Treatment

There are no antidotes. Naloxone was reported to have reversed valproic acid overdose in one anecdotal case. Consider hemodialysis (valproic acid) or hemoperfusion (carbamazepine) for massive intoxication (eg, carbamazepine levels > 100 mg/L or valproic acid levels > 1000 mg/L).

Cameron RJ et al: Efficacy of charcoal hemoperfusion in massive carbamazepine poisoning. *J Toxicol Clin Toxicol* 2002;40: 507. [PMID: 12217004]

ARSENIC

Arsenic is found in some pesticides and industrial chemicals. Symptoms of poisoning usually appear within 1 hour after ingestion but may be delayed as long as 12 hours. They include abdominal pain, vomiting, watery diarrhea, and skeletal muscle cramps. Profound dehydration and shock may occur. In chronic poisoning, symptoms can be vague but often include those of peripheral sensory neuropathy. Urinary arsenic levels may be falsely elevated after certain meals (eg, seafood) that contain large quantities of a nontoxic form of organic arsenic.

Treatment

A. Emergency Measures

Perform gastric lavage and administer 60-100 g of activated charcoal (see p 1551).

B. Antidote

For symptomatic patients or those with massive overdose, give dimercaprol injection (BAL), 10% solution in oil, 3-5 mg/kg intramuscularly every 4-6 hours for 2 days. The side effects include nausea, vomiting, headache, and hypertension. Follow dimercaprol with oral penicillamine, 100 mg/kg/d in four divided doses (maximum, 2 g/d), or succimer (DMSA), 10 mg/kg every 8 hours, for 1 week. Consult a medical toxicologist or regional poison control center (800-222-1222) for advice regarding chelation.

Hall AH: Chronic arsenic poisoning. *Toxicol Lett* 2002;128:69. [PMID: 11869818]

ATROPINE & ANTICHOLINERGICS

Atropine, scopolamine, belladonna, diphenoxylate with atropine, *Datura stramonium*, *Hyoscyamus niger*, some mushrooms, tricyclic antidepressants, and antihistamines are antimuscarinic agents with variable central nervous system effects. The patient complains of dryness of the mouth, thirst, difficulty in swallowing, and blurring of vision. The physical signs include dilated pupils, flushed skin, tachycardia, fever, delirium, myoclonus, ileus, and flushed appearance. Antidepressants and antihistamines may induce convulsions.

Antihistamines are commonly available with or without prescription. Diphenhydramine commonly causes delirium, tachycardia, and seizures. Massive overdose may mimic tricyclic antidepressant poisoning. The first-generation "nonsedating" agents terfenadine and astemizole have caused QT interval prolongation and torsade de pointes (atypical ventricular tachycardia) and were removed from the United States market. Loratadine and fexofenadine have not caused this problem.

Treatment

A. Emergency and Supportive Measures

Administer activated charcoal (see p 1551). Tepid sponge baths and sedation are indicated to control high temperatures (see p 1549).

B. Specific Treatment

For pure atropine or related anticholinergic syndrome, if symptoms are severe (eg, hyperthermia or excessively rapid tachycardia), give physostigmine salicylate, 0.5-1 mg slowly intravenously over 5 minutes, with electrocardiographic monitoring, until symptoms are controlled. Bradyarrhythmias and convulsions are a hazard with physostigmine administration, and it should not be used in patients with tricyclic antidepressant overdose.

Burns MJ et al: A comparison of physostigmine and benzodiazepines for the treatment of anticholinergic poisoning. Ann Emerg Med 2000;35:374. [\[PMID: 10736125\]](#)

BETA-ADRENERGIC BLOCKERS

There are a wide variety of β -adrenergic blocking drugs, with varying pharmacologic and pharmacokinetic properties (see [Table 11-6](#)). The most toxic beta-blocker is propranolol. Propranolol competitively blocks β_1 and β_2 adrenoceptors and also has direct membrane-depressant and central nervous system effects.

Clinical Findings

The most common findings with mild or moderate intoxication are hypotension and bradycardia. Cardiac depression from more severe poisoning is often unresponsive to conventional therapy with β -adrenergic stimulants such as dopamine and norepinephrine. In addition, with propranolol and other lipid-soluble drugs, seizures and coma may occur.

The diagnosis is based on typical clinical findings. Routine toxicology screening does not usually include beta-blockers.

Treatment

A. Emergency and Supportive Measures

Initially, treat bradycardia or heart block with atropine (0.5-2 mg intravenously), isoproterenol (2-20 ug/ min by intravenous infusion, titrated to the desired heart rate), or an external transcutaneous cardiac pacemaker. However, these measures are often ineffective, and specific antidotal treatment may be necessary (see below).

For ingested drugs, administer activated charcoal (see p 1551).

B. Specific Treatment

If the above measures are not successful in reversing bradycardia and hypotension, give glucagon, 5-10 mg intravenously, followed by an infusion of 1-5 mg/h. Glucagon is an inotropic agent that acts at a different receptor site and is therefore not affected by beta-blockade.

Love JN et al: Acute beta blocker overdose: factors associated with the development of cardiovascular morbidity. J Toxicol Clin Toxicol 2000;38:275. [\[PMID: 10866327\]](#)

CALCIUM CHANNEL BLOCKERS

Calcium channel blockers used in the United States include verapamil, diltiazem, nifedipine, nicardipine, amlodipine, felodipine, isradipine, nisoldipine, and nimodipine. These drugs share the ability to cause arteriolar vasodilation and depression of cardiac contractility, especially after acute overdose. Patients may present with bradycardia, AV nodal block, hypotension, or a combination of these effects. With severe poisoning, cardiac arrest may occur.

Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist ventilation, if necessary. Treat coma, hypotension, and seizures as described at the beginning of this chapter. Treat bradycardia with atropine (0.5-2 mg intravenously), isoproterenol (2-20 ug/min by intravenous infusion), or a transcutaneous or internal cardiac pacemaker.

For ingested drugs, administer activated charcoal (see p 1551). In addition, whole bowel irrigation should be initiated as soon as possible if the patient has ingested a sustained-release product.

B. Specific Treatment

If bradycardia and hypotension are not reversed with these measures, administer calcium chloride intravenously. Start with calcium chloride 10%, 10 mL; or calcium gluconate 10%, 20 mL. Repeat the dose every 3-5 minutes. The optimum (or maximum) dose has not been established, but there are reports of success after as much as 10-12 g of calcium chloride. Calcium is most useful in reversing negative inotropic effects and is less effective for AV nodal blockade and bradycardia. Epinephrine infusion (1-4 ug/min initially) and glucagon, 5-10 mg intravenously, have also been recommended.

CARBON MONOXIDE

Carbon monoxide is a colorless, odorless gas produced by the combustion of carbon-containing materials. Poisoning may occur as a result of suicidal or accidental exposure to automobile exhaust, smoke inhalation in a fire, or accidental exposure to an improperly vented gas heater or other appliance. Carbon monoxide avidly binds to hemoglobin, with an affinity approximately 250 times that of oxygen. This results in reduced oxygen-carrying capacity and altered delivery of oxygen to cells (see also Smoke Inhalation in [Chapter 9](#)).

Clinical Findings

At low carbon monoxide levels (carboxyhemoglobin saturation 10-20%), victims may have headache, dizziness, abdominal pain, and nausea. With higher levels, confusion, dyspnea, and syncope may occur. Hypotension, coma, and seizures are common with levels greater than 50-60%. Survivors of acute severe poisoning may develop permanent obvious or subtle neurologic and neuropsychiatric deficits. The fetus and newborn may be more susceptible because of high carbon monoxide affinity for fetal hemoglobin.

Carbon monoxide poisoning should be suspected in any person with severe headache or acutely altered mental status, especially during cold weather, when improperly vented heating systems may have been used. Diagnosis depends on specific measurement of the arterial or venous carboxyhemoglobin saturation, although the level may have declined if high-flow oxygen therapy has already been administered. Routine arterial blood gas testing and pulse oximetry are not useful because they may give falsely normal oxyhemoglobin saturation determinations.

Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist ventilation, if necessary. Remove the victim from exposure. Treat patients with coma, hypotension, or seizures, as described at the beginning of this chapter.

B. Specific Treatment

The half-life of the carboxyhemoglobin complex is about 4-5 hours in room air but is reduced dramatically by high concentrations of oxygen. Administer 100% oxygen by tight-fitting high-flow reservoir face mask or endotracheal tube. Hyperbaric oxygen (HBO) can provide 100% oxygen under higher than atmospheric pressures, further shortening the half-life; it may also reduce the incidence of subtle neuropsychiatric sequelae. Recent studies disagree about the benefit of HBO, but recommended indications for HBO in patients with carbon monoxide poisoning include a history of loss of consciousness, COHb greater than 25%, metabolic acidosis, age over 50 years, and cerebellar findings on neurologic examination.

CHEMICAL WARFARE AGENTS

Nerve agents used in chemical warfare work by cholinesterase inhibition and are most commonly organophosphorus compounds. Agents such as **tabun** (dimethylphosphoramidocyanidic acid ethyl ether) and **sarin** (methylphosphonofluoridic acid 1-methylethyl ester) are similar to insecticides such as malathion but are vastly more potent. They may be inhaled or absorbed through the skin. Systemic effects due to unopposed action of acetylcholine include miosis, salivation, abdominal cramps, diarrhea, and muscle paralysis producing respiratory arrest. Inhalation also produces severe bronchoconstriction and copious nasal and tracheobronchial secretions.

Treatment

A. Emergency and Supportive Measures

Perform thorough decontamination of exposed areas with repeated soap and shampoo washing. Personnel caring for such patients must wear protective clothing and gloves, since cutaneous absorption may occur through normal skin.

B. Specific Treatment

Give atropine in an initial dose of 2 mg intravenously, and repeat as needed to reverse signs of acetylcholine excess. (Some victims have required several hundred milligrams.) Treat also with the cholinesterase-reactivating agent pralidoxime, 1-2 g intravenously initially followed by an infusion at a rate of 200-400 mg/h. United States military personnel in the Persian Gulf war were equipped with autoinjectable units containing 2 mg of atropine plus 600 mg of the cholinesterase-reactivating agent pralidoxime.

CHLORINATED INSECTICIDES (CHLOROPHENOTHANE [DDT], LINDANE, TOXAPHENE, CHLORDANE, ALDRIN, ENDRIN)

Lindane (Kwell) and other chlorinated insecticides are central nervous system stimulants that can cause poisoning by ingestion, inhalation, or direct contact. Most of these agents have been removed from the United States market because of their acute toxicity and their potential to accumulate in the food chain. The estimated lethal dose is about 20 g for DDT, 3 g for lindane, 2 g for toxaphene, 1 g for chlordane, and less than 1 g for endrin and aldrin. The manifestations of poisoning are nervous irritability, muscle twitching, seizures, and coma. Arrhythmias may occur. Hepatic and renal damage are reported.

Treatment

Give activated charcoal and consider gastric lavage for large recent ingestions (see p 1561). Repeat-dose activated charcoal may be effective for large ingestions. For seizures, give diazepam, 5-10 mg slowly intravenously, or other anticonvulsants as described on p 1549.

Perform thorough decontamination of exposed areas with repeated soap and shampoo washing. Personnel caring for such patients must wear protective clothing and gloves, since cutaneous absorption may occur through normal skin.

Nordt SP et al: Acute lindane poisoning in three children. J Emerg Med 2000;18:51. [\[PMID: 10645838\]](#)

CLONIDINE & OTHER SYMPATHOLYTIC ANTIHYPERTENSIVES (CLONIDINE, GUANABENZ, GUANFACINE, METHYLDOPA)

Overdosage with these agents causes bradycardia, hypotension, miosis, respiratory depression, and coma. (Hypertension occasionally occurs after clonidine overdosage, a result of peripheral alpha-adrenergic effects of this drug in high doses.) Symptoms are usually resolved in less than 24 hours, and deaths are rare. Similar symptoms may occur after ingestion of topical nasal decongestants chemically similar to clonidine (oxymetazoline, tetrahydrozoline, naphazoline). Brimonidine is used as an ophthalmic preparation for glaucoma.

Treatment

A. Emergency and Supportive Measures

Give activated charcoal and a cathartic (see p 1551). Maintain the airway and support respiration if necessary. Symptomatic treatment is usually sufficient even in massive overdose. Maintain blood pressure with intravenous fluids. Dopamine can also be used. Atropine is usually effective for bradycardia.

B. Specific Treatment

There is no specific antidote. Although tolazoline has been recommended for clonidine overdose, its effects are unpredictable and it should not be used. Naloxone has been reported to be successful in a few anecdotal and poorly substantiated cases.

Berlin RJ et al: Ophthalmic drops causing coma in an infant. J Pediatr 2001;138:441. [\[PMID: 11241061\]](#)

COCAINE

See Amphetamines & Cocaine, above.

CYANIDE

Cyanide is a highly toxic chemical used widely in research and commercial laboratories and many industries. Its gaseous form, hydrogen cyanide, is an important component of smoke in fires. Cyanide-generating glycosides are also found in the pits of apricots and other related plants. Cyanide is generated by the breakdown of nitroprusside, and poisoning can result from rapid high-dose infusions. Cyanide is also formed by metabolism of acetonitrile, found in some over-the-counter fingernail glue removers. Cyanide is rapidly absorbed by inhalation, skin absorption, or ingestion. It disrupts cellular function by inhibiting cytochrome oxidase and preventing cellular oxygen utilization.

Clinical Findings

The onset of toxicity is nearly instantaneous after inhalation of hydrogen cyanide gas but may be delayed for minutes to hours after ingestion of cyanide salts or cyanogenic plants or chemicals. Effects include headache, dizziness, nausea, abdominal pain, and anxiety, followed by confusion, syncope, shock, seizures, coma, and death. The odor of "bitter almonds" may be detected on the victim's breath or in vomitus, though this is not a reliable finding. The venous oxygen saturation may be elevated (> 90%) in severe poisonings because tissues have failed to take up arterial oxygen.

Treatment

A. Emergency and Supportive Measures

Remove the victim from exposure, taking care to avoid exposure to rescuers. For suspected cyanide poisoning due to nitroprusside infusion, stop or slow the rate of infusion. (Metabolic acidosis and other signs of cyanide poisoning usually clear rapidly.)

For cyanide ingestion, administer activated charcoal (see p 1551). At the scene, induce emesis if charcoal is not immediately available (see p 1551). Although charcoal has a low affinity for cyanide, the usual doses of 60-100 g are adequate to bind typically ingested lethal doses (100-200 mg).

B. Specific Treatment

In the United States, the cyanide antidote package (Taylor Pharmaceuticals) ([Table 39-10](#)) contains nitrites (to induce methemoglobinemia, which binds free cyanide) and thiosulfate (to promote conversion of cyanide to the less toxic thiocyanate). Administer amyl nitrite by crushing an ampule under the victim's nose or at the end of the endotracheal tube, and administer 3% sodium nitrite solution, 10 mL intravenously. **Caution:** Nitrites may induce hypotension and dangerous levels of methemoglobin. Also administer 25% sodium thiosulfate solution, 50 mL intravenously (12.5 g).

Mannaioni G et al: Acute cyanide intoxication treated with a combination of hydroxycobalamin, sodium nitrite, and sodium thiosulfate. J Toxicol Clin Toxicol 2002;40:181. [\[PMID: 12126191\]](#)

DIGITALIS & OTHER CARDIAC GLYCOSIDES

Cardiac glycosides are derived from a variety of plants and are widely used to treat heart failure and supraventricular arrhythmias. These drugs paralyze the $\text{Na}^+ \text{-K}^+$ ATPase pump and have potent vagotonic effects. Intracellular effects include enhancement of calcium-dependent contractility and shortening of the action potential duration. Digoxin and ouabain are highly tissue-bound, but digitoxin has a volume of distribution of just 0.6 L/kg, making it the only cardiac glycoside accessible to enhanced removal procedures such as hemoperfusion or repeated doses of activated charcoal.

Clinical Findings

Intoxication may result from acute single exposure or chronic accidental overmedication. After acute overdosage, patients frequently develop nausea and vomiting, bradycardia, hyperkalemia, and atrioventricular block. Patients who develop toxicity gradually during chronic therapy are often hypokalemic and hypomagnesemic owing to concurrent diuretic treatment and more commonly present with ventricular arrhythmias (eg, ectopy, bidirectional ventricular tachycardia, or ventricular fibrillation).

Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist ventilation, if necessary. Monitor potassium levels and cardiac rhythm closely. Treat ventricular arrhythmias initially with lidocaine (2-3 mg/kg intravenously) or phenytoin (10-15 mg/kg intravenously slowly over 30 minutes) and treat bradycardia initially with atropine (0.5-2 mg intravenously), isoproterenol (1-5 ug/min initially), or a transcutaneous external cardiac pacemaker.

After acute ingestion, administer activated charcoal (see p 1551). Emesis is not recommended because it may enhance vagotonic effects such as bradycardia and AV block.

B. Specific Treatment

For patients with severe intoxication, administer digoxin-specific antibodies (digoxin immune Fab [ovine]; Digibind). Estimation of the Digibind dose is based on the body burden of digoxin calculated from the ingested dose or the steady-state serum digoxin concentration:

1. From the ingested dose—Number of vials = approximately $1.5 \times$ ingested dose (mg).

2. From the serum concentration—Number of vials = serum digoxin (ng/mL) $\times$ body weight (kg) $\times 10^2$. **Note:** This is based on the equilibrium digoxin level; after acute overdose, serum levels are falsely high before tissue distribution is complete, and overestimation of the Digibind dose is likely.

3. Empirical dosing—Empirical dosing of Digibind may be utilized if the patient's condition is relatively stable and an underlying condition (eg, atrial fibrillation) suggests a residual level of digitalis activity. Start with one or two vials and reassess the clinical condition after 20-30 minutes.

Note: After administration of Digibind, serum digoxin levels may be falsely elevated depending on the assay technique.

Eddleston M et al: Acute yellow oleander (*Thevetia peruviana*) poisoning: cardiac arrhythmias, electrolyte disturbances, and serum cardiac glycoside concentrations on presentation to hospital. Heart 2000;83:301 [\[PMID: 10677410\]](#)

Roever C et al: Comparing the toxicity of digoxin and digitoxin in a geriatric population: should an old drug be rediscovered? South Med J 2000;93:199. [\[PMID: 10701788\]](#)

ETHANOL, BARBITURATES, BENZODIAZEPINES, & OTHER SEDATIVE-HYPNOTIC AGENTS

The group of agents known as sedative-hypnotic drugs includes a variety of products used for the treatment of anxiety, depression, insomnia, and epilepsy. Ethanol and other selected agents are also popular recreational drugs. All of these drugs depress the central nervous system reticular activating system, cerebral cortex, and cerebellum.

Clinical Findings

Mild intoxication produces euphoria, slurred speech, and ataxia. Ethanol intoxication may produce hypoglycemia, even at relatively low concentrations. With more severe intoxication, stupor, coma, and respiratory arrest may occur. Carisoprodol commonly causes muscle jerking or myoclonus. Death or serious morbidity is usually the result of pulmonary aspiration of gastric contents. Bradycardia, hypotension, and hypothermia are common. Patients with massive intoxication may appear to be dead, with no reflex responses and even absent electroencephalographic activity. Diagnosis and assessment of severity of intoxication are usually based on clinical findings. Ethanol serum levels greater than 300 mg/dL (0.3 g/dL; 65 mmol/L) usually produce coma in persons who are not chronically abusing the drug, but regular users may remain awake at much higher levels. Phenobarbital levels greater than 80-100 mg/L usually cause coma.

Treatment

A. Emergency and Supportive Measures

Administer activated charcoal (see p 1551). Repeat-dose charcoal may enhance elimination of phenobarbital, but it has not been shown to improve clinical outcome. Hemoperfusion may be necessary for patients with severe phenobarbital intoxication.

B. Specific Treatment

Flumazenil is a benzodiazepine receptor-specific antagonist; it has no effect on ethanol, barbiturates, or other sedative-hypnotic agents. If used, flumazenil is given slowly intravenously, 0.2 mg over 30-60 seconds, repeated in 0.5 mg increments as needed up to a total dose of 3-5 mg. **Caution:** Flumazenil may induce seizures in patients with preexisting seizure disorder, benzodiazepine addiction, or concomitant tricyclic antidepressant overdose. If seizures occur, diazepam and other benzodiazepine anticonvulsants will not be effective. As with naloxone, the duration of action of flumazenil is short (2-3 hours) and resedation may occur, requiring repeated doses.

Mathieu-Nolf M et al: Flumazenil use in an emergency department: a survey. J Toxicol Clin Toxicol 2001;39:15. [\[PMID: 11327221\]](#)

GAMMA-HYDROXYBUTYRATE

Gamma-hydroxybutyrate (GHB) has become a popular drug of abuse. It originated as a short-acting general anesthetic and is occasionally used in the treatment of narcolepsy. It gained popularity among bodybuilders for its alleged growth hormone stimulation and found its way into social settings, where it is consumed as a liquid. Symptoms after ingestion include drowsiness and lethargy followed by coma with respiratory depression. Muscle twitching and seizures are sometimes observed. Recovery is usually rapid, with patients awakening within a few hours. Other related chemicals with similar effects include butanediol and gamma-butyrolactone (GBL). A prolonged withdrawal syndrome has been described in some heavy users.

Treatment

For recent ingestions, give activated charcoal orally or by gastric tube. There is no specific treatment. Most patients recover rapidly with supportive care. GHB withdrawal syndrome may require very large doses of benzodiazepines.

Dyer JE et al: Gamma-hydroxybutyrate withdrawal syndrome. Ann Emerg Med 2001;37:147. [\[PMID: 11174231\]](#)

Sivilotti ML et al: Pentobarbital for severe gamma-butyrolactone withdrawal. Ann Emerg Med 2001;38:660. [\[PMID: 11719746\]](#)

Zvosec DL et al: Adverse effects, including death, associated with the use of 1,4-butanediol. N Engl J Med 2001;344:87. [\[PMID: 11150358\]](#)

IRON

Iron is widely used therapeutically for the treatment of anemia and as a daily supplement in multiple vitamin preparations. Most children's preparations contain about 12-15 mg of elemental iron (as sulfate, gluconate, or fumarate salt) per dose, compared with 60-90 mg in most adult-strength preparations. Iron is corrosive to the gastrointestinal tract and, once absorbed, has depressant effects on the myocardium and on peripheral vascular resistance. Intracellular toxic effects of iron include disruption of Krebs cycle enzymes.

Clinical Findings

Ingestion of less than 30 mg/kg of elemental iron usually produces only mild gastrointestinal upset. Ingestion of more than 40-60 mg/kg may cause vomiting (sometimes with hematemesis), diarrhea, hypotension, and acidosis. Death may occur as a result of profound hypotension due to massive fluid losses and bleeding, metabolic acidosis, peritonitis from intestinal perforation, or sepsis. Fulminant hepatic failure may occur. Survivors of the acute ingestion may suffer permanent gastrointestinal scarring.

Serum iron levels greater than 350-500 ug/dL are considered potentially toxic, and levels over 1000 ug/dL are usually associated with severe poisoning. A plain abdominal x-ray may reveal radiopaque tablets.

Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist ventilation if necessary. Treat hypotension aggressively with intravenous crystalloid solutions (0.9% saline or lactated Ringer's solution). Fluid losses may be massive owing to vomiting and diarrhea as well as third-spacing into injured intestine.

Perform whole bowel irrigation to remove unabsorbed pills from the intestinal tract (see p 1551). Activated charcoal is not effective but may be needed if other ingestants are suspected.

B. Specific Treatment

Deferoxamine is a selective iron chelator. It is not useful as an oral binding agent. For patients with established manifestations of toxicity—and particularly those with markedly elevated serum iron levels (eg, greater than 800-1000 ug/dL)—administer 10-15 mg/kg/h by constant intravenous infusion; higher doses (up to 40-50 mg/kg/h) have been used in massive poisonings. Hypotension may occur. The presence of iron-deferoxamine complex in the urine may give it a "vin rose" appearance. Deferoxamine is safe for use in pregnant women with acute iron overdose. Caution: Prolonged infusion of deferoxamine (> 36- 48 hours) has been associated with development of acute respiratory distress syndrome (ARDS)—the mechanism is not known.

Tran T et al: Intentional iron overdose in pregnancy—management and outcome. J Emerg Med 2000;18:225. [\[PMID: 10699527\]](#)

ISONIAZID

Isoniazid (INH) is an antibacterial drug used mainly in the treatment and prevention of tuberculosis. It may cause hepatitis in certain patients with chronic use. It produces acute toxic effects by competing with pyridoxal 5-phosphate, resulting in lowered brain γ -aminobutyric acid (GABA) levels. Acute ingestion of as little as 1.5-2 g of isoniazid can cause toxicity, and severe poisoning is likely to occur after ingestion of more than 80-100 mg/kg.

Clinical Findings

Confusion, slurred speech, and seizures may occur abruptly after acute overdose. Severe lactic acidosis—out of proportion to the severity of seizures—is probably due to inhibited metabolism of lactate.

Diagnosis is based on a history of ingestion and the presence of severe acidosis associated with seizures. Isoniazid is not usually included in routine toxicologic screening, and serum levels are not readily available.

Treatment

A. Emergency and Supportive Measures

Seizures may require higher than usual doses of benzodiazepines (eg, lorazepam, 3-5 mg intravenously) or administration of pyridoxine as an antidote (see below).

Administer activated charcoal (see p 1551). Do *not* induce emesis, because of the risk of abrupt onset of seizures.

B. Specific Treatment

Pyridoxine (vitamin B₆) is a specific antagonist of the acute toxic effects of isoniazid and is usually successful in controlling convulsions that do not respond to benzodiazepines. Give 5 g intravenously over 1-2 minutes or, if the amount ingested is known, give a gram-for-gram equivalent amount of pyridoxine.

Santucci KA et al: Acute isoniazid exposures and antidote availability. Pediatr Emerg Care 1999;15:99. [\[PMID: 10220077\]](#)

Sullivan EA et al: Isoniazid poisonings in New York City. J Emerg Med 1998;16:57. [\[PMID: 9472761\]](#)

LEAD

Lead is used in a variety of industrial and commercial products, such as storage batteries, solders, paints, pottery, plumbing, and gasoline and is found in some traditional ethnic medicines. Lead toxicity usually results from chronic repeated exposure and is rare after a single ingestion. Lead produces a variety of adverse effects on cellular function and primarily affects the nervous system, gastrointestinal tract, and hematopoietic system.

Clinical Findings

Lead poisoning often goes undiagnosed initially because presenting symptoms and signs are nonspecific and exposure is not suspected. Common symptoms include colicky abdominal pain, constipation, headache, and irritability. Severe poisoning may cause coma and convulsions. Chronic intoxication can cause learning disorders (in children) and motor neuropathy (eg, wrist drop).

Diagnosis is based on measurement of the blood lead level. Whole blood lead levels less than 10 ug/dL are usually considered nontoxic. Levels between 10 and 25 ug/dL have been associated with impaired neurobehavioral development in children. Levels of 25-50 ug/dL may be associated with headache, irritability, and subclinical neuropathy. Levels of 50-70 ug/dL are associated with moderate toxicity, and levels greater than 70-100 ug/dL are often associated with severe poisoning. Other laboratory findings of lead poisoning include microcytic anemia with basophilic stippling and elevated free erythrocyte protoporphyrin.

Treatment

A. Emergency and Supportive Measures

For patients with encephalopathy, maintain a patent airway and treat coma and convulsions as described at the beginning of this chapter.

For recent acute ingestion, give activated charcoal (see p 1551). If a large lead-containing object (eg, fishing weight) is still visible in the stomach on abdominal x-ray, repeated cathartics, whole bowel irrigation, endoscopy, or even surgical removal may be necessary to prevent subacute lead poisoning. (The acidic gastric contents may corrode the metal surface, enhancing lead absorption. Once the object passes into the small intestine, the risk of toxicity declines.)

Conduct an investigation into the source of the lead exposure. Workers with a single lead level greater than 60 ug/dL (or three successive monthly levels greater than 50 ug/dL) or construction workers with any single blood lead level greater than 50 ug/dL must by federal law be removed from the site of exposure. Contact the regional office of the United States Occupational Safety and Health Administration (OSHA) for more information. Several states mandate reporting of cases of confirmed lead poisoning.

B. Specific Treatment

The indications for chelation depend on the blood lead level and the patient's clinical state. A medical toxicologist or regional poison control center (800-222-1222)

should be consulted for advice about selection and use of these antidotes.

Note: It is impermissible under the law to treat asymptomatic workers with elevated blood lead levels in order to keep their levels under 50 ug/dL rather than remove them from the exposure.

1. Severe toxicity—Patients with severe intoxication (encephalopathy or levels greater than 70-100 ug/dL) should receive edetate calcium disodium (EDTA), 1500 mg/m²/kg/d (approximately 50 mg/kg/d) in four to six divided doses or as a continuous intravenous infusion. Some clinicians also add dimercaprol (BAL), 4-5 mg/kg intramuscularly every 4 hours for 5 days.

2. Less severe toxicity—Patients with less severe symptoms and asymptomatic patients with blood lead levels between 55 and 69 ug/dL may be treated with edetate calcium disodium alone in dosages as above. An oral chelator, succimer (dimercaptosuccinic acid, DMSA), is available for use in patients with mild to moderate intoxication. The usual dose is 10 mg/kg orally every 8 hours for 5 days, then every 12 hours for 2 weeks.

LSD & OTHER HALLUCINOGENS

A variety of substances—ranging from naturally occurring plants and mushrooms to synthetic substances such as phencyclidine (PCP), toluene and other solvents, and LSD—are abused for their hallucinogenic properties. The mechanism of toxicity and the clinical effects vary for each substance.

Many hallucinogenic plants and mushrooms produce anticholinergic delirium (see p 1564), characterized by flushed skin, dry mucous membranes, dilated pupils, tachycardia, and urinary retention. Some plants and mushrooms may contain hallucinogenic indoles such as mescaline and lysergic acid diethylamide (LSD), which typically cause marked visual hallucinations and perceptual distortion, widely dilated pupils, and mild tachycardia. Phencyclidine (PCP), a dissociative anesthetic agent similar to ketamine, can produce fluctuating delirium and coma, often associated with vertical and horizontal nystagmus. Toluene and other hydrocarbon solvents (butane, trichloroethylene, "chemo," etc) cause euphoria and delirium and may sensitize the myocardium to the effects of catecholamines, leading to fatal dysrhythmias.

Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist respirations if necessary. Treat coma, hyperthermia, and seizures as outlined at the beginning of this chapter. For recent large ingestions, consider giving activated charcoal orally or by gastric tube.

B. Specific Treatment

Patients with anticholinergic delirium may benefit from a dose of physostigmine (see p 1559). However, this drug should not be used if poisoning by tricyclic antidepressants is suspected. Dysphoria, agitation, and psychosis associated with LSD or mescaline intoxication may respond to benzodiazepines (eg, lorazepam, 1-2 mg orally or intravenously) or haloperidol (2-5 mg orally or intravenously). Monitor patients who have sniffed solvents for cardiac dysrhythmias (most commonly premature ventricular contractions, ventricular tachycardia, ventricular fibrillation); treatment with beta-blockers such as propranolol (1-5 mg intravenously) or esmolol (250-500 ug/kg intravenously, then 50 ug/kg/min by infusion) may be more effective than lidocaine.

MERCURY

Acute mercury poisoning usually occurs by ingestion of inorganic mercuric salts or inhalation of metallic mercury vapor. Ingestion of the mercuric salts causes a metallic taste, salivation, thirst, a burning sensation in the throat, discoloration and edema of oral mucous membranes, abdominal pain, vomiting, bloody diarrhea, and shock. Direct nephrotoxicity causes acute renal failure. Inhalation of high concentrations of metallic mercury vapor may cause acute fulminant chemical pneumonia. Chronic mercury poisoning causes weakness, ataxia, intention tremors, irritability, and depression. Exposure to alkyl (organic) mercury derivatives from contaminated fish or fungicides used on seeds has caused ataxia, tremors, convulsions, and catastrophic birth defects.

Treatment

A. Acute Poisoning

There is no effective specific treatment for mercury vapor pneumonitis. Remove ingested mercuric salts by lavage, and administer activated charcoal (see p 1551). For acute ingestion of mercuric salts, give dimercaprol (BAL) at once, as for arsenic poisoning. Unless the patient has severe gastroenteritis, consider succimer (DMSA), 10 mg/kg orally every 8 hours for 5 days and then every 12 hours for 2 weeks. Maintain urine output. Treat oliguria and anuria if they occur.

B. Chronic Poisoning

Remove from exposure. Neurologic toxicity is not considered reversible with chelation, though some authors recommend a trial of succimer.

METHANOL & ETHYLENE GLYCOL

Methanol (wood alcohol) is commonly found in a variety of products, including solvents, duplicating fluids, record cleaning solutions, and paint removers. It is sometimes ingested intentionally by alcoholic patients as a substitute for ethanol and may also be found as a contaminant in bootleg whiskey. Ethylene glycol is the major constituent in most antifreeze compounds. The toxicity of both agents is caused by metabolism to highly toxic organic acids—methanol to formic acid; ethylene glycol to glycolic and oxalic acids.

Clinical Findings

Shortly after ingestion of either of these agents, patients usually appear "drunk." The serum osmolality (measured with the freezing point device) is usually increased, but acidosis is often absent early. After several hours, metabolism to toxic organic acids leads to a severe anion gap metabolic acidosis, tachypnea, confusion, convulsions, and coma. Methanol intoxication frequently causes visual disturbances, while ethylene glycol often produces oxalate crystalluria and renal failure.

Treatment

A. Emergency and Supportive Measures

For patients presenting within 30-60 minutes after ingestion, empty the stomach by gastric lavage and administer activated charcoal (see p 1551). (**Note:** Charcoal is not very effective.)

B. Specific Treatment

Patients with significant toxicity (manifested by severe metabolic acidosis, altered mental status, serum methanol or ethylene glycol level > 50 mg/dL, or osmolar gap > 10 mosm/L) should undergo hemodialysis as soon as possible to remove the parent compound and the toxic metabolites. Treatment with folic acid, thiamine, and pyridoxine may enhance the breakdown of toxic metabolites.

Ethanol blocks metabolism of the parent compounds by competing for the enzyme alcohol dehydrogenase. The desired serum ethanol concentration is 100 mg/dL. To achieve this, administer a loading dose of approximately 750 mg/kg orally or in a dilute intravenous solution (available from the pharmacy in 5% and 10% solution), and then provide a maintenance infusion of 100-150 mg/kg/h. The infusion will have to be increased to about 175-250 mg/kg/h during hemodialysis to replace dialysis elimination of ethanol. Fomepizole (4-methylpyrazole; Antizol), blocks alcohol dehydrogenase and can be used instead of ethanol. A regional poison control center (800-222-1222) should be contacted for indications and dosing.

METHEMOGLOBINEMIA- INDUCING AGENTS

A large number of chemical agents are capable of oxidizing ferrous hemoglobin to its ferric state (methemoglobin), a form that cannot carry oxygen. Drugs and chemicals known to cause methemoglobinemia include benzocaine (a local anesthetic found in some topical anesthetic sprays and a variety of nonprescription products), aniline, nitrites, nitrogen oxide gases, nitrobenzene, dapsone, phenazopyridine (Pyridium), and many others. Dapsone has a long elimination half-life and may produce prolonged or recurrent methemoglobinemia.

Clinical Findings

Methemoglobinemia reduces oxygen-carrying capacity and may cause dizziness, nausea, headache, dyspnea, confusion, seizures, and coma. The severity of symptoms depends on the percentage of hemoglobin oxidized to methemoglobin; severe poisoning is usually present when methemoglobin fractions are greater than 40-50%. Even at low levels (15-20%), victims appear cyanotic because of the "chocolate brown" color of methemoglobin, but they have normal PO₂ results on arterial blood gas determinations. Pulse oximetry gives inaccurate oxygen saturation measurements. Severe metabolic acidosis may be present. Hemolysis may occur, especially in patients susceptible to oxidant stress (ie, those with glucose-6-phosphate dehydrogenase deficiency).

Treatment

A. Emergency and Supportive Measures

Administer high-flow oxygen. If the causative agent was recently ingested, administer activated charcoal (see p 1551). Repeat-dose activated charcoal may enhance dapsone elimination (see p 1552).

B. Specific Treatment

Methylene blue enhances the conversion of methemoglobin to hemoglobin by increasing the activity of the enzyme methemoglobin reductase. For symptomatic patients, administer 1-2 mg/kg (0.1-0.2 mL/kg of 1% solution) intravenously. The dose may be repeated once in 15-20 minutes if necessary. Patients with hereditary methemoglobin reductase deficiency or glucose-6-phosphate dehydrogenase deficiency may not respond to methylene blue treatment.

MONOAMINE OXIDASE INHIBITORS (ISOCARBOXAZID, PHENELZINE, SELEGILINE, MOCLOBEMIDE)

Overdoses cause ataxia, excitement, hypertension, and tachycardia, followed several hours later by hypotension, convulsions, and hyperthermia.

Ingestion of tyramine-containing foods may cause a severe hypertensive reaction in patients taking monoamine oxidase inhibitors. Foods containing tyramine include aged cheese and red wines. Hypertensive reactions may also occur with any sympathomimetic drug. Severe or fatal hyperthermia (serotonin syndrome) may occur if patients receiving monoamine oxidase inhibitors are given meperidine, fluoxetine, paroxetine, fluvoxamine, venlafaxine, tryptophan, dextromethorphan, or other serotonin-enhancing drugs. This reaction can also occur with the newer selective MAO inhibitor moclobemide. The serotonin syndrome has also been reported in patients taking selective serotonin reuptake inhibitors in large doses or in combination with other SSRIs, even in the absence of an MAO inhibitor or meperidine.

Treatment

Administer activated charcoal (see p 1551). Treat severe hypertension with nitroprusside, phentolamine, or other rapid-acting vasodilators (see p 1548). Treat hypotension with fluids and positioning, but avoid use of pressor agents if possible. Observe patients for at least 24 hours, since hyperthermic reactions may be delayed. Treat hyperthermia with aggressive cooling; neuromuscular paralysis may be required (see p 1549). Cyproheptadine, 4 mg orally (or by gastric tube) every hour for three or four doses, has been reported to be effective against serotonin syndrome.

Vuori E et al: Death following ingestion of MDMA (ecstasy) and moclobemide. Addiction 2003;98:365. [\[PMID: 12603236\]](#)

MUSHROOMS

There are thousands of mushroom species that cause a variety of toxic effects. The most dangerous species of mushrooms are *Amanita phalloides*, *Amanita verna*, *Amanita virosa*, *Gyromitra esculenta*, and the *Galerina* species, all of which contain amatoxin, a potent cytotoxin. Ingestion of even a portion of one mushroom of a dangerous species may be sufficient to cause death.

The characteristic pathologic finding in fatalities from amatoxin-containing mushroom poisoning is acute massive necrosis of the liver.

Clinical Findings (Table 39-11)

A. Symptoms and Signs

1. Amatoxin-type cyclopeptides—(*Amanita phalloides*, *Amanita verna*, *Amanita virosa*, and *Galerina* species.) After a latent interval of 8-12 hours, severe abdominal cramps and vomiting begin and progress to profuse diarrhea, followed in 1-2 days by hepatic necrosis, hepatic encephalopathy, and frequently renal failure. The fatality rate is about 20%. Cooking the mushrooms does not prevent poisoning.

2. Gyromitrin type—(*Gyromitra* and *Helvella* species.) Toxicity is more common following ingestion of uncooked mushrooms. Vomiting, diarrhea, hepatic necrosis, convulsions, coma, and hemolysis may occur after a latent period of 8-12 hours. The fatality rate is probably less than 10%.

3. Muscarinic type—(*Inocybe* and *Clitocybe* species.) Vomiting, diarrhea, bradycardia, hypotension, salivation, miosis, bronchospasm, and lacrimation occur shortly after ingestion. Cardiac arrhythmias may occur. Fatalities are rare.

4. Anticholinergic type—(Eg, *Amanita muscaria*, *Amanita pantherina*.) This type causes a variety of symptoms that may be atropine-like, including excitement, delirium, flushed skin, dilated pupils, and muscular jerking tremors, beginning 1-2 hours after ingestion. Fatalities are rare.

5. Gastrointestinal irritant type—(Eg, *Boletus*, *Cantharellus*.) Nausea, vomiting, and diarrhea occur shortly after ingestion. Fatalities are rare.

6. Disulfiram type—(*Coprinus* species.) Disulfiram-like sensitivity to alcohol may persist for several days. Toxicity is characterized by flushing, hypotension, and vomiting after coingestion of alcohol.

7. Hallucinogenic—(*Psilocybe* and *Panaeolus* species.) Mydriasis, nausea and vomiting, and intense visual hallucinations occur 1-2 hours after ingestion. Fatalities are rare.

8. Cortinarius orellanus—This mushroom may cause acute renal failure due to tubulointerstitial nephritis.

Treatment

A. Emergency Measures

After the onset of symptoms, efforts to remove the toxic agent are probably useless, especially in cases of amatoxin or gyromitrin poisoning, where there is usually a delay of 12 hours or more before symptoms occur and patients seek medical attention. However, induction of vomiting or administration of activated charcoal is recommended for any recent ingestion of an unidentified or potentially toxic mushroom (see p 1551).

B. General Measures

1. Amatoxin-type cyclopeptides—A variety of antidotes (eg, thioctic acid, silybin, penicillin, corticosteroids) have been suggested for amatoxin-type mushroom poisoning, but controlled studies are lacking and experimental data in animals are equivocal. Aggressive fluid replacement for diarrhea and intensive supportive care for hepatic failure are the mainstays of treatment.

Interruption of enterohepatic circulation of the amatoxin by the administration of activated charcoal and laxatives may be of value. However, by the time this method is employed, most of the amatoxin has already caused cellular damage and has already been excreted. Charcoal hemoperfusion has been recommended but is of unproved value.

Liver transplant may be the only hope for survival in gravely ill patients—contact a liver transplant center early.

2. Gyromitrin type—For gyromitrin poisoning, give pyridoxine, 25 mg/kg intravenously.

3. Muscarinic type—For mushrooms producing predominantly muscarinic-cholinergic symptoms, give atropine, 0.005-0.01 mg/kg intravenously, and repeat as needed.

4. Anticholinergic type—For anticholinergic type, physostigmine, 0.5-1 mg intravenously, may calm extremely agitated patients and reverse peripheral anticholinergic manifestations, but it may also cause bradycardia, asystole, and seizures.

5. Gastrointestinal irritant type—Treat with antiemetics and intravenous or oral fluids.

6. Disulfiram type—For *Coprinus* ingestion, avoid alcohol. Treat alcohol reaction with fluids and supine position.

7. Hallucinogenic type—Provide a quiet, supportive atmosphere. Diazepam or haloperidol may be used for sedation.

8. Cortinarius—Provide supportive care and hemodialysis as needed for renal failure.

OPIOIDS (MORPHINE, HEROIN, CODEINE, PROPOXYPHENE, ETC)

Prescription and illicit opioids are popular drugs of abuse and the cause of frequent hospitalizations for overdose. These drugs have widely varying potencies and durations of action; for example, some of the illicit fentanyl derivatives are up to 2000 times more potent than morphine. All of these agents decrease central nervous system activity and sympathetic outflow by acting on opiate receptors in the brain. Tramadol is a newer analgesic that is unrelated chemically to the opioids but acts on opioid receptors.

Clinical Findings

Mild intoxication is characterized by euphoria, drowsiness, and constricted pupils. More severe intoxication may cause hypotension, bradycardia, hypothermia, coma, and respiratory arrest. Pulmonary edema may occur. Death is usually due to apnea or pulmonary aspiration of gastric contents. Propoxyphene may cause seizures and prolongation of the QRS interval. Tramadol, dextromethorphan, and meperidine also occasionally cause seizures. With meperidine, the metabolite normeperidine is probably the cause of seizures and is most likely to accumulate with repeated dosing in patients with renal insufficiency. While the duration of effect for heroin is usually 3-5 hours, methadone intoxication may last for 48-72 hours or longer. Most opioids, with the exception of illicit newer fentanyl derivatives, tramadol, and methadone, are detectable on routine urine toxicology screening. Wound botulism has been associated with skin-popping, especially involving "black tar" heroin.

Treatment

A. Emergency and Supportive Measures

Protect the airway and assist ventilation. Administer activated charcoal (see p 1551).

B. Specific Treatment

Naloxone is a specific opioid antagonist that can rapidly reverse signs of narcotic intoxication. Although it is structurally related to the opioids, it has no agonist effects of its own. Administer 0.4-2 mg intravenously, and repeat as needed to awaken the patient and maintain airway protective reflexes and spontaneous breathing. Very large doses (10-20 mg) may be required for patients intoxicated by some opioids (eg, propoxyphene, codeine, fentanyl derivatives). **Caution:** The duration of effect of naloxone is only about 2-3 hours; repeated doses may be necessary for patients intoxicated by long-acting drugs such as methadone. Continuous observation for at least 3 hours after the last naloxone dose is mandatory.

PARAQUAT

Paraquat is used as a herbicide. Concentrated solutions of paraquat are highly corrosive to the oropharynx, esophagus, and stomach. The fatal dose after absorption may be as small as 4 mg/kg. If ingestion of paraquat is not rapidly fatal because of its corrosive effects, the herbicide may cause progressive pulmonary fibrosis, with death ensuing after 2-3 weeks. Patients with plasma paraquat levels above 2 mg/L at 6 hours or 0.2 mg/L at 24 hours are likely to die.

Treatment

Remove ingested paraquat by immediate induced emesis, or by gastric lavage if the patient is already in a health care facility. Clay (bentonite or fuller's earth) and activated charcoal are effective adsorbents. Administer repeated doses of 60 g of activated charcoal by gastric tube every 2 hours for at least three or four doses. Charcoal hemoperfusion, 8 hours per day for 2-3 weeks, has been anecdotally reported to be lifesaving, but clinical and animal studies are equivocal. Supplemental oxygen should be withheld unless the PO₂ is less than 70 mm Hg because oxygen may contribute to the pulmonary damage, which is mediated through lipid peroxidation.

Yamashita M et al: A long-term follow-up of lung function in survivors of paraquat poisoning. *Hum Exp Toxicol* 2000;19:99. [PMID: 10773838]

PESTICIDES: CHOLINESTERASE INHIBITORS (ORGANOPHOSPHATES: PARATHION, MALATHION, ETC; CARBAMATES: CARBARYL, ALDICARB, ETC)

Organophosphorus and carbamate insecticides are widely used in commercial agriculture and home gardening and have largely replaced older, more environmentally persistent organochlorine compounds such as DDT and chlordane. The organophosphates and carbamates—also called anticholinesterases because they inhibit the enzyme acetylcholinesterase—cause an increase in acetylcholine activity at nicotinic and muscarinic receptors and in the central nervous system. There are a variety of chemical agents in this group, with widely varying potencies. Most of them are poorly water-soluble and are formulated with an aromatic hydrocarbon solvent such as xylene. Most of them are well absorbed through intact skin. Most chemical warfare "nerve agents" (see above) are organophosphates.

Clinical Findings

Inhibition of cholinesterase results in abdominal cramps, diarrhea, vomiting, excessive salivation, sweating, lacrimation, miosis (constricted pupils), wheezing and bronchorrhea, seizures, and skeletal muscle weakness. Initial tachycardia is usually followed by bradycardia. Profound skeletal muscle weakness, aggravated by excessive bronchial secretions and wheezing, may result in respiratory arrest and death. Symptoms and signs of poisoning may persist or recur over several days, especially with highly lipid-soluble agents such as fenthion or dimethoate.

The diagnosis should be suspected in patients who present with miosis, sweating, and hyperperistalsis. Serum and red blood cell cholinesterase activity can be measured in the laboratory and is usually depressed at least 50% below baseline in those victims who have severe intoxication.

Treatment

A. Emergency and Supportive Measures

If the agent was recently ingested, empty the stomach by gastric lavage and administer activated charcoal (see p 1551). Do not induce emesis because of the risk of abrupt onset of seizures. If the agent is on the victim's skin or hair, wash repeatedly with soap or shampoo and water. Providers must take care to avoid skin exposure by wearing gloves and waterproof aprons.

B. Specific Treatment

Atropine reverses excessive muscarinic stimulation and is effective for treatment of salivation, wheezing, abdominal cramping, and sweating. However, it does not interact with nicotinic receptors at autonomic ganglia and at the neuromuscular junction and has no effect on muscle weakness. Administer 2 mg intravenously, and give repeated doses as needed to dry bronchial secretions and decrease wheezing; as much as several hundred milligrams of atropine have been given to treat severe poisoning.

Pralidoxime (2-PAM, Protopam) is a specific antidote that reverses organophosphate binding to the cholinesterase enzyme; therefore, it is effective at the neuromuscular junction as well as other nicotinic and muscarinic sites. It should be started as soon as possible, to prevent permanent binding of the organophosphate to cholinesterase. Administer 1-2 g intravenously, and begin a continuous infusion (200-400 mg/h). Constant infusion is more effective because of the short duration of action of single doses. Continue to give pralidoxime as long as there is any evidence of acetylcholine excess. Pralidoxime is of questionable benefit for carbamate poisoning, because carbamates have only a transitory effect on the cholinesterase enzyme.

Lee P et al: Clinical features of patients with acute organophosphate poisoning requiring intensive care. Intensive Care Med 2001;27:694. [\[PMID: 11398695\]](#)

PETROLEUM DISTILLATES & SOLVENTS

Petroleum distillate toxicity may occur from inhalation of the vapor or as a result of pulmonary aspiration of the liquid during or after ingestion. Acute manifestations of aspiration pneumonitis are vomiting, coughing, and bronchopneumonia. Some hydrocarbons—ie, those with aromatic or halogenated subunits—can also cause severe systemic poisoning after oral ingestion ([Table 39-12](#)). Hydrocarbons can also cause systemic intoxication by inhalation. Vertigo, muscular incoordination, irregular pulse, myoclonus, and seizures occur with serious poisoning and may be due to hypoxemia or the systemic effects of the agents. Chlorinated and fluorinated hydrocarbons (trichloroethylene, freons, etc) and many other hydrocarbons can cause ventricular arrhythmias due to increased sensitivity of the myocardium to the effects of endogenous catecholamines.

Treatment ([Table 39-12](#))

Remove the patient to fresh air. Since aspiration is the primary danger after ingestion of many common products, use of lavage or emesis is not recommended; administration of activated charcoal may be helpful if the preparation contains toxic solutes (eg, an insecticide) or is an aromatic or halogenated product. Observe the victim for 6-8 hours for signs of aspiration pneumonitis (cough, localized rales or rhonchi, tachypnea, and infiltrates on chest radiograph). Corticosteroids are not recommended. If fever occurs, give a specific antibiotic only after identification of bacterial pathogens by laboratory studies. Because of the risk of arrhythmias, use bronchodilators only with caution in patients with chlorinated or fluorinated solvent intoxication.

Cording CJ et al: A fatality due to accidental PineSol ingestion. J Anal Toxicol 2000;24:664. [\[PMID: 11043678\]](#)

PHENOTHIAZINES & OTHER ANTIPSYCHOTIC AGENTS (CHLORPROMAZINE, PROMAZINE, HALOPERIDOL, PROCHLORPERAZINE, RISPERIDONE, CLOZAPINE, ETC)

Chlorpromazine and related drugs are used as antiemetics and antipsychotic agents and as potentiators of analgesic and hypnotic drugs.

Small doses of phenothiazines induce drowsiness and mild orthostatic hypotension in as many as 50% of patients. Larger doses can cause obtundation, miosis, severe hypotension, tachycardia, convulsions, and coma. Abnormal cardiac conduction may occur (particularly with thioridazine), resulting in prolongation of QRS or QT intervals (or both) and ventricular arrhythmias.

With therapeutic or toxic doses, some patients develop an acute extrapyramidal dystonic reaction similar to Parkinson's disease, with spasmodic contractions of the face and neck muscles, extensor rigidity of the back muscles, carpopedal spasm, and motor restlessness. Severe rigidity accompanied by hyperthermia and metabolic acidosis ("neuroleptic malignant syndrome") may occasionally occur and is life-threatening (see [Chapters 1](#) and [25](#)).

Treatment

A. Emergency and Supportive Measures

Administer activated charcoal. For severe hypotension, treatment with fluids and pressor agents may be necessary. Treat hyperthermia as outlined on p 1549. Maintain cardiac monitoring.

B. Specific Treatment

Hypotension and cardiac arrhythmias associated with widened QRS intervals on the ECG in a patient with thioridazine poisoning may respond to intravenous sodium bicarbonate as used for tricyclic antidepressants.

For extrapyramidal signs, give diphenhydramine, 0.5-1 mg/kg intravenously, or benztropine mesylate, 0.01-0.02 mg/kg intramuscularly. Treatment with oral doses of these agents should be continued for 24-48 hours.

Bromocriptine (2.5-7.5 mg orally daily) may be effective for mild or moderate neuroleptic malignant syndrome. Dantrolene (2-5 mg/kg intravenously) has also been used for muscle contractions but is not a true antidote.

Hustey FM: Acute quetiapine poisoning. J Emerg Med 1999;17: 995. [\[PMID: 10595886\]](#)

QUINIDINE & RELATED ANTIARRHYTHMICS

Quinidine, procainamide, and disopyramide are class Ia antiarrhythmic agents, and flecainide is a class Ic agent. These drugs have membrane-depressant effects on the sodium-dependent channel responsible for cardiac cell depolarization. Manifestations of cardiotoxicity include arrhythmias, syncope, hypotension, and widening of the QRS complex on the ECG (> 100-120 ms). With type Ia drugs, a lengthened QT interval and atypical or polymorphous ventricular tachycardia (torsade de pointes) may occur.

Treatment

A. Emergency and Supportive Measures

Administer activated charcoal (see p 1551); consider gastric lavage after large recent overdose. Assist ventilation if needed. Perform continuous cardiac monitoring.

B. Specific Treatment

Treat cardiotoxicity (hypotension, QRS interval widening) with intravenous boluses of sodium bicarbonate, 50-100 meq. Ventricular tachycardia of the torsade de pointes variety may be treated with intravenous magnesium or overdrive pacing.

Reddy VG et al: Chloroquine poisoning: report of two cases. Acta Anaesthesiol Scand 2000;44:1017. [\[PMID: 10981583\]](#)

SALICYLATES

Salicylates (aspirin, methyl salicylate, etc) are found in a variety of over-the-counter and prescription medications. Salicylates uncouple cellular oxidative phosphorylation, resulting in anaerobic metabolism and excessive production of lactic acid and heat, and they also interfere with several Krebs cycle enzymes. A single ingestion of more than 200 mg/kg of salicylate is likely to produce significant acute intoxication. Poisoning may also occur as a result of chronic excessive dosing over several days. Although the half-life of salicylate is 2-3 hours after small doses, it may increase to 20 hours or more in patients with intoxication.

Clinical Findings

Acute ingestion often causes nausea and vomiting, occasionally with gastritis. Moderate intoxication is characterized by hyperpnea (deep and rapid breathing), tachycardia, tinnitus, and elevated anion gap metabolic acidosis. Serious intoxication may result in agitation, confusion, coma, seizures, cardiovascular collapse, pulmonary edema, hyperthermia, and death. The prothrombin time is often elevated owing to salicylate-induced hypoprothrombinemia.

Diagnosis is suspected in any patient with metabolic acidosis and is confirmed by measuring the serum salicylate level. Patients with levels greater than 100 mg/dL (1000 mg/L) after an acute overdose are more likely to have severe poisoning. On the other hand, patients with subacute or chronic intoxication may suffer severe symptoms with levels of only 60-70 mg/dL. The arterial blood gas typically reveals a respiratory alkalosis with an underlying metabolic acidosis.

Treatment

A. Emergency and Supportive Measures

Administer activated charcoal (see p 1551). Gastric lavage followed by administration of extra doses of activated charcoal may be needed in patients who ingest more than 10 g of aspirin. The desired ratio of charcoal to aspirin is about 10:1 by weight; while this cannot always be given as a single dose, it may be administered over the first 24 hours in divided doses every 2-4 hours. Treat metabolic acidosis with intravenous sodium bicarbonate. This is critical because acidosis (especially acidemia, pH < 7.40) promotes greater entry of salicylate into cells, worsening toxicity. Intubation and controlled ventilation may cause sudden and severe deterioration if the pH is allowed to fall.

B. Specific Treatment

Alkalinization of the urine enhances renal salicylate excretion by trapping the salicylate anion in the urine. Add 100 meq (two ampules) of sodium bicarbonate to 1 L of 5% dextrose in 0.2% saline, and infuse this solution intravenously at a rate of about 150-200 mL/h. Unless the patient is oliguric, add 20-30 meq of potassium chloride to each liter of intravenous fluid. Patients who are volume-depleted often fail to produce an alkaline urine (paradoxical aciduria) unless potassium is given.

Hemodialysis may be lifesaving and is indicated for patients with severe metabolic acidosis, markedly altered mental status, or significantly elevated salicylate levels (eg, > 100-120 mg/dL [1000-1200 mg/L] after acute overdose or > 60-70 mg/dL [600-700 mg/L] with subacute or chronic intoxication).

SEAFOOD POISONINGS

A variety of intoxications may occur after eating certain types of fish or other seafood. These include scombroid, ciguatera, paralytic shellfish, and puffer fish poisoning. The mechanisms of toxicity and clinical presentations are described in [Table 39-13](#). In the majority of cases, the seafood has a normal appearance and taste (scombroid may have a peppery taste).

Treatment

A. Emergency and Supportive Measures

Caution: Abrupt respiratory arrest may occur in patients with acute paralytic shellfish and puffer fish poisoning. Observe patients for at least 4-6 hours. Replace fluid and electrolyte losses from gastroenteritis with intravenous saline or other crystalloid solution.

For recent ingestions, it may be possible to adsorb residual toxin in the gut with activated charcoal, 50-60 g orally.

B. Specific Treatment

There is no specific antidote for paralytic shellfish or puffer fish poisoning.

1. Ciguatera—There are anecdotal reports of successful treatment of acute neurologic symptoms with mannitol, 1 g/kg intravenously.

2. Scombroid—Antihistamines such as diphenhydramine, 25-50 mg intravenously, and the H₂ blocker cimetidine, 300 mg intravenously, are usually effective. For severe reactions, give also epinephrine, 0.3-0.5 mL of a 1:1000 solution subcutaneously.

SNAKE BITES

The venom of poisonous snakes and lizards may be predominantly neurotoxic (coral snake) or predominantly cytolytic (rattlesnakes, other pit vipers). Neurotoxins cause respiratory paralysis; cytolytic venoms cause tissue destruction by digestion and hemorrhage due to hemolysis and destruction of the endothelial lining of the blood vessels. The manifestations of rattlesnake envenomation are mostly local pain, redness, swelling, and extravasation of blood. Perioral tingling, metallic taste, nausea and vomiting, hypotension, and coagulopathy may also occur. Neurotoxic envenomation may cause ptosis, dysphagia, diplopia, and respiratory arrest.

Treatment

A. Emergency Measures

Immobilize the patient and the bitten part in a neutral position. Avoid manipulation of the bitten area. Transport the patient to a medical facility for definitive treatment. Do *not* give alcoholic beverages or stimulants; do *not* apply ice; do *not* apply a tourniquet. The trauma to underlying structures resulting from incision and suction performed by unskilled people is probably not justified in view of the small amount of venom that can be recovered.

B. Specific Antidote and General Measures

1. Pit viper (eg, rattlesnake) envenomation—A new antivenin (CroFab) has replaced the Wyeth horse serum-based product. With local signs such as swelling, pain, and ecchymosis but no systemic symptoms, give 4-6 vials of crotalid antivenin (CroFab) by slow intravenous drip in 250-500 mL saline. Repeated doses of 2 vials every 6 hours for up to 18 hours has been recommended. For more serious envenomation with marked local effects and systemic toxicity (eg, hypotension, coagulopathy), higher doses and additional vials may be required. Monitor vital signs and the blood coagulation profile. Type and cross-match blood. The adequacy of venom neutralization is indicated by improvement in symptoms and signs, and the rate of swelling slows.

2. Elapid (coral snake) envenomation—Give 1-2 vials of specific antivenom as soon as possible. To locate antisera for exotic snakes, call a regional poison control center (800-222-1222).

SPIDER BITES & SCORPION STINGS

The toxin of most species of spiders in the USA causes only local pain, redness, and swelling. That of the more venomous black widow spiders (*Latrodectus mactans*) causes generalized muscular pains, muscle spasms, and rigidity. The brown recluse spider (*Loxosceles reclusa*) causes progressive local necrosis as well as hemolytic reactions (rare). Stings by most scorpions in the USA cause only local pain. Stings by the more toxic *Centruroides* species (found in the southwestern USA) may cause muscle cramps, twitching and jerking, and occasionally hypertension, convulsions, and pulmonary edema.

Treatment

A. Black Widow Spider Bites

Pain may be relieved with parenteral narcotics or muscle relaxants (eg, methocarbamol, 15 mg/kg). Calcium gluconate 10%, 0.1-0.2 mL/kg intravenously, may relieve muscle rigidity, though its effectiveness is questionable. Antivenin is available, but because of concerns about acute hypersensitivity reactions it is often reserved for very young or elderly patients or those who do not respond to the above measures. Horse serum sensitivity testing is required. (Instruction and testing materials are included in the antivenin kit.)

B. Brown Recluse Spider Bites

Because bites occasionally progress to extensive local necrosis, some authorities recommend early excision of the bite site, whereas others use oral corticosteroids. Anecdotal reports have claimed success with dapsone and colchicine. An antivenin is being developed. All of these treatments remain of unproved value.

C. Scorpion Stings

No specific treatment is available. For *Centruroides* stings, some toxicologists use a specific antivenom developed in Arizona, but this is neither FDA-approved nor widely available.

THEOPHYLLINE

Theophylline toxicity may be caused by several of its pharmacologic effects, including inhibition of phosphodiesterase and adenosine and release of catecholamines. Theophylline may cause intoxication after an acute single overdose, or intoxication may occur as a result of chronic accidental repeated overmedication or reduced elimination resulting from hepatic dysfunction or interacting drug (eg, cimetidine, erythromycin). The usual serum half-life of theophylline is 4-6 hours, but this may increase to more than 20 hours after overdose. Caffeine and caffeine-containing herbal products can produce similar toxicity.

Clinical Findings

Mild intoxication causes nausea, vomiting, tachycardia, and tremulousness. Severe intoxication is characterized by ventricular and supraventricular tachyarrhythmias, hypotension, and seizures. Status epilepticus is common and often intractable to usual anticonvulsants. After acute overdose (but not chronic intoxication), hypokalemia, hyperglycemia, and metabolic acidosis are common. Seizures and other manifestations of toxicity may be delayed for several hours after acute ingestion, especially if a sustained-release preparation such as Theo-Dur was taken.

Diagnosis is based on measurement of the serum theophylline concentration. Acute overdose patients with serum levels greater than 100 mg/L are likely to develop seizures and hypotension. Patients with chronic intoxication may develop serious toxicity at lower levels (ie, 40-60 mg/L).

Treatment

A. Emergency and Supportive Measures

After acute ingestion, administer activated charcoal (see p 1551). Repeated doses of activated charcoal may enhance theophylline elimination by "gut dialysis." Addition of whole bowel irrigation should be considered for large ingestions involving sustained-release preparations.

Hemodialysis (or hemoperfusion) is effective in removing theophylline and is indicated for patients with status epilepticus or markedly elevated serum theophylline levels (eg, > 100 mg/L after acute overdose or > 60 mg/L with chronic intoxication).

B. Specific Treatment

Treat seizures with benzodiazepines (lorazepam, 2-3 mg intravenously, or diazepam, 5-10 mg intravenously) or phenobarbital (10-15 mg/kg intravenously). Phenytoin is not effective. Hypotension and tachycardia—which are mediated through excessive beta-adrenergic stimulation—may respond to beta-blocker therapy even in low doses: Administer esmolol, 25-50 µg/kg/min by intravenous infusion, or propranolol, 0.5-1 mg intravenously.

TRICYCLIC & OTHER ANTIDEPRESSANTS

Tricyclic and related cyclic antidepressants are among the most dangerous drugs involved in suicidal overdose. These drugs have anticholinergic and cardiac depressant properties ("quinidine-like" sodium channel blockade). Tricyclic antidepressants produce more marked membrane-depressant cardiotoxic effects than the phenothiazines.

Newer antidepressants such as trazodone, fluoxetine, citalopram, paroxetine, sertraline, bupropion, venlafaxine, and fluvoxamine are not chemically related to the tricyclic antidepressant agents and do not generally produce cardiotoxic effects. However, they may cause seizures in overdoses and they may cause serotonin syndrome (see Monoamine Oxidase Inhibitors, above). Seizures are also reported rarely after therapeutic doses of bupropion.

Clinical Findings

Signs of severe intoxication may occur abruptly and without warning within 30-60 minutes after acute tricyclic overdose. Anticholinergic effects include dilated pupils, tachycardia, dry mouth, flushed skin, muscle twitching, and decreased peristalsis. Quinidine-like cardiotoxic effects include QRS interval widening (> 0.12 s; see [Figure 39-2](#)), ventricular arrhythmias, atrioventricular block, and hypotension. Seizures and coma are common with severe intoxication. Life-threatening hyperthermia may result from status epilepticus and anticholinergic-induced impairment of sweating.

The diagnosis should be suspected in any overdose patient with anticholinergic side effects, especially if there is widening of the QRS interval or seizures. For intoxication by most tricyclics, the QRS interval correlates with the severity of intoxication more reliably than the serum drug level.

Serotonin syndrome should be suspected if a patient taking serotonin reuptake inhibitors develops agitation, delirium, muscular hyperactivity, and fever.

Treatment

A. Emergency and Supportive Measures

Observe patients for at least 6 hours, and admit all patients with evidence of anticholinergic effects (eg, delirium, dilated pupils, tachycardia) or signs of cardiotoxicity (see above).

Administer activated charcoal, and consider gastric lavage after recent large ingestions (see p 1551). All of these drugs are highly tissue-bound and are not effectively removed by hemodialysis procedures.

B. Specific Treatment

Cardiotoxic sodium channel-depressant effects may respond to boluses of sodium bicarbonate (50-100 meq intravenously). Sodium bicarbonate provides a large sodium load that alleviates depression of the sodium-dependent channel. Reversal of acidosis may also have beneficial effects at this site. Maintain the pH between 7.45 and 7.50. Alkalinization does not promote excretion of tricyclics.

Mild serotonin syndrome may be treated with benzodiazepines and withdrawal of the antidepressant. Moderate cases may respond to cyproheptadine (4 mg orally or via gastric tube hourly for three or four doses). Severe hyperthermia should be treated with neuromuscular paralysis and endotracheal intubation in addition to external cooling measures.

Table 39-6. Use of the osmolar gap in toxicology.¹
The osmolar gap (∑osm) is determined by subtracting the calculated serum osmolality from the measured serum osmolality.

Calculated	Glucose		BUN
osmolality = 2 [Na ⁺ (meq/L) +	mg/dL	+	(mg/dL)
(osm)	18		2.8

Serum osmolality may be increased by contributions of circulating alcohols and other low-molecular-weight substances. Since these substances are not included in the calculated osmolality, there will be a gap proportionate to their serum concentration and inversely proportionate to their molecular weight:

Serum			
concentration	= ∑osm ×	Molecular weight	
(mg/dL)		10	

	Molecular Weight	Toxic Concentration	Approximate Corresponding ∑osm (mosm/L)
Ethanol	46	300	65
Methanol	32	50	16
Ethylene glycol	60	100	16
Isopropanol	60	150	25

¹Modified from Saunders CE, Ho MT (editors): *Current Emergency Diagnosis & Treatment*, 4th ed. Originally published by Appleton & Lange. Copyright © 1992 by The McGraw-Hill Companies, Inc.
Note: Most laboratories use the freezing point method for calculating osmolality. If the vaporization point method is used, alcohols are driven off and their contribution to osmolality is lost.

Table 39-7. Examples of common drugs screened for in blood and urine in a reference toxicology laboratory.^{1,2}

Blood

Acetaminophen	Ethchlorvynol
Alcohols	Glutethimide
Barbiturates	Meprobamate
Benzodiazepines	Phenytoin
Carbamazepine	Salicylates
Carisoprodol	

Urine

Acetaminophen	Meperidine
Alcohols	Meprobamate
Amphetamines	Methadone
Barbiturates	Morphine
Chlorpheniramine	Pentazocine
Cocaine	Phencyclidine
Codeine	Phenothiazines
Dextromethorphan	Propoxyphene
Diphenhydramine	Salicylates
Lidocaine	Tricyclic antidepressants

¹The urine screen is usually more comprehensive, detecting drugs of abuse (opioids, stimulants), antihistamines, and, in many cases, drugs also found in serum.

²Many drugs and poisons are not screened for (eg, limited screens; newer drugs; a variety of drugs and poisons such as cyanide, digitalis, ethylene glycol, isoniazid, theophylline).

-

Table 39-8. Specific quantitative levels and potential therapeutic interventions.¹

Drug or Toxin	Treatment
Acetaminophen	Specific antidote (acetylcysteine) based on serum level
Carbon monoxide	High carboxyhemoglobin level indicates need for 100% oxygen, consideration of hyperbaric oxygen
Carbamazepine	High level may indicate need for hemoperfusion or hemodialysis
Digoxin	On basis of serum digoxin level and severity of clinical presentation, treatment with Fab antibody fragments (Digibind) may be indicated
Ethanol	Low serum level may suggest nonalcoholic cause of coma (eg, trauma, other drugs, other alcohols). Serum ethanol may also be useful in monitoring ethanol therapy for methanol or ethylene glycol poisoning.
Iron	Level may indicate need for chelation with deferoxamine
Lithium	Serum levels can guide decision to institute hemodialysis
Methanol, ethylene glycol	Acidosis, high levels indicate need for hemodialysis, therapy with ethanol or fomepizole
Methemoglobin	Methemoglobinemia can be treated with methylene blue intravenously
Salicylates	High level may indicate need for hemodialysis, alkaline diuresis
Theophylline	Immediate hemodialysis or hemoperfusion may be indicated based on serum level
Valproic acid	Elevated levels may indicate need to consider hemodialysis

¹Some drugs or toxins may have profound and irreversible toxicity unless rapid and specific management is provided outside of routine supportive care. For these agents, laboratory testing may provide the serum level or other evidence required for administering a specific antidote or arranging for hemodialysis.

•

Table 39-13. Common seafood poisonings.

Type of Poisoning	Mechanism	Clinical Presentation
Ciguatera	Reef fish ingest toxic dinoflagellates,whose toxins accumulate in fish meat. Commonly implicated fish in the USA are barracuda, jack, snapper, and grouper.	1-6 hours after ingestion, victims develop abdominal pain, vomiting, and diarrhea accompanied by a variety of neurologic symptoms, including paresthesias, reversal of hot and cold sensation, vertigo, headache, and intense itching. Autonomic disturbances, including hypotension and bradycardia, may occur.
Scombroid	Improper preservation of large fish results in bacterial degradation of histidine to histamine. Commonly implicated fish include tuna, mahimahi, bonita, mackerel, and kingfish.	Allergic-like (anaphylactoid) symptoms are due to histamine, usually begin within 15-90 minutes, and include skin flushing, itching, urticaria, angioedema, bronchospasm, and hypotension as well as abdominal pain, vomiting, and diarrhea.
Paralytic shellfish poisoning	Dinoflagellates produce saxitoxin, which is concentrated by filter-feeding mussels and clams. Saxitoxin blocks sodium conductance and neuronal transmission in skeletal muscles.	Onset is usually within 30-60 minutes. Initial symptoms include perioral and intraoral paresthesias. Other symptoms include nausea and vomiting, headache, dizziness, dysphagia, dysarthria, ataxia, and rapidly progressive muscle weakness that may result in respiratory arrest.
Puffer fish poisoning	Tetrodotoxin is concentrated in liver, gonads, intestine, and skin. Toxic effects are similar to those of saxitoxin. Tetrodotoxin is also found in some North American newts and Central American frogs.	Onset is usually within 30-40 minutes but may be as short as 10 minutes. Initial perioral paresthesias are followed by headache, diaphoresis, nausea, vomiting, ataxia, and rapidly progressive muscle weakness that may result in respiratory arrest.

■ INTRODUCTION

This chapter mainly covers the clinical aspects of cancer: prevention, diagnosis, primary treatment, management of complications, and paraneoplastic syndromes. Further information may be obtained by calling the NCI Cancer Information Service at 1-800-4CANCER or accessing NCI's comprehensive cancer information database "Physician Data Query" (PDQ) via the Internet at www.cancernet.nci.nih.gov. PDQ is also available on CD-ROM. The CANCERLIT feature of Medline (PubMed) is a familiar resource for articles about cancer that can be accessed by author or by subject words. A series of oncology practice guidelines compiled by a panel of United States experts and encompassing diagnosis and treatment of a wide variety of cancers as well as pain management is now available on CD-ROM at the National Comprehensive Cancer Network Web site (www.nccn.org). This site also provides a stepwise guide to diagnosis and to treatment options for patients as well as links to a variety of useful sites, including the American Cancer Society, and is updated regularly.

Many new Web sites are now available for both clinician and patient use. Information includes statistics, treatment, and clinical trial information. Consultations can also be obtained. Web sites can be found by searching for the words "cancer" or "oncology." The American Society of Clinical Oncology has a new information Web site for patients and their families (www.PeopleLivingWithCancer.org) as well as patient guides on subjects such as follow-up care for breast and colorectal cancers, understanding tumor markers, treatment of nausea and vomiting, and advanced lung cancer. Two Web sites provide updated data as well as review articles on advances in oncology; these sites allow the user to search for specific areas of interest as well: Peerviewpress and Medscape.

■ INCIDENCE & ETIOLOGY

Cancer is the second most common cause of death in the United States. It is estimated that over 1.3 million new cases of invasive cancer will be diagnosed in the year 2002, with over 550,000 deaths. One out of every two (men) to three (women) individuals in the United States will develop some type of invasive cancer during their lifetime; based on the SEER 2002 database, the lifetime probability of developing cancer is 42%. [Table 40-1](#) summarizes current United States incidence and mortality figures for the ten leading types of cancer. Women have an approximately 1:8 lifetime chance of developing breast cancer, and men have an approximately 1:6 chance of developing prostate cancer. Cancers of the lung, prostate, and breast and of the colon and rectum account for about 55% of all new cancer diagnoses and for over 50% of cancer deaths in the United States. Lung cancer is the leading cause of cancer death in the United States, accounting for about one-third of deaths in men and one-fourth of deaths in women.

[Table 40-2](#) summarizes the lifetime risk of being diagnosed with or dying from the leading causes of cancer as well as from all types of cancer. Most rates are now age-adjusted to the year 2000 standard million population based on the 2000 census data. The incidence of and the mortality from cancer decreased an average of 1.4% per year from 1993 to 1999 in the United States, with variations by gender and race. This is the first sustained decline in the past 30 years and is attributed to changes in lifestyle as well as improved prevention, early detection, and treatment. However, the single most important risk factor for cancer is age. As the United States population increases in numbers and grows older, it is estimated that the number of cancer cases will double, by the year 2050, from 1.3 million cases per year to 2.6 million cases per year.

Cancer incidence and mortality vary significantly among racial and ethnic groups, with blacks having the highest rates of mortality even in diseases where the incidence of the specific cancer is lower than that seen in the white population. Stage for stage, 5-year survival rates are lower, even when the fact that cancers are less likely to be diagnosed when localized disease is taken into account. This difference may be due to the influence of variations in the biology of the specific cancers that control growth rates and response to treatment and is contributed to by differences in treatment as well as comorbid conditions. Data from the new census confirms the existence of geographic variability in cancer incidence; for example, breast cancer rates in Marin County in California appear to be among the highest in the United States. Interestingly, the increased incidence is similar to that seen in higher socioeconomic groups with higher attained education, delayed childbearing, a lower rate of breast feeding, and high alcohol intake—and appears to affect mostly the white population and is lower than previously thought. The contribution of environmental factors, exposure to toxins, and other dietary factors is not fully understood. Current research is focusing on exposures and risks that occur in adolescence.

The cause of most cancers remains unknown, although workers in the field of molecular biology have begun to unravel the complex pathways leading to cancer cell growth and metastases. Mutations in DNA sequences leading to abnormal or unregulated expression of proto-oncogenes or deletion of tumor suppressor genes—or both—have been linked to abnormal cellular proliferation. Oncogenes encode for cellular growth factor receptors, growth factors, or elements of the proliferative machinery of the cancer cell. Tumor suppressor genes either code for or control regulatory proteins that normally suppress cellular proliferation; loss of these genes leads to cell growth. Cancer results from these and other mutations, which may be due to environmental exposure, genetic susceptibility, infectious agents, and other factors.

Most tumors exhibit chromosomal abnormalities such as deletions, inversions, translocations, or duplications. Although usually nonspecific, certain genetic alterations are strongly associated with specific malignancies and in some cases can be used to assess prognosis. In Burkitt's lymphoma, the *c-myc* oncogene is activated by translocation of genetic material from chromosome 8 to chromosome 14. Chronic myelogenous leukemia (CML) is defined by a reciprocal translocation of the long arms of chromosomes 9 and 22, resulting in the generation of a fusion protein (BCR-ABL) with tyrosine kinase activity. In colon cancer, loss of the long arm of chromosome 18 (18q) predicts a poor outcome, whereas mutations in the gene for the type II receptor for transforming growth factor β 1 (TGF- β 1) with microsatellite instability predict a favorable outcome. In one study, 5-year survival following adjuvant chemotherapy for stage III colon cancer was 74% in those who retained the 18q allele and 50% in those with loss of the allele. Five-year survival was 74% for patients whose cancers had both microsatellite instability and a mutated gene for the type II receptor for TGF- β 1 and 46% if the tumor did not have the mutation. Genetic mutations in chronic lymphocytic leukemia (CLL) have been shown to occur in up to 82% of cases and strongly predict outcomes. For example, patients with deletions of the short arm of chromosome 17 had a survival of only 2.7 years, whereas those with deletions of the long arm of chromosome 13 had a survival of 11 years.

The *P53* gene appears to trigger programmed cell death (apoptosis) as a way of regulating uncontrolled cellular proliferation in the setting of aberrant growth signals. Mutations in the *P53* gene result in loss of the ability of the gene product to bind to DNA, thereby removing its suppressive effect. *P53* can also be inactivated by overexpression of an oncogene whose protein product binds to normal *P53* and prevents its action. This occurs in many soft tissue sarcomas. The Bcl-2 family of proteins act as "arbiters of cell death" with a balance of both "antideath" and "prodeath" activity. Bcl-2 and Bcl-X_L appear to function as "antideath" proteins to prevent programmed cell death of cancer cells; overexpression of these proteins in cancer confers resistance to chemotherapy and radiation therapy. Bcl-2 and Bcl-X_L are overexpressed at a high level (50-100%) on common cancers, including cancers of the breast, colon, prostate, head and neck, and ovary. Agents that target production of these proteins might work to overcome cancer resistance (see section on novel therapies at the end of this chapter).

Another control against abnormal cellular proliferation also contributes to cellular aging. As a cell divides and ages, there is progressive shortening of the ends of the chromosomes, or telomeres. A striking correlation between cancer and the overexpression of telomerase (an enzyme capable of preventing the shortening of telomeres) suggests that it might be partially responsible for tumor cell immortality. Telomerase activity is present in about 85% of malignant tumors but absent in most normal somatic tissues. The stage and severity of neuroblastoma, breast cancer, and other cancers have been found to correlate with levels of telomerase activity, indicating a prognostic role of enzyme activity. Normal human cells transfected with the telomerase gene in vitro far exceeded their normal life span and ability to divide, thereby establishing a firmer causal relationship between telomere shortening and cellular senescence. This suggests important possibilities for targeting telomerase activity as part of cancer therapy.

The development of cancer is a complicated multistep process that appears to involve the acquisition of an increasing number of genetic mutations, eventually resulting in invasive disease. Clinical examples of this stepwise progression can be found in many common cancers, including breast, colon, and prostate cancers. A history of the benign finding of atypical ductal hyperplasia on breast biopsy is clearly associated with a two- to fourfold increase in the risk of subsequent invasive cancer. Noninvasive breast cancer (ductal carcinoma in situ) is a preinvasive lesion that can progress into invasive cancer if left untreated. Understanding the cascade of genetic changes associated with the progression of benign cells to invasive cancer is a critical step in developing therapies targeted to a specific cancer. These genetic changes can now be mapped by a process called comparative genomic hybridization; this is an intense area of research. DNA microarray studies can detect activation of thousands of genes in a single experiment. The resulting DNA expression profile can be used not only to understand the development of cancer but also to assess prognosis, predict response to therapy, and direct targeted therapies. Over the last year, studies have associated certain DNA profiles with specific cancer phenotypes, an important first step in this exciting area of research. In non-small cell lung cancer, reduced expression of the adhesion molecule E-cadherin detected by tissue microarray analysis correlated with reduced survival as well as local invasion and regional metastases.

Defining chromosomal aberrations and their association with prognosis will help in designing targeted therapies as well as risk-adapted treatment strategies. Several recent studies suggest that clusters of genes may help both to define specific chemotherapy sensitivities of specific tumors and to more accurately estimate prognosis. **Gene expression analysis** using array technologies allows the simultaneous examination of the relative abundance of thousands of genes in a cell or tissue and avoids the need to identify each gene individually. Specific gene expression profiles have been associated with survival in breast cancer. In one study, frozen tissues from diagnostic biopsies of breast tumors were analyzed and the results then correlated with responses to neoadjuvant chemotherapy administered before surgery. A specific clustering of genes was highly correlated to complete disappearance of tumor at the time of surgery. There were very few patients in this pilot trial; ongoing studies are examining serial biopsies during chemotherapy in an attempt to further predict response to treatment. Ideally, these data will be used in the future to individualize treatment for specific cancers.

A second study evaluated gene expression in 86 patients with newly diagnosed stage I adenocarcinoma of the lung. Clustering of gene expression profiles with 4966 genes revealed three clusters of lung adenocarcinomas with a significant relationship between the specific cluster and tumor stage or differentiation. In addition, high-risk and low-risk groups were identified with very different survival statistics. Understanding differences in the behavior of early-stage cancers using gene expression profiling will in the future permit differential treatment directed toward maximizing outcome and choosing appropriate therapy.

Genetic analysis may help to determine appropriate dosing of effective but toxic chemotherapeutic agents. Specific polymorphisms or variations in the *UGT1A1* gene have recently been shown to predict severe neutropenia resulting from the colorectal cancer drug irinotecan. The *UGT1A1* gene produces a protein that metabolizes the active metabolite of irinotecan; alterations in this gene are quite common. Genotyping using a simple blood test may be able to identify patients at high risk for life-threatening side effects, allowing individualization of dosing to improve the therapeutic ratio for patients with colorectal cancer. A screening test could become available within the next few years.

Another area of study is the field of **proteomics**. Genes encode proteins, and proteins may be easier to evaluate than genes. Identifying and analyzing individual proteins is difficult and time-consuming, but describing patterns or panels of proteins is more straightforward. The field of proteomics seeks to associate specific patterns of protein expression with disease states, prognosis, and response to treatment in both tissue and serum. Proteomics has already been used successfully to aid in early detection of cancer; a good example is the use of prostate-specific antigen for the detection of prostate cancer. A division of the National Cancer Institute is devoted to the study of proteomics and will also serve as an important source of information for researchers.

Hereditary Factors

Hereditary predisposition to some cancers has been linked to genetic events and is manifested by a family history of a common cancer occurring frequently—and in a younger than expected age group—or any history of a relatively rare cancer. Examples include familial retinoblastoma, familial adenomatous polyposis (FAP), multiple endocrine neoplasia syndromes (MEN), and the hereditary breast and ovarian cancer syndromes. Although FAP is a rare syndrome, somatic mutations in the affected gene (adenomatous polyposis coli; *APC*) occur in more than 60% of patients with colonic carcinomas and in an equal proportion of patients with adenomas. Genetic mutations associated with an increased risk of developing breast and ovarian cancers appear to be much more common than previously thought and are strongly related to age at diagnosis of cancer. It is estimated that 5-10% of all breast cancers and more than 40% of breast cancers occurring in women under 30 are due to inheritance of an abnormal gene. The risk of ovarian and other cancers is also significantly increased in carriers of these susceptibility genes.

A tumor suppressor gene termed *BRCA1* on chromosome 17 has been shown to be abnormal in some families with early onset and high frequencies of breast cancer and ovarian cancer. More than 100 mutations have been identified in the *BRCA1* gene, making identification of high-risk individuals difficult. Two population-based studies found that up to 20% of Jewish women with breast cancer at or before the age of 40 and approximately 10% of all women with breast cancer diagnosed before the age of 35 harbor mutations in the *BRCA1* gene. Inheritance of a mutated *BRCA1* gene confers a lifelong risk of approximately 85% for breast cancer and 50% for ovarian cancer. Inheritance of the *BRCA1* gene also appears to increase the risk of developing both colon and prostate cancers. Another susceptibility gene, *BRCA2*, has been associated with an increased risk for male breast cancer as well as malignant melanoma and other cancers. There is clearly an association of phenotype and inheritance of susceptibility genes. Breast cancers in *BRCA1* carriers tend to be hormone receptor-negative, whereas cancers in *BRCA2* carriers are generally hormone receptor-positive. For a woman diagnosed with breast cancer between the ages of 30 and 34 years, the likelihood of a *BRCA1* mutation is as high as 27% if her tumor is both hormone receptor-negative and of high grade.

Risk Factors & Prevention

Carriers of *BRCA* mutations who have children appear to be at higher risk for developing breast cancer by age 40 than carriers who are nulliparous—in contrast to the usual risk factors for sporadic breast cancer. Interestingly—and despite the association of *BRCA1* with an increased risk of hormone receptor-negative breast tumors—recent data confirm that oophorectomy in women with either mutation before the age of 40 significantly reduces the risk of breast cancer (up to 75%) and ovarian cancer, presumably by decreasing exposure of breast tissue to estrogen. The use of oral contraceptives for more than 5 years appears to significantly reduce the risk of ovarian cancer as well, perhaps by regulating ovarian cycling. Compared with sporadic ovarian cancers, those associated with the *BRCA1* mutation appeared to have a better clinical course, with a median survival of 77 months in women carrying the mutation compared with 29 months in controls. Many other less common genes have been identified that increase the risk of breast and other cancers, although clearly there are many yet to be identified. One recent study found that women who have an identical twin sister with breast cancer are at least three times more likely than average to develop cancer. If the twin was diagnosed before age 40, 25% of the remaining siblings developed cancer over the next 20 years. Increased risk in this setting is probably due to a combination of genes that will be more difficult to discern.

Screening for Genetic Risk Factors

With the discovery and cloning of cancer susceptibility genes such as *BRCA1*, commercial testing has been developed for "screening" using linked genetic markers. Tests for genes linked to familial cancer have raised concerns about the impact of positive results on patients. One study has evaluated indications for testing of the *APC* gene. Of the patients tested, 85% were felt to have valid indications for testing. However, only 20% received genetic counseling before the test; only 15% gave informed consent; and in 30% of cases the clinicians misinterpreted the results. It is essential that clinicians recognize the limitations of these tests and that genetic testing be made available in the appropriate setting. Educational programs and publications are available to help educate patients regarding genetic testing. Many cancer centers now have genetic screening and counseling programs. Patients with a strong family history of cancer should be referred to such programs before testing is performed. Early and regular cancer screening is recommended for affected members of the family, and aggressive but relatively effective preventive measures such as prophylactic mastectomy and oophorectomy should also be discussed. Updated guidelines for testing—including indications for testing, counseling about medical management, confidentiality of results, insurance coverage, and protection from discrimination—have recently been published (see reference below) and are available without cost at www.asco.org (search under genetic testing).

Other Familial Cancers

Other familial clusterings of cancer have been described that have not yet been associated with inheritance of a particular gene. Evaluation of participants in a study of colonic polyps revealed an increased risk of colorectal cancer in the siblings and parents of patients with adenomatous polyps, particularly when the adenoma was diagnosed before age 60 or (for a sibling) when a parent had colorectal cancer. This syndrome, referred to as a hereditary nonpolyposis colorectal cancer (HNPCC), has been associated with a germline mutation of DNA mismatch-repair genes. At least 2% of patients with colorectal cancer had these mutations in one European cohort. Testing for replication errors should be considered in patients under age 50 with colorectal cancer who have a family history of colorectal or endometrial cancer. Family members of patients with this syndrome may benefit from early screening.

In addition to the germline mutations found in HNPCC, up to 10-15% of sporadic colorectal cancers have somatic mutations in DNA repair genes resulting in microsatellite instability (MSI) or alterations in the size of repetitive nucleotide sequences. These cancers are usually in the right side of the colon and have been associated both with a better prognosis and a striking sensitivity to adjuvant chemotherapy. The *HER-2/neu* oncogene is a somatic (not inherited or germline) mutation that encodes a tyrosine kinase receptor in the epidermal growth factor receptor (EGFR) family and is overexpressed in about 20% of breast cancers. *HER-2/neu* overexpression is associated with more aggressive cancers, a worse prognosis, and enhanced tumor sensitivity to anthracycline chemotherapy. A recent study found that *HER-2/neu* overexpression in prostate cancer also correlated with a poorer 5-year prognosis, though this result must be validated. Identifying genetic factors that are associated with specific cancer phenotypes may allow effective tailoring of adjuvant chemotherapy.

Immune Factors

Autoimmune suppression may contribute to the development of cancer. Tumors are allowed to exist by virtue of tolerance—the ability of the tumor to escape the host immune system. The host immune system cannot recognize the tumor as foreign because of an absence of critical immunostimulatory molecules on the tumor itself, resulting in a state of anergy (deletion of tumor-specific lymphocytes) toward the growing cancer. Novel therapies aimed at correcting this immunodeficient state and stimulating the host immune response against tumor cells are now being tested clinically. (See section on novel therapies at the end of this chapter.)

Environmental, Infectious, & Therapeutic Carcinogens

It is difficult to link exposures to specific carcinogens with the development of cancer, since latency is long and the nature of exposure poorly documented. Environmental carcinogens include chemical carcinogens such as benzene and asbestos, oncogenic viruses such as the human papillomavirus and the Epstein-Barr virus, and physical agents such as ionizing radiation and ultraviolet light.

Certain viral infections may increase the risk of cancer and clearly have a pathogenetic role, such as the association between Epstein-Barr virus infection and endemic Burkitt's lymphoma and non-Hodgkin's lymphoma. Chronic infection with hepatitis B or C viruses increases the risk of hepatocellular carcinoma. Largely owing to the increase in chronic hepatitis, the incidence of hepatocellular carcinoma significantly increased during the 1990s compared with the 1970s. Interestingly, treatment with the antiviral agent interferon alfa following resection of hepatitis C-related hepatocellular carcinoma in a randomized trial appeared to significantly reduce the risk of cancer recurrence. Infection with HIV has been associated with non-Hodgkin's lymphoma, Hodgkin's disease, Kaposi's sarcoma, and cervical and anal cancers. The finding of human herpesvirus-8 (HHV-8) DNA sequences in both AIDS-associated and non-AIDS-associated Kaposi's sarcoma supports a possible causative role of

the herpesviruses in the development of some cancers. It appears that HHV-8 is sexually transmitted among men. Antibodies to HHV-8 correlate with the subsequent development of Kaposi's sarcoma, supporting an etiologic role of HHV-8 in this malignancy. The sexually transmitted papillomavirus (HPV) is a major risk factor for the development of cervical carcinoma and anal cancer. The prognosis of cervical cancer is dependent on the oncogenic potential of the associated HPV type, with the worst prognosis associated with HPV-18. Typing of the virus strain in each cancer may allow risk-adjusted treatment planning.

An additional cause of cancer is chemotherapy or radiation therapy for a prior malignancy. More aggressive chemotherapeutic and radiation regimens—and especially those combining the two treatment modalities—have been associated with increased rates of both secondary leukemias and solid tumors. The latency period may be short (2-5 years for leukemia) or very long (10-20 years for solid tumors), but the prognosis is uniformly poor. Chemotherapeutic agents known to cause secondary malignancies include alkylating agents—busulfan, cyclophosphamide, mechlorethamine, etc—and topoisomerase II inhibitors, including epipodophyllotoxins (etoposide) anthracyclines, ie, doxorubicin and epirubicin and anthracenediones (mitoxantrone). Secondary leukemias can be characterized to some degree by the causative agent. Alkylator-induced leukemias are usually associated with abnormalities involving chromosomes 5 and 7 and generally occur within 5-7 years after exposure. In contrast, topoisomerase II-induced leukemias occur within 2-3 years following exposure and involve aberrations in a specific gene within the long arm of chromosome 11 (11q23). Abnormalities of 11q23 often occur at a specific breakpoint region thought to be involved in DNA transcription. An increase in the rate of secondary acute leukemia has been reported in breast cancer patients treated with dose intensification of cyclophosphamide in combination with doxorubicin (a topoisomerase II active drug) from 1992 to 1994. The incidence is approximately 0.3% in a multicenter study involving over 2500 women with positive axillary nodes. Increased dosages and frequency of administration of anthracyclines, anthracenediones, and the alkylating agent cyclophosphamide have been reported to increase the risk of breast cancer to as high as 3-4%. Prolonged oral exposure to etoposide or alkylator agents can result in a much higher risk of secondary leukemia. Platinum-based chemotherapy for ovarian cancer has been reported to increase the risk of leukemia twofold to eightfold, with larger doses and longer treatment courses associated with higher risks. This risk was significantly higher in women who had also received intravenous melphalan.

The risk of certain secondary cancers may be age-dependent. Radiation therapy for Hodgkin's disease increases the risk of breast cancer (including bilateral disease) if the radiation occurred in women under the age of 30. The relative risk of solid tumors and leukemias has been found to increase significantly with younger age at first chemotherapy treatment for Hodgkin's disease. This risk is especially high when chemotherapy and radiation are combined. Nevertheless, the risk of secondary malignancies in children surviving at least 5 years after diagnosis is relatively low at 3.2% 20 years post diagnosis, with primary disease recurrence remaining the most common cause of mortality. The Childhood Cancer Survivor Study (CCSS) is a large prospective study of over 14,000 survivors of childhood cancer designed to characterize the late effects of therapy in this increasing population.

Estrogen & Progesterone

Retrospective data indicate that the combination of estrogen and progesterone given as long-term hormonal replacement to postmenopausal women may significantly increase the risk of breast cancer over estrogen therapy alone. The best evidence for the risks and benefits of postmenopausal hormone use comes from the Women's Health Initiative (WHI), a large randomized clinical trial of over 16,000 healthy women ages 50-79 which compared the effects of combined estrogen and progesterone to placebo on a variety of health outcomes. The trial, sponsored by the National Institutes of Health (NIH), was halted early when, in July 2002, investigators reported that the overall risks of estrogen plus progestin—specifically Prempro—outweighed the benefits. The WHI found that use of Prempro increased the risk of breast cancer (by 24%, or an additional eight cases of breast cancer for every 10,000 women treated), heart disease, stroke, and blood clots, although there were fewer cases of hip fractures and colon cancer in the treatment arm. Follow-up is short, and at this time there is no difference in mortality. However, recent data from this trial tell us that the breast cancers developing in women receiving combined hormonal therapy were significantly larger than those developing in women on placebo and were diagnosed at a more advanced stage. Hormonal therapy increases breast density, increasing the difficulty in diagnosing cancers at an early stage. The WHI study has also shown that almost twice the number of women receiving Prempro had abnormal mammograms at 1 year compared with women receiving placebo medication.

An update of the WHI study showed that in women aged 65 and over, use of estrogen plus progestin doubled the risk of developing dementia. Additionally, an analysis of the quality of life of a subgroup of WHI participants aged 50-79 found no change in general health, vitality, mental health, depressive symptoms, or sexual satisfaction associated with use of combined hormonal replacement.

The risks and benefits of estrogen alone are less clear. The study of women in the WHI study taking estrogen alone is scheduled to continue until 2005, and the results of this trial will provide evidence for the associated health effects. In an observational study of over 40,000 women, those who used estrogen alone for 10-19 years were twice as likely to develop ovarian cancer as women who did not use menopausal hormones. For women who used estrogen for 20 or more years, the risk of ovarian cancer increased to three times that of women who did not use menopausal hormones. Another study suggests that the increased risk appears to be limited to women who used estrogens for 10 or more years. There are insufficient data on which to base a conclusion about whether or not combined estrogen and progesterone use affects the risk of ovarian cancer.

It is clear that other dietary and lifestyle factors play a significant role in the risk of developing specific cancers, although much of the specifics still need to be elucidated (see section on Primary Prevention, below).

■ PREVENTION OF CANCER

PRIMARY PREVENTION

1. Lifestyle Modifications

Population studies suggest that lifestyle—including tobacco use, diet, and alcohol consumption—accounts for a majority of avoidable cancer deaths in the United States. Other factors, including obesity, parity, and length of lactation, have also been associated with increased cancer risk. Although prostate and breast cancers are

the most common malignancies in men and women, respectively, the most common cause of cancer death in both sexes is still lung cancer. Since 1973, there has been only a 10% increase in the incidence of lung cancer in men compared with a 124% increase in women, reflecting a marked increase in the number of women who smoke. Since tobacco-related cancers account for at least 29% of all fatal forms of cancer and since lung cancer is the leading cause of cancer death, smoking cessation is an important area for continued education and prevention efforts. Strategies for helping patients stop smoking are described in [Chapter 1](#). Programs directed both at cessation of smoking and at reversing the social acceptability of cigarette smoking have been more successful than programs encouraging cessation alone. In California and Massachusetts, increasing the excise tax on cigarettes combined with an antismoking campaign resulted in a substantial decrease in the prevalence of adult smoking. In California, this program was responsible for halving of the per capita consumption of cigarettes and translated into a significant decline (almost five times greater than the rest of the United States) in the incidence of lung cancer in both men and women in the state from 1988 to 1997. The decline in women is even more striking when compared with the rest of the United States, where the rate of lung cancer in women is still increasing. For an excellent article (with graphics) on this topic, go to www.asco.org and search under Tobacco Control and Global Issues.

The molecular targets for carcinogens such as alcohol and tobacco have not yet been identified. However, an evaluation of tumor samples from over 100 patients with squamous cell carcinoma of the head and neck associated cigarette smoking with genetic mutations in the P53 gene, thought to result in the initiation or progression of this cancer. This supports epidemiologic evidence that abstinence from smoking is important in preventing head and neck cancer. Cigarette smoking has been linked to cancers of the lung, mouth, pharynx, esophagus, pancreas, kidney, and bladder. In addition, a study by the American Cancer Society found a 30-40% increase in the risk of death from colorectal cancer in cigarette smokers, with the increased risk occurring after 20 years of smoking and increasing with the number of cigarettes smoked daily. The risk decreased each year after quitting smoking, indicating that change in this major lifestyle factor can still reduce risk of death from cancer. In addition, a recent study showed that patients who stopped smoking following a diagnosis of small cell lung cancer treated with chemotherapy and radiation had significantly longer 2-year and 5-year survivals than those who continued smoking. A similar prolongation in survival occurs in patients with head and neck cancer who quit smoking following diagnosis. Although cigarette smoking has not been related to the incidence of breast cancer, early data suggest that mortality from established breast cancer is higher in smokers than in nonsmokers. This supports the hypothesis that ongoing toxicity even in patients already diagnosed with cancer contributes to mortality. However, up to 50% of all lung cancers occur in those who have stopped smoking for at least 1 year, indicating that at least some of the carcinogenic effect of cigarette smoking may be irreversible.

Diet is an important area of intervention for primary cancer prevention. Epidemiologic studies suggest an inverse relationship between fruit and vegetable intake and the risk of common carcinomas, indicating a potential protective role of these dietary components. A case-control study in South Asia found a small reduction in the risk of breast cancer associated with a diet rich in vegetables. High intakes of fat and specific fatty acids have been postulated to increase the risk of breast, colon, prostate, and lung cancer, although a recent study in Canada found no association between carbohydrate intake and risk of colorectal cancer in women. Linoleic acids in essential fatty acids are the food source for arachidonic acid—and this metabolic pathway has been postulated to play an important role in the development of cancer. However, the Nurses' Health Study, which followed more than 88,000 women for 14 years with food frequency questionnaires every 4 years beginning in 1980, found no evidence that a lower intake of total fat or specific major types of fat decreased the risk of breast cancer. Data from the Nurses' Health Study and other epidemiologic studies suggest that a high consumption of red meat and excess alcohol consumption (probably also in combination with a diet low in possible preventive vitamins such as folate) may increase the risk of colorectal cancer. A meta-analysis published in 1999 evaluated dietary fat intervention studies (published from 1966 through 1998) on serum estradiol levels and fat consumption. These findings did not rule out the possibility that reducing fat consumption below 20% of calories might reduce breast cancer risk by lowering serum estradiol levels. Another study compared the dietary intake of saturated fat of 1665 men with prostate cancer to the diet of an equal number of men without the disease. A high intake of saturated fat increased the risk of prostate cancer in all four major ethnic groups evaluated. There was no increase in prostate cancer among men with the lowest intake of saturated fats.

Obesity or a high body mass index has been implicated as a risk factor for breast, colorectal, and lung cancers (in nonsmokers) as well as others. Body mass index and elevated blood pressure have been found to be associated with an increased risk of renal cell cancer in men. Dietary factors may further increase risk in already high-risk populations. A high intake of saturated fat in 27,111 smokers participating in the Alpha-Tocopherol, Beta-Carotene Cancer Prevention study significantly increased the risk of developing pancreatic cancer, suggesting that diet may be a modifiable factor in the prevention of pancreatic cancer in this population.

Increased intake of dietary fiber has been thought to reduce the risk of colorectal cancer and adenomas. The Nurses' Health Study investigated the intake of dietary fiber in the same population specified above, and no association was found between the intake of dietary fiber and the risk of colorectal cancer or adenomas. A prospective study of over 10,000 men likewise did not find a significant association between fiber intake and the risk of developing adenomas. Two prospective, randomized trials tested the value of a high-fiber, low-fat diet or a high-fiber cereal supplement versus a standard diet in reducing the risk of recurrent colorectal adenomas in men and women with a recent prior diagnosis of adenoma and demonstrated no difference in the risk of recurrent adenoma based on dietary regimens. Other dietary factors such as folate, methionine, and vitamin D may reduce the risk of colorectal malignancy, but this too will require further investigation.

Various lifestyle and dietary factors have been associated with a reduced risk of breast cancer. Increased duration of lactation, particularly for at least 1 year and with more than one pregnancy, reduced the subsequent risk of breast cancer in one large meta-analysis. In another study, Korean women who breast-fed for less than a year had a 20% lower risk of breast cancer, and those who breast-fed for more than 24 months had a 40% reduced risk compared with those who had no history of lactation. The California Teachers Study is a prospective study of over 133,000 active and retired teachers and administrators that will evaluate a variety of factors related to cancer diagnosis over time. At 2 years of follow-up, the only dietary factor associated with an increased risk of breast cancer was alcohol ingestion, with two or more glasses of wine per day associated with a 50% increased risk (relative risk 1.5) compared with nondrinkers. It may be that women with a higher risk of breast cancer could modify their risk by reducing overall alcohol intake.

The Women's Health Initiative, begun in 1992, examined the effects of three distinct interventions—a low-fat eating pattern, hormone replacement therapy, and calcium and vitamin D supplementation—on the prevention of cancer, cardiovascular disease, and osteoporosis in 64,500 postmenopausal women of all races. An additional 100,000 women will be enrolled in an observational study. The estrogen-progesterone component of this study has been closed (see Incidence and Etiology, above); the estrogen-alone component continues. Information on the dietary and vitamin intervention component of this trial should be available in the next 1-2 years. Other ongoing intervention trials include the Women's Healthy Eating and Living (WHEL) study, which targets women 1-3 years following a diagnosis of breast cancer to assess the effects of a low-fat, high-fiber diet on recurrence and death from cancer.

Given the general lack of specific information linking diet to the risk of cancer, what should we recommend to patients right now? A diet low in saturated fat and rich in whole grains, fruits, and vegetables appears to improve health in a variety of ways—certainly in reducing cardiovascular disease and diabetes and, based on epidemiologic data, reducing the overall risk of cancer. Similarly, weight loss appears to be a prudent recommendation. For more specific diets—in particular, reducing the risk of recurrence of a known cancer or precancer—we will have to wait for more data.

Another lifestyle factor with important implications for primary prevention is exposure to ultraviolet light. Chronic cumulative exposure to solar ultraviolet radiation is the major risk factor for nonmelanomatous skin cancer. Regular use of sunscreen prevents the development of precancerous solar keratoses and results in regression of existing keratoses, although the effect of sunscreens on the incidence of melanoma is not clear. Protection from sunlight and the regular use of sunscreens should be recommended for the primary prevention of skin cancers.

2. Chemoprevention

Chemoprevention focuses on the prevention of cancer by administering chemical compounds that interfere with the multistaged carcinogenic process. Better understanding of the biochemical and molecular mechanisms of carcinogenesis has made possible the identification of potential chemopreventive agents. Four risk groups have been identified for intervention: (1) previous cancer patients (to prevent second malignancies), (2) patients with preneoplastic lesions, (3) patients at high risk for malignancy (family history, lifestyle, occupation), and (4) the general population.

Chemicals used in chemoprevention must be nontoxic and well tolerated by otherwise asymptomatic individuals. Because of the long natural history of carcinogenesis, there must also be a method of evaluating the efficacy of chemopreventive agents other than waiting for the development of tumors. Biomarkers, including the premalignant markers such as leukoplakia, colonic polyps, and aberrant crypt formation in the colon, are currently in clinical use. Other less specific surrogate markers

for cancer risk such as breast density are also in use as primary end points in prevention studies. Molecular susceptibility markers may become useful; nuclear retinoic acid receptor agonists are under investigation in chemoprevention studies of patients with head and neck cancer.

Retinoids, the natural derivatives and synthetic analogs of vitamin A, are the best-studied chemopreventive agents. NSAIDs—specifically, the selective COX-2 inhibitors—and hormonal agents such as tamoxifen, raloxifene, and finasteride appear to have an important role in prevention of some cancers. Numerous additional investigations include the role of specific dietary components such as vitamins and of pharmaceutical agents such as the statins. Ongoing research in this area is assessing the impact and appropriate use of selective NSAIDs, vitamins, hormonal agents, and, more recently, statins in cancer prevention.

Isotretinoin & Acyclic Retinoids

Retinoids are modulators of epithelial cell differentiation both in vivo and in vitro that are thought to act on nuclear receptors to regulate both cellular growth and differentiation and cell apoptosis.

Isotretinoin has been shown to suppress leukoplakia, a premalignant lesion of the aerodigestive tract. Effectiveness and tolerability of low doses of isotretinoin have been demonstrated. In a randomized maintenance trial, only patients with a demonstrated response to high-dose induction (1.5 mg/kg/d) were placed on low-dose maintenance therapy (0.5 mg/kg/d). The disease progression rate was only 8% compared with a rate of 55% in a separate group taking beta-carotene.

High doses of isotretinoin may prevent the development of second primary tumors in patients with early squamous cell carcinoma of the head and neck. An initial phase III study showed a statistically significant reduction in the incidence of new aerodigestive cancers when isotretinoin versus placebo was given for 1 year following definitive local therapy (4% versus 24%). There were no significant differences in disease recurrence or survival at a median follow-up of 55 months, and 30-40% of patients required reduced dosages or discontinued therapy due to toxicity. A second randomized study using lower doses of a different and probably less active retinoid showed no differences in the incidence of second primary tumors. Based on these preliminary results, three large randomized trials were performed to assess the preventive effects of retinoids on second primary tumors.

The first trial (Euroscan) studied 2 years of treatment with retinyl palmitate and acetylcysteine in over 2500 patients with either lung cancer or head and neck cancer. No differences were found in the incidence of second primary tumors. A United States intergroup trial studied the use of isotretinoin to prevent second primary tumors following definitive therapy of stage I non-small cell lung cancer. Because of side effects seen with the higher (50- to 100-mg) dose, the drug was given at a dosage of 30 mg/d for 3 years. After a median follow-up of 3.5 years, there was no difference in time to second primary tumor, recurrence, or mortality. Subset analysis suggested that never-smokers might benefit from isotretinoin, whereas there was a higher risk of cancer recurrence and mortality in smokers in the isotretinoin arm. The major toxicity at higher doses includes skin dryness, cheilitis, hypertriglyceridemia, and conjunctivitis. These toxicities require dose reduction or temporary discontinuation of the drug. The third double-blind randomized study investigated the effect of low-dose isotretinoin for 3 years in the prevention of second primary tumors in 1200 patients definitively treated for stage I or stage II head and neck cancer, with 4 years of subsequent follow-up. The annual second primary tumor rate was 4.7% in both arms and was highest in current smokers, with the most common tumor being tumor of the lung. Although there was a transient protective effect on local recurrence in patients who received isotretinoin, this effect was lost after treatment was discontinued. A number of trials have confirmed a significantly higher rate of second primary tumor formation in smokers versus former smokers or never-smokers as well as a significant adverse effect on survival—prospectively proving the impact of active smoking on second primary tumor development. An interesting recent report suggests that nicotine may suppress the antigrowth effects of retinoids in lung cancer cells.

Retinoids have been synthesized that may be more potent chemopreventive agents with less side effects. The acyclic retinoid polyprenoic acid inhibits chemically induced hepatocarcinogenesis in rats and spontaneous hepatomas in mice. In patients with hepatocellular carcinoma, the rate of recurrent and second primary tumors is high despite curative therapy with surgical resection and ethanol injection therapy. In one study, 89 patients who were free of disease after either method of treatment were randomized to receive either 600 mg/d of polyprenoic acid or placebo for 12 months. After a median follow-up of 38 months, 27% of patients in the polyprenoic acid group versus 49% of the patients in the placebo group had recurrent or new hepatocellular carcinomas, a result which was statistically significant. The difference was even greater in the groups that had secondary hepatomas. Longer follow-up has also shown a survival advantage. At a median of 62 months of follow-up, 75% of the treatment group versus 45% of the placebo group are alive. Toxicity was quite modest (headache, nausea), with none of the side effects usually described with isotretinoin.

Three strategies that have been proved to prevent liver carcinogenesis are vaccination against hepatitis B, treatment of chronic active hepatitis C with interferon, and deletion of premalignant and latent malignant cells in the remnant livers of patients undergoing complete resection of hepatocellular carcinomas. The retinamide fenretinide (4-HPR) is a potent apoptosis-inducing synthetic vitamin A analog with significant in vitro activity. Fenretinide appears to reduce the activity of telomerase, which is important in lung carcinogenesis. Expression of telomerase reverse transcriptase (TERT), the catalytic subunit of telomerase, was evaluated on bronchial biopsies in 57 heavy smokers before and after 6 months of treatment with fenretinide or placebo. A 25% reduction in expression of TERT was found in the fenretinide-treated patients. Although clinical follow-up is clearly critical, the hope is that this type of surrogate marker will improve our ability to assess the effectiveness of possible chemopreventive agents and perhaps also identify patients at higher risk for cancer development. A large randomized trial evaluated the effect of fenretinide versus placebo for 5 years to prevent contralateral breast cancer in women aged 30-70 years with a history of resected breast cancer and no other adjuvant therapy. Although no overall effect was observed, subset analysis found a reduction in contralateral and ipsilateral breast cancer rates in premenopausal women. Fenretinide is being studied in randomized trials as a chemopreventive agent in patients with superficial bladder cancer and in women at increased risk for ovarian cancer. Newer and more potent retinoids are being developed and tested in a variety of cancers.

Aspirin & Other NSAIDs

Aspirin and other NSAIDs inhibit tumor growth in experimental systems. Prostaglandin inhibitors reduce in rats the size and number of colon tumors induced by chemicals or radiation by inhibiting cyclooxygenase activity in the arachidonic acid pathway (COX-1 and COX-2). Regular aspirin administration at low doses (16 or more doses of 325 mg per month for at least 1 year) may reduce the risk of fatal colon cancer by as much as 40-50%. Low-dose aspirin may also protect against cancers of the esophagus, stomach, and rectum.

A study evaluating the use of sulindac versus placebo in patients with familial adenomatous polyposis showed reduction of both the number and the size of colorectal adenomas. The effect was incomplete, without complete regression of all polyps in any patient. After the sulindac was discontinued, both polyp size and polyp number increased. A large prospective cohort study was subsequently published evaluating aspirin use and the risk for both colorectal cancer and adenoma in 48,000 male health professionals over a 4-year period. The subsequent risk of developing colorectal cancer and adenomas was lower in men reporting regular use of aspirin (250 mg more than twice a week) on the study entry questionnaire even when multiple other variables were taken into account. In the Nurses' Health Study, 90,000 women were evaluated for the risk of colorectal cancer over a 12-year period according to the number of consecutive years of regular aspirin use (two or more 325 mg tablets per week) reported on three consecutive questionnaires. There was a statistically significant decrease in the risk of colorectal cancer after 20 years of consistent aspirin use, with the maximal reduction seen in women who took four to six tablets per week. A slight reduction in risk was seen in women who took aspirin for 10-19 years as well. Known risk factors such as diet did not influence this risk reduction. The Physicians' Health Study is the only randomized prospective trial of aspirin (325 mg every other day for 5 years) versus placebo. At the end of the trial, no differences were seen in the frequency of self-reported new colorectal cancers.

The selective COX-2 enzyme inhibitors are the subject of intense research in the area of prevention and treatment of cancer. COX-2 expression is inducible, unlike the constitutive expression of COX-1, and COX-2 up-regulation occurs in most epithelial tumors, including colorectal cancer and cancers of the lung and breast. This up-regulation is thought to be secondary to other initiating events, such as oncogene activation or mutation of a tumor suppressor gene. COX-2 levels increase throughout oncogenesis, and expression appears to promote angiogenesis (new blood vessel growth) and decrease apoptosis (programmed cell death). The COX-2 inhibitors are less toxic and more specific and therefore suitable as chemopreventive agents. One selective COX-2 inhibitor, celecoxib, has been shown to induce regression of polyps in patients with familial adenomatous polyposis at a dosage of 400 mg twice a day for 6 months. Based on these data, celecoxib was approved by the FDA for chemoprevention of polyps in patients with familial adenomatous polyposis. The major side effect of high-dose celecoxib is gastrointestinal bleeding. Celecoxib should not be used for routine chemoprevention of sporadic colorectal cancers. A broad range of cancer prevention studies using COX-2 inhibitors are ongoing through the National Cancer Institute. COX-2 has been found to be overexpressed in a number of common cancers, and this overexpression has recently been correlated with worse outcomes. Based on in vitro data suggesting antitumor activity of NSAIDs, including antiangiogenic effects, induction of apoptosis, and reduction of proliferation, selective COX-2 inhibitors are being studied as part of combination therapy with both hormonal therapy and chemotherapy of established cancers. One large national randomized clinical trial in the United States will evaluate the effect of the COX-2 inhibitor celecoxib or placebo in combination with hormonal therapy as treatment for early-stage breast cancer. Smaller ongoing trials are evaluating chemoprevention with celecoxib of lung cancer in former smokers and the regression of Barrett's esophagus.

Beta-Carotene & Vitamin E

The carotenoids are plant pigments that protect plant cells from damage and were thought to have an antioxidant role in human tissues. Beta-carotene is a carotenoid found in high concentrations in human tissues; its importance as an antioxidant is controversial. A role for beta-carotene and another antioxidant, vitamin E, in the prevention of either premalignant or malignant disease has not been established.

Several randomized studies have evaluated the effect of beta-carotene and vitamin E on the prevention of cancer in high-risk populations. The Alpha-Tocopherol, Beta Carotene (ATBC) Cancer Prevention Study randomized 29,000 Finnish male smokers to receive beta-carotene, vitamin E, both agents, or neither agent for an average

of 6 years. A minimal (2%) and statistically insignificant reduction in the incidence of lung cancer was seen in the men who received vitamin E. In contrast, there was a statistically significant 18% higher incidence of lung cancer in the group taking beta-carotene. Vitamin E supplementation reduced prostate cancer incidence by 34% and colorectal cancer by 16%, though only the reduction in prostate cancer incidence was statistically significant. Men in the control group with higher levels of vitamin E or beta-carotene before the study was initiated developed fewer lung cancers, suggesting that other components of foods high in these vitamins may be responsible for the protective effects noted in epidemiologic studies.

The Beta-Carotene and Retinol Efficacy Trial (CARET), a lung cancer chemoprevention study targeting high-risk populations, randomized a total of 18,000 smokers, nonsmokers, and workers with extensive occupational exposure to asbestos to receive either a combination of 30 mg/d of beta-carotene (as an antioxidant) and 25,000 IU/d of retinol (vitamin A—as a tumor suppressor) or placebo. With an average of 4 years and 73,000 person-years of follow-up, the combination of beta-carotene and vitamin A had no benefit on the incidence of lung cancer. In fact, the active treatment group had a 28% higher incidence of lung cancer than the placebo group, and the mortality from all causes and the rate of death from cardiovascular disease were higher by 17% and 26%, respectively. On the basis of these results, this study was stopped early.

The Physician's Health Study randomized 22,000 United States male physicians to receive beta-carotene (50 mg on alternate days) or placebo. The physicians were treated for an average of 12 years; 11% were current smokers and 39% were former smokers at the beginning of the study. In this trial, no evidence either of benefit or of increased risk for cancer was found, with a much longer follow-up than either of the two other studies. There were no differences in the overall incidence of malignant neoplasms, cardiovascular disease, or overall mortality in the group as a whole or in the smokers.

One additional randomized study in which a positive effect of beta-carotene supplementation was found evaluated a poorly nourished population group rather than the well-nourished populations described above. Linxian, China, is an area with one of the world's highest rates of esophageal and stomach cancers and a habitually low intake of several nutrients. In nearly 30,000 participants from the general population, the mortality rates from cancer were substantially lower among those who received daily supplementation with a combination of beta-carotene, alpha-tocopherol, and selenium over a 5-year period. A marked reduction in the cancer death rate (13%) was observed in the supplemented group, largely due to a 21% decrease in stomach cancer mortality. Over 85% of cancers arose in the esophagus or stomach, but 31 deaths were caused by lung cancer. The risk of death from lung cancer was reduced by 45% among those receiving supplements, though the numbers were very small (11 versus 20 lung cancer deaths), and only 30% were cigarette smokers. A second study evaluated the effect of supplements, including beta-carotene, on prevention of esophageal and gastric cancers in over 3300 people with esophageal dysplasia. Although esophageal cancer mortality and total cancer mortality were not significantly lower in the supplemented group, the incidence of mortality due to stomach cancer was higher. On repeat endoscopy comparing results 2 and 6 years after randomization, dysplasia had resolved in about two-thirds of patients in both arms at 6 years. These findings underscore the need for placebo-controlled trials in the area of cancer prevention. The NCI is currently collaborating with agencies in China to pursue further chemoprevention studies in this unique population.

In summary, there is no evidence to support the use of beta-carotene in the primary prevention of cancer in well-nourished populations. The major criticism of the large studies conducted to date is that increasing one type of vitamin—even one stereoisomer of a vitamin—does not reflect the vitamin content of a diet high in vegetables. In addition, intake of beta-carotene is a marker of increased fruit and vegetable consumption. The balanced mixture of antioxidants found in a diet rich in fruit and vegetables may be more important and more effective in reducing cancer risk than beta-carotene supplementation. Other micronutrients such as vitamin E may prove more promising.

The Women's Health Study, begun in 1992, is a randomized, double-blind, placebo-controlled trial testing the risks and benefits of vitamin E, beta-carotene, and aspirin in the primary prevention of cancer and cardiovascular disease in 40,000 healthy female health professionals in the USA. Results are expected in the next couple of years.

Calcium & Selenium

Dietary patterns continue to be associated with a risk of colorectal neoplasia. The changes in risk may be contributed to by alterations in bile acids. Calcium appears to bind bile acids in the bowel lumen, inhibiting bile-induced mucosal damage and perhaps carcinogenesis. A modest reduction in the incidence of adenomas in patients taking calcium supplementation has been shown in patients receiving it over a 4-year period. The Selenium and Vitamin E Cancer Prevention Trial (SELECT) is the largest chemoprevention study ever to be undertaken and began in August of 2001. This NCI-sponsored trial will randomize 32,400 men aged 50-55 and older to selenium, vitamin E, both, or placebo for 7-12 years in 435 sites in the United States, Canada, and Puerto Rico. This study is based on the results of the Alpha-Tocopherol, Beta-Carotene Cancer Prevention Study, in which vitamin E reduced prostate cancer incidence by 32%, and the selenium and skin cancer trial, in which selenium reduced the incidence of prostate cancer by 63%. As of January 2003, there were 18,881 participants enrolled in this trial, and results are not expected until 2012. Further information on the SELECT trial can be found at the following web sites: www.crab.org/select and www.cancer.gov/select. Vitamin D induces bile acid breakdown in vitro and may have a role in protection against colon cancer. This effect will need in vivo evaluation.

Tamoxifen

Tamoxifen is a selective estrogen receptor modulator (SERM) with both antiestrogen and proestrogen activity that has an important role in the treatment of both early and advanced breast cancer. Studies of women taking tamoxifen as adjuvant therapy for unilateral breast cancer have shown a 30-40% reduction in the risk of developing a second primary in the opposite breast. The Breast Cancer Prevention Trial (BCPT) is a nationwide trial that randomized 13,400 women at high risk for breast cancer to receive either tamoxifen (20 mg/d) or placebo for 5 years. The trial was stopped at a median follow-up of 4 years due to a striking 50% reduction in the risk of breast cancer in the women taking tamoxifen—89 women taking tamoxifen developed breast cancer, compared with 175 taking placebo. This benefit was restricted solely to the development of estrogen-receptor-positive cancers. In addition to invasive cancer, there was a similar reduction in the risk of noninvasive breast cancer such as ductal or lobular carcinoma in situ. Tamoxifen also decreased the number of bone fractures. Two much smaller European studies that used different parameters to determine risk (and study eligibility) did not show a significant reduction in cancers with the use of tamoxifen. It is likely that tamoxifen is not as effective in preventing breast cancer in very high risk groups, ie, those with genetic predispositions. Side effects of tamoxifen include an age-dependent small increase in the risk of endometrial cancer (including sarcoma of the uterus), deep vein thrombosis, and pulmonary embolism. These side effects are seen primarily in women over age 50.

The use of tamoxifen for primary prevention of cancer is controversial because of its known secondary effects, mainly the increase in endometrial cancer. This risk is small when compared with the incidence of breast cancer in younger women on placebo in the trial. Even if the incidences of endometrial cancer and breast cancer are considered together, there was still a 30% reduction in the risk of cancer in the women receiving tamoxifen.

Raloxifene

Early results of the MORE (Multiple Outcomes of Raloxifene Evaluation) trial have provided more information regarding prevention of breast cancer. Raloxifene is a novel SERM with estrogenic effects on bone and lipids and estrogen antagonist effects on the breast and uterus. Two different doses of raloxifene or placebo were administered to 7700 postmenopausal women to test the hypothesis that raloxifene would reduce the risk of bone fractures. After 21/2 years, a 70% reduction in the risk of breast cancer was found in the women taking raloxifene compared with the women taking placebo. A suggestion of decreased risk of endometrial cancer was also found. The long-term safety and follow-up of raloxifene in these women is ongoing. The effects of raloxifene in women with breast cancer or in women at high risk for developing breast cancer has not been evaluated (see below).

Ongoing Trials in Breast Cancer

The Study of Tamoxifen and Raloxifene (STAR) started in 1999 with a goal of randomizing 22,000 American and Canadian postmenopausal women who are at least 35 years of age and who are at increased risk of breast cancer to either daily tamoxifen (20 mg/d) or raloxifene (60 mg/d) for 5 years. The accrual goal has been reduced to 19,000 because of a higher than expected breast cancer risk in participants. As of February 2003, a total of 15,390 women had been randomized, and results are projected to be available in 2007. This study should answer the question whether raloxifene is as effective as tamoxifen at reducing the chance of breast cancer—with additional benefits such as fewer side effects. Additional information regarding the STAR trial and eligibility criteria as well as other studies on breast cancer can be found at the NCI clinical trials Web site (www.cancer.gov/star) or by calling 800-4-CANCER. At the prevention Web site (www.breastcancerprevention.com), a link is provided to permit calculation of the risk for an individual patient of developing breast cancer and determining eligibility for the trial.

A new class of hormonal agents are now in early clinical trials for primary prevention. The aromatase inhibitors block the peripheral conversion of androstenedione and testosterone to estradiol in menopausal women and are effective in the treatment of metastatic breast cancer. Preliminary data from a large randomized trial (Arimadex and Tamoxifen Alone or in Combination; ATAC) comparing tamoxifen alone with anastrozole alone and with the combination of the two agents as adjuvant therapy for early-stage breast cancer have documented a small but significant reduction from the use of anastrozole alone, particularly in the incidence of second primary cancers of the breast. The combination arm was no better than tamoxifen.

The aromatase inhibitors do not appear to cause either an increased risk of thrombosis or endometrial cancer, making them much more suitable agents for prevention in a healthy population. Further follow-up and results from ongoing prevention trials will be needed to understand the impact of aromatase inhibitors in this area. Ongoing prevention trials have targeted women at particularly high risk of developing breast cancer.

Isoflavones

Isoflavones are found in a variety of natural substances, including soy. Laboratory studies have shown that isoflavones such as those found in soy inhibit the growth of breast cancer cell lines; however, epidemiologic studies evaluating consumption of isoflavone-containing foods have shown inconsistent results. The Japan Public Health Center-based Prospective Study on Cancer and Cardiovascular Diseases enrolled almost 22,000 Japanese women between the ages of 40 and 59. Women who consumed three or more bowls of miso soup daily containing over 25 mg of genistein had one-half the risk of breast cancer as women who consumed less than one bowl (about 7 mg genistein), and this effect was greatest among postmenopausal women. Interestingly, consumption of other foods containing soy—soybeans, tofus, etc—were not associated with a reduction in risk of breast cancer. Further trials, including trials in Caucasian women who have a higher baseline risk of breast cancer, are required to confirm this interesting observation.

Finasteride

Finasteride is a 5 α -reductase inhibitor used to treat benign prostatic hyperplasia. This agent inhibits the enzyme responsible for converting testosterone to 5 α -dihydrotestosterone, suppressing prostate cell and organ growth. In rats, finasteride prevented macroscopic but not microscopic prostate carcinogenesis—supporting the use of this agent in the prevention of conversion of latent prostate carcinoma to life-threatening disease. The Prostate Cancer Prevention Trial (PCPT) randomized 18,000 healthy men aged 55 years or older with normal digital rectal examinations and prostate-specific antigen (PSA) concentrations to finasteride or placebo. The trial was closed a year before its planned completion in response to the documented strength of prostate cancer reduction in the treatment arm. There was a 25% reduction in the incidence of prostate cancer in the treatment arm, with absolute rates of 18% versus 24% in the placebo arm. This corresponds to 15 less cancers in 1000 older men. Interestingly—and similar to results seen in prevention trials targeting breast cancer with tamoxifen—more high-grade tumors were seen in the finasteride group at a rate of 37% versus 22% in the placebo-treated men. Although there was enthusiasm about these data—supporting manipulation of androgen levels as a way of preventing prostate cancer—caution was advised in the use of finasteride across the board. There are no survival data from the PCPT as yet, and it is not clear that the tumors prevented in this trial posed a significant threat to life or health. However, finasteride may be a reasonable preventive option for men with a high risk of prostate cancer until additional data are obtained. Side effects from finasteride, given at a dose of 5 mg by mouth every day, include reduced libido and improved ability to urinate in men with prostatic hyperplasia (the current approved use of this drug).

Other Current Trials

Additional trials are under way investigating the effect of both diet and pharmacologic agents in the prevention of cancer. These include studies of folic acid, dietary fat and fish oils, vitamin supplementation, and others. Dietary agents such as polyphenols in green tea are thought to play a role in chemoprevention and are under investigation. There is great interest in moving the new biologic therapies that target specific pathways important in carcinogenesis into the prevention setting. These include farnesyl transferase inhibitors and agents that block the epidermal growth factor receptor (EGFR).

A recent case-control study of 300,000 residents in Europe found a 20% reduction in cancer risk in those taking cholesterol-lowering statin drugs. Data were adjusted for diabetes mellitus, hospitalizations, comorbidities, use of other medications, and sex hormone levels. When specific cancer rates were analyzed separately, reductions in risk were significant only for prostate cancer and renal carcinoma since the rates of other cancers were too low to show significance. Only people who took statins for more than 4 years had a significant 36% reduction in cancer risk, and an increase in cumulative dose also appeared to have a protective effect. The majority of patients took simvastatin as their cholesterol-lowering agent. Inhibition of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase reduces endogenous production of mevalonate, resulting eventually in decreased biologic activity of several oncogenes, including *ras*. These data are preliminary but intriguing; future studies must also control for important risk factors such as smoking and diet. A prospective prevention trial is planned to start in the next year, investigating the use of statins to prevent progression of in situ cancer of the breast to invasive disease.

Further information about ongoing chemoprevention trials can be obtained from the Chemoprevention Branch of the National Cancer Institute (301-496-8563) and at www3.cancer.gov. An excellent article summarizing ongoing prevention and early detection trials, including eligibility, risks, and contact information, is available at CAonline.AmCancerSoc.org (see reference below.)

SECONDARY PREVENTION (EARLY DETECTION)

Given the inadequacy of current knowledge concerning the causes of cancer, effective prevention can be achieved for only a minority of malignancies. Other than primary prevention and perhaps chemoprevention, the most effective clinician intervention is early diagnosis. Screening is used for early detection of cancer in otherwise asymptomatic populations. Detection of cancer may be achieved through observation (eg, skin, mouth, external genitalia, cervix), palpation (eg, breast, mouth, thyroid, rectum and anus, prostate, testes, ovaries and uterus, lymph nodes), and laboratory tests and procedures (eg, Papanicolaou smear, sigmoidoscopy or colonoscopy, mammography). Effective screening requires that a test will specifically detect early cancers or premalignancies, be cost-effective, and result in improved therapeutic outcomes. For most cancers, stage at presentation is related to curability, with the highest cure rates reported when the tumor is small and there is no evidence of metastasis. However, for some tumors (eg, lung or ovarian cancer), distant metastases tend to occur early, even from a small primary. More sensitive detection methods such as tumor markers are being developed for many forms of cancer. Some tumor markers, such as PSA, are already a regular (though controversial) part of routine cancer screening (see section on tumor markers). Screening is not useful if a method of early detection does not exist (eg, cancer of the pancreas) or if there is no apparent localized stage (eg, leukemia). Current guidelines for cancer screening from the American Cancer Society can be found on line at CAonline.AmCancerSoc.org in the January/February issue of 2003 (see below) and in [Table 1-9](#). These recommendations include general cancer-related check-ups as well as screening for cancers of the prostate, breast, colorectum, and cervix.

Cancers for which screening or early detection has led to an improvement in outcome include cancers of the breast, cervix, colon, prostate, oral cavity, and skin. Ongoing trials are evaluating the use of newer screening methods for the most common malignancies, including cancers of the breast, lung, and prostate as well as colorectal and ovarian cancers.

It is critical that clinicians involve patients in decisions about whether to order tests for early detection of breast and prostate cancers so that patients will understand the risks and benefits. The rates of routine cancer screening in the United States remain low, with less than 50% having recent screening for colorectal cancer and less than 60% having recent mammography and clinical breast examination. Data from the Women's Health Initiative Observational Study cohort, which represents a large and diverse group of older women, indicate that health insurance is among the most important determinant of cancer screening independent of other factors. Improving insurance coverage of screening and access to health insurance for older adults in the United States may have an important role in improving early detection of cancer through screening. Screening is underutilized in minority groups in the United States, especially in inner city and rural areas. This results in the diagnosis of cancers at more advanced stages. Educational and outreach programs should be directed at these underserved areas.

Screening for Breast Cancer

Techniques for early detection of breast cancer include self-examination, clinical examination, and mammography. The benefits of screening mammography have been reviewed in two large meta-analyses—these results remain controversial based on a number of factors. First, several of the large published studies evaluating the value of mammography have serious flaws. Second, mammography increases the detection of the preinvasive ductal carcinoma in situ (DCIS), which has an extremely low 10-year mortality. Lastly, available data suggest that the most significant reduction in mortality obtained from mammographic screening may be in women over the age of 60 (24-33% reduction), with smaller benefits in younger women. The Agency for Healthcare Research and Quality (AHRQ) conducted its own review of the meta-analysis and rated the included studies based on the quality of data and the inclusion of younger age groups as well as other factors. They concluded that there is a demonstrated 20% reduction in the number of breast cancer deaths in women undergoing screening mammography both in the over-50 and under-50 age groups, though the times required in follow-up to see these benefits may be quite different. The AHRQ—along with the ACS and the NCI—recently put forth the following recommendations for mammographic screening: Every 1-2 years for women between the ages of 40 and 59, then annually in women 50 years and older. The upper age limit for mammographic screening has not been established.

Both mammography and clinical examination of the breast are associated with a significant number of false-positive results, leading to further testing. Screening mammograms and clinical breast examinations in 2400 women over a 10-year period found that 24% and 13% (respectively) of women had at least one false-positive mammogram or false-positive clinical examination. The controversy regarding mammographic screening is thus far from resolved; however, it is the best screening method currently available. Women between the ages of 40 and 49 should be active participants in decisions regarding screening and should have an understanding of known risks and benefits. Despite the sensitivity of mammography, between 15% and 25% of breast cancers are not visible by this radiographic technique; this is particularly true for young women with dense breasts. All clinically suspicious lesions should be biopsied regardless of a negative mammogram.

Digital mammography is a newer technique that uses computers and special detectors to produce a digital image displayed on high-resolution monitors. The NCI launched the Digital Mammographic Imaging Screening (DMIST) Trial in October 2001 to determine if digital mammography is as good as or better than standard screen (x-ray) mammography with regard to sensitivity, specificity, and predictive values. This will enroll 49,500 women in the United States and Canada, and all women will have both types of radiographic screening with 2 years of follow-up. As of January 2003, approximately 21,000 women have been enrolled in this important trial. Further information about the DMIST can be found at cancer.gov/DMIST or www.dmist.org.

MRI screening of the breast appears to be a useful technique in women at very high risk for developing breast cancer. This highly sensitive test is unfortunately not very specific, leading to unnecessary biopsies. It is currently of value only in very high-risk women when regular screening might result in neglect or delay of prophylactic mastectomy.

The value of clinical breast examination for the early detection of breast cancer remains unclear. A large study in China found no benefit in survival in women trained to perform monthly examinations; however, these data may not apply to the United States population for a variety of reasons. At this time, screening guidelines include monthly breast self-examination as well as yearly mammography.

Screening for Lung Cancer

It is clear that current and former smokers are at high risk of developing lung cancer and that early detection of lung cancer may result in detection of lesions when they are still surgically resectable and, therefore, potentially curable. However, data available so far are inconclusive as to whether either chest x-rays or the more sensitive CT scan can reduce lung cancer mortality. The National Lung Screening Trial (NLST) is a large randomized trial designed to determine whether lung cancer mortality is reduced in long-term or heavy current and former smokers by screening with chest x-ray versus spiral CT. The trial, which opened in September 2002, had enrolled 13,279 participants out of a total goal of 50,000 as of February 2003 and included men and women in good health between the ages of 55 and 74. Spiral CT or chest x-ray is performed once a year for 3 years. Interim results are hoped for in 2005. Further information regarding the NLST can be found at www.cancer.gov/nlst.

Screening for Cervical Cancer

Regular screening for cervical cancer (every 3 years in standard risk groups) with Pap tests has been found to decrease the mortality rate in women who are sexually active or are 18 years of age or older. Testing for HPV DNA in high-risk populations may improve early detection and management of cervical cancer, helping to determine which women with low-grade cytologic abnormalities require colposcopic evaluation. Recent data indicate that screening every 2 years with both Pap and HPV testing is more cost-effective than screening with either test alone. A large German study found that HPV testing was a highly sensitive method for detecting high-grade cervical intraepithelial neoplasia (CIN), suggesting that routine HPV testing might be of value in higher-risk women. Self-collected vaginal swabs for DNA testing may improve screening in areas where cytologic study is not readily available or in populations in which women are hesitant to undergo regular examinations. The American Cancer Society has recently updated its screening guidelines to include HPV DNA testing in high-risk individuals. Routine screening with vaginal Pap smears in women who have previously undergone a hysterectomy for benign gynecologic disease is not useful because of the very low incidence of squamous cell cancers of the vagina.

Screening for Colorectal Cancer

Annual fecal occult blood testing and screening with sigmoidoscopy every 5 years in people over age 50 decreases the mortality rate from colorectal cancer. An evaluation of over 46,000 people aged 50-80 in the Minnesota Colon Cancer Control study over an 18-year follow-up period showed that either annual or biennial screening of two stool samples significantly reduced the incidence of colorectal cancer when an abnormal fecal blood screen was followed by colonoscopy. Removing polyps detected by colonoscopy reduces the risk of colorectal cancer, and, following polypectomy, colonoscopy is superior to double-contrast barium enema for the detection of recurrent polyps. Even adenomatous polyps 5 mm or less in diameter detected in the rectosigmoid by sigmoidoscopy are markers for more advanced proximal neoplasms. These patients should undergo colonoscopy to evaluate the proximal bowel. However, colonoscopic screening can detect advanced colonic neoplasms in asymptomatic adults even in the absence of distal adenomas. Regular fecal occult blood testing and flexible sigmoidoscopy are still recommended for general screening because of the lower cost and facility of sigmoidoscopy compared with colonoscopy. A novel test to examine stool for DNA alterations that might help to screen for colorectal cancer is in development.

PLCO

The Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial (PLCO) is a large cancer screening study that was opened between 1992 and 2001 and randomized over 154,000 healthy men and women between the ages of 55 and 74 to routine health care versus prescribed screening. The goal of this study is to determine the effect of cancer screening tests on site-specific cancer mortality. Screening will occur for a total of 6 years, with 10 years of follow-up. Screening tests include PSA annually for 6 years; digital rectal examination (DRE) annually for 4 years; chest x-ray annually for 4 years in smokers and for 3 years in never-smokers; sigmoidoscopy at entry and then after 3 or 5 years on study (see below); transvaginal ultrasound annually for 4 years; and CA 125 (an ovarian cancer tumor marker; see section on tumor markers) annually for 6 years. Preliminary results are available on the role of sigmoidoscopy repeated at a 3-year interval in 9317 participants. A polyp or growth was detected in 13.9%, with 3.1% having a distal colon advanced adenoma or cancer—in an area that had been carefully evaluated 3 years earlier. These data suggest that higher-risk patients might benefit from more frequent sigmoidoscopic screening, though there are no data on mortality at this time.

Screening for Other Cancers

Unfortunately, screening for ovarian cancer with serum markers (eg, CA 125), transvaginal ultrasound, or pelvic examinations has not been shown to decrease the mortality rate from this disease. The PLCO trial should help to assess the impact of combined markers and ultrasound on both detection and mortality for this difficult disease. Screening for prostate cancer and hepatocellular cancer is discussed in the section on tumor markers; prostate cancer is evaluated in the PLCO trial (see above).

SPECIAL TOPICS IN PREVENTION

Patients with a family history of colorectal cancer are at increased risk to develop this disease and should undergo regular screening, which clearly reduces the incidence and mortality from invasive cancer. Guidelines for patients with a risk of hereditary nonpolyposis colon cancer are referenced below.

Approximately 10% of breast and ovarian cancers are due to inherited genetic mutations, occurring primarily in women with mutations of *BRCA1* and *BRCA2*. Patients with a family history of breast or ovarian cancer are at higher risk to develop these cancers and require frequent monitoring for early detection, though screening is inadequate to detect early ovarian cancer. Women with a family history of premenopausal or bilateral breast cancer—or any family history of ovarian cancer—should be referred for genetic counseling to better assess their risk of carrying one of the known mutations.

Prophylactic oophorectomy after completion of childbearing can decrease but not eliminate the risk of ovarian cancer in high-risk women; there is still a risk of peritoneal cystadenocarcinoma. The actual risk reduction is not known but has been estimated to be about 50%, still leaving women at a substantial risk for ovarian cancer. Bilateral prophylactic oophorectomy also appears to reduce the risk of subsequent breast cancer by up to 75%, presumably because of decreased exposure to ovarian estrogens. Oral contraceptive use for 6 years or more decreased the risk of ovarian cancer by as much as 60% in women with a family history of ovarian cancer. Prophylactic mastectomy has been used for decades to reduce the risk of breast cancer in high-risk women and is associated with a substantial reduction in breast cancer risk. In women at both high and moderate risk of breast cancer based on family history, the incidence of breast cancer (and death from breast cancer) is reduced by at least 90%. Decisions about such prophylactic surgery in high-risk women must be made taking full account of many other factors—clearly, breast or ovarian cancer would not have developed in all women undergoing the procedure.

Any patient with a history of dysplasia or premalignant lesions is at high risk for development of invasive cancer and should undergo frequent and thorough screening for subsequent malignancy. Patients at a particularly high individual risk for cancer may require additional screening procedures. Enthusiasm about the ability of **spiral CT** to image early lung cancers has reawakened interest in screening high-risk individuals with the goal of reducing lung cancer mortality with detection of early, treatable lesions. Randomized trials are ongoing (see above) to investigate whether screening for lung cancer with this expensive test can actually reduce mortality rates. At the present time, general guidelines are to consider routine chest x-ray screening on an annual basis for heavy current or former smokers (more than 20 pack years) over the age of 55.

■ STAGING OF CANCER

Standardized staging for tumor burden at the time of diagnosis is important both for determining prognosis and for making decisions about treatment. The American Joint Committee on Cancer (AJCC) has developed a simple classification scheme that can be incorporated into a form for staging and universally applied. This scheme is designed to encompass the life history of a tumor and is referred to as the TNM system. The untreated primary tumor (T) will gradually increase in size, leading to regional lymph node involvement (N) and, finally, distant metastases (M). The tumor is usually not clinically evident until local invasion or even spread to regional draining lymph nodes has occurred.

TNM staging is used clinically to indicate the extension of cancer before definitive therapy begins. The manner in which staging is accomplished—eg, by clinical examination or pathologic examination of a surgical specimen—must be carefully documented. Certain types of tumors, such as lymphomas and Hodgkin's disease, are usually staged by a different classification scheme that reflects the natural history of this type of tumor spread and helps to direct treatment decisions.

The TNM system allows a numerical assessment of the extent of primary tumor (T), the absence or presence and extent of regional lymph node metastases (N), and the absence or presence of distant metastases (M). The AJCC has just published a new version of the TNM staging criteria with major revisions directed toward providing a standardized method for classifying the extent of cancer at diagnosis and estimating the risk of recurrence and death from cancer. Examples of changes in staging included in the new system are staging melanoma based on the thickness and ulceration of the lesion instead of the level of invasion and the stratification of breast cancer stage based on the number of involved axillary nodes. Based on data that indicate prolonged survival in breast cancer patients with a single involved ipsilateral supraclavicular node, this presentation is now staged as stage IIb rather than stage IV. The new staging system took effect internationally in January 2003 and is a required part of medical records for all cancer patients. Details regarding these revisions may be found at the AJCC Web site: www.cancerstaging.net.

Traditional staging does not take into account the biology or aggressiveness of a particular tumor and may not allow differentiation of prognostic risk groups. For this reason, specific pathologic characteristics are added into the prognostic evaluation for certain tumors (eg, estrogen and progesterone receptors, grade and proliferative index for breast cancer; histologic grade for sarcomas and the majority of adenocarcinomas). Overexpression or underproduction of oncogene products (eg, HER-2/*neu* in breast cancer), infection of cancer cells with specific viral genomes (eg, HPV18 in cervical cancer), and certain chromosomal translocations or deletions (eg, alteration of the retinoic acid receptor gene in acute promyelocytic leukemia) have important prognostic significance and may direct risk-adapted or cancer-specific therapy. As these characteristics become standardized and better understood, they may allow us to identify patients with a poorer prognosis early in the course of disease when the patient might benefit from more aggressive therapy. In addition, characterizing cancers with genetic profiling or proteomics may completely change our concept of cancer staging in the future.

Greene FL et al (editors): *AJCC Cancer Staging Manual*, 6th ed. Springer, 2002.

■ PRIMARY CANCER TREATMENT

The reader is referred to the NCCN Oncology Practice Guidelines: www.cancernet.com. These guidelines are updated yearly.

SURGERY & RADIATION THERAPY

Most cancers present initially as localized tumor nodules and cause local symptoms. Depending on the type of cancer, initial therapy may be directed locally in the form of surgery or radiation therapy. Surgical excision or local radiation (or both) is the treatment of choice for a variety of potentially curable cancers, including most gastrointestinal and genitourinary cancers, central nervous system tumors, and cancers arising from the breast, thyroid, or skin as well as most sarcomas.

Surgery at presentation has both diagnostic and therapeutic effectiveness, since it permits pathologic staging of the extent of local and regional invasion as well as an opportunity for removal of the primary neoplasm. CT and MRI play an increasing role in noninvasive tumor staging. Based on results of a prospective clinical trial, **positron emission tomography (PET)** appears to be a more sensitive method than traditional imaging with CT scanning for detecting local and distant metastases in patients with non-small cell lung cancer. The effect on survival is unknown. One way to improve the specificity and sensitivity of these scans is to integrate the PET and CT images with computer technology rather than the traditional visual correlation. A recent study evaluated integrated PET-CT in 50 patients with non-small cell lung cancer. Additional information was obtained on 41% of patients compared with visual correlation; this included improved tumor staging, detection of involved nodes, and certainty of metastases. PET has also been shown to improve detection of recurrent disease for the purpose of second-look laparotomy and debulking in colon cancer patients with rising levels of carcinoembryonic antigen (CEA).

A **monoclonal antibody against CEA labeled with technetium Tc 99m (arcitumomab, CEA-Scan)** is now approved for imaging of cancers with increased levels of CEA and has been found to be more sensitive and specific than CT scans in the detection of both resectable and nonresectable disease. High-resolution MRI scanning with highly lymphotropic superparamagnetic nanoparticles may improve radiographic detection of occult lymph node metastases in patients with prostate cancer. The nanoparticles gain access to lymph nodes by means of interstitial-lymphatic fluid transport. Eighty patients with prostate cancer were evaluated before surgery; MRI with nanoparticles correctly identified all patients with nodal metastases, compared with a detection rate of only 30% using standard imaging. These newer, more sensitive (and much more expensive) scans may allow better assessment of resectability before surgery, sparing patients needless surgery but also providing appropriate surgery when cure with local treatment alone is possible. The best and most cost-effective use of these techniques remains to be determined.

Although standard surgery for breast cancer has included excision of axillary nodes, this can result in chronic lymphedema, pain, and decreased range of motion of the arm. Sentinel axillary nodes can be detected by injection of radioactive colloid or blue dye into the breast around the tumor or the biopsy cavity. "Hot spots" are then identified with a gamma probe and resected. **Biopsy of sentinel nodes** can predict the presence or absence of axillary node metastases and direct more aggressive surgery with up to 97% accuracy. However, the procedure is technically challenging and the success rate thus varies with the surgeon. This technique is also used for staging of malignant melanoma. Cryosurgical ablation of localized prostate cancers has been used instead of radiotherapy by some investigators and appears to reduce postablation voiding dysfunction. Radiofrequency ablation (frictional heating) and cryosurgical ablation are being tested as primary treatment of small, localized breast cancers.

Surgery may also play an important role in the treatment of selected patients with limited metastatic cancer. Resection of isolated metastases has been used most commonly for breast cancer with single brain lesions or isolated liver or lung lesions. Removal of isolated liver metastases may result in long-term survival, with 20% of patients living more than 5 years. Additional surgery after subsequent limited recurrence may also result in long-term disease-free survival. Surgical resection of both hepatic and pulmonary metastases may improve survival in appropriately selected colon cancer patients.

For certain tumor sites, complete surgical removal of the tumor can be disfiguring, disabling, or unachievable. Under those circumstances, primary local therapy with ionizing radiation may prove to be the treatment of choice. In other instances, surgery and radiation therapy are used in sequence. For stage I and stage II breast cancer, local incision or "lumpectomy" with axillary node dissection combined with radiation results in equivalent 10-year survivals when compared with the more disfiguring and extensive mastectomy procedure. Despite these well-established data, breast-conserving therapy is still underused in patients with larger tumors, mainly because of surgeon bias. Preoperative or "neoadjuvant" chemotherapy and radiation therapy allow limb-sparing surgery in osteosarcoma and organ preservation in oropharyngeal cancer, among others. Laser surgery is used to minimize surgical resection in esophageal and non-small cell lung cancers.

Radiation therapy is usually delivered as brachytherapy or teletherapy. In **brachytherapy**, the radiation source is placed close to the tumor. This intracavitary approach is used for many gynecologic or oral neoplasms and occasionally for breast cancer. In **teletherapy**, supervoltage radiotherapy is usually delivered with a linear accelerator, as this instrument permits more precise beam localization and avoids the complication of skin radiation toxicity. Various beam-modifying wedges, rotational techniques, and other specific approaches are used to increase the radiation dosage to the tumor bed while minimizing toxicity to adjacent normal tissues. Examples of new approaches to minimize radiation to surrounding tissues while maximizing radiation to the cancer include **three-dimensional conformal radiation therapy (3D CRT)** and **intensity modulated radiation therapy (IMRT)**. Conventional radiation beams are of uniform intensity. In contrast, IMRT's beam intensity is modulated to produce maximum doses where desired and minimal radiation to sensitive surrounding normal tissues. Improved outcomes have been shown for prostate cancer patients receiving IMRT.

Novel modalities are occasionally used to enhance penetrance into large tumors or to specifically target the site of radiation. **Gamma knife radiosurgery** allows focused radiation for limited brain metastases and is associated with fewer long-term complications such as cognitive dysfunction compared with whole brain irradiation. **Cyberknife** is a newer radiosurgical technique designed to perform tumor ablation in any site in the body. This unique system combined robotics and advanced image guidance to deliver radiosurgery treatment to tumors along the spinal cord or at other critical locations previously considered untreatable with surgery or radiation. It can also be used to treat recurrences in a previously radiated site or to boost standard radiotherapy.

Well-oxygenated tumors are more radiosensitive than hypoxic ones. Hypoxic tumors are often bulky, implying a potential synergistic role of surgical debulking prior to radiotherapy. Radiation therapy is normally delivered in a fractionated fashion over 4-6 weeks, this method appearing to have radiobiologic superiority by permitting time for recovery of normal host tissues (but not the tumor) from sublethal damage during treatment. However, a more accelerated fraction radiation schedule improves local-regional control in patients with head and neck cancer compared with standard fractionated radiation.

For most tumor types, there is a sigmoid curve of increasing rate of control of the local tumor with increasing radiation dose. Radiosensitive tumors usually exhibit radiosensitivity over the dose range of 3500- 5000 cGy.

Currently, more than half of all patients with cancer receive radiation therapy during the course of their illness. Radiation therapy is frequently the sole agent used with curative intent for tumors of the larynx (permitting cure without loss of the voice), oral cavity, pharynx, esophagus, uterine cervix, vagina, prostate, skin, Hodgkin's disease, and some tumors of the brain and spinal cord. For more extensive cancers, radiation is combined with surgery (eg, cancer of the breast, ovary, uterus, cervix, urinary bladder, rectum, lung, soft tissue sarcomas, and seminoma of the testis). Following mastectomy for breast cancer, radiation has been shown to reduce the risk of local recurrence from large or high-risk tumors and may increase overall survival by decreasing distant recurrence.

Radiation given in combination with chemotherapy may improve long-term disease control. The combination of chemotherapy and radiation therapy for the treatment of invasive carcinoma of the cervix is significantly superior to radiation therapy alone. There is at least a 10% improvement in 3-year survival and a 30-50% reduction in the risk of death from cervical cancer with combination therapy. Twice-daily radiation given concurrently with combination chemotherapy for the treatment of limited small cell lung cancer results in significantly improved 5-year survival rates compared with any prior treatment results. Twice-daily radiation also appears superior to once-daily treatment for this disease. Radiation combined with chemotherapy for cancer of the rectum or hormone therapy for cancer of the prostate improves survival over treatment with radiation alone, and concurrent radiation and chemotherapy for cancer of the head and neck reduces mortality from that disease compared with either treatment alone. Radiation can also improve disease control when given as an adjuvant to chemotherapy for bulky lymphomas, for non-small cell lung cancer, and for some cancers in children.

Occasionally, chemotherapy is used to sensitize tumor cells to the toxic effects of radiation. Radiation therapy for palliation of pain or dysfunction (eg, bone pain associated with advanced breast or other cancers) may improve the quality of life of patients suffering from incurable malignancies.

Various normal tissues (particularly skin, mucosa, myocardium, spinal cord, bone marrow, and lymphoid system) can exhibit early or late toxicity from radiation therapy. Acute toxicity may include generalized fatigue and malaise, anorexia, nausea and vomiting, local skin changes, diarrhea, and mucosal ulceration of the irradiated area. Radiation of large areas, especially the pelvis and proximal long bones, may result in bone marrow suppression. Radiation of the lungs, heart, and gastrointestinal tract must be approached with appropriate shielding to avoid toxicity such as radiation pneumonitis, congestive heart failure, or radiation gastroenteritis. Long-term toxicity from radiation therapy has significant long-term side effects that must be weighed against its possible benefits. Women under age 60 treated with left-sided adjuvant radiation for breast cancer with 10-15 years of follow-up have a significant increase in risk of death from myocardial infarction. Increased cardiac mortality has also been seen in patients who received radiation at a young age for Hodgkin's disease. Secondary leukemias and solid tumors can be seen after radiation therapy for a wide variety of cancers. This risk is particularly high in patients receiving a combination of both radiation and chemotherapy that includes alkylating agents. Treatment programs now combine less toxic chemotherapy with limited field radiation therapy to limit these fatal long-term side effects in long-term survivors from cancer. Other long-term toxicities include decreased function of the radiation organ (eg, decreased cognitive function after whole brain radiation), myelopathy, osteonecrosis, and hyperpigmentation of the involved skin.

Regional hyperthermia (40-42 °C) is an adjunct to ionizing irradiation for some tumor sites. The most useful application of hyperthermia to date has been in superficial or easily implantable tumors as well as in relatively bulky hypovascular tumors with some degree of hypoxia. **Electron beam therapy** has been used effectively to treat superficial tumors in the skin. **Radiolabeled antibodies** are currently under investigation as a means of delivering high levels of radiation locally to the tumor bed, thereby avoiding systemic toxicity. Ibritumomab tiuxetan and tositumomab are the first radiolabeled antibodies to be FDA-approved for the treatment of cancer—specifically, relapsed low-grade non-Hodgkin's lymphoma (see section on novel therapies at the end of this chapter).

Increasingly, the primary local therapy of cancer is integrated with systemic therapy, an approach that has proved to be superior for apparently localized tumor types with a high propensity for early metastatic spread and for which anticancer drugs are available.

SYSTEMIC CANCER THERAPY

Use of cytotoxic drugs, hormones, antihormones, and biologic agents has become a highly specialized and increasingly effective means of treating cancer. Therapy is usually administered by a medical oncologist. Selection of specific drugs or protocols for various types of cancer has traditionally been based on results of prior clinical trials. Many patients are treated on protocols to search for optimal therapy for refractory or poorly responsive malignancies. Treatment may be inadequate or ineffective because of drug resistance of the tumor cells. This has been attributed to spontaneous genetic mutations in subpopulations of cancer cells prior to exposure to chemotherapy. After chemotherapy has eliminated the sensitive cells, the resistant subpopulation grows to become the predominant cell type (Goldie-Coldman hypothesis). This has been the basis of alternating non-cross-resistant chemotherapy regimens.

Molecular mechanisms of drug resistance are now the subject of intense study. In many instances, specific drug resistance results from an amplification in the number of gene copies for an enzyme inhibited by a specific chemotherapeutic agent. A more general form of "multidrug resistance" (MDR) has been described in association with expression of a gene (*MDR1*) encoding a 170-kDa transmembrane glycoprotein (P-glycoprotein) on tumor cells. This protein is an energy-dependent transport pump that facilitates drug efflux from tumor cells and promotes resistance to a broad spectrum of unrelated cancer drugs. Although a variety of agents have been shown to at least partially and temporarily reverse acquired multidrug resistance in multiple myeloma and lymphoma, the doses of these agents required to overcome drug resistance are associated with serious side effects. MDR modulators will need to be both less toxic and more potent to be clinically useful. PSC 833 is a cyclosporine analog with little of the immunosuppressive effects or renal toxicities of cyclosporine but with fivefold to tenfold greater MDR-modulating activity. Unfortunately, clinical benefits from adding this agent to chemotherapy have been limited. Both improved response rates and improved survival with a tolerable toxicity profile using novel therapy such as this will have to be demonstrated to prove the effectiveness of this approach.

Variation in drug metabolism due to gene polymorphisms is emerging as a cause of relative resistance or sensitivity to chemotherapeutic agents. In one study, women with breast cancer who had single-nucleotide polymorphisms in the *CYP3A4* and *CYP3A5* genes were not able to metabolize cyclophosphamide and had a significantly shorter survival than women without this polymorphism. Polymorphisms in *CYP* have also been shown to increase sensitivity to some environmental carcinogens. Genetic variations in the DNA repair genes *XPD* and *XRCC1* may predict response to the chemotherapy drugs cisplatin or carboplatin in lung cancer, with certain variations associated with a shortened survival. With an increased understanding of individual susceptibility or resistance factors, pretreatment evaluation of drug metabolism genes might allow individualization of therapy.

Chemotherapy is used primarily to cure a small percentage of malignancies, as adjuvant therapy to decrease the rate of relapse or improve the disease-free interval, and to palliate symptoms and prolong survival in some patients with incurable malignancies. In addition, chemotherapy is playing an increasing role as preoperative or "neoadjuvant" therapy to reduce the size and extent of the primary tumor, thereby allowing complete excision at the time of surgery. Neoadjuvant (preoperative) chemotherapy results in identical survival when compared with standard postsurgical chemotherapy for breast cancer and allows more limited or complete surgical excision of the primary tumor as well as giving important information about chemosensitivity. Randomized studies now suggest that neoadjuvant chemotherapy may improve survival in patients with esophageal cancer and bladder cancer. Combined neoadjuvant chemotherapy and radiation followed by surgery and additional chemotherapy has been shown to prolong survival in patients with non-small cell lung cancer that has metastasized to mediastinal nodes compared with those who received only chemotherapy and radiation. In addition, survival rates at 3 years exceeded those seen in prior studies.

Chemotherapy was first shown to be curative in the treatment of advanced stages of choriocarcinoma in women. It is also curative in Hodgkin's disease, diffuse large cell and some high-grade lymphomas (including Burkitt's), carcinoma of the testis, some cases of acute leukemia, and embryonal rhabdomyosarcoma. When combined with initial surgery—and in some instances with irradiation—chemotherapy increases the rate of long-term control and cure of breast cancer, cervical cancer, small cell and non-small cell lung cancer, colon cancer, gastric cancer, esophageal cancer, rectal cancer, and osteogenic sarcomas. Combination chemotherapy provides palliation and prolongation of survival in adults with low-grade non-Hodgkin's lymphoma, mycosis fungoides, multiple myeloma and Waldenstrom's macroglobulinemia, acute and chronic leukemias, and breast, ovarian, cervical, and small cell lung carcinoma as well as carcinoid. Patients with incurable tumors who desire aggressive treatment should be referred for experimental therapy in well-designed clinical trials. (See section on novel therapies at the end of this chapter.)

High-dose chemotherapy followed by bone marrow transplantation is curative therapy for various types of leukemia, high-risk or relapsed lymphoma, and testicular cancer and occasionally for multiple myeloma. Allogeneic or autologous bone marrow or peripheral blood stem cells with or without ex vivo purging is used depending on the disease. The use of growth factors and blood stem cells has decreased the toxicity and cost of bone marrow transplantation. Autologous transplantation may now be used with low morbidity and mortality on selected patients up to age 70. Dose-intense chemotherapy with autologous bone marrow or peripheral blood stem cell rescue has been intensely studied for the treatment of both high-risk and metastatic breast cancer for the past decade with unfortunately negative or poor-quality data. Details of these studies are presented in the section on adjuvant therapy.

Nonmyeloablative allogeneic peripheral blood stem cell transplantation ("mini" transplant) is now being investigated as immunotherapy for some advanced cancers. This highly toxic and intensive therapy has been shown to result in sustained regression of chemotherapy-resistant metastatic renal cell carcinoma in ten out of nineteen treated patients, with three complete remissions. Tumor response was associated with acquisition of the donor immune system, resulting in a "graft-versus-tumor" effect. Further investigation is required to confirm sustained beneficial effects, reduce toxicity, improve efficacy, and better understand in which diseases this type of therapy can be effective.

Chemotherapeutic agents are increasingly being given on different schedules to reduce toxicity and enhance antitumor effects. "Dose-dense" chemotherapy can be given in two ways, either as standard doses of chemotherapy given more frequently with growth factor support or as smaller doses given on a weekly or more frequent schedule. Animal studies have suggested that these dosing regimens may reverse some types of chemotherapy resistance. A recent study found that standard doses of chemotherapy for breast cancer given every 2 weeks was superior to the same doses given at the standard 3-week interval. Both disease-free and overall survival were compared in these preliminary results. Somewhat surprisingly, toxicity was lower in the "dose-dense" arm, presumably because of the routine use of myeloid growth factors to avoid neutropenia and its associated complications.

While most anticancer drugs are used systemically, there are selected indications for local or regional administration. Regional administration involves direct infusion of active chemotherapeutic agents into the tumor site (eg, intravesical therapy for bladder cancer, intraperitoneal therapy for ovarian cancer, hepatic artery infusion with or without embolization of the main blood supply of the tumor for cancers metastatic to the liver or as primary therapy for hepatocellular carcinoma). These treatments can result in palliation and prolonged survival.

A summary of the types of cancer responsive to chemotherapy and the current treatments of choice is offered in [Table 40-3](#). In some instances (eg, Hodgkin's disease, breast cancer, ovarian and lung cancers), optimal therapy may require a combination of therapeutic resources, eg, radiation plus chemotherapy rather than either modality alone. Patients with stage I or stage II Hodgkin's disease are often treated with radiation alone, avoiding the potential toxicity of systemic chemotherapy. A small percentage of these patients may require chemotherapy later for disease recurrence.

Newer Anticancer Drugs

New drugs to treat cancer are under constant development and testing, with the aim of reducing toxicity to normal cells and increasing the toxicity to resistant cancer cells. Several of these newer agents developed over the last decade that are currently available are described in this section.

We have entered an exciting new era in the understanding and treatment of malignancies. Molecular techniques have allowed insight into the biologic events resulting in cancer, and these same techniques have developed just the beginning of a cascade of biologic therapies directed toward specific molecular or cellular factors critical to the pathogenesis of cancer growth and survival. Rather than the traditional cytotoxic therapy, newer treatments are more specific, less globally cytotoxic, and associated with fewer side effects. New biologic therapies are either approved or under investigation for use in the treatment of cancer. The time from development of a novel agent to clinical use and FDA approval has been markedly shortened; in the first 6 months of year 2001, two biologic therapies, imatinib mesylate and alemtuzumab, were rapidly approved for use based on marked efficacy with low toxicity for the treatment of two different hematologic malignancies. The next decade will probably see the development of a whole new class of agents and, consequently, a new paradigm for the treatment of cancer.

Cladribine & Fludarabine

A purine analog, cladribine (2-chlorodeoxyadenosine; 2-CdA), is used as the primary agent to treat hairy cell leukemia. A 1-week course of therapy results in high and durable remission rates with modest and short-lived toxicity. Repeated courses for disease recurrence are also effective. Pentostatin (2-deoxycoformycin, an adenosine deaminase inhibitor) is also used to treat hairy cell leukemia.

Fludarabine phosphate, another purine analog, has shown improved response rates and progression-free survival compared with oral chlorambucil or combination chemotherapy for chronic lymphocytic leukemia (CLL). Fludarabine is now indicated as first-line therapy for most patients with CLL. Side effects include an increased risk of opportunistic infections as well as very rare problems such as hemolytic anemia and severe bone marrow suppression. Fludarabine is also effective therapy for low-grade lymphomas and Waldenstrom's macroglobulinemia. Cladribine and pentostatin are also used to treat CLL and the above disorders.

Alemtuzumab

Alemtuzumab is a humanized monoclonal antibody that is approved to treat relapsed or resistant CLL. It targets the CD52 antigen, which is prevalent on the abnormal

B lymphocytes found in this common leukemia. In clinical trials of patients with CLL refractory to fludarabine and with prior exposure to alkylating agents, response rates of 33% were seen with a median duration of response of 7 months. Early studies in untreated patients suggest a response rate up to 87% with a high rate of complete responses. Alemtuzumab is given by subcutaneous injection, and side effects include infusion-related events, infections, and bone marrow suppression.

Newer Cytotoxics

Paclitaxel (Taxol) is a novel agent isolated from the pacific yew tree that has replaced cyclophosphamide as front-line therapy (combined with carboplatin) for the treatment of ovarian cancer. Intraperitoneal instillation may also be helpful for advanced disease. Paclitaxel (and docetaxel; see below) has also been shown to be one of the most effective agents against metastatic breast cancer; it is also effective in AIDS-associated Kaposi's sarcoma and other cancers. The primary toxicities of paclitaxel are hematologic and neurologic. Both are dose-dependent—the hematologic toxicity can be ameliorated by the use of myeloid growth factors.

Docetaxel is a synthetic analog of paclitaxel that has also been shown to be highly effective in breast cancer as well as other advanced malignancies, including non-small cell lung cancer and ovarian cancer. Its toxicities include bone marrow suppression and significant peripheral edema. The edema can be treated and generally prevented with steroids.

Vinorelbine, a semisynthetic vinca alkaloid, has been shown to be effective in treating advanced non-small cell lung cancer. Response rates of 30% have been observed when vinorelbine is used as a single agent against this poorly responsive tumor. Vinorelbine is also used to treat metastatic breast cancer as well as other tumors.

Capecitabine is an oral 5-FU prodrug that is now approved to treat anthracycline- and taxane-resistant breast cancers as well as metastatic colorectal cancer. Response rates range from 25% to 35%. Treatment can be complicated by a painful, red, and sometimes blistering rash on the palms and soles and severe diarrhea that resolves upon withholding therapy. A variety of other 5-FU prodrugs are in clinical trials but are not yet approved for use. A recent study showed a 3-month improvement in survival using the combination of docetaxel and capecitabine versus docetaxel alone in the treatment of advanced metastatic breast cancer, though there were considerably more side effects in the combination arm. This combination is now FDA-approved, and newer dosing schedules with reduced toxicity are being evaluated.

Gemcitabine, a pyrimidine analog for intravenous use, has been approved to treat pancreatic cancer and non-small cell lung cancer but is active in other advanced malignancies, including breast cancer.

Topotecan was the first of a class of drugs called camptothecans that inhibit the enzyme topoisomerase I to be FDA-approved for use. It is used to treat advanced ovarian cancer and has shown some efficacy in the treatment of several other tumors.

Irinotecan is highly effective in the treatment of metastatic colorectal cancer. Two randomized studies compared standard therapy (fluorouracil and leucovorin) to standard therapy with irinotecan (the Saltz regimen) in patients with untreated metastatic colorectal cancer. The use of irinotecan resulted in a significantly higher response rate, delayed time to progression, and, in one study, improved survival. Toxicity in the irinotecan arm was also significantly higher, and with longer follow-up mortality was concerningly high at 3.5%. With appropriate management, much of the toxicity appears to be reversible and includes severe diarrhea and neutropenia. Guidelines are available to improve management and reduce mortality from this regimen, which was due either to inflammation of the bowel, leading to sepsis, or to thrombosis. A newer agent, **oxaliplatin**, may replace irinotecan as first-line therapy for colorectal cancer (see below). Antitumor responses have been shown using irinotecan to treat non-small cell lung cancer, small cell lung cancer, ovarian cancer, gliomas, and others.

Results of a phase III randomized trial demonstrated prolongation in time to progression and disease-free survival using a new regimen to treat metastatic colorectal cancer consisting of the platinum derivative oxaliplatin combined with fluorouracil and leucovorin (FOLFOX4) compared with the Saltz regimen. Oxaliplatin was approved for use in the United States in 2002 based on the results of this trial. Additional data support the importance of oxaliplatin in the treatment of colorectal cancers. The primary toxicity of oxaliplatin is modest and reversible neuropathy.

Inhibitors of Thymidylate Synthase

Novel inhibitors of thymidylate synthase are under study for the treatment of advanced colorectal cancer. **Raltitrexed** is currently being used in Europe based on early data showing similar efficacy compared with fluorouracil and high-dose leucovorin. Treatment of malignant mesothelioma with the multitargeted antifolate agent **pemetrexed**—in combination with cisplatin—was recently shown to significantly improve survival from this highly resistant disease when compared with treatment with cisplatin alone. This is the first chemotherapeutic agent that has been shown to alter survival from malignant mesothelioma, a cancer that is rising in incidence due to occupational exposure to asbestos. Pemetrexed must be given with folic acid and vitamin B₁₂ supplementation.

Liposomal encapsulation of active chemotherapeutic agents may improve drug delivery and decrease systemic toxicity. Two liposomally encapsulated drugs, doxorubicin and daunorubicin, are indicated in the treatment of Kaposi's sarcoma and have shown efficacy in treating many other diseases, including breast cancer and lymphoma.

Monoclonal Antibodies

An increasing number of monoclonal antibodies are used in cancer chemotherapy. **Rituximab**, a chimeric antibody against the B lymphocyte antigen CD20, is effective therapy for relapsed or resistant low-grade lymphomas and has shown limited usefulness in higher-grade lymphomas as well. Almost 50% of patients with low-grade lymphoma respond with shrinkage of lymph nodes to once-weekly dosing for 4 weeks. Responses lasted a median of over 1 year. Rituximab has been shown to be effective in longer courses lasting 8 weeks and as re-treatment following relapse. A randomized study compared standard CHOP chemotherapy with rituximab combined with CHOP as initial therapy for patients aged 60 years or older with diffuse large B cell lymphomas. Response rates, 12-month event-free survival, and overall survival were significantly improved in the combination arm. These results will require further follow-up in this high-risk older population and in younger patients. Toxicities are generally quite mild, though anaphylaxis (resulting in death) and infusion-related side effects have been reported.

The HER-2/*neu* oncogene (also called *c-erbB-2*), a gene that encodes a receptor tyrosine kinase, is known to be overexpressed in many human cancers and is associated with tumors with poorer prognoses. In breast cancer, overexpression of HER-2/*neu* is seen in about 20% of women and is associated with a higher risk of metastatic disease and poorer survival. **Trastuzumab (Herceptin)** is a recombinant humanized monoclonal antibody directed against the HER-2/*neu* gene product that is indicated for the treatment of HER-2/*neu*-expressing metastatic breast cancer. When trastuzumab was used as a single agent to treat anthracycline-resistant breast cancer, the response rate was about 15%, with a median duration of response of over 8 months. However, when trastuzumab was added to first-line chemotherapy for metastatic breast cancer and compared with chemotherapy alone, patients receiving the combination therapy had a response rate of almost 50% with improvement in both remission duration and survival. The most promising combination appears to be trastuzumab and paclitaxel (Taxol) or docetaxel (Taxotere); combinations with other agents, including vinorelbine and gemcitabine, also appear to be effective. The combination of trastuzumab and doxorubicin (Adriamycin) resulted in an increase in subclinical and clinical cardiac toxicity; combinations with anthracyclines should be avoided. Other toxicities of trastuzumab appear to be primarily infusion-related. Ongoing randomized trials are evaluating trastuzumab therapy in combination with neoadjuvant or adjuvant therapy for node-positive breast cancer. In addition, trastuzumab is being tested for use in other HER-2/*neu*-expressing tumors such as prostate and ovarian cancers.

Antibodies Linked to Cytotoxic Agents or Radiation

Radiolabeled and toxin-linked antibodies have been used to treat lymphomas with very encouraging results and appear more effective than antibody therapy alone. **Ibritumomab tiuxetan** is an yttrium 90-labeled antibody to CD20 that is FDA-approved for the treatment of low-grade non-Hodgkin's lymphoma refractory to rituximab or transformed B cell non-Hodgkin's lymphoma. This is the first targeted radioimmunotherapy to be FDA-approved for clinical use. This unique drug consists of an antibody to CD20 bound to tiuxetan, a high-affinity chelator for yttrium 90 and indium 111. A recently published randomized controlled trial compared ibritumomab tiuxetan with rituximab in patients with relapsed or refractory low-grade non-Hodgkin's lymphoma or transformed non-Hodgkin's lymphoma. The overall response rate was 80% for the radiolabeled antibody versus 56% for rituximab alone, with a corresponding prolongation in duration of response and time to disease progression. Durable responses were significantly longer in the ibritumomab tiuxetan group. The primary toxicity is reversible but significant myelosuppression. This agent must not be used in patients with impaired marrow function or extensive involvement of marrow with lymphoma. Treatment is given in two steps. On day 1, a dose of rituximab is given followed by indium 111-labeled ibritumomab tiuxetan to determine biodistribution of antibody. One week later, a second dose of rituximab is followed by yttrium 90-labeled antibody. Yttrium 90 is a pure beta emitter with a half-life of 64 hours and a short path length of 5 mm, making it relatively safe to use in clinical practice.

A second radiolabeled antibody, **tositumomab**, is linked to ¹³¹I, which requires dosimetry and shielding, making clinical use more cumbersome. Tositumomab was recently approved by the FDA for the treatment of low-grade non-Hodgkin's lymphoma refractory to rituxan and chemotherapy and is given in two steps—the dosimetric and therapeutic steps. Each step includes an infusion of tositumomab followed by radiolabeled tositumomab. Toxicity is similar to that of ibritumomab tiuxetan. Many other antibody combinations are either under development or in preliminary clinical trials.

Another agent approved for the treatment of cutaneous T cell lymphomas (CTCL) such as mycosis fungoides resistant to standard therapy is **denileukin diftitox (ONTAK)**, a recombinant DNA-derived cytotoxic protein composed of amino acid sequences for diphtheria toxin fragments followed by the sequences for interleukin-2

(IL-2). This fusion protein was designed to direct the cytotoxic action of diphtheria toxin to cells that express the IL-2 receptor (CD25), such as the tumor cells in CTCL. Thirty percent of patients with advanced CTCL responded to denileukin diftotox in a phase III randomized trial. Toxicity is significant, including acute hypersensitivity reactions—requiring administration of this agent in a close- observation setting—and delayed pulmonary and peripheral edema.

Gemtuzumab ozogamicin is an antibody to CD33 linked to a potent antitumor antibiotic, calicheamicin, that is approved for the treatment of patients over the age of 60 with relapsed or refractory acute myelogenous leukemia (AML). This is the first example of antibody-targeted chemotherapy used clinically. In clinical trials, gemtuzumab ozogamicin resulted in a 31% remission rate in elderly patients with AML in first relapse who could not tolerate standard chemotherapy. Side effects are primarily infusion-related events and bone marrow suppression.

Agents With Novel Mechanisms of Action

Tretinoin is the first agent designed to target a specific fusion protein caused by a chromosome translocation. This oral agent induces differentiation and decreased proliferation without cytotoxicity of acute promyelocytic leukemia cells. Use of tretinoin combined with chemotherapy has been shown to improve disease-free and overall survival from this form of leukemia. **Arsenic trioxide** has been shown to induce remission in 70% of patients with relapsed or refractory acute promyelocytic leukemia (APL). It is indicated both for induction of remission and for consolidation in this high-risk group of patients.

Retinoids modulate the growth and differentiation of a variety of epithelial cells. **Bexarotene**, a retinoid that selectively activates the retinoid X receptor (RXR), is now FDA-approved to treat cutaneous T cell lymphomas such as mycosis fungoides. Targretin is also in clinical trials for use in a variety of advanced solid tumors including breast cancer.

Recombinant Growth Factors

Several recombinant growth factors have been shown to be effective in the treatment of malignancy. **Recombinant alpha interferon** has marked antitumor effects in hairy cell leukemia and chronic myelogenous leukemia, moderate effects in lymphomas, in the epidemic (AIDS-associated) form of Kaposi's sarcoma, in multiple myeloma, and as adjuvant therapy for malignant melanoma. Interferon alfa has some utility also in metastatic melanoma, renal cell carcinoma, and carcinoid syndrome. Unfortunately, chronic use of interferon alfa is associated with fatigue, cytopenias, and fluid retention.

The addition of interferon alfa to systemic chemotherapy for multiple myeloma appears to enhance the degree of cytoreduction achieved as compared with chemotherapy alone; however, toxicity is additive. Use of interferon alfa for myeloma following chemotherapy or autologous bone marrow transplant has prolonged remission duration, though overall survival is not altered. High-dose interferon for about 1 year in patients with malignant melanoma and lymph node metastases has been shown to improve disease-free and overall survival. Combinations of interferon alfa-2b and **interleukin-2** given with standard chemotherapy for metastatic melanoma prolongs time to progression and survival (by a median of 2.7 months) but is associated with a significant increase in toxicity. Interleukin-2 treatment is effective in a subset of patients with advanced renal cell carcinoma. Recent data indicate improved survival in patients with AL type amyloidosis treated with a combination of dexamethasone and interferon alfa compared with standard treatment with oral melphalan and prednisone.

Prior to the availability of imatinib, patients with chronic myelogenous leukemia (CML) were treated with interferon alfa given with low doses of the chemotherapeutic agent cytarabine. About 30% of patients achieved a cytogenetic response to this combination, which was associated with a significantly longer survival than that of patients treated with standard oral chemotherapy. CML is unusual in that almost all cases are associated with a specific reciprocal chromosomal translocation resulting in activation of a tyrosine kinase that is critical to the pathogenesis of the disease.

Oral Small Molecule Tyrosine Kinase Inhibitors

A novel and exciting oral agent, **imatinib mesylate (Gleevec)**, specifically blocks the active tyrosine kinase in CML and is now approved for clinical use in both early-stage and late-stage CML. The response in patients with chronic phase CML was striking, with a 94% hematologic and an 83% cytogenetic response rate. These responses appear to be durable; progression-free survival at 12 months was significantly longer with imatinib mesylate than with the combination of interferon and cytarabine at 97% versus 80% in a recently presented phase III trial. Lower but significant response rates are seen in more advanced disease. The effect of imatinib mesylate on long-term disease control will require further follow-up of treated patients. Imatinib mesylate also inhibits two other tyrosine kinases, receptors encoded by *c-kit* and platelet derived growth factor (PDGF). Expression of the c-kit receptor is found in high frequency in a relatively uncommon tumor of the gastrointestinal tract, gastrointestinal stromal tumor (GIST). GISTs are highly resistant to chemotherapy, and there is no effective therapy for advanced disease. Imatinib mesylate has demonstrated significant activity in GISTs, with a 60% overall response rate. This drug is also being tested in conditions such as myelofibrosis, chronic myelomonocytic leukemia, prostate cancer, and glioblastoma that express PDGF.

Gemfitinib (Iressa) is another small molecule tyrosine kinase inhibitor that has recently been approved to treat advanced lung cancer progressing despite at least two prior chemotherapy regimens. Response rates in a phase III trial were low at just over 10% overall, but no other treatments are available to this population of patients. In a separate prospective randomized trial, combining gemfitinib with chemotherapy as first-line therapy for advanced lung cancer was no better than chemotherapy alone. Unlike imatinib, gemfitinib blocks the epidermal growth factor receptor, which is overexpressed on a number of tumors and correlates with poorer prognosis. One trial demonstrated a 9-12% response rate to single-agent gemfitinib in refractory non-small cell lung cancer, with up to 43% of treated individuals experiencing symptom relief. In patients who had failed up to two prior treatments, the response rate rose to about 19%. Toxicity is modest and consists primarily of skin rash and diarrhea. A number of other agents in this class are in clinical trials.

Thalidomide

Thalidomide, approved for treatment of lepromatous leprosy, has been found to induce significant responses in advanced and relapsed multiple myeloma. It is now being tested in many clinical trials, and the combination of thalidomide with dexamethasone results in enhanced responses.

Bortezomib

Bortezomib (Velcade) is the first of a new class of agents, termed proteasome inhibitors, to be approved for the treatment of cancer. Bortezomib is a reversible inhibitor of the chymotrypsin-like activity of the 26S proteasome that degrades ubiquitinated proteins. The ubiquitin-proteasome pathway plays an essential role in regulating the intracellular concentration of specific proteins, thereby maintaining homeostasis within cells. Inhibition of the 26S proteasome prevents targeted breakdown of proteins, which affects multiple signaling cascades within the cell. The disruption in these normal homeostatic mechanisms can lead to cell death. In an open-label study of bortezomib in patients with multiple myeloma who had failed at least two prior therapies, the overall response rate was 28%, with 18% obtaining a clinical remission. The median duration of response was long at about 1 year. Bortezomib is approved for the treatment of multiple myeloma progressing despite at least two prior therapies. It is given intravenously twice weekly for 2 weeks followed by a 10-day rest, then repeated every 3 weeks. The major side effects are peripheral neuropathy, cytopenias, and hypersensitivity reactions.

Hormonal Therapy

Hormonal therapy plays a critical role in the management of specific cancers. Hormonal therapy or ablation is important in treatment and palliation of breast and prostatic carcinoma, while added progestins are useful in suppression of endometrial carcinoma. Women with metastatic breast cancer who show objective improvement with hormonal therapy have tumors that contain nuclear estrogen and progesterone receptors. The selective estrogen response modulator (SERM) **tamoxifen** has been shown to be effective in prolonging survival in both early-stage and late-stage breast cancer. Tamoxifen has both antiestrogen and proestrogen effects, resulting in side effects that include an increase in the risk of endometrial cancer and thrombosis. Newer SERMs without estrogen-like effects are being developed.

Aromatase inhibitors (eg, **anastrozole, letrozole**) and inactivators (**exemestane**) block the peripheral conversion of adrenal androgens into estrogens and have been shown to be at least as effective as or more effective than tamoxifen as first-line therapy for metastatic hormone receptor-expressing breast cancer. Aromatase inhibitors are effective only in postmenopausal women and are now being tested in the adjuvant setting. Preliminary data from the ATAC trial comparing the results achieved with tamoxifen alone, with anastrozole alone, and with a combination of the two agents have been presented. At 4 years of follow-up, treatment with anastrozole improved disease-free survival and reduced the risk of new breast cancers in the opposite breast. Toxicities were modest. Longer-term follow-up, survival, and toxicity data—in particular the impact of aromatase inhibitors on bone mineral density and lipid profiles—must be awaited before this becomes the standard of care for postmenopausal women with early-stage breast cancer. For postmenopausal women who require hormone therapy but are intolerant to tamoxifen, the aromatase inhibitors are a reasonable alternative. New trials will explore the use of ovarian suppression and aromatase inhibition or inactivation in the treatment of early-stage breast cancer in premenopausal women.

A new pure antiestrogen, **fulvestrant**, has now been FDA-approved as second-line therapy for metastatic hormone receptor-positive breast cancer. This agent is unique in its class and is given by intramuscular injection once a month. Hormonal approaches are also available to treat prostate cancer, though androgen receptors remain difficult to measure. These include the use of estrogen therapy, gonadotropin-releasing hormone agonists (eg, leuprolide, triptorelin, goserelin), and antiandrogens (eg, bicalutamide, flutamide). The use of leuprolide plus flutamide can be considered as an alternative to orchiectomy but also causes erectile

dysfunction. High-dose ketoconazole has been used to rapidly suppress adrenal production of steroids in crises such as cord compression. Use of this agent requires hydrocortisone supplementation.

Bisphosphonates

Bisphosphonates inhibit osteoclast activation and may also have antitumor and antiangiogenic effects. In addition to reducing bone pain, **pamidronate** reduces by approximately 50% the frequency of new skeletal events in breast cancer and prostatic cancer metastatic to bone and in multiple myeloma. Pamidronate must be given intravenously on a monthly basis, with an estimated cost of \$775 a month, and may worsen pain for the first few days following the infusion. For this reason, pamidronate therapy may be limited to patients with multiple lytic bone lesions or disease in weight-bearing bones or vertebrae. A new and significantly more potent intravenous bisphosphonate, **zoledronic acid**, was FDA-approved in early 2002 for the treatment of metastatic bone lesions. Its advantage compared with pamidronate is a shorter infusion time (15 minutes compared with 2 hours or more). Faster-than-indicated infusion rates of this bisphosphonate can result in reversible renal insufficiency. Once-yearly infusions of zoledronic acid have been shown to improve bone mineral density in osteopenic postmenopausal women. Ongoing trials are evaluating the ability of zoledronic acid to prevent bone loss associated with hormonal therapy and chemotherapy in breast and prostate cancers.

Clodronate is an oral bisphosphonate that has been shown to reduce the number of new bone metastases in women with breast cancer. A study of women with a primary diagnosis of breast cancer and microscopic evidence of tumor cells in bone marrow randomized to receive either clodronate, 1600 mg/d for 2 years, or placebo—in addition to standard adjuvant therapy—showed a significant reduction of both osseous metastases as well as mortality. Preliminary results of a larger study of women with operable breast cancer but no other specific high-risk features showed a reduction in the incidence of bone metastases but no difference in visceral metastases or survival. These observations suggest that bisphosphonates may be useful in a very high-risk subset of women with primary breast cancer. Clodronate is a less potent bisphosphonate than pamidronate and is currently available only in Europe. A clinical trial testing clodronate in women with node-positive breast cancer is now being conducted in the United States. Zoledronic acid will be tested as adjuvant therapy in the United States as well in women with node-positive breast cancer to see if the results of the clodronate study can be reproduced.

Growth Factors

Hematologic or other toxicity may limit the therapeutic effectiveness of treatment. It is possible to avoid the need for dose reductions or delay in therapy by using granulocyte colony-stimulating factor (G-CSF; filgrastim) or granulocyte-macrophage colony-stimulating factor (GM-CSF; sargramostim) to stimulate white blood cell recovery. A long-acting pegylated G-CSF (pegfilgrastim) is now FDA-approved to reduce the incidence of neutropenic fever associated with chemotherapy. This agent can be given as a single 6 mg dose subcutaneously on day 2 of each 3-week chemotherapy cycle and in randomized trials was equivalent to 11 doses of filgrastim. Interleukin-11 can be used to reduce the need for delay or dose reductions due to thrombocytopenia; however, the usefulness of this cytokine is quite limited because of its ineffectiveness in severe thrombocytopenia and its toxicity, which includes significant edema. Guidelines are available to direct usage of these expensive but critical growth factors.

[Table 40-4](#) sets forth the dosage schedules and toxicities of the most commonly used cancer chemotherapeutic agents. The dosage schedules given are for single-agent therapy; combination therapy is used for most cancers.

Newer experimental therapies are discussed briefly at the end of this chapter.

ADJUVANT CHEMOTHERAPY FOR MICROMETASTASES

One of the most important roles of cancer chemotherapy is as adjuvant therapy to eradicate or suppress minimal residual disease after local treatment with surgery or irradiation. Failure of local therapy to eradicate tumor is due principally to occult micrometastases of tumor stem cells outside the primary field. These distant micrometastases are more likely to be present in patients with positive lymph nodes at the time of surgery (eg, breast and prostate cancer), in patients with tumors known to have a propensity for early hematogenous spread (eg, osteogenic sarcoma, Wilms' tumor), and in patients with certain pathologic or molecular risk factors (eg, high proliferative index, vascular invasion, oncogene amplification). Given specific risk factors, the risk of recurrent or metastatic disease can be extremely high (> 80%). Only systemic therapy can adequately eradicate micrometastases. Chemotherapeutic regimens that have been shown to be effective in inducing regression of advanced cancers may be curative when combined with surgery for high-risk "early" cancer.

More data are now available to support the use of adjuvant therapy in several neoplasms. Prolongation of survival has been shown for women with breast cancer and negative or positive axillary lymph nodes (stages I, II, and III) from combination chemotherapy following surgical resection; several regimens are used. Node-negative patients are treated with CMF (cyclophosphamide, methotrexate, and fluorouracil), whereas high-risk, node-positive patients are treated with regimens that include anthracyclines (eg, doxorubicin, epirubicin) and in some cases taxanes as well. The SERM tamoxifen and other agents that block the effect of estrogen on the breast cancer cell are used routinely either with or without antecedent chemotherapy if receptors for estrogen or progesterone are present (see preceding section on hormonal therapy). The main challenge in treating women with node-negative (stage I) breast cancer is to identify prognostic factors that distinguish patients at higher risk who are more likely to benefit from adjuvant therapy. Amplification of the *HER-2/neu* oncogene clearly correlates with a poorer prognosis, and these patients appear to have a marked benefit from adjuvant chemotherapy containing anthracyclines. In contrast, patients whose cancers express receptors for estrogen or progesterone have a better prognosis than those whose tumors are hormone receptor-negative. Current research is focusing on the identification of additional and more specific risk factors early in diagnosis that can aid in prognosis and treatment decisions. A study using cytokeratin staining of bone marrow aspirates in women with newly diagnosed breast cancer found a 36% incidence of occult marrow metastases that correlated with a fourfold increased risk of death from breast cancer. This result must be confirmed before it can be used in clinical practice to direct therapy. The goal is to identify patients with high-risk features at the time of diagnosis with localized disease and provide risk-directed (and effective) therapy.

Adjuvant chemotherapy with fluorouracil plus leucovorin is indicated in Dukes B and C (node-positive) colon cancer and has been shown to reduce the risk of cancer recurrence. Many other cancers may be cured with adjuvant chemotherapy, including cancers of the ovary and testes, malignant melanoma, and choriocarcinoma. Still other malignancies are cured when radiation and chemotherapy are used concurrently as described in the section on radiation therapy.

Other tumors that have been shown to respond to adjuvant therapy include gastric, esophageal, and bladder cancers, prostate cancer, osteogenic sarcoma, ovarian cancer, and malignant melanoma—and, recently, non-small cell cancer of the lung. Adjuvant therapy remains investigational for a number of common tumors, including pancreatic cancer. Chemotherapy is often given with curative intent after surgical remission in testicular cancer, non-Hodgkin's lymphoma, and Hodgkin's lymphoma.

Although adjuvant therapy has been shown to reduce the rate of recurrence for some cancers, there is still a high failure rate (up to 60-80% in some high-risk breast cancers despite adjuvant therapy). In most cases, tumor recurrence signifies incurability. The evidence for a dose-response effect of adjuvant chemotherapy for most cancers remains unclear. Although high-dose chemotherapy with either bone marrow or peripheral blood stem cell rescue is curative for some otherwise incurable

patients with testicular cancer, efficacy data are lacking for other solid tumors. Research in the past focused on very high doses of chemotherapy for high-risk and metastatic breast cancer; this has translated into thousands of transplants and several randomized clinical trials. Phase II data suggested clinical benefit to this toxic and expensive procedure, but the studies were biased by inappropriate historical controls, rigorous selection criteria, and short follow-up. To date, all randomized studies, including three recently reported ones, have failed to show any benefit to high-dose chemotherapy with stem cell rescue compared with intermediate or standard-dose chemotherapy. Two studies performed in South Africa appeared encouraging; however, an on-site review revealed significant scientific misconduct that invalidated all results. At present, high-dose chemotherapy for breast cancer should be performed only in the setting of a properly designed clinical trial; it is still experimental therapy. Bone marrow transplantation for other malignancies is covered in more detail in [Chapter 13](#).

TOXICITY & DOSE MODIFICATION OF CHEMOTHERAPEUTIC AGENTS

A number of cancer chemotherapeutic agents have cytotoxic effects on rapidly proliferating normal cells in bone marrow, mucosa, and skin. Still other drugs such as the vinca alkaloids and taxanes produce neuropathy, and hormones often have psychologic as well as physical effects. Acute and chronic toxicities of various drugs used to treat cancer are summarized in [Table 40-4](#). Appropriate dose modification may minimize these side effects, so that therapy can be continued with relative safety. Dose modifications are usually considered in settings where treatment is given with palliative intent. Dose intensity and schedule should be maintained if at all possible in the adjuvant setting, when treatment is directed toward preventing recurrence or metastases of the cancer.

Bone Marrow Toxicity

Depression of bone marrow is usually the most serious limiting toxicity of cancer chemotherapy. Autologous bone marrow or peripheral blood stem cell transplantation or rescue can reduce the myelosuppressive toxicity of high-dose chemotherapy; however, cost and toxicity limit its general use. Growth factors that stimulate myeloid proliferation (eg, **granulocyte colony-stimulating factor [G-CSF; filgrastim]**, the longer acting **peg-filgrastim**, and **granulocyte-macrophage stimulating factor [GM-CSF; sargramostim]**) or erythroid proliferation (epoetin alfa [erythropoietin]) are now used to ameliorate bone marrow toxicity. G-CSF and GM-CSF have been shown to shorten the period of neutropenia following both standard and high-dose chemotherapy. Mucosal toxicity is reduced as well. The myeloid growth factors are also used to stimulate circulation of stem cells in the peripheral blood either at steady state or during white blood cell recovery following myelosuppressive chemotherapy. These cells are then harvested using an apheresis machine and frozen for later use. When stimulated peripheral blood stem cells are used instead of or in conjunction with bone marrow for autologous transplantation following high-dose chemotherapy and radiotherapy, recovery of both neutrophils and platelets may be hastened by as much as 7-10 days as opposed to the use of bone marrow alone. Recombinant growth factors are expensive and must be used judiciously. Published standard practice guidelines are referenced at the end of this section.

Epoetin alfa (erythropoietin) has been shown to improve anemia associated with malignancy. Patients must have adequate iron stores to respond to this agent, and even patients with marrow infiltration with tumor may benefit. Higher doses are necessary for patients with cancer than for patients with renal failure (100-150 units/kg compared with 50 units/kg). It is useful to check the level of erythropoietin before instituting therapy. Very high levels (= 500 ng/mL) predict a poor response. Epoetin alfa may be given as a subcutaneous injection once a week. This dosage schedule is as effective as the traditional three times a week dosing and is much more convenient. For anemia related to cancer chemotherapy or marrow infiltration, a dose of 40,000 units a week is used. Novel **erythropoiesis-stimulating protein (NESP; darbepoetin alfa)** is now approved to treat anemia associated with renal failure. Its main advantage over epoetin alfa is its longer half-life, which it is hoped will allow for dosing once every 3 weeks to once every 4 weeks. Clinical trials in cancer treatment are ongoing.

Thrombocytopenia remains a problem with high doses of or prolonged exposure to chemotherapeutic agents and may limit therapy. **Oprelvekin (recombinant interleukin-11)** may be used in treating and preventing chemotherapy-induced thrombocytopenia. It is less effective in treating very severe thrombocytopenia, and its use can be associated with significant fluid retention, arrhythmias, and congestive heart failure.

Commonly used short-acting drugs that affect the bone marrow are the alkylating agents (eg, cyclophosphamide, melphalan, chlorambucil), procarbazine, mercaptopurine, methotrexate, vinblastine, fluorouracil, dactinomycin, anthracyclines, and taxanes. In general, it is preferable to use alkylating agents in intensive "pulse" courses every 3-4 weeks rather than to administer the drugs in continuous daily schedules. This allows for complete hematologic (and immunologic) recovery between courses rather than continuously suppressing the bone marrow with a cytotoxic agent. Pulse therapy reduces side effects to some degree but does not reduce therapeutic efficacy. The standard dosage schedules for tumor response often induce bone marrow suppression. Continuing some drugs in the face of falling blood counts may result in severe bone marrow aplasia with pancytopenia, bleeding, or infection. Simple guidelines for treatment and follow-up can usually prevent this complication.

In patients with normal blood counts as well as normal liver and kidney function, drugs should be started in full dosages. Bone marrow toxicity is cumulative over time, and this must be anticipated during follow-up. Cumulative toxicity from long-term chemotherapy can require cessation of therapy or reduction in dose. Patients with bone marrow involvement may tolerate chemotherapy poorly initially, with improved counts on future cycles as the tumor burden is reduced.

Drug dosage may be modified as a function of the peripheral white blood cell count or platelet count (or both). These modifications assume that the blood counts are checked shortly before the next course of chemotherapy is to be administered. Dosage modifications are used primarily for repeated courses of oral alkylator or antimetabolite therapy but should be avoided if treatment is given with curative intent. A scheme for dosage modification is presented in [Table 40-5](#). Alternatively, the interval between drug courses can be lengthened, thereby permitting more complete hematologic recovery and repetition of full-dose chemotherapy. Both dosage modification and delay of chemotherapy limit the efficacy of treatment.

Ozer H et al: 2000 update of recommendations for the use of hematopoietic colony-stimulating factors: evidence-based, clinical practice guidelines. J Clin Oncol 2000;18:3558. [\[PMID: 11032599\]](#)

Chemotherapy-Induced Nausea & Vomiting

A number of cytotoxic anticancer drugs induce nausea and vomiting. In general, these symptoms are thought to originate in the central nervous system rather than peripherally. Parenteral administration of agents such as doxorubicin, etoposide, or cyclophosphamide is usually associated with mild to moderate nausea and vomiting, whereas nitrosoureas, dacarbazine, and particularly cisplatin cause more severe symptoms. Combination chemotherapy can also cause severe symptoms. Antiemetics clearly reduce and often eliminate nausea and vomiting associated with these drugs and are especially useful in conjunction with cisplatin.

5-Hydroxytryptamine-3 receptor antagonists (ondansetron, granisetron, dolasetron) have now replaced other drugs as the primary agents for the prevention and treatment of emesis from chemotherapy. These drugs are serotonin receptor-blocking agents with few side effects. They are also effective against radiation-induced and postanesthetic emesis and can be useful in the treatment of delayed and refractory nausea and vomiting following chemotherapy. **Ondansetron** is administered by the parenteral route as a single dose of 32 mg prior to chemotherapy and may be repeated every 24 hours, or it may be given orally at a dose of 8 mg every 8 hours. Lower parenteral doses may be just as effective. **Granisetron** is given as a single dose of 10 ug/kg intravenously 30 minutes before chemotherapy, or orally at a dose of 1-2 mg per day. The dose of **dolasetron** is 1.8 mg/kg intravenously or 100-200 mg orally before chemotherapy. The serotonin receptor-blocking agents are more effective when given in conjunction with dexamethasone. Dexamethasone has antiemetic effects when administered at a dosage of 6-10 mg either as a single dose prior to—or both prior to and every 6 hours following—the administration of chemotherapy for two to four total doses.

Substance P appears to have a causative role in chemotherapy-induced nausea. Its biologic actions are mediated through the neurokinin-1 receptor. A novel agent, **aprepitant**, is a selective high-affinity neurokinin-1 receptor antagonist that is effective in preventing chemotherapy-induced nausea. Two randomized trials comparing granisetron and dexamethasone with or without this agent showed a significant reduction in acute emesis following chemotherapy with cisplatin with the three-drug

combination. In addition, aprepitant was effective in preventing delayed emesis from cisplatin. Aprepitant has recently been approved by the FDA for the treatment of acute and delayed nausea and vomiting associated with initial and repeat courses of highly emetogenic cancer chemotherapy. It is given orally for 4 days beginning on the day chemotherapy starts.

Other active agents often used in combination as premedication for less emetogenic chemotherapy or as treatment for delayed nausea and vomiting include prochlorperazine, metoclopramide, thiethylperazine, and lorazepam. The phenothiazines (prochlorperazine, thiethylperazine) and metoclopramide can induce extrapyramidal side effects; their incidence is increased with prolonged use. **Prochlorperazine** is given at a dose of 10 mg orally or intravenously every 6-8 hours. The total dose given over 24 hours should not exceed 40 mg. A 25 mg suppository may be used for patients who are too nauseated to swallow pills without inducing further emesis. **Metoclopramide** is given at a dose of 10-20 mg orally or intravenously before and then every 6 hours after chemotherapy, usually in combination with dexamethasone. **Lorazepam** has both antiemetic and sedative effects and is administered at a dose of 0.5-1 mg every 4-6 hours by the sublingual or oral route, making it particularly useful in the outpatient setting. Older patients may experience intolerable psychologic side effects.

Combinations of antiemetics are usually more effective than maximal doses of any one agent to block severe emesis. A typical antiemetic regimen might include ondansetron combined with sublingual lorazepam or prochlorperazine and dexamethasone with aprepitant for severely emetogenic regimens. For less emetogenic regimens, the serotonin antagonists can be reserved for failure to control nausea with less expensive regimens.

Dronabinol (?^9 -tetrahydrocannabinol) is effective in some patients at a dose of 5 mg/m² prior to and then every 2-4 hours following chemotherapy for a total of four to six doses a day. Dronabinol may cause undesirable side effects such as dysphoria, and it is available only for oral administration.

A patient receiving antiemetics (eg, lorazepam, prochlorperazine, metoclopramide) along with chemotherapy on an outpatient basis must be escorted to and from the clinic, since the antiemetics often induce marked sedation and transient impairment of balance and reflexes. Antiemetics are more effective when given prophylactically. Therefore, regular dosing of an agent such as lorazepam or prochlorperazine is recommended after chemotherapy until the emetogenic effects have dissipated. This is dependent on the patient as well as on the type of chemotherapy administered. One problem with all combinations of antiemetic agents is the development of tachyphylaxis over 4-5 days with continuing highly emetogenic chemotherapy. This limits the effectiveness of any regimen. Acute mucosal injury to the upper gastrointestinal tract may complicate nausea associated with chemotherapy or delayed nausea and vomiting. Agents that reduce acid secretion (eg, omeprazole, ranitidine) can be useful adjunctive therapy to the antinausea regimen.

Gastrointestinal & Skin Toxicity

Chemotherapeutic agents generally act on rapidly proliferating cells, resulting in damage to the normal cells lining the gastrointestinal tract and mouth. This can result in mouth and throat sores, chronic nausea, and diarrhea. Erythema is an early sign of mucosal toxicity. Ulcerations in the mouth due to chemotherapy must be carefully evaluated for the presence of herpes simplex virus. Herpes ulcerations are common in immunosuppressed cancer patients and may be treated with acyclovir or other antiviral agents.. Throat or esophageal pain may be due to either chemotherapy or infection from fungal or viral pathogens. These infections are more common in patients receiving steroids with their chemotherapy regimens. Chemotherapy should be delayed or withheld to allow healing or treatment of infection.

Adequate mouth care with antimicrobial mouthwashes and attention to dental hygiene are essential and may prevent severe toxicity. Common mouthwashes include the microbicidal oral rinse chlorhexidine and a mixture of salt and bicarbonate of soda in warm water, which aids in debridement of dead mucosa. A prophylactic antifungal mouthwash such as nystatin oral suspension may also be used. Certain chemotherapeutic agents can also cause toxicity to the skin, particularly the palms and soles and the skin in the axilla and groin. Common findings are erythema and hyperpigmentation, which may be painful or pruritic. Blistering is uncommon but can occur if chemotherapy is continued after the early signs of skin irritation occur. Toxicities to the gastrointestinal tract and skin may be more serious and harder to treat than bone marrow suppression. Patients receiving drugs that cause these side effects should be monitored closely.

Radiation therapy may cause xerostomia, which can lead to difficulty in swallowing, discomfort, and gum disease. **Pilocarpine hydrochloride**, 5-10 mg orally three times a day, can relieve symptoms of dry mouth but must be used regularly. **Amifostine**, a thiol-containing compound that reduces cisplatin-induced nephrotoxicity, has also been shown to reduce acute and chronic xerostomia in patients with head and neck cancers receiving radiation therapy. The dose of amifostine is 200 mg/m² intravenously daily 15-30 minutes before irradiation. Side effects include nausea and vomiting.

Radiation therapy to areas that include the gastrointestinal tract can cause diarrhea that resolves gradually with cessation of therapy and healing of normal cells. Topical butyrate appears to improve symptoms of acute radiation proctitis following radiation therapy for malignant pelvic disease. The **sodium butyrate** is given per rectum. Skin toxicity in the form of erythema and occasionally blistering and exfoliation of the area receiving radiation can also occur. Severe skin toxicity requires holding the radiation doses; the affected area is treated with local application of emollients.

Miscellaneous Drug-Specific Toxicities

The toxicities of individual drugs have been summarized in [Table 40-4](#). Several of these warrant additional mention, since they occur with commonly administered agents, and special preventive measures are often indicated.

A. Hemorrhagic Cystitis Induced by Cyclophosphamide or Ifosfamide

Metabolic products of cyclophosphamide that retain cytotoxic activity are excreted into the urine. Some patients appear to metabolize more of the drug to these active excretory products. If their urine is concentrated, the toxic metabolite may cause severe bladder damage. Patients receiving cyclophosphamide must be advised to maintain a high fluid intake. Early symptoms of bladder toxicity include dysuria and frequency despite the absence of bacteriuria. If microscopic hematuria develops, it is advisable to stop the drug temporarily or switch to a different alkylating agent, increase fluid intake, and administer a urinary analgesic such as phenazopyridine. With severe cystitis, large segments of bladder mucosa may be shed and the patient may have prolonged gross hematuria. Such patients should be observed for signs of urinary obstruction and may require cystoscopy for removal of obstructing blood clots. The risk of developing hemorrhagic cystitis is dose-related and more common in patients who take the drug orally over a prolonged period of time. The cyclophosphamide analog ifosfamide or very high doses of cyclophosphamide can cause severe hemorrhagic cystitis when either is used alone. However, when they are used in conjunction with the neutralizing agent mesna, bladder toxicity can usually be prevented. Mesna is given with the chemotherapeutic agent and in a series of doses over the following 24 hours. Continuous bladder irrigation with 0.9% saline has been used with high-dose cyclophosphamide to prevent hemorrhagic cystitis. This appears to be less effective than mesna and may result in complications from Foley catheter trauma to the urethra, so it is used infrequently in high-risk situations—often in combination with mesna.

B. Neuropathy Induced by Vincristine and Other Agents

Neuropathy is a toxic side effect that is peculiar to the vinca alkaloid drugs, especially vincristine. A primarily sensory peripheral neuropathy is also commonly caused by two of the newer anticancer therapeutic agents, paclitaxel and vinorelbine. The peripheral neuropathy associated with vincristine can be sensory, motor, autonomic, or a combination of these effects. In its mildest form, it consists of paresthesias of the fingers and toes. Occasional patients develop acute jaw or throat pain after vincristine therapy. This may be a form of trigeminal or glossopharyngeal neuralgia. With continued vincristine therapy, the paresthesias may extend to the proximal interphalangeal joints, hyporeflexia can appear in the lower extremities, and weakness may develop in the quadriceps muscle group. At this point, it is wise to discontinue vincristine therapy until the neuropathy has subsided. A useful means of judging whether peripheral motor neuropathy is severe enough to warrant stopping treatment is to have the patient attempt to do deep knee bends or rise from a chair without using the arm muscles. In general, the neuropathy associated with paclitaxel and vinorelbine is mild, well-tolerated, and both dose-sensitive and schedule-sensitive. More frequent dosing of smaller amounts of chemotherapy can reduce this side effect; the neuropathy significantly improves when the chemotherapy is stopped.

Constipation is the most common symptom of autonomic neuropathy associated with vincristine therapy. Patients receiving vincristine should be started on stool softeners and mild cathartics when therapy is begun; otherwise, severe impaction may result as a consequence of an atonic bowel. More serious autonomic involvement can lead to acute intestinal ileus with signs indistinguishable from those of an acute abdomen.

Bladder neuropathies are uncommon but may be severe. Paralytic ileus and bladder atony are absolute contraindications to continued vincristine therapy. The majority of symptoms from vincristine are mild and resolve slowly after therapy has been completed. Docetaxel, cisplatin, carboplatin, and topotecan can also cause peripheral neuropathy, though in general symptoms improve gradually after treatment is stopped.

C. Methotrexate Toxicity and Leucovorin Rescue

In addition to standard uses of methotrexate for cancer chemotherapy, this drug is also used in very high doses that could lead to fatal bone marrow toxicity if given without an antidote. High-dose methotrexate therapy with leucovorin rescue is routinely used to treat osteogenic sarcoma, acute lymphocytic leukemia, and some cases of non-Hodgkin's lymphoma as well as primary lymphoma of the central nervous system.

The bone marrow and mucosal toxicity of methotrexate can be prevented by early administration of leucovorin (folinic acid). Serum levels of methotrexate are usually monitored and doses of leucovorin adjusted accordingly. Rescue is required for methotrexate doses over 80 mg/m² and is usually begun within 4 hours after completing treatment. Up to 100 mg/m² of leucovorin is given initially every 6 hours, with further doses adjusted for the serum methotrexate level. Rescue is usually continued orally for 3 days or longer until the serum methotrexate level is below 0.05 umol/L. Asparaginase can be given as rescue for methotrexate in the treatment of lymphoblastic leukemia. If an overdose of methotrexate is administered accidentally, leucovorin therapy should be initiated as soon as possible, preferably within 1 hour. Intravenous infusion should be employed for larger overdosages to ensure adequate drug delivery. It is generally advisable to give leucovorin repeatedly in this situation.

Vigorous hydration and bicarbonate loading also appear to be important in preventing crystallization of high-dose methotrexate in the renal tubular epithelium. Serum creatinine is determined before beginning therapy and daily thereafter, since methotrexate excretion is slowed by renal insufficiency and toxicity will be enhanced. In high doses, methotrexate can itself cause renal injury. Methotrexate doses are reduced in renal insufficiency. Concomitant use of certain drugs will slow methotrexate excretion, and they are avoided during therapy. These drugs include aspirin, NSAIDs, penicillins, sulfonamides, and probenecid.

D. Busulfan Toxicity

The alkylating agent busulfan, occasionally used for the treatment of myeloproliferative diseases, has curious delayed toxicities, including increased skin pigmentation, a wasting syndrome similar to that seen in adrenal insufficiency, and progressive pulmonary fibrosis. Patients who develop either of the latter two problems should be switched to a different drug (eg, melphalan) when further therapy is needed. The pigmentary changes are innocuous and will usually regress slowly after treatment is discontinued. Long-term treatment with busulfan also results in an increased risk of secondary leukemias.

E. Bleomycin Toxicity

This antibiotic is used to treat squamous cell carcinoma, Hodgkin's disease, non-Hodgkin's lymphoma, and testicular cancer. Bleomycin can produce edema of the interphalangeal joints and hardening of the palmar and plantar skin. More serious toxicities include an anaphylactic or serum sickness-like reaction and a potentially fatal pulmonary fibrotic reaction (seen especially in elderly patients receiving a total dose of over 300 units). If a nonproductive cough, dyspnea, and pulmonary infiltrates develop, the drug is discontinued, and high-dose corticosteroids are instituted as well as empirical antibiotics pending cultures. Fever alone or with chills is an occasional complication of bleomycin treatment and is not an absolute contraindication to continued treatment. The fever may be avoided by hydrocortisone administration just prior to the injection. Fever alone is not predictive of pulmonary toxicity. About 1% of patients (especially those with lymphoma) may have a severe or even fatal hypotensive reaction after the initial dose of bleomycin. In order to identify and treat such patients, it is wise to administer a test dose of 5 units of bleomycin first and to have adequate monitoring and emergency facilities available. Patients exhibiting a hypotensive reaction should not receive further bleomycin therapy.

F. Anthracycline-Induced Cardiomyopathy

The anthracycline antibiotics doxorubicin, daunomycin, and idarubicin and the similar drug mitoxantrone both have acute and delayed cardiac toxicity. The problem is greater with doxorubicin because it has a major role and is used in repeated doses in the treatment of sarcomas, breast cancer, lymphomas, acute leukemia, and certain other solid tumors. Studies of left ventricular function and endomyocardial biopsies indicate that changes in cardiac dynamics occur in most patients by the time they have received 300 mg/m² of doxorubicin. The *multiple-gated* ("MUGA") radionuclide cardiac scan is the most reproducible noninvasive test for assessing toxicity. Patients should not receive a total dose in excess of 450 mg/m², and 1-10% of patients who receive this dose develop cardiomyopathy. Doxorubicin should not be used in patients with intrinsic cardiac disease. Prior chest or mediastinal radiotherapy increases the risk of doxorubicin heart disease at lower total doses. The appearance of a high resting pulse may herald the appearance of cardiac toxicity. Unfortunately, the toxicity may be irreversible at dosage levels above 550 mg/m². At lower doses (eg, 350 mg/m²), the symptoms and signs of cardiac failure generally respond well to medical therapy and cessation of doxorubicin.

Laboratory studies suggest that cardiac toxicity may be due to a mechanism involving the formation of intracellular free radicals in cardiac muscle. Pretreatment with **dexrazoxane**, an iron chelator that decreases free radical formation, appears to protect the myocardium from anthracycline-induced injury but may also reduce the anticancer efficacy of the anthracycline. Dexrazoxane is useful for the prevention of cardiomyopathy in women with metastatic breast cancer receiving cumulative doxorubicin doses > 300 mg/m². Liposomally encapsulated doxorubicin and daunorubicin have been FDA-approved and appear to have minimal cardiac toxicity. Their main use to date has been to treat Kaposi's sarcoma, but they are also effective in the treatment of other anthracycline-sensitive cancers. The anthracycline analog idarubicin has shown efficacy against acute nonlymphocytic leukemia and breast cancer when used in combination with other agents. Idarubicin appears to have a similar potential for causing cardiotoxicity when compared with other anthracyclines, though a maximum lifetime dosage recommendation has not been made. Epirubicin, an anthracycline with lower cardiac toxicity than doxorubicin (but similar gastrointestinal toxicity) is approved for the treatment of breast cancer. A dose of up to 900 mg/m² can be tolerated without significant cardiac toxicity. There are no data comparing the effects of doxorubicin with epirubicin, which has been studied primarily in Europe and Canada.

G. Cisplatin Nephrotoxicity and Neurotoxicity

Cisplatin is effective in the treatment of testicular, bladder, and ovarian cancer as well as in several other types of tumor. Nausea and vomiting are common, but nephrotoxicity and neurotoxicity are more serious. Vigorous hydration with or without mannitol diuresis may substantially reduce nephrotoxicity. Renal function must be carefully monitored during cisplatin therapy, as should serum magnesium, which may fall during therapy with this agent. Ototoxicity is a potentially serious neurotoxicity that can result in deafness. Other manifestations include peripheral neuropathy of mixed sensorimotor type that may be associated with painful paresthesias. The neurotoxicity of this drug is delayed and is more common after a total dose of 300 mg/m². The second-generation platinum analog carboplatin has been shown to be as effective as cisplatin in ovarian cancer. Carboplatin is less nephrotoxic and causes less severe nausea or vomiting, but it does induce significant myelosuppression along with neurotoxicity. **Amifostine**, an organic thiophosphate initially developed as a radioprotective agent, is effective in preventing renal toxicity from cisplatin. It is approved to reduce cumulative renal toxicity associated with repeat administration of cisplatin in advanced ovarian cancer. In addition, amifostine may reduce chemotherapy-induced hematologic toxicity and neurotoxicity. Glutathione also appears to be a promising agent in preventing cisplatin neurotoxicity. Glutathione has been given at a dose of 1.5 g/m² intravenously before cisplatin administration, then at a dose of 600 mg by intramuscular injection on days 2-5. These supportive measures do not appear to reduce the therapeutic effectiveness of platinum agents.

H. Alpha Interferon Toxicities

While interferon alfa is generally tolerated in the standard doses listed in [Table 40-4](#), it has significant toxicity with the higher doses required to treat chronic myelogenous leukemia and malignant melanoma and is more toxic in elderly patients. Even standard doses may be intolerable to some patients. Fever and chills are initial side effects but are infrequent after continued treatment. These symptoms may be ameliorated or prevented by premedication with acetaminophen and bedtime dosing. However, anorexia, fatigue, and weight loss can be cumulative and with time may become severe. These symptoms may be dose- or treatment-limiting. Thirty percent or more of patients are intolerant of interferon therapy even at low doses. In some patients, central nervous system symptoms develop, usually manifested as confusion or somnolence. Interferon causes a reduction in blood counts, but this is usually not clinically important and is part of the desired effect in the treatment of chronic myelogenous leukemia. Interferon-induced side effects are sometimes confused with the symptoms of progressive cancer but usually clear within 1-2 weeks following cessation of interferon therapy.

■ EVALUATION OF TUMOR RESPONSE

Inasmuch as cancer chemotherapy can induce clinical improvement, serious toxicity, or both, it is important to critically assess the beneficial effects of treatment in patients with advanced cancer to determine that the net effect is favorable. The most valuable signs to follow during therapy include the following.

TUMOR SIZE

Shrinkage in tumor size can be demonstrated by physical examination, chest film or other x-ray, sonography, or a procedure such as radionuclide bone scanning (breast, lung, prostate cancer). CT scanning is important for the evaluation of tumor size and location and the extent of distant spread for a wide variety of tumors and sites. MRI is now the best noninvasive means of evaluating posterior fossa brain tumors, spinal cord tumors, spinal cord compression, and pelvic disease, but CT scanning remains useful and may provide additional information. Sonography is also helpful in the evaluation of pelvic neoplasms. Gallium scanning can be useful to

detect residual disease in lymphomas, but some tumors are not gallium-avid, which limits the usefulness of this test. Positron emission tomography (PET scanning) is an emerging radiographic detection method that depends on metabolic activity for visualization. It appears to be very useful in detection of residual disease in lymphomas and in assessing the extent of disease in several solid tumors.

A partial response (PR) is defined as a 50% or greater reduction in the original tumor mass. A complete response (CR) refers to the complete disappearance of detectable tumor. Progression is an increase of more than 25% in the size of the tumor or the appearance of any new lesions. Criteria for measuring responses of solid tumors have been established by the World Health Organization to avoid conflicts and inconsistency in measurements that influence reporting of tumor responses and to lead to more uniform reporting of outcomes of clinical trials. The RECIST criteria are based on measuring the largest single diameter of any tumor mass and include a minimum diameter for measurable lesions. These criteria will be incorporated into all new cancer treatment protocols.

The effectiveness of any agent or combination of agents in the treatment of cancer is determined by the response rates (combination of CR, PR, and, for some aggressive neoplasms, stable disease), response duration, and survival. Treatment efficacy for metastatic or incurable disease is often measured by event-free survival (EFS) or time to progression (TTP). The usefulness of treatment given to prevent recurrence of potentially curable neoplasms is measured by relapse-free survival (RFS) or disease-free survival (DFS) as well as overall survival (OS). The goal of effective palliative therapy for advanced incurable malignancy is to increase survival and improve quality life. Newer agents and new delivery methods have expanded the treatment options and increased their tolerability for some common cancers. Generally, response to therapy is associated with palliation, but it often happens that just stabilization of disease will have the same effect. Tumor response in this setting must be measured against toxicity, and treatment decisions should be made after available options have been discussed with the patient and family. Because patients tend to have unrealistic expectations of the benefits of palliative chemotherapy, clinician-patient communication is critical.

TUMOR MARKERS

A decrease in the quantity of a tumor product or marker substance reflects a reduced amount of tumor in the body. Examples of such markers include paraproteins (abnormal immunoglobulins) in multiple myeloma and macroglobulinemia, human chorionic gonadotropin (hCG) in choriocarcinoma and testicular cancer, prostatic acid phosphatase and PSA in prostatic cancer, urinary steroids in adrenal carcinoma and paraneoplastic Cushing's syndrome, and 5-hydroxyindoleacetic acid (5-HIAA) in carcinoid syndrome.

Tumor-secreted fetal antigens are also used to follow the course and response to treatment of cancers. These include alpha₁-fetoprotein (AFP) in hepatocellular carcinoma, testicular cancer, teratoembryonal carcinoma, and in occasional cases of gastric carcinoma; ovarian tumor antigen (CA 125) in ovarian cancer; and carcinoembryonic antigen (CEA) in carcinomas of the colon, lung, breast, and pancreas. CA 15-3 and CA 27.29 may become important in detecting early recurrence of breast cancer but are mainly used to follow response to therapy in metastatic disease. The CA 19-9 radioimmunoassay is used to monitor response to therapy of pancreatic cancer. Monoclonal antibodies are now used for measurement of a number of tumor markers and offer the potential of delineating a number of additional markers for diagnostic purposes.

Tumor markers may play an important role in the early detection of some common tumors when combined with good physical examinations. PSA, an immunogenic glycoprotein produced solely by the prostate, is currently the only tumor marker with widespread (and controversial) use in cancer screening. PSA was initially used to indicate tumor bulk and disease progression, but it is now commonly used as a screening tool when paired with the digital rectal examination. The American Cancer Society National Prostate Cancer Detection Project is a multicenter study evaluating the use of PSA, digital rectal examination (DRE), and transrectal ultrasound (TRUS) in a large cohort of healthy men. In this and other studies, the combination of a monoclonal PSA greater than 4 ng/mL and an abnormal digital rectal examination was felt to produce a highly sensitive and specific method for detecting prostate cancer. A large Canadian study showed a significant reduction in death from prostate cancer in men undergoing regular screening. This study randomized more than 46,000 men aged 45-80 years to screening, with PSA (using 3 ng/mL as the upper limit of normal) and digital rectal examination followed by transrectal ultrasound for abnormal test results or for a 10% increase in PSA over 12 months. There was an almost threefold advantage of screening and early treatment to reduce mortality.

Annual screening for prostate cancer with digital rectal examination and PSA beginning at age 50 should be offered to men with a life expectancy of at least 10 years. Data obtained from the Prostate, Lung, Colorectal, and Ovarian Cancer (PLCO) Screening Trial and presented at the international oncology meetings in 2002 suggest that the initial PSA level can be used as a guide to the frequency of testing. Thirty thousand men aged 55-74 qualified for inclusion in the trial, and over 90% had normal PSA levels of < 4 ng/mL at baseline. A PSA < 1 ng/mL was associated with only a 1.4% chance of rise over 5 years, and a high percentage of those with a level of 1-2 ng/mL were normal over a period of 2 years. In contrast, 83% of those with an initial screening level of 3-4 ng/mL became abnormal over 5 years. The recommendations are to screen men with an initial level of < 1 ng/mL every 5 years; 1-1.9 ng/mL every 2 years; and = 2 ng/mL yearly. It is estimated that this schedule could reduce PSA testing by 55%, with only a 2.6% risk of missing a positive test. As always, patients need to be involved in the decision to obtain screening PSA testing and should understand the advantages and possible consequences of testing or not testing. A major concern is that PSA testing will detect tumors that would not have resulted in mortality—small, slow-growing tumors in older men.

An abnormal PSA or digital rectal examination requires further evaluation by transrectal ultrasound and possible biopsy. The role of PSA screening must be carefully evaluated for each patient and the risks of screening (unnecessary biopsies and surgeries) discussed in detail. The PSA may be elevated in benign prostatic hypertrophy and in prostatitis. Levels in benign disease are usually between 4 and 10 ng/mL; a level greater than 10 ng/mL increases the likelihood of finding cancer. In addition, 25-45% of patients with localized prostate cancer may have a normal PSA value. The increase in screening for prostate cancer over the last few years has markedly increased the reported incidence of this disease, though prostate cancer-specific mortality has been essentially stable. (See [Table 40-1](#).) The PSA is also used to define early relapse following local treatment with surgery or radiotherapy. One recent study indicated that pelvic radiotherapy and adjuvant androgen deprivation initiated at the time when elevation of the PSA is detected significantly improves survival and decreases the prostate cancer death rate. This effect was most prominent in patients with more aggressive, high-grade disease.

Tumor markers may be useful to screen populations at high risk for a specific cancer. A recent study has shown that elevated and altered profiles of AFP can serve as predictive markers for the development of hepatocellular carcinoma in patients with cirrhosis. Most tumor markers are not specific or sensitive enough to be useful as screening tools owing to their frequent elevation in benign disease and their absence in some cases of malignancy. Although screening for ovarian cancer with CA 125 is still being investigated, a rapid fall in levels to normal (versus a slow fall or plateau) following surgery or chemotherapy has favorable prognostic significance.

In general, tumor markers are used to follow response to therapy of a specific cancer. In diseases where early treatment of recurrence can influence survival (eg, testicular cancer and now prostate cancer), tumor markers may be used to screen for recurrent disease before it becomes radiographically or clinically evident.

GENERAL WELL-BEING, PERFORMANCE STATUS, & SUPPORTIVE CARE

The functional status of the cancer patient at diagnosis (or at the start of treatment) is a major prognostic factor and determinant of outcome with or without tumor-directed therapy. It is therefore important to assess functional status as well as tumor burden and symptoms before deciding on possible anticancer therapy. Functional status or performance status evaluates the patient's ability to perform activities of daily living and is clearly related to tumor burden, tumor site, and the patient's underlying physical condition.

Two scales are commonly used to measure performance status. The Eastern Cooperative Oncology Group (ECOG) scale is a five-point system that is simple and easy to apply to clinical practice. The ECOG scoring system ranges from 0 to 4 as follows: 0, entirely asymptomatic; 1, symptomatic but fully ambulatory; 2, symptomatic and in bed less than 50% of the day; 3, symptomatic and in bed more than 50% of the day but not bedridden; and 4, bedridden. The Karnofsky scale ranges from 100% (asymptomatic and fully functional) through 0% (dead) in steps of 10%. For example, a Karnofsky performance status of 40% implies a patient who is disabled and requires special care and assistance. This patient would be unable to work but would be able to live at home with special assistance. These two systems are often the basis for clinical decisions despite their obvious lack of precision. They are also useful in assessing the impact of therapy and disease progression.

The measures assessing functional status described above do not adequately assess quality of life, a major goal of cancer chemotherapy. Performance status is only one component of quality of life, which is a combination of subjective and objective factors. Factors included in the assessment of general well-being include improved appetite and weight gain and decreased pain as well as improved performance status. In general, cancer patients perceive that they receive inadequate analgesia and have impairment of function because of pain. The adequate use of pain medications is hampered by their sedating side effects. New guidelines for the management of

pain and long-acting opioids delivered by a transdermal system may help (eg, fentanyl patch, changed every 3 days). In addition, a short-acting oral transmucosal fentanyl preparation is available that may allow easier titration of analgesia. Tramadol is a centrally acting synthetic opioid analgesic that is available alone or in combination with acetaminophen for management of acute pain. (See [Chapter 5](#))

Sedating effects can sometimes be avoided by adding nonsteroidal anti-inflammatory agents or antidepressants to opioid therapy. Gabapentin can be a useful adjunct to management of pain characterized by nerve compression-like symptoms and can also treat insomnia if given at bedtime. In general, depression is underdiagnosed and undertreated by clinicians; treatment of depression in patients with advanced cancer has been shown to improve functional status. Occasionally, opioids may be given epidurally to relieve severe pain. As with the use of antiemetics, pain medications work better when given prophylactically on a regular schedule rather than as needed for chronic or severe pain. It is only by completely evaluating all of the factors described above that the physician is able to judge whether the net effect of chemotherapy is worthwhile palliation. See [Chapters 1](#) and [5](#) for further discussions of pain management and care at the end of life.

In addition to opioids, agents that inhibit bone resorption may decrease bone pain and protect against skeletal complications (thereby improving quality of life) in patients with cancer metastatic to bone. Either the bisphosphonate pamidronate or the more potent zoledronic acid is well tolerated; the indications for zoledronic acid are broader and include both lytic and blastic bone lesions in any type of cancer. Pamidronate is given at a dosage of 90 mg intravenously over 2 hours once a month; zoledronic acid, 4 mg intravenously over 15 minutes once a month. In addition to spot radiation, two radioactive agents are available for the palliation of bone pain. Strontium-89 and samarium-153 lexidronam are both given intravenously and have been shown to be effective in reducing bone pain from osteoblastic lesions. The major toxicity is hematopoietic suppression, which may limit the ability to give other palliative therapy. The use of agents such as pamidronate, dronabinol, growth factors such as epoetin alfa (erythropoietin), and appetite stimulants such as megestrol acetate (given in dosages ranging from 40 mg orally four times a day up to 800 mg once a day) can improve the quality of life for cancer patients.

As early detection of cancer increases and cancer therapy improves, a growing area of concern is the long-term care of cancer survivors. Careful attention must be paid to psychosocial as well as physical problems resulting from therapy. Chemotherapy often leads to early menopause, depression, sexual difficulties, and osteoporosis, among other problems. Clinician awareness and referral to the appropriate resources is critical for maintaining quality of life in patients who are "survivors." Patient advocacy groups can play a very important role in patient education and support. Local groups can be located through cancer resource centers or at the local branch of the American Cancer Society.

■ CANCER COMPLICATIONS: DIAGNOSIS & MANAGEMENT

ONCOLOGIC EMERGENCIES

Cancer is a chronic disease, but acute emergencies may occur as a consequence of local involvement (spinal cord compression, superior vena cava syndrome, malignant effusions, etc) or generalized systemic effects (hypercalcemia, opportunistic infections, hypercoagulability, hyperuricemia, etc). These complications may be the presenting manifestation of cancer. Two relatively common complications covered elsewhere will not be discussed here: superior vena cava syndrome ([Chapter 12](#)) and hypercoagulability ([Chapter 13](#)).

Brigden ML: Hematologic and oncologic emergencies. Doing the most good in the least time. Postgrad Med 2001;109:143. [\[PMID: 11265352\]](#)

Merrill P: Oncologic emergencies. Lippincotts Prim Care Pract 2000;4:400. [\[PMID: 11261116\]](#)

1. Spinal Cord Compression

Spinal cord compression by tumor mass is manifested by back pain, progressive weakness, and sensory loss (usually in the lower extremities). Less commonly, spinal cord disease may present as chest or abdominal pain or as signs of nerve root compression due to the epidural location of the tumor. Bowel and bladder dysfunction are late findings. Spinal cord compression may occur as a complication of metastatic solid tumor, lymphoma, or myeloma. Back pain at the level of the spinal cord lesion occurs in over 80% of cases and may be aggravated by lying down, weight-bearing, sneezing, or coughing. Because back pain may precede the development of neurologic symptoms or signs, it is important to investigate this complaint thoroughly in any patient with cancer.

If neurologic deficits are present at diagnosis, they are usually irreversible, though treatment immediately after symptoms develop may result in partial recovery. Neurologic impairment can progress rapidly. Treatment of early lesions may completely avoid significant compromise. Although patients who present with paralysis may not recover function, they should still be treated for pain relief and to limit the extent of progression. In addition, patients may respond to systemic therapy depending on the specific tumor type.

The diagnosis of spinal cord compression is made by MRI scan with contrast. With this noninvasive and sensitive test, it is possible to obtain detailed views of the area in question as well as sagittal images of the entire spinal cord and vertebral canal. A detailed examination is important for detection and treatment of multiple lesions. Bone radiographs and bone scans are useful for detecting vertebral metastases, but they do not aid in assessing spinal cord compromise.

Emergency Treatment

Classic treatment of spinal cord compression from tumor metastases has included corticosteroids and radiation therapy to the area of compression as well as two adjacent vertebrae above and below the lesion, with surgery reserved for progression following radiation. However, a recent randomized controlled trial demonstrated a marked improvement in outcome in patients treated with surgery followed by radiation versus those treated with radiation alone—so dramatic that the trial was closed early. Patients receiving combined therapy were more likely to walk and regain mobility—and actually walked for more total time, with a trend toward longer survival compared with those who received radiation without surgery. Based on this observation, surgery followed by radiation has become the standard of care for patients presenting with spinal cord compression from metastatic cancer.

High doses of glucocorticoids (usually dexamethasone, 10-100 mg intravenously) are administered as soon as the diagnosis is suspected or confirmed. A lower dose (eg, 4-6 mg every 6 hours intravenously or orally) is continued throughout the course of radiation therapy and tapered at or near the end of treatment. Chemotherapy is useful in treating lymphomas and multiple myeloma in conjunction with or following completion of radiation therapy.

2. Leptomeningeal Disease

Leptomeningeal disease, or carcinomatous meningitis, is an uncommon complication occurring in about 3-8% of all cancer patients, though it is being diagnosed more frequently with improved imaging studies and increased longevity in patients with advanced cancer. The most common tumors involving the meninges are cancers of the breast and lung and malignant melanoma. Patients present with varied symptoms, including sequential cranial nerve abnormalities, stroke, and hydrocephalus. The diagnosis is made by finding malignant cells on cerebrospinal fluid cytologic examination or by enhancement of the meninges on gadolinium-enhanced MRI scans. The prognosis is poor, with median survival ranging from 3 months to 6 months despite treatment.

Emergency Treatment

Treatment is by radiation to symptomatic areas (usually whole brain and spinal cord) or with intrathecal chemotherapeutic agents, most commonly methotrexate and cytarabine. For this purpose, an intraventricular reservoir system is recommended. Aggressive therapy (particularly the combination of intrathecal therapy and radiation) can be complicated by necrotizing leukoencephalopathy. Patients with chemotherapy-sensitive cancers and an excellent performance status have the best chance of benefiting from therapy. Temozolomide, a newer agent approved for treatment of primary brain tumors, is being tested for recurrent metastatic disease to the brain as well as leptomeningeal disease with some preliminary success. Temozolomide is given orally for 5 days each month; its primary side effects are nausea and cytopenias.

Quinn JA et al: Neurologic emergencies in the cancer patient. Semin Oncol 2000;27:311. [PMID: [10864219](#)]

3. Hypercalcemia

Hypercalcemia occurs in 10-20% of patients with cancer. Common causes include breast, lung, kidney, and head and neck carcinomas as well as multiple myeloma and lymphoma. Although the majority of cancers associated with hypercalcemia metastasize to the bones, approximately 20% of cases are not associated with bony lesions. The identification of a novel protein called parathyroid hormone-related protein (PTHrP) has revised some previously held views about the pathogenesis of hypercalcemia. Radioimmunoassays have identified this peptide in the serum of approximately two-thirds of cancer patients with hypercalcemia. High levels have been found in patients with hypercalcemia that was previously thought to be due solely to local osteolysis. PTHrP may become a useful tumor marker in normocalcemic patients. In addition, antibodies to PTHrP may be useful as treatment.

The symptoms and signs of hypercalcemia include nausea, vomiting, constipation, polyuria, muscular weakness and hyporeflexia, confusion, psychosis, tremor, and lethargy. Some patients may be asymptomatic. Electrocardiography often shows a shortening of the QT interval. The presence of hypercalcemia does not invariably indicate a dismal prognosis, especially in breast or prostate cancer and multiple myeloma or lymphoma. In the absence of signs or symptoms of hypercalcemia, a laboratory finding of elevated serum calcium should be rechecked to exclude the possibility of laboratory error.

Emergency Treatment

A. Hydration

Emergency treatment consists of aggressive intravenous hydration with 3-4 L/d of 0.9% saline followed by diuresis with 10-40 mg of intravenous furosemide. It is essential that the patient be well hydrated before beginning diuretic therapy and that hydration be maintained after diuresis is initiated. Although hydration alone is effective at slowly reducing the calcium level, it is rarely sufficient treatment and can lead to problems with fluid overload.

B. Drug Therapy

There are several options for the emergent treatment of hypercalcemia used in conjunction with aggressive hydration.

1. Bisphosphonates—Bisphosphonates are potent inhibitors of osteoclast bone resorption and are currently the most important and least toxic agents for the treatment of cancer-related hypercalcemia. Zoledronic acid is the most potent bisphosphonate available and will replace pamidronate disodium as the treatment of choice for malignant hypercalcemia. A single 15-minute intravenous infusion of 4 mg with adequate hydration produces complete normalization of serum calcium in less than 3 days in 80-100% of patients—with a more rapid onset and duration of effect than pamidronate. Zoledronic acid administration can be repeated as necessary to control hypercalcemia. The most commonly reported side effects have been transient fever, myalgias, and an infusion site reaction. Zoledronic acid has also been found to reduce the incidence of new skeletal lesions and decrease pain from bone disease in cancers with metastatic lesions to bone.

2. Gallium nitrate—For treatment of hypercalcemia, gallium nitrate is given by continuous intravenous infusion at a dose of 100-200 mg/m²/d for 5 days. Gallium nitrate is superior to calcitonin both in reducing calcium levels acutely and in keeping the levels low after treatment is completed. Renal function must be carefully monitored.

3. Calcitonin—Synthetic calcitonin-salmon works immediately to inhibit bone resorption, whereas pamidronate may take 2-3 days to achieve its maximum effect. The usual dose of 4 IU/kg intramuscularly, subcutaneously, or intranasally every 12 hours may be increased to 8 IU/kg every 12 hours after 1-2 days. Calcitonin-salmon alone is not effective at lowering serum calcium levels but can be added to pamidronate if necessary to achieve normal calcium levels. Repeated treatment with calcitonin is usually not as effective, and tachyphylaxis usually occurs after 1-3 days of treatment.

4. Other drugs—Prednisone has not been shown to be effective as a single agent to treat hypercalcemia, though it can be used in diseases that are responsive to steroids such as multiple myeloma or lymphoma. Refractory hypercalcemia may be treated with intravenous plicamycin, 25 ug/kg/d for 3 or 4 days. Although often effective, its effect may be short-lived, and its use is often associated with hepatic, renal, and bone marrow toxicity.

C. Chemotherapy

Patients with breast cancer may develop hypercalcemia as a "flare" associated with bone pain after initiation of estrogen or antiestrogen therapy. These patients often achieve excellent tumor response with continued therapy. Tumors may respond to chemotherapy or radiation therapy, leading to resolution of hypercalcemia. If chronic hypercalcemia persists and is refractory to chemotherapy, pamidronate and aggressive oral hydration may be tried but are unfortunately rarely effective for long. When the more potent bisphosphonates become available in oral formulations, the management of chronic hypercalcemia may improve.

4. Hyperuricemia & Acute Urate Nephropathy

Hyperuricemia can occur both as a complication of rapidly proliferating malignancies or with treatment-associated tumor lysis of hematologic malignancies such as leukemia, lymphoma, and multiple myeloma. Neoplasms with a high nucleic acid turnover such as acute leukemia and lymphoma may present with elevated serum uric acid and associated renal insufficiency. This problem may be compounded by use of thiazide diuretics, which decreases urate excretion. If a patient presents with hyperuricemia, care must be taken to reduce the uric acid before institution of cancer therapy. Patients at risk for tumor lysis syndrome should be followed with twice-daily measurements of uric acid, phosphate, calcium, and creatinine for the first 2-3 days following initiation of chemotherapy. Rapid elevation of serum uric acid can result in acute urate nephropathy caused by uric acid crystallization in the distal tubules, collecting ducts, and renal parenchyma. A serum urate concentration above 15 mg/dL is associated with a high risk of uric acid nephropathy. Gouty arthritis is usually a problem only in patients with a history of gout.

Prophylactic therapy consists of decreasing the production and increasing the renal excretion of uric acid. Allopurinol is a competitive inhibitor of xanthine oxidase and prevents conversion of highly soluble hypoxanthine and xanthine to the relatively insoluble uric acid. Twelve to 24 hours before beginning chemotherapy, a dose of 600 mg is given, followed by 300 mg/d during the period of high risk. Higher doses (up to 900-1200 mg/d) are used when severe hyperuricemia is anticipated following chemotherapy. Patients receiving the purine antagonists mercaptopurine or azathioprine should be given only 25-35% of the calculated dose of chemotherapy if they are also receiving allopurinol, since the latter drug will potentiate both the therapeutic effects and the toxicity of these agents. Renal excretion of uric acid is enhanced by maintaining a high urine flow and by alkalinizing the urine to prevent uric acid crystallization, which occurs at acid pH. The urine can be alkalinized with 6-8 g of oral sodium bicarbonate per day or by adding two or three ampules of sodium bicarbonate to 1 L of D₅W by infusion. Alkaline diuresis to maintain a urine pH near 7.0 is required only for prophylaxis in patients expected to have a rapid tumor response with marked hyperuricemia.

Emergency Treatment

Emergency therapy for established severe hyperuricemia consists of (1) hydration with 2-4 L of fluid per day; (2) alkalinization of the urine with 6-8 g of sodium bicarbonate per day; (3) allopurinol, 900- 1200 mg/d; and (4) in severe cases, emergency hemodialysis. When severe hyperuricemia is present, adequate therapy may be impossible because of associated renal insufficiency and inadequate urine output. Intravenous allopurinol is available for use in patients unable to tolerate the oral form of this drug. Even if renal failure occurs and dialysis is required, renal function may return to normal after the acute tumor lysis has resolved.

Jeha S: Tumor lysis syndrome. Semin Hematol 2001;38:4. [PMID: [11694945](#)]

5. Malignant Carcinoid Syndrome

Although tumors of argentaffin cells are uncommon, they are important because they secrete a variety of vasoactive materials. These include serotonin, histamine, catecholamines, prostaglandins, and vasoactive peptides. Carcinoid syndrome is usually associated with carcinoid tumors of the small bowel metastatic to the liver and, less commonly, with primary carcinoid tumors in other sites such as the lung or stomach. These tumors tend to metastasize early but have a relatively indolent

course, making control of the syndrome important. Related syndromes occur in patients with pancreatic tumors secreting vasoactive peptides, which can cause severe watery diarrhea (pancreatic cholera).

The manifestations of carcinoid syndrome include facial flushing, edema of the head and neck (especially with bronchial carcinoid), abdominal cramps and diarrhea, bronchospasm, cardiac lesions (tricuspid or pulmonary stenosis or regurgitation), telangiectasias, and increased urinary 5-hydroxyindoleacetic acid (5-HIAA). The most common symptoms are flushing and diarrhea. The diagnosis is made by finding elevated levels of 5-HIAA in a 24-hour urine collection. Patients with symptomatic carcinoid usually excrete more than 25 mg of 5-HIAA per day in the urine. Ideally, all drugs and serotonin-rich foods such as bananas should be withheld for several days before beginning the urine collection.

Emergency Treatment

Emergency therapy for patients with symptomatic bronchial carcinoid includes prednisone, 15-30 mg/d. The associated abdominal cramping and diarrhea of intestinal carcinoids can often be managed by hydration and diphenoxylate with atropine. For severe diarrhea, the H₁ histamine receptor antagonist cyproheptadine (4 mg orally three times daily) or an antiserotonin agent such as methysergide maleate (2 mg orally three times daily until 16 mg has been given) may be effective. Other useful agents include cimetidine and the phenothiazines.

The synthetic peptide somatostatin agonist, octreotide acetate, is the most effective agent for reducing symptoms due to the carcinoid syndrome in association with achieving a reduction in levels of urinary 5-HIAA. The dose of octreotide in carcinoid syndrome is 100-600 ug/d in two to four divided doses by subcutaneous injection. Octreotide is also effective in the treatment of symptoms related to vasoactive intestinal peptide-secreting pancreatic tumors (VIPomas), markedly reducing the watery diarrhea syndrome associated with this neoplasm. The dosage of octreotide used to treat patients with VIPomas is 200-300 ug/d in two to four divided doses.

Surgery is important in the treatment of localized carcinoid. Chemotherapy is moderately effective for patients with progressive advanced-stage disease. Active agents include fluorouracil, streptozocin, dacarbazine, cisplatin, doxorubicin, and interferon alfa.

■ OTHER COMPLICATIONS

MALIGNANT EFFUSIONS

The development of effusions in the pleural, pericardial, and peritoneal spaces may be the presenting sign of some tumors or may cause diagnostic and therapeutic problems in patients with advanced neoplasms. Although the cause of an effusion can be elusive in a newly diagnosed asymptomatic patient, it is rarely difficult in the patient with advanced cancer. Approximately half of undiagnosed effusions in patients not known to have cancer will be malignant. The differential diagnosis includes congestive heart failure, pulmonary embolism, trauma, and infections such as tuberculosis. Direct involvement of the serous surface of the involved space with tumor appears to be the most frequent initiating factor, though many other mechanisms such as obstruction of lymphatic drainage that control the flow of fluid in the pleural space may play a role.

Most patients with pleural or pericardial effusions are symptomatic at presentation with chest pain, shortness of breath, or cough. The diagnosis is made by tapping the involved space. Pericardial effusions are aspirated under fluoroscopic guidance or direct vision through a subxiphoid incision. The fluid should be heparinized and sent for cell count and differential, protein content, lactate dehydrogenase level, and cytologic study. The gross appearance of the fluid is often helpful as well. Bloody effusions are usually due to cancer but occasionally are due to pulmonary embolism, tuberculosis, or trauma. Chylous effusions may be associated with thoracic duct obstruction or may result from enlarged mediastinal lymph nodes in lymphoma. If the cytologic smear is negative on two occasions but the suspicion of tumor is still high, closed pleural biopsy may be helpful.

The management of effusions should be appropriate to the severity of involvement. Treatment of the underlying neoplasm would be ideal but is often not effective in controlling local effusions. Treatment may result in palliation and improve short-term survival when there is substantial pulmonary or cardiac compromise. Diuretics are used as initial treatment for small to moderate-sized peritoneal effusions and as an adjunct to drainage of large effusions to minimize the possibility of reexpansion pulmonary edema that can occur after thoracentesis. Small or loculated effusions may require ultrasonographic localization, but drainage of a large pleural or peritoneal effusion can be accomplished rapidly using an intravenous catheter and phlebotomy tubing connected to a vacuum bottle. Thoracentesis alone controls fewer than 10% of effusions but may be useful in conjunction with systemic chemotherapy for sensitive tumors (eg, lymphoma, small cell lung cancer, breast cancer). Pleural effusions may occasionally be managed by closed water-seal drainage with a chest tube for 3-4 days, though this procedure is usually performed in conjunction with chemosclerosis (see below). The aim of this procedure is to allow the pleural surfaces to come into close contact and become adherent.

Recurrent symptomatic effusions can often be controlled by drainage followed by chemosclerosis. In this procedure, a chemotherapeutic or nonchemotherapeutic agent is instilled with lidocaine into the involved space. The intended effect is local inflammation and sclerosis to encourage adherence of the serosal surfaces. Several drugs used in the past for this purpose have been abandoned because of severe pain or systemic toxicity, including myelosuppression. Agents currently in use include talc, bleomycin, and the anthracenedione compound mitoxantrone.

Talc poudrage has been used successfully to control malignant pleural effusions and appears to be relatively painless. For these reasons as well as cost considerations, talc is now the sclerosing agent of choice for malignant pleural effusions.

Bleomycin is more effective at controlling pleural effusions than tetracycline; when tetracycline was used, the recurrence rate 90 days after sclerosis was almost double, and the side effects were similar. Tetracycline is no longer manufactured or available for intracavitary instillation. The major side effects of bleomycin are pain, fever, and hypersensitivity reactions.

Mitoxantrone has been reported to be effective in controlling malignant pleural effusions, causing minimal fever and local pain. However, one trial evaluated the effectiveness of mitoxantrone versus chest tube alone and found no differences in response or in duration of response. The instillation of sclerosing agents may best be reserved for patients who fail pleural tube drainage alone.

Sclerosis is generally less useful for the management of malignant ascites, but success has been reported using bleomycin, doxorubicin, thiotepe, and other agents.

Before instilling the sclerosing agent, it is important that the space be drained as thoroughly as possible. For pleural effusions, a small-bore chest tube or pigtail catheter is usually placed and fluid is removed by negative suction until the drainage is under 100 mL per 24 hours and the lung has expanded. Sclerotherapy is ineffective if there is a large residual effusion. Talc is insufflated into the pleural space via a thoracoscope or instilled in a 5 g slurry with iodide via a chest tube. Talc instillation via a thoracoscope under anesthesia can be done quickly, has minimal complications, and appears highly effective. To use chemotherapeutic agents, the patient is premedicated with an opioid, and 60 units of bleomycin or 30 mg of mitoxantrone in 50-100 mL of 0.9% saline is instilled directly into the chest tube. The chest tube is then clamped, and the patient is placed in different positions every 15 minutes for 4 hours to distribute the agent equally within the pleural space. At the end of this period, the clamp is removed and the chest tube is allowed to drain with suction. After 24 hours, the chest tube is removed from suction, and when the drainage is minimal, the tube is removed. The whole process takes 3-5 days. Occasionally, repeated doses of the sclerosing agent may be required to stop persistent reaccumulation of the effusion.

Surgery is infrequently used for patients with pleural or pericardial effusions who have failed sclerosis and who continue to have a long expected survival. Pleuroperitoneal shunting may have limited value in selected patients with high performance status who can participate actively in pumping the shunt the 100 times on five separate occasions each day required for adequate shunt function and fluid drainage. Pleurectomy has a high complication rate but offers excellent control of effusion in carefully selected patients. For malignant pericardial effusion, a pericardial window or stripping also offers good control with a lower complication rate and may also be performed for constrictive pericarditis following radiation therapy to the chest.

INFECTIOUS COMPLICATIONS

The reader is referred also to the section on infections in the immunocompromised patient in [Chapter 30](#).

Many patients with cancer have increased susceptibility to both bacterial and opportunistic infections. This may result from impaired host defense mechanisms (eg, Hodgkin's or non-Hodgkin's lymphoma, chronic lymphocytic leukemia, multiple myeloma, acute leukemia or preleukemia) or from the myelosuppressive and immunosuppressive effects of cancer chemotherapy. Impaired host defense mechanisms include defects in neutrophil function, abnormalities in antibody production, depressed cell-mediated immune function, impairment of mechanical barriers by indwelling intravenous catheters, and impairment of mucosal integrity. At least half of the infections seen in neutropenic patients are felt to be endogenous.

The bacterial organisms accounting for the majority of infections in cancer patients include Enterobacteriaceae (klebsiella, enterobacter, serratia, *Escherichia coli*), pseudomonas, staphylococcus, and streptococcus. Other important pathogens include corynebacterium, *Clostridium difficile*, mycobacterium, and legionella. Patients with prolonged neutropenia or those who have undergone bone marrow transplantation are at risk for infections with fungi such as candida, aspergillus, and pneumocystis and with viruses such as herpes zoster, cytomegalovirus, respiratory syncytial virus, and influenza virus. Infections with resistant bacteria, such as vancomycin-resistant enterococcus, are being seen with increasing frequency. The incidence of bacteremia rises dramatically when the white count is less than 1000/uL or when there are fewer than 200 granulocytes per microliter. In patients with neutropenia, hematologic malignancies, or following bone marrow transplantation, infection must be treated emergently and empirically. Although fever may be due to multiple causes, including mucositis, drugs, and the malignancy itself, infection must be the first consideration and may be present even in the absence of fever, especially in patients who are receiving glucocorticoids. Negative cultures in febrile neutropenic patients do not rule out infection, and treatment should be instituted immediately without waiting for culture results to become available. If an indwelling line is present, blood cultures should be drawn from the periphery as well as through the line itself.

Prevention

Details of prevention in immunocompromised hosts are outlined in [Chapter 30](#).

Prophylaxis of infections in high-risk or neutropenic patients can prevent the complications of sepsis. Two randomized clinical trials tested oral versus intravenous antibiotic therapy for hospitalized low-risk febrile patients with neutropenia during cancer chemotherapy. Oral ciprofloxacin plus amoxicillin and potassium clavulanate appeared as effective as intravenous ceftazidime or ceftriaxone and amikacin, indicating that for low-risk patients, outpatient therapy is feasible and safe.

In patients who are severely immunocompromised, some bacterial infections may be prevented with intravenous immune globulin. This is important in patients with chronic lymphocytic leukemia, multiple myeloma, and following bone marrow transplantation if associated immunoglobulin deficiencies are observed.

The availability of recombinant bone marrow growth factors has helped to reduce the morbidity and mortality of infections in immunocompromised hosts. Granulocyte colony-stimulating factor (G-CSF; filgrastim) and granulocyte-macrophage colony-stimulating factor (GM-CSF; sargramostim) have been shown to be effective at reducing the duration of neutropenia and the frequency and severity of infection after myelosuppressive chemotherapy or autologous bone marrow transplantation for nonmyeloid malignancies. These growth factors improve bone marrow tolerance of escalating doses of chemotherapy, allowing higher doses to be given at shorter intervals. G-CSF and GM-CSF have been used to stimulate bone marrow stem cell production in both the circulating blood and in bone marrow cell populations collected for autologous transplantation. Administration of growth factors may improve survival after the failure of autologous or allogeneic bone marrow grafts.

Treatment

Infection management has been aimed at treatment of gram-negative bacterial sepsis, the most rapidly lethal infection. Current concepts have been broadened to include prophylaxis and prevention of the most common infections, including those caused by gram-negative, gram-positive, and fungal pathogens. Until recently, empirical therapy of fever consisted of two- or three-drug combinations, including an aminoglycoside and an antipseudomonal penicillin, with resolution of fever and bacteremia in about 70% of patients. Current results using initial monotherapy with a third-generation cephalosporin such as ceftazidime or cefepime or a combination β -lactam appear to yield similar results. Vancomycin or amphotericin B may be added on the basis of clinical suspicion, culture results, or prolonged fever in the absence of positive cultures. A recent study found that the newer antifungal agent, voriconazole, was as effective as and less toxic than amphotericin B in the empiric treatment of neutropenic patients with persistent fever. For persistent fevers or clinical deterioration, gram-negative rod coverage should be changed to an agent with a broader spectrum (eg, ciprofloxacin or imipenem). If stenotrophomonas is suspected, trimethoprim-sulfamethoxazole should be added.

■ THE PARANEOPLASTIC SYNDROMES (TABLE 40-6)

The clinical manifestations of cancer are usually nonspecific—eg, anorexia, malaise, weight loss, fever—or are due to local effects of tumor growth, either in the primary site or at a distant site. The term "paraneoplasia" has been coined to denote the remote effects of malignancy that cannot be attributed either to direct invasion or metastatic lesions. These syndromes may be the first sign of a malignancy and may affect up to 15% of patients with cancer.

The paraneoplastic syndromes are of considerable clinical importance for the following reasons:

- (1) They may accompany relatively limited neoplastic growth and provide an early clue to the presence of certain types of cancer.
- (2) The course of the paraneoplastic syndrome usually parallels the course of the tumor. Therefore, effective treatment should be accompanied by resolution of the syndrome, and, conversely, recurrence of the cancer may be heralded by return of systemic symptoms.
- (3) The metabolic or toxic effects of the syndrome may constitute a more urgent hazard to life than the underlying cancer (eg, hypercalcemia, hyponatremia).

The paraneoplastic syndromes are usually caused by the secretion of proteins not normally associated with a cancer's normal tissue equivalent. Clinical findings may resemble those of primary endocrine, metabolic, hematologic, or neuromuscular disorders. The mechanisms for such remote effects can be classified into three groups: (1) effects initiated by a tumor product (eg, carcinoid syndrome), (2) effects due to the destruction of normal tissues by tumor products (eg, hypercalcemia due to local secretion of cytokines), and (3) effects due to unknown mechanisms such as unidentified tumor products or circulating immune complexes stimulated by the tumor (eg, osteoarthropathy due to bronchogenic carcinoma and some neurologic syndromes). Even such nonspecific symptoms as fever and weight loss are truly paraneoplastic and are due to the production of specific factors (eg, tumor necrosis factor) by tumor cells or by normal cells in response to the tumor.

Paraneoplastic syndromes associated with ectopic hormone production are the best-characterized entities. Tumor cells secrete a hormone or prohormone that may be of a higher or lower molecular weight than hormones secreted by the more differentiated normal endocrine cell (eg, PTH-related peptide in hypercalcemia, ACTH in Cushing's syndrome, ADH in the syndrome of inappropriate antidiuretic hormone secretion). This ectopic hormone production by cancer cells is believed to result from activation of genes in malignant cells that are normally suppressed in most somatic cells. A single syndrome such as hypercalcemia may be due to more than one of a variety of causes. Effective antitumor treatment usually results in return of the serum calcium to normal, though additional therapy may be required (see Hypercalcemia, above). In some cases, a rapid response to cytotoxic chemotherapy may briefly increase the severity of the paraneoplastic syndrome in association with tumor lysis (eg, hyponatremia with SIADH). Several neurologic paraneoplastic syndromes have been found to be caused by the production of antineuronal antibodies that circulate in the serum and spinal fluid. It is thought that the underlying tumor expresses a similar antigen, resulting in production of a cross-reactive antibody. Treatment of the underlying tumor usually results in only modest improvement of the neurologic deficit. Examples of antineuronal antibodies include the anti-Hu antibody causing sensory neuropathy or encephalitis, associated with small cell cancer of the lung; the anti-Yo antibody causing cerebellar degeneration, associated most often with breast or gynecologic malignancies; the stiff man syndrome, associated with breast cancer; and anti-Purkinje cell antibodies causing cerebellar ataxia, associated with Hodgkin's disease as well as gynecologic, breast, and lung cancers.

Other well-described paraneoplastic syndromes include those involving the skin with or without other organ involvement (eg, dermatomyositis, Sweet's syndrome), hematologic syndromes (eg, polycythemia, thrombocytosis), and those involving the kidneys, the gastrointestinal tract, and the joints.

The most common cancer associated with paraneoplastic syndromes is small cell cancer of the lung. This is thought to be due to its neuroectodermal origin.

■ NOVEL THERAPIES FOR CANCER TREATMENT

The use of cytotoxic drugs against cancer is limited by a number of factors, including toxicity, tumor resistance, and lack of targeted cell death. New strategies are based on increasing and improved knowledge of the molecular events responsible for disordered cellular growth and include antibodies to block receptors, small molecules that inhibit receptor tyrosine kinase-mediated cell signaling, agents directed at suppressing growth of blood vessels that feed cancer growth, vaccines to stimulate immune recognition of cancer cells, cell cycle inhibitors, and gene therapy to turn off signaling pathways or provide a missing tumor suppressor.

One way to block cellular growth is to block growth factor receptors. These receptors cross the cell membrane; the extracellular portion is the ligand-binding site, and the intracellular portion is the receptor tyrosine kinase. Activation of the receptor with ligand phosphorylates the tyrosine kinase and results in cell signaling through a complex series of events. A sketch of the growth factor receptors and various methods to block their activation is presented in [Figure 40-1](#). The epidermal growth factor (EGF) receptor is expressed on most epithelial cells, and activation of the receptor has been shown to promote tumor cell growth, proliferation, and survival. Preclinical models have shown that blockade of this receptor results in tumor growth delay or regression and can potentiate radiation and chemotherapy effects. **Trastuzumab** (Herceptin) is a monoclonal antibody directed against the HER-2/*neu* receptor, one of the EGF family of receptors, and was the first growth factor receptor inhibitor approved for clinical use.

Agents that block the EGF receptor are directed against the HER-1 receptor. Two agents targeting the EGF receptor are in clinical trials with encouraging results. **Cetuximab** (IMC-C225) is a monoclonal antibody that binds to the extracellular domain of the EGF receptor, resulting in inhibition of the receptor tyrosine kinase. Preliminary data indicate that cetuximab potentiates the effect of radiation therapy in head and neck cancer, and this effect is being studied in the setting of an ongoing phase III clinical trial. A phase II trial combined cetuximab with irinotecan in 121 patients with colorectal cancer resistant to both irinotecan and fluorouracil whose tumors expressed the EGF receptor. Twenty-one patients (17%) achieved a partial response, and 37 (31%) had stable disease or a minor response. A recent trial randomized patients with colorectal cancer whose disease had clearly progressed on irinotecan to either cetuximab alone or cetuximab in combination with irinotecan. The response rate in the combination arm was double that of the cetuximab alone arm at 23% versus 11%. In addition, time to progression was significantly longer at 4 months in patients receiving both drugs versus just over 1 month in patients receiving the antibody alone. Side effects attributed to cetuximab alone were minimal. Two phase III studies are ongoing comparing cetuximab in combination with irinotecan, fluorouracil, and leucovorin versus irinotecan, fluorouracil, and leucovorin (ie, without cetuximab) to the chemotherapy regimen alone as first-line therapy for metastatic colorectal cancer.

Erlotinib is an oral small-molecule tyrosine kinase inhibitor that blocks EGF receptor by directly blocking phosphorylation of the intracellular receptor tyrosine kinase, similar to gefitinib. Partial remissions have been seen in a variety of cancers in phase II trials with either erlotinib or gefitinib. One recent study evaluated the effect of erlotinib in patients with bronchoalveolar carcinoma, a form of non-small cell lung cancer. Twenty-seven percent of patients responded to this novel agent, which was quite striking given that this form of cancer does not usually respond to treatment. Ongoing trials are evaluating the effect of these agents in combination with standard chemotherapy or hormonal therapy. Gefitinib and erlotinib have also been shown to inhibit the HER-2/*neu* receptor tyrosine kinase in preclinical models; trials are planned to evaluate the effects of these agents in advanced breast cancers in combination with trastuzumab. The primary toxicity of gefitinib and erlotinib is a follicular rash. At least two additional small molecule tyrosine kinase inhibitors that block multiple receptors within the EGF family are in clinical trials. These oral agents block receptor combinations of EGF, HER1, and HER4.

Angiogenesis (the growth of new blood vessels) is thought to be an essential component of the ability of tumors to invade locally and to metastasize from the primary tumor site. Tumor angiogenesis is regulated by angiogenic stimulators such as vascular endothelial growth factor (VEGF, the ligand for the VEGF receptor) and the newly described inhibitors of angiogenesis: angiostatin and endostatin. There is now intense interest in using inhibitors of angiogenesis to suppress tumor growth and metastases. This type of therapy might avoid the development of chemotherapy resistance and have less toxicity than standard cytotoxic therapy.

A recombinant humanized antibody to VEGF (anti-VEGF, rhuMAb VEGF, **bevacizumab**) has been tested alone and with chemotherapy in colon, breast, and lung cancers. The most promising results have been seen in patients with advanced colon cancer; a recent phase III trial compared standard chemotherapy with irinotecan, fluorouracil, and leucovorin (IFL) to the same chemotherapy in combination with bevacizumab in 815 patients with metastatic colorectal cancer that had not received prior chemotherapy. Patients who received bevacizumab in combination with IFL had a higher response rate, longer time to disease progression, and longer survival compared with patients receiving IFL alone. The median survival was 20.3 months in the bevacizumab arm compared with 15.6 months in the IFL-alone arm. Bevacizumab was generally well tolerated, with the primary toxicity being hypertension. Six patients had gastrointestinal perforation in the bevacizumab arm, raising a question regarding the role of antiangiogenic therapy in delayed organ healing. These exciting results represent the first clear benefit from antiangiogenic therapy in the treatment of cancer.

Although a dose-finding phase II trial in advanced refractory breast cancer with bevacizumab found an overall response rate of 11-20%, a phase III randomized trial using anti-VEGF in combination with chemotherapy versus chemotherapy alone in the treatment of advanced and chemotherapy-resistant breast cancer failed to show an improvement in time to disease progression. A second phase III study evaluating the combination of bevacizumab in combination with paclitaxel as first-line therapy for metastatic breast cancer is ongoing. Treatment with bevacizumab in patients with renal cell cancer resulted in significant slowing of cancer cell growth, with a 2.5-fold prolongation in time to progression from 2 months to 5 months. Tumor regression was rare, with three partial responses. The antibody was well tolerated in this trial, and a confirmatory multi-institution trial is planned. Combinations of bevacizumab with the EGF inhibitor erlotinib are being tested in a variety of cancers.

Endostatin and angiostatin are potent inhibitors of angiogenesis that appear to be promising. A preclinical study showed that transfer of cells engineered to produce angiostatin into mice inhibited the growth of both the primary tumor and lung metastases from fibrosarcoma. Trials using endostatin to treat patients with advanced malignancy began in late 1999. Two phase I dose-escalation trials using recombinant human endostatin (rHE) or angiostatin (rHA) in patients with advanced solid tumors showed few tumor responses, although both agents were associated with minimal side effects at the doses used. Tumor blood flow decreased with both agents. Phase II trials are ongoing to assess the antitumor effects of endostatin and angiostatin.

Another novel way to suppress angiogenesis is with small molecules that inhibit receptor tyrosine kinases and block VEGF-mediated receptor signaling. Several agents are in clinical trials treating various advanced metastatic cancers, usually in combination with chemotherapy. One agent, SU5416, was found to have unfavorable pharmacokinetics after extensive clinical trials had been conducted; development of this agent has been halted. It is now clear that standard pharmacokinetic studies must be done for novel agents before undertaking large randomized clinical trials. One newer agent, SU11248, has been shown to have striking antitumor effects in gastrointestinal stromal tumor (GIST) that has progressed on imatinib. Ongoing trials are evaluating the effects of this and other agents in a variety of cancers.

Thalidomide has been shown to have antiangiogenic properties as well as other antitumor effects. Striking responses have been seen in advanced and resistant multiple myeloma. Clinical trials using thalidomide in combination with chemotherapy in multiple myeloma, prostate cancer, and other malignancies are ongoing. An interesting therapy targets matrix metalloproteases that are thought to be important in the ability of cancer cells to metastasize. Unfortunately, phase III results in small cell lung cancer have been disappointing, indicating at least that the current products are not active enough for clinical use.

Immunotherapy is an exciting area of investigation of the treatment of cancer. The most extensively treated disease with immunotherapeutic modalities is malignant melanoma—for a variety of reasons, including easily identified immunogenic antigens, easy access to tumor cells, and the ability to grow these cells in vitro. Active specific immunotherapy with melanoma vaccines has been evaluated in phase II trials for advanced melanoma as well as in the adjuvant setting with encouraging results. A phase III trial testing the **allogeneic melanoma cell lysate vaccine Melacine** in 689 patients with intermediate-thickness and clinically node-negative melanoma showed no evidence of improvement in disease-free survival at a median follow-up of 5.6 years among patients receiving the vaccine. Criticisms of the trial include the lack of sentinel node biopsy and lack of ability to detect small differences in recurrence. However, when patients expressing two or more specific HLA class I antigens were evaluated separately, a highly significant benefit was seen in patients receiving adjuvant treatment with Melacine. This suggests that specific HLA types can determine the immune response and disease impact of vaccine strategies. Further studies are ongoing. Identification of a suitable target is critical for the development of any vaccine. Interesting agents in clinical trials include a vaccine directed against human papillomavirus (HPV) to prevent cervical cancer and individualized vaccines directed toward the unique set of B cell tumor antigens that comprise each participating patient's low-grade lymphoma. This type of vaccine has been demonstrated to induce an immune response as well as either stable disease or actual tumor shrinkage in preliminary trials. Other interesting vaccines include monoclonal antibodies directed toward tumor products such as CA-125 for ovarian cancer and CEA for colon cancer.

The field of cancer vaccines is growing rapidly. One type of tumor vaccine in many clinical trials capitalizes on dendritic cells, which are antigen-presenting cells that enhance the response of the immune system to foreign antigens. Dendritic cells may be loaded with a particular abnormal protein to stimulate the immune response to a specific cancer. Early clinical trials in melanoma, multiple myeloma, and other cancers are in progress. One interesting strategy is to target the dendritic cells to a

known growth factor present on the tumor cell. A clinical trial using dendritic cells loaded with HER-2/*neu* for the treatment of metastatic breast cancer is evaluating the ability of this type of vaccine to stimulate a specific immune response in women with advanced breast cancer. Preliminary results indicate stability of disease, with an immune response generated in all treated patients. In one study, patients with late-stage colorectal cancer were treated with a growth factor, FLT-3 ligand, to expand the number of circulating dendritic cells in vivo. The cells were then harvested, loaded with CEA antigen, and reinfused as a cellular vaccine. Early results in all four patients include tumor response or disease stabilization. A larger trial is planned. This type of therapy might also be useful early in the disease course of an aggressive tumor. **Dendritic cell vaccines** can be used in conjunction with autologous stem cell transplantation; cells are removed at the time of stem cell harvesting, undergo in vitro stimulation, and are then returned to the patient after completion of chemotherapy and radiation therapy to eradicate bulk tumor.

Several problems with vaccine therapy exist, including the difficulty of generating an immune response in an immunosuppressed cancer patient and the fact that an immune response does not necessarily correlate with tumor response. In order to enhance the immune response to vaccines, growth factors such as GM-CSF are given with the treatment. A GM-CSF gene-modified vaccine is now in clinical trials that produces GM-CSF locally to enhance the immune response. Early results show some evidence of tumor response in non-small cell lung cancer.

The arachidonic acid metabolic pathway is thought to be important in the pathogenesis of cancer. COX-2 is overexpressed in many solid tumors, including tumors of the lung, colon, and breast. Higher levels are thought to increase angiogenesis and decrease apoptosis. Multiple clinical trials are under way to evaluate the effects of the COX-2 inhibitor celecoxib in the treatment or prevention of cancer—often in combination with either chemotherapeutic or hormonal agents. One recent small phase II study suggested that celecoxib might improve the response to preoperative chemotherapy in patients with non-small cell lung cancer and to hormonal therapy in breast cancer; these hypotheses need to be explored in the setting of larger trials, which are already planned.

The goal of gene therapy for cancer is to inhibit the constitutive signals that drive tumor growth. Expanding knowledge about signal transduction has provided multiple possible attack points within this complicated multistep process involving a variety of somatic gene alterations. Although at present it is impossible to deliver therapeutic genes to every cancer cell, bystander effects or the cytotoxic effects produced by engineered cells on nonengineered cells may allow broad effects from a limited number of transduced cells. A variety of approaches are being investigated. These include enhancing the ability of the host immune system to respond to a specific tumor, sensitizing tumor cells to relatively nontoxic drugs or prodrugs, and selective replacement of altered or missing tumor suppressor genes or inactivation of oncogenes. Selective targeting of cells would allow either cell death or return of normal growth patterns without toxicity to nonneoplastic cells. One area of research in active clinical trial is replacement of the missing function of the mutated tumor suppressor gene, *P53*, or to inhibit the function of a dominant oncogene such as *ras*. One approach is to create a vaccine directed against cells with mutant *P53* in order to generate a cytotoxic T cell response to tumor cells expressing the *P53* protein. A vaccine made from a disabled adenovirus (the vector or carrier) and the *P53* gene and injected into the arterial circulation is delivered to tumors that have metastasized to the liver with subsequent expression of the *P53* gene.

Another unique approach to tumor killing is the use of an adenovirus engineered to selectively kill tumor cells that are lacking *P53* but leave normal cells alone. This agent, ONYX-015, is also in clinical trials both with and without chemotherapy. It appears to be more effective when injected directly into tumors. Results from this and other agents are limited by a variety of problems, including difficulty in delivering the agent, identifying tumors that lack *P53*, and production of the novel agent. The Bcl-2 protein, overexpressed in many common solid tumors, is thought to be responsible for blocking apoptosis or natural cell death and appears to confer tumor cell resistance to chemotherapy and radiation therapy. An antisense oligonucleotide that blocks production of the Bcl-2 protein, thereby restoring this principal pathway of cell death, is in clinical trials in combination with chemotherapy in melanoma, multiple myeloma, non-small cell lung cancer, and chronic lymphocytic leukemia. This agent binds to Bcl-2 messenger RNA, causing fragmentation of the protein message. Gene therapy is also being investigated in autologous stem cell transplantation for a variety of malignancies. In this setting, antitumor genes are added to cells that have been removed for transplantation following myeloablative chemotherapy. Trials are ongoing to study this form of therapy in chronic myelogenous leukemia. Multiple other trials, including the introduction of new genes that encode inhibitors of oncogene products or enhance tumor cell immunogenicity, are in progress.

Other areas of investigation include discovery of novel agents that induce apoptosis (programmed cell death), stimulate differentiation, prevent tumor invasion or metastases, and specifically target hormone pathways that stimulate tumor growth. In addition, new antiproliferative agents with improved toxicity profiles and less cross-resistance to known agents are being evaluated or are already in use. These include novel taxanes that cross the blood-brain barrier, with encouraging results in phase II trials. Ongoing research is focusing on the identification of new growth factor receptors associated with malignant behavior that can be targeted to suppress cancer growth, such as the HER-2/*neu* receptor targeted by the antibody trastuzumab. The current proliferation of clinical trials targeting various pathways of tumor growth as well as ongoing research to identify antigenic targets should lead to a new paradigm for cancer therapy in the coming decades.

■ ALTERNATIVE & COMPLEMENTARY THERAPIES FOR CANCER TREATMENT

New areas of cancer therapy are rapidly expanding, and the next decade could bring important changes in the treatment of common malignancies. Many alternatives to traditional cancer therapy exist (one well-known example is shark cartilage, which is widely available and purported to have anti-angiogenic properties), but there is little evidence to support their efficacy or assess their potential toxicity, and at present there is no federal regulation of these products. Agents that are commonly used include green tea, echinacea, essiac tea, flaxseed, mistletoe, and coenzyme Q as well as others.

It is critical that herbs be tested with the same rigorous standards as chemotherapeutic agents in scientifically based clinical trials. Most herbal preparations are available over the counter, and no information exists regarding the interaction of these herbs with other medications. Many interactions have been described between St. John's wort and critical medications such as antiretrovirals, cyclosporine, chemotherapeutic agents, and hormonal agents, among others, that resulted in decreased drug levels due to enhanced metabolism.

A dietary supplement containing a combination of eight Chinese herbs with potent estrogenic activity, PC-SPES, has been tested in prostate cancer. All patients with hormone-sensitive and about 60% of patients with hormone-refractory prostate cancer responded with a decline in PSA; some patients also had improvement in bone scans. Toxicity was modest, including allergic reactions and thromboembolic events in about 4% of patients. Unfortunately, recent laboratory analysis of PC-SPES by the California Department of Health Services found significant contamination of this product with undeclared prescription drugs such as warfarin and alprazolam as well as hormonal agents. Based on these data, the manufacturer of PC-SPES and SPES has voluntarily recalled the products nationwide, and research has been halted. Investigations will need to be repeated if a noncontaminated product is produced, as the finding of hormonal agents in the herbal preparation suggests that the responses seen in published studies could have been due to contaminants instead of the herbs themselves.

Ongoing research is evaluating the effects of herbal combinations on side effects of adjuvant chemotherapy for breast cancer. The NCI is actively supporting research in the field of alternative therapies for cancer through the National Center for Complementary and Alternative Medicine (NCCAM). Additional information on alternative treatment modalities can be found in [Chapter 44](#).

There are now many Web sites devoted to providing information on alternative cancer therapies. NCCAM lists new research and research trials as well as an introduction to alternative medicine. There is also an extensive bibliography. This Web site may be reached at nccam.nih.gov. Additional resources can be found at the Cancer Guide Material on Alternative Medicine Web site cancerguide.org/alternative.html. The Center for Alternative Medicine Research in Cancer at the University of Texas-Houston Health Science Center (UT-CAM) maintains an excellent Web site with data pertaining to a wide variety of alternative medications and therapies. The site can be reached at nccam.nih.gov.

Table 40-3. Treatment choices for cancers responsive to systemic agents.

Diagnosis	Current Treatment of Choice	Other Valuable Agents and Procedures
Acute lymphocytic leukemia	Induction: Combination chemotherapy. <i>Adults:</i> Vincristine, prednisone, daunorubicin, and asparaginase. Consolidation: Multiagent alternating chemotherapy. Allogeneic bone marrow transplant for young adults or high-risk disease or second remission. CNS prophylaxis with intrathecal methotrexate with or without whole brain radiation. Remission maintenance: Methotrexate, thioguanine.	Doxorubicin, cytarabine, cyclophosphamide, etoposide, teniposide, allopurinol, ¹ autologous bone marrow transplantation
Acute myelocytic and myelomonocytic leukemia	Induction: Combination chemotherapy with cytarabine and an anthracycline (daunorubicin, idarubicin). Tretinoin with idarubicin for acute promyelocytic leukemia. Consolidation: High-dose cytarabine. Autologous (with or without purging) or allogeneic bone marrow transplantation for high-risk disease or second remission.	Gemtuzumab ozogamicin (Mylotarg), mitoxantrone, idarubicin, etoposide, mercaptopurine, thioguanine, azacitidine, ² amsacrine, ² methotrexate, doxorubicin, tretinoin, allopurinol, ¹ leukapheresis, prednisone, arsenic trioxide for acute promyelocytic leukemia
Chronic myelocytic leukemia	Imatinib mesylate (Gleevec), hydroxyurea, alpha interferon. Allogeneic bone marrow transplantation for younger patients.	Busulfan, mercaptopurine, thioguanine, cytarabine, plicamycin, melphalan, autologous bone marrow transplantation, ² allopurinol ¹
Chronic lymphocytic leukemia	Fludarabine, chlorambucil, and prednisone (if treatment is indicated). Second-line therapy: alemtuzumab (Campath-1H).	Vincristine, cyclophosphamide, doxorubicin, cladribine (2-chlorodeoxyadenosine; CdA), rituximab, allogeneic bone marrow transplant, androgens, ² allopurinol ¹
Hairy cell leukemia	Cladribine (2-chlorodeoxyadenosine; CdA).	Pentostatin (deoxycofomycin), alpha interferon
Hodgkin's disease (stages III and IV)	Combination chemotherapy: doxorubicin (Adriamycin), bleomycin, vinblastine, dacarbazine (ABVD) or alternative combination therapy without mechlorethamine. Autologous bone marrow transplant for high-risk patients or relapsed disease.	Mechlorethamine, vincristine, prednisone, procarbazine (MOPP); carmustine, lomustine, etoposide, thiotepa, autologous bone marrow transplantation
Non-Hodgkin's lymphoma (intermediate to high grade)	Combination therapy depending on histologic classification but usually including cyclophosphamide, vincristine, doxorubicin, and prednisone (CHOP) with or without rituximab in older patients. Autologous bone marrow transplantation in high-risk first remission or first relapse.	Bleomycin, methotrexate, etoposide, chlorambucil, fludarabine, lomustine, carmustine, cytarabine, thiotepa, amsacrine, mitoxantrone, allogeneic bone marrow transplantation
Non-Hodgkin's lymphoma (low-grade)	Fludarabine, rituximab, ibritumomab tiuxetan for relapsed or refractory disease	Combination chemotherapy: cyclophosphamide, prednisone, doxorubicin, vincristine; chlorambucil, autologous or allogeneic transplantation
Cutaneous T cell lymphoma (mycosis fungoides)	Topical carmustine, electron beam radiotherapy, photochemotherapy, targretin, denileukin diftitox (ONTAK) for refractory disease	Interferon, combination chemotherapy, denileukin diftitox (ONTAK), targretin
Multiple myeloma	Combination chemotherapy: vincristine, doxorubicin, dexamethasone; melphalan and prednisone; melphalan, cyclophosphamide, carmustine, vincristine, doxorubicin, prednisone. Autologous transplantation in first complete or partial remission, mini-allogeneic transplant for poor-prognosis disease. Thalidomide for relapsed or refractory disease	Clarithromycin, etoposide, cytarabine, alpha interferon, dexamethasone, autologous bone marrow transplantation
Waldenstrom's macroglobulinemia	Fludarabine or chlorambucil or cyclophosphamide, vincristine, prednisone. Allogeneic bone marrow transplantation for high-risk young patients.	Cladribine, etoposide, alpha interferon, doxorubicin, dexamethasone, plasmapheresis, autologous bone marrow transplantation
Polycythemia vera, Essential thrombocytosis	Hydroxyurea, phlebotomy for polycythemia	Busulfan, chlorambucil, cyclophosphamide, alpha interferon, radiophosphorus ³² P
Carcinoma of the lung Small cell	Combination chemotherapy: cisplatin and etoposide. Palliative radiation therapy.	Cyclophosphamide, doxorubicin, vincristine
Non-small cell ³	Localized disease: cisplatin, vinblastine Advanced disease: cisplatin, vinorelbine, docetaxel	Doxorubicin, etoposide, mitomycin, ifosfamide, paclitaxel, radiation therapy
Carcinoma of the head and neck ³	Combination chemotherapy: cisplatin and fluorouracil	Methotrexate, bleomycin, hydroxyurea, doxorubicin, vinblastine
Carcinoma of the esophagus ³	Combination chemotherapy: fluorouracil, cisplatin, mitomycin	Methotrexate, bleomycin, doxorubicin, mitomycin
Carcinoma of the stomach and pancreas ³	Stomach: etoposide, leucovorin, ¹ fluorouracil (ELF) Pancreas: fluorouracil or ELF, gemcitabine	Carmustine, mitomycin, lomustine, doxorubicin, gemcitabine, doxorubicin, methotrexate, cisplatin, combinations for stomach.

Carcinoma of the colon and rectum ³	Colon: fluorouracil plus levamisole (adjuvant) or with leucovorin and irinotecan or oxaliplatin ² (advanced) Rectum: fluorouracil with radiation therapy (adjuvant)	Capecitabine, methotrexate, mitomycin, carmustine, cisplatin, floxuridine.
Carcinoma of the kidney ³	Floxuridine, vinblastine, IL-2, alpha interferon; consider mini-allogeneic transplantation ²	Alpha interferon, progestins, infusional FUDR, fluorouracil
Carcinoma of the bladder ³	Intravesical BCG or thiotepa. Combination chemotherapy: methotrexate, vinblastine, doxorubicin (Adriamycin), cisplatin (M-VAC) or CMV alone	Cyclophosphamide, fluorouracil, intravesical valrubicin, gemcitabine, cisplatin
Carcinoma of the testis ³	Combination chemotherapy: etoposide and cisplatin. Autologous bone marrow transplantation for high-risk or relapsed disease.	Bleomycin, vinblastine, ifosfamide, mesna, ¹ carmustine, carboplatin
Carcinoma of the prostate ³	Estrogens or LHRH analog (leuprolide, goserelin or triptorelin) plus an antiandrogen (flutamide)	Ketoconazole, doxorubicin, aminoglutethimide, progestins, cyclophosphamide, cisplatin, vinblastine, etoposide, suramin ² ; PC-SPES; estramustine phosphate
Carcinoma of the uterus ³	Progestins or tamoxifen	Doxorubicin, cisplatin, fluorouracil, ifosfamide
Carcinoma of the ovary ³	Combination chemotherapy: paclitaxel and cisplatin or carboplatin	Docetaxel, doxorubicin, topotecan, cyclophosphamide, doxorubicin, etoposide, liposomal doxorubicin
Carcinoma of the cervix ³	Combination chemotherapy: methotrexate, doxorubicin, cisplatin, and vinblastine; or mitomycin, bleomycin, vincristine, and cisplatin with radiation therapy	Carboplatin, ifosfamide, lomustine
Carcinoma of the breast ³	Combination chemotherapy: A variety of regimens are used for adjuvant therapy. For node-positive disease—combinations including doxorubicin or epirubicin and at least one of the following additional drugs: 5-FU, cyclophosphamide, docetaxel, paclitaxel . For node-negative disease—a combination of the drugs listed above or cyclophosphamide, methotrexate, and 5-FU (CMF). For estrogen- or progesterone-positive disease, tamoxifen is given for 5 years regardless of the use of adjuvant chemotherapy.	Trastuzumab (Herceptin) with chemotherapy, paclitaxel, docetaxel, epirubicin, mitoxantrone, topotecan, capecitabine, vinorelbine, thiotepa, vincristine, vinblastine, carboplatin or cisplatin, plicamycin, anastrozole, letrozole, exemestane, fulvestrant, toremifene, progestins
Choriocarcinoma (trophoblastic neoplasms) ³	Methotrexate or dactinomycin (or both) plus chlorambucil	Vinblastine, cisplatin, mercaptopurine, doxorubicin, bleomycin, etoposide
Carcinoma of the thyroid gland ³	Radioiodine (¹³¹ I)	Doxorubicin, cisplatin, bleomycin, melphalan
Carcinoma of the adrenal gland ³	Mitotane	Doxorubicin, suramin ²
Carcinoid ³	Fluorouracil plus streptozocin with or without alpha interferon	Doxorubicin, cyclophosphamide, octreotide, cyproheptadine, ¹ methysergide ¹
Osteogenic sarcoma ³	High-dose methotrexate, doxorubicin, vincristine	Cyclophosphamide, ifosfamide, bleomycin, dacarbazine, cisplatin, dactinomycin
Soft tissue sarcoma ³	Doxorubicin, dacarbazine	Ifosfamide, cyclophosphamide, etoposide, cisplatin, high-dose methotrexate, vincristine
Melanoma ³	Dacarbazine, alpha interferon, IL-2	Carmustine, lomustine, melphalan, thiotepa, cisplatin, paclitaxel, tamoxifen, vincristine, vaccine therapy (melacine) ²
Kaposi's sarcoma	Doxorubicin, vincristine alternating with vinblastine or vincristine alone. Palliative radiation therapy.	Alpha interferon, bleomycin, etoposide, doxorubicin
Neuroblastoma ³	Combination chemotherapy: variations of cyclophosphamide, cisplatin, vincristine, doxorubicin, dacarbazine	Melphalan, ifosfamide, autologous or allogeneic bone marrow transplantation

¹Supportive agent; not oncolytic.

²Investigational agent or procedure. Treatment is available through qualified investigators and centers authorized by the National Cancer Institute and Cooperative Oncology Groups.

³These tumors are generally managed initially with surgery with or without radiation therapy with or without adjuvant chemotherapy. For metastatic disease, the role of palliative radiation therapy is as important as that of chemotherapy.

TABLES
Table 40-3. Treatment choices for cancers responsive to systemic agents.

•

Table 40-4. Single-agent dosage and toxicity of anticancer drugs.

Drug	Dosage	Acute Toxicity	Delayed Toxicity
Alkylating agents			
Mechlorethamine	6-10 mg/m ² IV every 3 weeks	Severe vesicant; severe nausea and vomiting	Moderate suppression of blood counts. Melphalan effect may be delayed 4-6 weeks. Excessive doses produce severe bone marrow suppression with leukopenia, thrombocytopenia, and bleeding. Alopecia and hemorrhagic cystitis occur with cyclophosphamide, while busulfan can cause hyperpigmentation, pulmonary fibrosis, and weakness (see text). Ifosfamide is always given with mesna to prevent cystitis. Acute leukemia may develop in 5-10% of patients receiving prolonged therapy with melphalan, mechlorethamine, or chlorambucil; all alkylators probably increase the risk of secondary malignancies with prolonged use. Most cause either temporary or permanent aspermia or amenorrhea.
Chlorambucil	0.1-0.2 mg/kg/d orally (6-12 mg/d) or 0.4 mg/kg pulse every 4 weeks	None	
Cyclophosphamide	100 mg/m ² /d orally for 14 days; 400 mg/m ² orally for 5 days; 1-1.5 g/m ² IV every 3-4 weeks	Nausea and vomiting with higher doses	
Melphalan	0.25 mg/kg/d orally for 4 days every 6 weeks	None	
Busulfan	2-8 mg/d orally; 150-250 mg/course	None	
Estramustine	14 mg/kg orally in 3 or 4 divided doses	Nausea, vomiting, diarrhea	Thrombosis, thrombocytopenia, hypertension, gynecomastia, glucose intolerance, edema.
Carmustine (BCNU)	200 mg/m ² IV every 6 weeks	Local irritant	Prolonged leukopenia and thrombocytopenia. Rarely hepatitis. Acute leukemia has been observed to occur in some patients receiving nitrosoureas. Nitrosoureas can cause delayed pulmonary fibrosis with prolonged use.
Lomustine (CCNU)	100-130 mg orally every 6-8 weeks	Nausea and vomiting	
Procarbazine	100 mg/m ² /d orally for 14 days every 4 weeks	Nausea and vomiting	Bone marrow suppression, mental suppression, MAO inhibition, disulfiram-like effect.
Dacarbazine	250 mg/m ² /d IV for 5 days every 3 weeks; 1500 mg/m ² IV as single dose	Severe nausea and vomiting; anorexia	Bone marrow suppression; flu-like syndrome.
Cisplatin	50-100 mg/m ² IV every 3 weeks; 20 mg/m ² IV for 5 days every 4 weeks	Severe nausea and vomiting	Nephrotoxicity, mild otic and bone marrow toxicity, neurotoxicity.
Carboplatin	360 mg/m ² IV every 4 weeks	Severe nausea and vomiting	Bone marrow suppression, prolonged anemia; same as cisplatin but milder.
Structural analogs or antimetabolites			
Methotrexate	2.5-5 mg/d orally; 20-25 mg IM twice weekly; high-dose: 500-1000 mg/m ² IV every 2-3 weeks; 12-15 mg intrathecally every week for 4-6 doses	None	Bone marrow suppression, oral and gastrointestinal ulceration, acute renal failure; hepatotoxicity, rash, increased toxicity when effusions are present. Note: Citrovorum factor (leucovorin) rescue for doses over 100 mg/m ² .
Mercaptopurine	2.5 mg/kg/d orally; 100 mg/m ² /d orally for 5 days for induction	None	Well tolerated. Larger doses cause bone marrow suppression.
Thioguanine	2 mg/kg/d orally; 100 mg/m ² /d IV for 7 days for induction	Mild nausea, diarrhea	Well tolerated. Larger doses cause bone marrow suppression.
Fluorouracil	15 mg/kg/d IV for 3-5 days every 3 weeks; 15 mg/kg weekly as tolerated; 500-1000 mg/m ² IV every 4 weeks	None	Nausea, diarrhea, oral and gastrointestinal ulceration, bone marrow suppression, dacryocystitis.
Capecitabine	2500 mg/m ² orally twice daily on days 1-14 every 3 weeks	Nausea, diarrhea	Hand and foot syndrome, mucositis.
Cytarabine	100-200 mg/m ² /d for 5-10 days by continuous IV infusion; 2-3 g/m ² IV every 12 hours for 3-7 days; 20 mg/m ² SC daily in divided doses	High-dose: nausea, vomiting, diarrhea, anorexia	Nausea and vomiting; cystitis; severe bone marrow suppression; megaloblastosis; CNS toxicity with high-dose cytarabine.
Temozolamide	150 mg /m ² orally for 5 days; repeat every 4 weeks	Headache, nausea, vomiting	Unknown
Androgens and androgen antagonists			
Testosterone propionate	100 mg IM 3 times weekly	None	Fluid retention, masculinization, leg cramps. Cholestatic jaundice in some patients receiving fluoxymesterone.
Fluoxymesterone	20-40 mg/d orally	None	
Flutamide	250 mg 3 times a day orally	None	Gynecomastia, hot flushes, decreased libido, mild gastrointestinal side effects, hepatotoxicity.
Bicalutamide	50 mg/d orally		
Nilutamide	300 mg/d orally for 30 days, then 150 mg/d		
Ethinyl estradiol	3 mg/d orally	None	Fluid retention, feminization, uterine bleeding, exacerbation of cardiovascular disease, painful gynecomastia, thromboembolic disease.
Selective estrogen receptor modulators			
Tamoxifen	20 mg/d orally in 2 divided doses	Transient flare of bone pain; nausea, hot flushes, joint aching	Thromboembolic disease, anovulation, endometrial cancer, cataracts; vaginal bleeding, acne.
Toremifene	60 mg/d orally		
Aromatase inhibitors			
Anastrozole	1 mg orally daily	Hot flushes, joint aching	Thromboembolic disease, vaginal bleeding.

Letrozole	2.5 mg/d orally		
Exemestane	25 mg/d orally		
Pure estrogen receptor antagonist			
Fulvestrant	250 mg IM once a month	Transient injection site reactions	Nausea, vomiting, constipation, diarrhea, abdominal pain, headache, back pain, hot flushes.
Progestins			
Megestrol acetate	40 mg orally 4 times daily	Hot flushes	Fluid retention; rare thrombosis, weight gain.
Medroxyprogesterone	100-200 mg/d orally; 200-600 mg orally twice weekly	None	
GnRH analogs			
Leuprolide	7.5 mg IM (depot) once a month or 22.5 mg every 3 months as depot injection	Local irritation, transient flare of symptoms	Hot flushes, decreased libido, impotence, gynecomastia, mild gastrointestinal side effects, nausea, diarrhea, fatigue.
Goserelin acetate	3.6 mg SC monthly or 10.8 mg every 3 months as depot injection		
Triptorelin pamoate	3.75 mg IM once a month (a 3-month depot formulation also exists)		
Adrenocorticosteroids			
Prednisone	20-100 mg/d orally or 50-100 mg every other day orally with systemic chemotherapy	Alteration in mood	Fluid retention, hypertension, diabetes, increased susceptibility to infection, "moon facies," osteoporosis, electrolyte abnormalities, gastritis.
Dexamethasone	5-10 mg orally daily or twice daily		
Ketoconazole	400 mg orally 3 times daily	Acute nausea	Gynecomastia, hepatotoxicity
Biologic response modifiers			
Interferon alfa-2a	3-5 million units SC	Fever, chills, fatigue, anorexia	General malaise, weight loss, confusion, hypothyroidism, retinopathy, autoimmune disease
Interferon alfa-2b	3 times weekly or daily		
Aldesleukin (IL-2)	600,000 units/kg IV over 15 minutes every 8 hours for 14 doses, repeated after 9-day rest period. Some doses may be withheld or interrupted because of toxicity. Caution: High doses must be administered in an ICU setting by experienced personnel.	Hypotension, fever, chills, rigors, diarrhea, nausea, vomiting, pruritus; liver, kidney, and CNS toxicity; capillary leak (primarily at high doses), pruritic skin rash, infections (can be severe)	Hypoglycemia, anemia.
Peptide hormone inhibitor			
Octreotide acetate	100-600 µg/d SC in 2 divided doses	Local irritant; nausea and vomiting	Diarrhea, abdominal pain, hypoglycemia.
Natural products and miscellaneous agents			
Vinblastine	0.1-0.2 mg/kg or 6 mg/m ² IV weekly	Mild nausea and vomiting; severe vesicant	Alopecia, peripheral neuropathy, bone marrow suppression, constipation, SIADH, areflexia.
Vincristine	1.5 mg/m ² (maximum: 2 mg weekly)	Severe vesicant	Areflexia, muscle weakness, peripheral neuropathy, paralytic ileus, alopecia (see text), SIADH.
Vinorelbine	30 mg/m ² IV weekly	Mild nausea and vomiting, fatigue, severe vesicant	Granulocytopenia, constipation, peripheral neuropathy, alopecia.
Paclitaxel (Taxol)	135 mg/m ² by continuous infusion over 24 hours every 3 weeks	Hypersensitivity reaction (premedicate with diphenhydramine and dex-amethasone), mildnausea and vomiting	Peripheral neuropathy, bone marrow suppression, fluid retention.
Docetaxel (Taxotere)	60-100 mg/m ² IV every 3 weeks	Nausea, fever, red urine (not hematuria); severe vesicant; acute cardiotoxicity	
Dactinomycin	0.04 mg/kg IV weekly	Nausea and vomiting; severe vesicant	Alopecia, stomatitis, diarrhea, bone marrow suppression.
Daunorubicin	30-60 mg/m ² daily IV for 3 days, or 30-60 mg/m ² IV weekly		Alopecia, stomatitis, bone marrow suppression, late cardiotoxicity. Risk of cardiotoxicity increases with radiation, cyclophosphamide.
Idarubicin	12 mg/m ² daily IV for 3 days		
Doxorubicin	60 mg/m ² IV every 3 weeks to a maximum total dose of 550 mg/m ²		
Epirubicin	60-100 mg/m ² IV every 3 weeks		
Liposomal doxorubicin (Doxil)	20 mg/m ² IV every 3 weeks	Mild nausea	Hand and foot syndrome; alopecia, stomatitis, and bone marrow suppression uncommon.
Liposomal daunorubicin (DaunoXome)	40 mg/m ² IV every 2 weeks		
Etoposide	100 mg/m ² /d IV for 5 days or 50-150 mg/d orally	Nausea and vomiting; occasionally hypotension	Alopecia, bone marrow suppression, secondary leukemia.
Plicamycin (mithramycin)	25-50 µg/kg IV every other day for up to 8 doses	Nausea and vomiting	Thrombocytopenia, diarrhea, hepatotoxicity, nephrotoxicity, stomatitis.
Mitomycin	10-20 mg/m ² every 6-8 weeks	Severe vesicant; nausea	Prolonged bone marrow suppression, rare hemolytic-uremic syndrome.
Mitoxantrone	12-15 mg/m ² /d IV for 3 days with cytarabine; 8-12 mg/m ² IV every 3 weeks	Mild nausea and vomiting	Alopecia, mild mucositis, bone marrow suppression.
Bleomycin	Up to 15 units/m ² IM, IV, or SC twice weekly to a total dose of 200 units/m ²	Allergic reactions, fever, hypotension	Fever, dermatitis, pulmonary fibrosis.
Hydroxyurea	500-1500 mg/d orally	Mild nausea and vomiting	Hyperpigmentation, bone marrow suppression.
Mitotane	6-12 g/d orally	Nausea and vomiting	Dermatitis, diarrhea, mental suppression, muscle tremors.

Fludarabine	25 mg/m ² /d IV for 5 days every 4 weeks	Nausea and vomiting	Bone marrow suppression, diarrhea, mild hepatotoxicity, immune suppression.
Cladribine (CdA)	0.09 mg/kg/d by continuous IV infusion for 7 days	Mild nausea, rash, fatigue	Bone marrow suppression, fever, immune suppression.
Topotecan	1.5 mg/m ² IV daily for 5 days every 3 weeks	Nausea, vomiting, diarrhea, headache, dyspnea	Alopecia, bone marrow suppression.
Gemcitabine	1000 mg/m ² every week up to 7 weeks, then 1 week off, then weekly for 3 out of 4 weeks	Nausea, vomiting, diarrhea, fever, dyspnea	Bone marrow suppression, rash, fluid retention, mouth sores, flu-like symptoms, paresthesias.
Irinotecan	125 mg/m ² weekly for 4 weeks, then a 2-week rest, then repeat	Flushing, salivation, lacrimation, bradycardia, abdominal cramps, diarrhea	Bone marrow suppression, diarrhea.
Novel therapeutic agents			
Imatinib mesylate (STI571; Gleevec)	400-600 mg/d orally	Mild nausea	Myalgias, edema, bone marrow suppression, abnormal liver function tests.
Alemtuzumab (Campath-1H)	30 mg 3 times a week by SC injection for up to 12 weeks. (Use dose escalation to reduce infusion-related events.)	Severe infusion-related events, injection site irritation	Infections, short-term bone marrow suppression, autoimmune hemolytic anemia.
Gemtuzumab ozogamicin (Mylotarg)	9 mg/m ² for 2 doses given 14 days apart	Infusion-related events	Profound bone marrow suppression.
Tretinoin	45 mg/m ² by mouth daily until remission or for 90 days	Retinoic acid syndrome (fever, dyspnea, pleural or pericardial effusion) must be treated emergently with dexamethasone.	Headache, dry skin, rash, flushing.
Arsenic trioxide	Induction: 0.15 mg/kg IV daily until remission; maximum 60 doses Consolidation: 0.15 mg/kgIV daily for 25 doses	Same as tretinoin	Nausea, vomiting, diarrhea, edema.
Trastuzumab (Herceptin)	Load: 4 mg/kg IV followed by 2 mg/kg weekly	Low-grade fever, chills, fatigue, constitutional symptoms with first infusion	Cardiac toxicity, especially when given with anthracyclines.
Denileukin diftitox (ONTAK)	9-10 µg/kg/d IV for 5 days every 21 days	Hypersensitivity type reactions with first infusion	Vascular leak syndrome, low albumin, increased risk of infections, diarrhea, rash.
Rituximab	375 mg/m ² IV weekly for 4-8 doses	Hypersensitivity type reactions with first infusion; fever, tumor lysis syndrome (can be life-threatening)	Mild cytopenias, rare red cell aplasia or aplastic anemia, severe mucocutaneous reactions.
Ibritumomab tiuxetan (Zevalin)	0.3-0.4 mCi/kg (not to exceed 32 mCi); dosing must follow rituximab	Rituximab infusion reaction symptom complex	Prolonged and severe myelosuppression, nausea, vomiting, abdominal pain, arthralgias.
Targretin	300 mg/m ² /d/orally	Nausea	Hyperlipidemia, dry mouth, dry skin, constipation, leukopenia, edema.
Supportive agents			
Allopurinol	300-900 mg/d orally for prevention or relief of hyperuricemia	None	Rash, Stevens-Johnson syndrome; enhances effects and toxicity of mercaptopurine when used in combination.
Mesna	20% of ifosfamide dosage at the time of ifosfamide administration, then 4 and 8 hours after each dose of chemotherapy to prevent hemorrhagic cystitis	Nausea, vomiting, diarrhea	None.
Leucovorin	10 mg/m ² every 6 hours IV or orally until serum methotrexate levels are below 5 × 10 ⁻⁸ mol/L with hydration and urinary alkalinization (about 72 hours)	None	Enhances toxic effects of fluorouracil.
Amifostine	910 mg/m ² IV daily, 30 minutes prior to chemotherapy	Hypotension, nausea, vomiting, flushing	Decrease in serum calcium.
Dexrazoxane	10:1 ratio of anthracycline IV, before (within 30 minutes of) chemotherapy infusion	Pain on injection	Increased bone marrow suppression.

Figure 40-1. Signaling through growth factor receptors can be blocked by antibodies to either the growth factor (ligand) **(A)** (eg, antibody to VEGF; bevacizumab) or to the extracellular portion of the receptor for the growth factor (tyrosine kinase receptor) **(B)** (eg, trastuzumab, cetuximab). The binding of growth factors to their receptors **(C)** leads to phosphorylation of the intracellular portion of the receptor or the receptor tyrosine kinase **(D)**. Phosphorylation activates the receptor and results in many downstream signals in the cell that activate gene transcription, and consequently proliferation. Blockade of receptor phosphorylation—eg, by erlotinib or gemfitinib (oral small molecule tyrosine kinase inhibitors)—interrupts the pathway, with the hoped-for result of blocking tumor growth.

■ INTRODUCTION

The rapid and in some cases spectacular advances in human genetics during the past decade have had important implications for clinical medicine. Familiarity with the fundamental principles of both basic and clinical genetics is now necessary if the clinician is to provide a high standard of care. Virtually all of the 3 billion nucleotides of the human genome have been sequenced. The great hope, of course, is that with this exponential growth in information will come new insights into the causes and pathogenetic mechanisms of human disease, more accurate diagnosis, and effective treatment for many disorders now considered beyond the practitioner's therapeutic reach. Along with this optimistic prospect, however, have come some urgent concerns about (1) the ethical, legal, and sociologic implications of what has been termed "genetic engineering" but is better and more broadly called "molecular medicine"; (2) the problem for medical educators of how best to transmit such an enormous body of information to their students and to primary care practitioners; and (3) the seemingly esoteric nature of much of that information paired with the realization that any one of the obscure facts of medical genetics might achieve clinical relevance at any time.

■ INTRODUCTION TO MEDICAL GENETICS

Physicians at one time concerned themselves only with what they could discover by bedside evaluation and laboratory investigation. In the parlance of genetics, the patient's symptoms and signs constitute his or her **phenotype**. Now the means are at hand for defining a person's **genotype**, the actual information content inscribed in the 2 meters of coiled DNA present in each cell of the body—or half that amount in every mature ovum or sperm. Virtually all phenotypic characteristics—and this includes diseases as well as human traits such as personality, adult height, and intelligence—are to some extent determined by the genes. The importance of the genetic contribution varies widely among human phenotypes, and methods are only now being developed to identify the genes involved in complex traits and most common diseases. Moreover, the importance of interactions between environment and genotype in producing phenotypes cannot be overstated despite the obscurity of the actual mechanisms.

The billions of nucleotides in the nucleus of a cell are organized linearly along the DNA double helix in functional units called **genes**, and each of the 35,000-50,000 human genes is accompanied by various regulatory elements that control when it is active in producing **messenger RNA (mRNA)** by a process called **transcription**. In most situations, mRNA is transported from the nucleus to the cytoplasm, where its genetic information is **translated** into **proteins**, which perform the functions that ultimately determine phenotype. For example, proteins serve as enzymes that facilitate metabolism and cell synthesis; as DNA binding elements that regulate transcription of other genes; as structural elements of cells and the extracellular matrix; and as receptor molecules for intra- and intercellular communication.

Chromosomes are the vehicles in which the genes are carried from generation to generation. Each chromosome is a complex of protein and nucleic acid in which an unbroken double helix of DNA is coiled and supercoiled into a space many orders of magnitude less than the extended length of the DNA. Within the chromosome there occur highly complicated and integrated processes, including DNA replication, recombination, and transcription. In the nucleus of each somatic cell, humans normally have 46 chromosomes, which are arranged in 23 pairs. One of these pairs, the **sex chromosomes** X and Y, determines the sex of the individual; females have the pair XX and males the pair XY. The remaining 22 pairs are called **autosomes** ([Figure 41-1](#)). In addition to these nuclear chromosomes, each mitochondrion—found in varying numbers in the cytoplasm of all cells—contains multiple copies of a small chromosome. This **mitochondrial chromosome** encodes a few of the proteins for oxidative metabolism and all of the transfer RNAs used in translation of proteins within this organelle. Mitochondrial chromosomes are inherited almost entirely from the cytoplasm of the fertilized ovum and are therefore maternal in origin.

In all somatic cells, the 44 autosomes and one of the X chromosomes are transcriptionally active. In males, the active X is the only X; portions of the Y chromosome are also active. In females, the requirement for **dosage compensation** (to be equivalent to the situation in males) is satisfied by inactivation of most of one X chromosome early in embryogenesis. This process of X chromosomal inactivation, while incompletely understood, is known to be random, so that on average, in 50% of a female's cells, one of the X chromosomes will be active, and in the other 50% the **homologous** member of the pair will be active. The phenotype of the cell is determined by which genes on the chromosomes are active in producing mRNA at any given time.

GENES & CHROMOSOMES

In all genes, information is contained in parcels called **exons**, which are interspersed with stretches of DNA called **introns** that do not encode any information about the protein sequence. However, introns may contain genetic regulatory sequences, and some introns are so large that they encode an entirely distinct gene.

The exact location of a gene on a chromosome is its **locus**, and the array of loci constitutes the **human gene map**. Currently, the chromosomal sites of more than 8300 genes (for which normal or abnormal function has been identified) are known, often to a high degree of resolution. A variation of this map, identifying selected loci known to be involved in human disease, is shown in [Figure 41-2](#). The difference in the higher resolution of the ordering of genes achievable by molecular techniques (such as linkage analysis) compared to cytogenetic techniques (such as visualization of small defects) is substantial, though the gap is narrowing. The chromosomes in the "standard" karyotype shown in [Figure 41-1](#) have about 450 visible bands; under the best of cytologic and microscopic conditions, a total of about 1600 bands can be seen. But even in this extended configuration, each band contains dozens—sometimes hundreds—of individual genes. Thus, loss (**deletion**) of a small band will involve loss of many coding sequences and will have diverse effects on the phenotype.

The number and arrangement of genes on homologous chromosomes are identical even though the actual coding sequences of homologous genes may not be. Homologous copies of a gene are termed **alleles**. In comparing alleles, it must be specified at what level of analysis the comparison is being made. When alleles are truly identical—in that their coding sequences are invariant—the individual is **homozygous** at that locus. At a coarser level, the alleles may be functionally identical despite subtle variations in nucleotide sequence—with the result either that the proteins produced from the two alleles are identical or that whatever differences there may be in amino acid sequence will have no bearing on the function of the protein. If the individual is being analyzed at the level of the protein phenotype, allelic homozygosity would again be an apt descriptor. However, if the analysis were at the level of the DNA—as occurs in restriction enzyme examination or nucleotide sequencing—then, despite functional identity, the alleles would be viewed as different and the individual would be **heterozygous** for that locus. Heterozygosity based on differences in the protein products of alleles has been detectable for decades and was the first hard evidence concerning the high degree of human biologic variability. In the past decade, analysis of DNA sequences has shown this variability to be much more remarkable—differences in nucleotide sequence between individuals occur about once every 400 nucleotides.

MUTATION

Allelic heterozygosity most often results when different alleles are inherited from the egg and the sperm, but it also occurs as a consequence of spontaneous alteration in nucleotide sequence (**mutation**). Genetic change occurring during formation of an egg or a sperm is called a **germinal mutation**. When the change occurs after conception—from the earliest stages of embryogenesis to dividing cells in the body of the oldest adult—it is termed a **somatic mutation**. As is discussed below, the role of somatic mutation in the etiology of human disease is now increasingly recognized.

The coarsest type of mutation is alteration in the number or physical structure of chromosomes. For example, **nondisjunction** (failure of chromosome pairs to separate) during **meiosis**—the reduction division that leads to production of mature ova and sperms—causes the embryo to have too many or too few chromosomes, a situation called **aneuploidy**. Rearrangement of chromosome arms, such as occurs in **translocation** or **inversion**, is a mutation even if breakage and reunion does not disrupt any coding sequence. Thus, the phenotypic effect of gross chromosomal mutations can range from profound (as in aneuploidy) to nil.

A bit less coarse, but still detectable cytologically, are **deletions** of part of a chromosome. Such mutations almost always alter phenotype, because a number of genes

are lost; however, a deletion may involve only a single nucleotide, whereas about 1-2 million nucleotides (1-2 megabases) must be lost before the defect can be visualized by the most sensitive cytogenetic methods short of in situ hybridization. Molecular biologic techniques are needed to detect smaller losses.

Mutations of one or a few nucleotides in exons have several potential consequences. Changes in one nucleotide can alter which amino acid is encoded; if the amino acid is in a critical region of the protein, function might in this way be severely disturbed (eg, sickle cell disease). On the other hand, some amino acid substitutions have no detectable effect on function, and the phenotype is therefore unaltered by the mutation. Similarly, because the genetic code is **degenerate** (two or more different three-nucleotide sequences called **codons** encode the same amino acids), nucleotide substitution does not necessarily alter the amino acid sequence of the protein. Three specific codons signal termination of translation; thus, a nucleotide substitution in an exon that generates one of the stop codons usually causes a truncated protein, which is nearly always dysfunctional. Other nucleotide substitutions can disrupt the signals that direct splicing of the mRNA molecule and grossly alter the protein product. Finally, insertions and deletions of one or more nucleotides can have dramatic effects—any change that is not a multiple of three nucleotides disrupts the reading frame of the remainder of the exon—or potentially minimal effects (if the protein can tolerate the insertion or loss of an amino acid).

Mutations in introns may disrupt mRNA splicing signals or may be entirely silent with respect to the phenotype. A great deal of variation in nucleotide sequences among individuals (averaging one difference every few hundred nucleotides) resides within introns. Mutations in the DNA between adjacent genes may also be silent or may have a profound effect on phenotype if regulatory sequences are disrupted. A novel mechanism for mutation, which also helps explain clinical variation among relatives, has been discovered in myotonic dystrophy, Huntington's disease, fragile X mental retardation syndrome, Friedreich's ataxia, and other disorders. A region of repeated trinucleotide sequences close to or within a gene can be unstable in some families; expansion of the number of repeated units within this segment beyond a critical threshold is associated with a more severe phenotype, a phenomenon termed **anticipation**.

Mutations may occur spontaneously or may be induced by such environmental factors as radiation, medication, or viral infections. Both advanced maternal and paternal age favor mutation, but of different types. In women, meiosis is completed only when an egg ovulates, and chromosomal nondisjunction is more common the older the egg. The risk that an aneuploid egg will result increases exponentially and becomes a major clinical worry for women older than their early 30s. In men, mutations of a subtler sort—affecting nucleotide sequences—increase with age. Offspring of men over 40 are at an increased risk of having mendelian conditions, primarily autosomal dominant ones.

GENES IN INDIVIDUALS

For some quantitative traits such as adult height or serum glucose concentration in normal individuals, it is virtually impossible to distinguish the contributions of individual genes; this is because in general, phenotypes are the products of multiple genes acting in concert. However, if one of the genes in the system is aberrant, a major departure from the "normal" or expected phenotype might arise. Whether the aberrant phenotype is serious (ie, a disease) or even recognized will depend on the nature of the defective gene product and how resilient the system is to disruption. The latter point emphasizes the importance of homeostasis in both physiology and development—many mutations go unrecognized because the system can cope, even though tolerances for further perturbation might be narrowed.

In other words, virtually all human characteristics are **polygenic**, while many of the disordered phenotypes thought of as "genetic" are **monogenic** but still influenced by other loci in a person's genome.

Phenotypes due to alterations at a single gene are also characterized as **mendelian**, after the monk and part-time biologist who studied the reproducibility and recurrence of variation in garden peas. Gregor Mendel showed that some traits were **dominant** to others, which he called **recessive**. The dominant traits required only one copy of a "factor" to be expressed, regardless of what the other copy was, whereas the recessive traits required two copies before expression occurred. In modern terms, the mendelian factors are genes, and the alternative copies of the gene are alleles. Let *A* be the common (normal) allele and let *a* be a mutant allele at a locus: If the same phenotype is present no matter whether the genotype is *A/a* or *a/a*, the phenotype is dominant, whereas if the phenotype is present only when the genotype is *a/a*, it is recessive.

In medicine, it is important to keep two considerations in mind: First, dominance and recessiveness are attributes of the phenotype, not the gene; and second, the concepts of dominance and recessiveness depend on how one defines the phenotype. To illustrate both points, consider sickle cell disease. This condition occurs when a person inherits two alleles for β^S -globin, in which the normal glutamate at position 6 of the protein has been replaced by valine; the genotype for the β -globin locus is *HbS/HbS*, compared to the normal *HbA/HbA*. When the genotype is *HbS/HbA*, the individual does not have sickle cell disease, so this condition satisfies the criteria for being a recessive phenotype. But now consider the phenotype of sickled erythrocytes. Red cells with the genotype *HbS/HbS* clearly sickle—but, if the oxygen tension is reduced, so do cells with the genotype *HbS/HbA*. Therefore, sickling is a dominant trait.

A mendelian phenotype is characterized not only in terms of dominance and recessiveness but also according to whether the determining gene is on the X chromosome or on one of the 22 pairs of autosomes. Traits or diseases are therefore called autosomal dominant, autosomal recessive, X-linked recessive, and X-linked dominant.

GENES IN FAMILIES

Since the first decade of this century, the patterns of recurrence of specific human phenotypes have been explained in terms of principles first described by Mendel in the garden pea plant. Mendel's second principle—usually referred to as his first*—is called the **law of segregation** and states that a pair of factors (alleles) that determines some trait separates (segregates) during formation of gametes. In simple terms, a heterozygous (*A/a*) person will produce two types of gametes with respect to this locus—one containing only *A* and one containing only *a*, in equal proportions. Offspring of this person will have a 50-50 chance of inheriting the *A* allele and a similar chance of inheriting the *a* allele.

The concepts of genes in individuals and in families can be combined to specify how mendelian traits will be inherited.

*Mendel's first law stated that—from the perspective of the phenotype—it mattered not from which parent a particular mutant allele was inherited. For years this principle was thought to be too obvious to be codified as anybody's "law" and was therefore ignored. In fact, however, recent evidence from studies of human disorders suggests that certain genes are "processed" (**imprinted**) as they move through the gonad and that processing in the testis is different from that in the ovary. Thus, not only is this first mendelian principle important, it was incorrect as originally formulated from observations in peas.

Autosomal Dominant Inheritance

The characteristics of autosomal dominant inheritance in humans can be summarized as follows: (1) There is a vertical pattern in the pedigree, with multiple generations affected ([Figure 41-3](#)). (2) Heterozygotes for the mutant allele show an abnormal phenotype. (3) Males and females are affected with equal frequency and severity. (4) Only one parent must be affected for an offspring to be at risk for developing the phenotype. (5) When an affected person mates with an unaffected one, each offspring has a 50% chance of inheriting the affected phenotype. This is true regardless of the sex of the affected parent—specifically, male-to-male transmission occurs. (6) The frequency of sporadic cases is positively associated with the severity of the phenotype. More precisely, the greater the **reproductive fitness** of affected persons, the less likely it is that any given case resulted from a new mutation. (7) The average age of fathers is advanced in the case of isolated (sporadic or new mutation) cases.

Autosomal dominant phenotypes are often age-dependent, less severe than autosomal recessive ones, and associated with malformations or other physical features. They are **pleiotropic** in that multiple, even seemingly unrelated clinical manifestations derive from the same mutation; and **variable** in that expression of the same mutation among people will differ.

Penetrance is a concept associated with mendelian conditions—especially dominant ones—and the term is often misused. It should be defined as an expression of the

frequency of appearance of a phenotype (dominant or recessive) when one or more mutant alleles are present. For individuals, penetrance is an all-or-none phenomenon—the phenotype is either present (penetrant) or not (nonpenetrant). The term **variability**—not "incomplete penetrance"—should be used to denote differences in expression of an allele.

The most frequent cause of apparent nonpenetrance is insensitivity of the methods for detecting the phenotype. If an apparently normal parent of a child with a dominant condition were in fact heterozygous for the mutation, the parent would have a 50% chance at each subsequent conception of having another affected child. A common cause of nonpenetrance in adult-onset mendelian diseases is death of the affected person before the phenotype becomes evident but after transmission of the mutant allele to offspring. Thus, accurate genetic counseling demands careful attention to the family medical history and high-resolution scrutiny of both parents of a child with a condition known to be a mendelian dominant trait.

When both alleles are expressed in the heterozygote, as in blood group AB, in sickle trait (HbS/HbA), in the major histocompatibility antigens (eg, A2B5/A3B17), or in sickle-C disease (HbS/HbC), the phenotype is called **codominant**.

In human dominant phenotypes, the homozygous state for the mutant allele is almost always more severe than in heterozygotes.

Autosomal Recessive Inheritance

The characteristics of autosomal recessive inheritance in humans can be summarized as follows: (1) There is a horizontal pattern in the pedigree, with a single generation affected ([Figure 41-4](#)). (2) Males and females are affected with equal frequency and severity. (3) Inheritance is from both parents, each a heterozygote (carrier) and each usually clinically unaffected. (4) Each offspring of two carriers has a 25% chance of being affected, a 50% chance of being a carrier, and a 25% chance of inheriting neither mutant allele. Thus, two-thirds of all clinically unaffected offspring are carriers. (5) In matings between individuals, each with the same recessive phenotype, all offspring will be affected. (6) Affected individuals who mate with unaffected individuals who are not carriers have only unaffected offspring. (7) The rarer the recessive phenotype, the more likely it is that the parents are **consanguineous** (related).

Autosomal recessive phenotypes are often associated with deficient activity of enzymes and are thus termed **inborn errors of metabolism**. Such disorders include phenylketonuria, Tay-Sachs disease, and the various glycogen storage diseases and tend to be more severe, less variable, and less age-dependent than dominant conditions.

When an autosomal recessive condition is quite rare, the chance that the parents of affected offspring are consanguineous is increased. As a result, the prevalence of rare recessive conditions is high among inbred groups such as the Old Order Amish. On the other hand, when the autosomal recessive condition is common, the chance of consanguinity between parents of cases is no higher than in the general population (about 0.5%).

Two different *mutant* alleles at the same locus, as in HbS/HbC, form a **genetic compound** (compound heterozygote). The phenotype usually lies between those produced by either allele present in the homozygous state. Because of the large number of mutations possible in a given gene, many autosomal recessive phenotypes are probably due to genetic compounds. Sickle cell disease is an exception. Consanguinity is strong presumptive evidence for true homozygosity of mutant alleles and against a genetic compound.

X-Linked Inheritance

The general characteristics of X-linked inheritance in humans can be summarized as follows: (1) There is no male-to-male transmission of the phenotype ([Figure 41-5](#)). (2) Unaffected males do not transmit the phenotype. (3) All of the daughters of an affected male are heterozygous carriers. (4) Males are usually more severely affected than females. (5) Whether a heterozygous female is counted as affected—and whether the phenotype is called "recessive" or "dominant"—depends often on the sensitivity of the assay or examination. (6) Some mothers of affected males will not themselves be heterozygotes (ie, they will be homozygous normal) but will have a germinal mutation. The proportion of heterozygous (carrier) mothers is negatively associated with the severity of the condition. (7) Heterozygous women transmit the mutant gene to one-half of sons, who are affected, and to one-half of daughters, who are heterozygotes. (8) If an affected male mates with a heterozygous female, half of the male offspring will be affected, giving the false impression of male-to-male transmission. One-half of the female offspring of such matings will be affected as severely as the average hemizygous male; in small pedigrees, this pattern may simulate autosomal dominant inheritance.

The characteristics of X-linked inheritance depend on phenotypic severity. For some disorders, affected males do not survive to reproduce. In such cases, about two-thirds of affected males have a carrier mother; in the remaining third, the disorder arises by new germinal mutation in an X chromosome of the mother. When the disorder is nearly always manifest in heterozygous females (X-linked dominant inheritance), females tend to be affected about twice as often as males; and on average an affected female transmits the phenotype to half of her sons and half of her daughters.

X-linked phenotypes are often clinically variable—particularly in heterozygous females—and suspected of being autosomal dominant with nonpenetrance. For example, Fabry's disease (a-galactosidase A deficiency) may be clinically silent in carrier women or may cause stroke, renal failure, or myocardial infarction by middle age.

Germinal mosaicism occurs in mothers of boys with X-linked conditions. The chance of such a mother having a second affected son or a heterozygous daughter depends on the fraction of her oocytes that carries the mutation. Currently, this fraction is impossible to determine. However, the presence of germinal mosaicism can be detected in some conditions (eg, Duchenne's muscular dystrophy) in a family by analysis of DNA, and this knowledge becomes crucial for genetic counseling.

Mitochondrial Inheritance

Mutations in the genes encoded by the mitochondrial chromosome cause a variety of diseases that affect (in particular) organs highly dependent on oxidative metabolism, such as the retina, brain, kidneys, and heart. Because a person's mitochondria derive virtually entirely from the ovum, the inheritance pattern is distinct from that of mendelian disorders and is termed "maternal" or, more appropriately, "mitochondrial." An affected woman can pass the defective mitochondrial chromosome to all of her offspring, whereas an affected man has virtually no risk of passing his mutation to a child ([Figure 41-6](#)). Because each cell and the ovum contain many mitochondria and because each mitochondrion contains many chromosomes, two situations are possible: If every chromosome in every mitochondrion carries the same mutation, the person is said to be **homoplasmic** for the mutation. On the other hand, if only some of the mitochondrial chromosomes carry the mutation, the person is **heteroplasmic**. In the latter case, an offspring may inherit relatively few mitochondria bearing the mutation and have mild disease or no disease.

Over 14,000 human genes have been identified through their phenotypes and inheritance patterns in families. This total represents 20-30% of all genes thought to be encoded by the 22 autosomes, two sex chromosomes, and the mitochondrial chromosome. Victor McKusick coordinates an international effort to catalogue human mendelian variation.

DISORDERS OF MULTIFACTORIAL CAUSATION

Many disorders cluster in families but are not associated with evident chromosomal aberrations or mendelian inheritance patterns. Examples include congenital malformations such as cleft lip, pyloric stenosis, and spina bifida; coronary artery disease; type 2 diabetes mellitus; and various forms of neoplasia. They are often characterized by varying frequencies in different racial or ethnic groups, disparity in sexual predilection, and greater frequency (but less than full concordance) in monozygotic than in dizygotic twins. This inheritance pattern is called "multifactorial" to signify that multiple genes interact with various environmental agents to produce the phenotype. The familial clustering is assumed to be due to sharing of both alleles and environment.

For most multifactorial conditions, there is little understanding of which particular genes are involved, how they and their products interact, and in what way different nongenetic factors contribute to the phenotype. For some disorders, biochemical and genetic studies have identified mendelian conditions within the coarse phenotype: Defects of the low-density lipoprotein receptor account for a small fraction of cases of ischemic heart disease (a larger fraction if only patients under age 50 are

considered); familial polyposis of the colon predisposes to adenocarcinoma; and some patients with emphysema have inherited deficiency of α_1 -proteinase inhibitor. Despite these notable examples, this reductionistic preoccupation with mendelian phenotypes is unlikely to explain the great majority of human disease; but even so, in the last analysis, much of human pathology will prove to be associated with genetic factors in cause, pathogenesis, or both.

Our ignorance about fundamental genetic mechanisms in development and physiology has not completely restricted practical approaches to the genetics of multifactorial disorders. For example, recurrence risks are based on empirical data derived from observation of many families. The risk of recurrence of multifactorial disorders is increased in several instances: (1) in close relatives (sibs, offspring, and parents) of an affected individual; (2) when two or more members of a family have the same condition; (3) when the first case in a family is in the less commonly affected sex (eg, pyloric stenosis is five times more common in boys; an affected woman has a three- to fourfold greater risk of having a child with pyloric stenosis); and (4) in ethnic groups in which there is a high incidence of a particular condition (eg, spina bifida is 40 times more common in Caucasians—and even more frequent among the Irish—than in Asians).

For many apparently multifactorial disorders, enough families have not been examined to have established empirical risk data. A useful approximation of recurrence risk in close relatives is the square root of the incidence. For example, many common congenital malformations have an incidence of 1:2500 to 1:400 live births; the calculated recurrence risks are thus in the 2-5% range—values that correspond closely to experience.

CHROMOSOMAL ABERRATIONS

Any deviation from the structure and number of chromosomes as displayed in [Figure 41-1](#) is, technically, a chromosomal aberration. Not all aberrations cause problems in the affected individual, but some that do not may lead to problems in offspring. About 1:200 live-born infants have a chromosomal aberration that is detected because of some effect on phenotype. This frequency increases markedly the earlier in fetal life the chromosomes are examined. By the end of the first trimester of gestation, most fetuses with abnormal numbers of chromosomes have been lost through spontaneous abortion. For example, Turner's syndrome—due to absence of one sex chromosome and the presence of a single X chromosome—is a relatively common condition, but it is estimated that only 2% of fetuses with this form of aneuploidy survive to term. Even more striking in live-born children is the complete absence of most autosomal trisomies and monosomies despite their frequent occurrence in young fetuses.

Types of Chromosomal Abnormalities

Major structural changes occur in either **balanced** or **unbalanced** form. In the latter, there is a gain or loss of genetic material; in the former, there is no change in the amount of genetic material but only a rearrangement of it. At the sites of breaks and new attachments of chromosome fragments, there may be permanent structural or functional damage to one gene or to only a few genes. Despite no visible loss of material, the aberration may nonetheless be recognized as unbalanced through an abnormal phenotype and the chromosomal defect confirmed by molecular analysis of the DNA.

Aneuploidy results from nondisjunction—the failure of a chromatid pair to separate in a dividing cell. Nondisjunction in either the first or second division of meiosis results in gametes with abnormal chromosomal constitutions. In aneuploidy, more or fewer than 46 chromosomes are present ([Table 41-1](#)). The following are all forms of aneuploidy: (1) **monosomy**, in which only one member of a pair of chromosomes is present; (2) **trisomy**, in which three chromosomes are present instead of two; and (3) **polysomy**, in which one chromosome is represented four or more times.

If nondisjunction occurs in mitosis, **mosaic** patterns occur in somatic tissue, with some cells having one karyotype and other cells of the same organism another karyotype. Patients with a mosaic genetic constitution often have manifestations of each of the genetic syndromes associated with the various abnormal karyotypes.

Translocation results from an exchange of parts of two chromosomes.

Deletion is loss of chromosomal material.

Duplication is the presence of two or more copies of the same region of a given chromosome. The redundancy may occur in the same chromosome or in a nonhomologous chromosome. In the latter case, a translocation will also have occurred.

An **isochromosome** is one in which the arms on either side of the centromere have the same genetic material in the same order—ie, the chromosome has at some time divided in such a way that it has a double dose of one arm and absence of the other.

In an **inversion**, a chromosomal region becomes reoriented 180 degrees out of ordinary phase. The same genetic material is present, but in a different order.

■ THE TECHNIQUES OF MEDICAL GENETICS

Hereditary disorders affect multiple organ systems and people of all ages. Many disorders are chronic ones, but often there are acute crises. The concerns of patients and families span a wide range of medical, psychologic, social, and economic issues. These characteristics emphasize the need for pediatricians, internists, obstetricians, and family practitioners to provide medical genetics services for their patients. This section reviews the laboratory and consultative services available from clinical geneticists and the indications for their use.

FAMILY HISTORY & PEDIGREE ANALYSIS

The first step in considering how important genetic factors might be in the clinical situation of a patient is obtaining a detailed family history. At a minimum, a patient should be queried in detail about all first-degree relatives—parents, sibs, and offspring—(age, sex, health status if alive, including major illnesses; cause of death), and more distant relatives with reference to the particular condition at issue. Ethnicity of both sides of the family should be noted; any disorders known to be especially prevalent in a particular ethnic group should be asked about specifically. Once the family history is obtained, it should be analyzed; medical geneticists and genetic counselors are trained in this task and are especially valuable when the busy clinician has neither the time nor the staff to pursue the information. A pedigree diagram (eg, [Figure 41-3](#)) with the symbols filled in to indicate the presence of a condition can be instructive in suggesting a mode of inheritance. Once targeted genetic testing of the **proband** produces a result, the diagram also proves useful in identifying relatives who might benefit from counseling about similar testing.

CYTOGENETICS

Cytogenetics is the study of chromosomes by light microscopy. The chromosomal constitution of a single cell or an entire individual is specified by a standardized notation. The total chromosome count is determined first, followed by the sex chromosome complement and then by any abnormalities. The autosomes are all designated by numbers from 1 to 22. A plus (+) or minus (-) sign indicates, respectively, a gain or loss of chromosomal material. For example, a normal male is 46,XY, while a girl with Down's syndrome caused by trisomy 21 is 47,XX,+21; a boy with Down's syndrome caused by translocation of chromosome 21 to chromosome 14 in a sperm or an egg is 46,XY, -14,+t(14;21).

Chromosomal analyses are done by growing human cells in tissue culture, chemically inhibiting mitosis, and then staining, observing, photographing, sorting, and counting the chromosomes. The display of all of the chromosomes is termed the **karyotype** ([Figure 41-1](#)) and is the end result of the technical aspect of cytogenetics.

Specimens for cytogenetic analysis can be obtained for routine analysis from the peripheral blood, in which case T lymphocytes are examined; from amniotic fluid for culture of amniocytes; from trophoblastic cells from the chorionic villus; from bone marrow; and from cultured fibroblasts, usually obtained from a skin biopsy. Enough cells must be examined so that the chance of missing a cytogenetically distinct cell line (a situation of mosaicism) is statistically low. For most clinical indications, 20 mitoses are examined and counted under direct microscopic visualization, and two are photographed and karyotypes prepared. Observation of aberrations usually prompts more extended scrutiny and in many cases further analysis of the original culture.

A variety of methods can be used to reveal banding patterns—unique to each pair of chromosomes—in the analysis of aberrations. The number of bands that can be visualized is a function of how "extended" the chromosomes are, which in turn depends chiefly on how early in metaphase (or even in prophase for the most extensive banding) mitosis was arrested. The "standard" karyotype reveals about 400 bands per haploid set of chromosomes, whereas a prophase karyotype might reveal four times that number. As invaluable as extended karyotypes are in certain clinical circumstances, their interpretation is often difficult—in terms of the time and effort

required and of ambiguity about what is abnormal, what is a normal variation, and what is a technical artifact. In situ hybridization with DNA probes for specific chromosomes or regions of chromosomes can be labeled and used to identify subtle aberrations. Given proper technique, fluorescent in situ hybridization (FISH) yields sensitivities and specificities of virtually 100%. Some applications are being used routinely and marketed commercially, though the FDA has only recently begun to approve probes for clinical use.

An area of particular relevance is the use of FISH to detect heretofore undetectable deletions in the regions of chromosomes just proximal to their tips (subtelomeric). A remarkable number of patients with unexplained mental retardation or dysmorphology have been found to have such deletions, either because of de novo mutation or because of rearrangements due to balanced parental translocations.

Indications for Cytogenetic Analysis

The current indications are listed in [Table 41-2](#). A wide array of clinical syndromes have been found to be associated with chromosomal aberrations, and analysis of the karyotype is useful any time a patient is discovered to have the manifestations of one of these syndromes. When a chromosomal aberration is revealed, not only does the patient's physician obtain valuable information about prognosis, but the parents gain insight into the cause of their child's problems and the family can be counseled accurately—and usually reassured—about the risks of recurrence.

Mental retardation is a frequent component of congenital malformation syndromes. Any person with unexplained mental retardation should be studied by chromosomal analysis.

The tips of chromosomes are called **telomers**. Recent studies using fluorescent probes for the genetic sequences just proximal to the telomers have shown subtle rearrangements or deletions in about 6% of patients who have otherwise unexplained mental retardation with or without dysmorphic features. These chromosomal aberrations are generally too small to be detected by routine cytogenetic analysis.

Abnormalities of sexual differentiation can only be understood once the patient's **genetic sex** is clarified. Hormonal therapy and plastic surgery can to some extent determine **phenotypic sex**, but genetic sex is dictated by the complement of sex chromosomes. The best-known example of dichotomy between the genetic sex and phenotypic sex is the **testicular feminization syndrome**, in which the chromosomal constitution is 46,XY but, because of a defect in the testosterone receptor protein (specified by a gene on the Y chromosome), the external phenotype is completely female.

Failure or delay in developing secondary sexual characteristics occurs in **Turner's syndrome** (the most common cause being a form of aneuploidy, ie, monosomy for the X chromosome, 45,X), in **Klinefelter's syndrome** (the most common karyotype is 47,XXY), and in other much rarer chromosomal aberrations.

Tall stature is perhaps the only consistent phenotypic feature associated with having an **extra Y chromosome** (karyotype 47,XYY); most men with this chromosomal aberration lead normal lives, and thus tall stature in a male is itself no indication for chromosomal analysis. However, some evidence suggests that an increased prevalence of learning difficulties may be associated with this aberration. Furthermore, Klinefelter's syndrome often causes tall stature, albeit with a eunuchoid habitus, and learning and behavioral problems. Thus, the combination of learning or behavioral difficulties and unexpectedly increased height in a male should prompt consideration of cytogenetic analysis.

As discussed below, most tumors are associated with chromosomal aberrations, some of which are highly specific for certain malignancies. Cytogenetic analysis of tumor tissue may assist in diagnosis, prognosis, and management.

Whenever a person is shown to have a chromosome translocation—whether it be balanced and asymptomatic or unbalanced, causing a syndrome—the physician should consider the importance of identifying the source of the translocation. If the proband is a child and the parents are interested in having more children, both parents should be studied cytogenetically. How far the primary physician or consultant should go in tracking a translocation through a family is an unsettled question with legal and ethical as well as medical implications. Certainly the proband (if an adult) or the parents of the proband need to be counseled and the potential risks to relatives discussed. The physician should document, both in the medical record and by correspondence, that the burden of disclosing relevant data to the extended family has been assumed by specific named individuals.

Inability to produce offspring, either through failure to conceive or as a result of repeated miscarriages, is a frustrating and discouraging problem for affected couples and their physicians. Considerable progress in the urologic and gynecologic understanding of infertility has benefited many couples. However, chromosomal aberrations remain an important problem in reproductive medicine, and cytogenetic analysis should be utilized at some stage in extended evaluation. Infertility is common in both Klinefelter's and Turner's syndromes, either of which may be associated with mild external signs—particularly if the chromosomal aberration is mosaic. Any early spontaneous abortion may be due to fetal aneuploidy. Recurrence may be due to parental translocation predisposing to an unbalanced fetal karyotype.

BIOCHEMICAL GENETICS

Biochemical genetics deals not only with enzymatic defects but also with proteins of all functions, including cytoskeletal and extracellular structure, regulation, and receptors. The principal functions of the biochemical genetics laboratory are to determine the presence or absence of proteins, to assess the qualitative characteristics of proteins, and to verify the effectiveness of proteins in vitro. The key elements from the referring clinician's perspective are (1) to indicate what the suspected clinical diagnoses are and (2) to make certain that the proper specimen is obtained and transported to the laboratory in a timely manner.

Indications for Biochemical Investigations

Some inborn errors are relatively common in the general population, eg, hemochromatosis, defects of the low-density lipoprotein receptor, and cystic fibrosis ([Table 41-3](#)). Others, while rare across the entire population, are common in certain ethnic groups, such as Tay-Sachs disease in Ashkenazic Jews, sickle cell disease in African-Americans, and thalassemias in populations from around the Mediterranean basin and Asia. Many of these disorders are autosomal recessive, and the frequency of heterozygotes is many times that of the fully expressed disease. Screening for carrier status can be effective if certain requirements are satisfied ([Table 41-4](#)). For example, all of the United States and the District of Columbia require screening of newborns for phenylketonuria and often other metabolic diseases. Such programs are cost-effective even for rare conditions such as phenylketonuria, which occurs in only one of every 11,000 births. Unfortunately, not all disorders that meet the requirements in [Table 41-4](#) are screened for in every state. Furthermore, compliance is highly variable among programs, and follow-up diagnostic tests, management, and counseling are in some cases inadequate. Babies most likely to be missed are those born at home and those discharged before they have digested much milk or formula. In some states, parents can refuse to have their infants studied. Several commercial laboratories have marketed screening for over 35 inborn errors of metabolism to hospitals. This **supplemental newborn screening** involves tandem mass spectroscopic analysis of the same blood spots used in state-mandated programs.

Use of the biochemical genetics laboratory for other than screening purposes must be justified by the need for data on which to base a diagnosis of specific disorders or classes of related disorders. The possibilities are limited only by the extent of knowledge, the enthusiasm of the primary clinician or consultant, the willingness of the patient or family to pursue the diagnosis and specimens to be taken, and the availability of a laboratory to examine the specimens.

Though many inborn defects are so subtle they escape detection, there are a number of clinical situations in which an inborn error should be part of the differential diagnosis. The urgency with which the investigation is undertaken will vary depending on the severity of the disorder and the availability of treatment. [Table 41-5](#) lists various clinical presentations.

The possibility of acute metabolic disease of the neonate is the most important indication, because prompt diagnosis and treatment may often make the difference between life and death. The clinical features are nonspecific because the newborn has a limited repertoire of responses to severe metabolic insults. The physician must be both inclusive and systematic in evaluating such ill babies.

DNA ANALYSIS

Direct inspection of nucleic acids—often called "molecular genetics" or "DNA diagnosis"—is achieving an increasingly prominent role in a number of clinical areas, including oncology, infectious disease, forensics, and the general study of pathophysiology. A major impact has been in the diagnosis of mendelian disorders. Molecular testing is available for more than 400 separate hereditary conditions. Once a particular gene is shown to be defective in a given condition, the nature of the mutation itself can be determined, often by sequencing the nucleotides and comparing the array with that of a normal allele. One of a variety of techniques can then be used to determine whether that same mutation is present in other patients with the same disorder. Genetic heterogeneity is so extensive that most mendelian conditions are associated with numerous mutations at one locus—or occasionally multiple loci—that produce the same phenotype. Mutations at no less than 26 different genes cause retinitis pigmentosa, and changes in at least seven genes cause familial hypertrophic cardiomyopathy. This fact complicates DNA diagnosis of patients and screening for carriers of defects in specific genes.

A few conditions are associated with relatively few mutations or with only one highly prevalent mutation. For example, all sickle cell disease is caused by exactly the same change of glutamate to valine at position 6 of β -globin, and that substitution in turn is due to a change of one nucleotide at the sixth codon in the β -globin gene. But such uniformity is the exception. In cystic fibrosis, about 70% of heterozygotes have an identical deletion of three nucleotides that causes loss of a phenylalanine residue from a chloride transport protein; however, the remaining 30% of mutations of that protein are diverse (over 800 have been discovered), so that no simple screening test will detect *all* carriers of cystic fibrosis.

Reviews of the current technical status of DNA analysis appear regularly in the medical literature. Polymerase chain reaction (PCR) studies have revolutionized many aspects of molecular biology, and DNA diagnosis has come to involve this technique in many instances. If the sequences of the 10-20 nucleotides at the ends of a region of DNA of interest (such as a portion of a gene) are known, then "primers" complementary to these sequences can be synthesized. When even a minute amount of DNA from a patient (eg, from a few leukocytes, buccal mucosal cells, or hair bulbs) is combined with the primers in a reaction mixture that replicates DNA—and after several dozen cycles are then performed—the region of DNA between the primers will be amplified exponentially. For example, the presence of early HIV infection can be detected after PCR amplification of a portion of the viral genome. A variety of new techniques are being studied in an attempt to permit analysis of many potential genetic variations in one individual in a very short time. For example, "DNA chip arrays," about the size of a microscope cover slip, can contain tens of thousands of specific nucleotide sequences. When an individual's DNA is denatured and allowed to hybridize to the array, pairing of sequences causes a fluorescent signal that can be detected by a laser microscope and recorded and interpreted by a computer.

Indications for DNA Diagnosis

The basic requirement for the use of nucleic acids in the diagnosis of hereditary conditions is that a **probe** be available for the gene in question. The probe may be a piece of the actual gene, a sequence close to the gene, or just a few nucleotides at the actual mutation. The closer the probe is to the actual mutation, the more accurate and the more useful will be the information derived. DNA diagnosis involves one of two general approaches: (1) direct detection of the mutation or (2) linkage analysis, whereby the presence of a mutation is inferred from the nature of a probe DNA sequence remote from the mutation. In the latter approach, as the probe moves farther from the mutation, the chances increase that recombination will have separated the two sequences and confused the interpretation of the data.

Some of the conditions for which direct detection is possible are listed in [Table 41-6](#). Conditions that can be diagnosed only indirectly are also listed; while their number also is increasing, there is a gratifying shift to diagnosis by direct detection as the molecular nature of mutations is defined.

DNA diagnosis is finding frequent application in presymptomatic detection of individuals with age-dependent disorders such as Huntington's disease and adult polycystic kidney disease, screening for carriers of autosomal recessive conditions such as cystic fibrosis and thalassemias, screening for female heterozygotes of X-linked conditions such as Duchenne's muscular dystrophy and hemophilia A and B, and prenatal diagnosis (see below). For some conditions in which serious complications occur in adolescence or early adulthood—such as von Hippel-Lindau syndrome and familial polyposis coli—genetic testing at an early age can identify those relatives who need frequent clinical monitoring and prophylactic management; almost as important, relatives who test negative for the mutation can be spared the inconvenience, cost, and risk of clinical tests. In all instances of DNA testing, primary care providers and specialists alike must be mindful that substantive ethical, psychologic, legal, and social issues remain unresolved. For example, some conditions for which hereditary susceptibility can be readily defined (such as Alzheimer's disease, Huntington's disease, and many cancers) have no effective therapy at this time. For these same conditions, health insurance and life insurance providers may be especially interested in learning who among their current or prospective customers is at higher risk. Some states have enacted legislation to protect people identified as having a heightened genetic risk of disease.

Logistics of DNA Diagnosis

Lymphocytes are a ready source of DNA; 10 mL of whole blood yields up to 0.5 mg of DNA, enough for dozens of analyses based on hybridization, each of which requires only 5 ug. If the analysis is quite narrowly focused on a specific mutation (such as in a family study, in which only one specific nucleotide change is addressed), PCR analysis can often be used and the amount of DNA needed is truly infinitesimal—a few hair bulbs or sperm are adequate. Once isolated, the DNA sample can be divided into aliquots and frozen. Alternatively, lymphocytes can be transformed with viruses into lymphoblasts; these cells are immortal, can be frozen, and—whenever DNA is required—can be thawed, propagated, and their DNA isolated. These stored specimens provide access to a person's genome long after the individual dies. This is such an important advantage that many clinical genetics centers and commercial laboratories "bank" DNA from patients and informative relatives even if the samples cannot be put to use immediately. The specimens may later prove invaluable to relatives or to other patients being evaluated. DNA in some instances has become more reliable than the medical records.

Blood for DNA isolation should be drawn in EDTA anticoagulant (lavender-top tubes); blood for lymphoblast culture should be drawn in heparin (green-top tubes). Neither should be frozen. Specimens for DNA isolation can be stored or shipped at room temperature over a period of a few days. Lymphoblast cultures should be established within 48 hours, so prompt shipment is essential. For one or a few specific DNA analyses, some laboratories accept a cotton swab that has been placed between the cheek and gum for a minute (buccal swab); enough cells adhere to the fibers that DNA from the subject can be isolated.

Fetal DNA can be isolated from amniotic cells, from trophoblastic cells taken by chorionic villus sampling, or from either cell type grown in culture. Samples need to be processed promptly but can be shipped by overnight mail and must not be frozen.

PRENATAL DIAGNOSIS

It is possible to diagnose in utero, before the middle of the second trimester, several hundred mendelian disorders, all chromosome aberrations, and a number of congenital malformations that are not mendelian. The first step toward prenatal diagnosis is taken when the expecting couple, the primary care provider, or the obstetrician thinks of the need for it. Recent surveys suggest that even for the most common indication for such service—advanced maternal age—less than half of all women 35 years and older in the United States are offered prenatal testing.

Techniques Used in Prenatal Diagnosis

Prenatal diagnosis depends on the ability to assay the fetus directly (fetal blood sampling, fetoscopy), indirectly (analysis of amniotic fluid, amniocytes or trophoblastic

cells, ultrasound), or remotely (analysis of maternal serum). Some of these techniques satisfy the requirements for screening ([Table 41-4](#)) and should be offered to all pregnant women; others carry considerable risk and should be reserved for specific circumstances. A few centers are developing preimplantation diagnosis of the embryo; a single cell is plucked from the six- to eight-cell blastocyst, which has been cultured after in vitro fertilization, without harming future development. The chromosomes of the cell can be studied by FISH or the genes by PCR. Another new approach, with considerable potential, is isolation of fetal cells that are circulating in minute numbers in the maternal circulation.

Ultrasound scanning of the fetus is a safe, noninvasive procedure that can diagnose gross skeletal malformations as well as nonbony malformations known to be associated with specific diseases. Some obstetricians routinely perform fetal ultrasound at least once between 12 and 20 weeks of gestation.

Other prenatal diagnostic procedures—fetoscopy, fetography, and amniography—are more invasive and a definite risk to the mother and fetus. They are indicated only if the risk of the suspected abnormality is high and the information cannot be obtained by other means.

All of the cytogenetic, biochemical, and DNA analytic techniques discussed above can be applied to specimens from the fetus. Aside from screening for a-fetoprotein in maternal serum to detect neural tube defects, analysis of fetal chromosomes is the most frequently performed test. Chromosomal analysis can be performed on amniotic cells and on trophoblastic cells grown in culture and directly on any trophoblastic cells that happen to be undergoing mitosis. Amniotic fluid cells are derived chiefly from the fetal urinary system. Amniocentesis can be performed during gestational weeks 16-18 to permit unhurried sample analysis, transmission of results, and reproductive decisions. The time from obtaining the sample to a final reading of the karyotype has now been shortened to an average of 10-14 days, and automated methods may reduce the time a bit further. Chorionic villus sampling (CVS) for trophoblastic cells (derived embryologically from the same fertilized egg as the fetus) is usually done during gestational weeks 10-13. If the tissue can be analyzed directly, cytogenetic results can be obtained within a few hours; however, the quality of the karyotypes is inferior to that from cultured cells, and most laboratories routinely culture cells and reexamine any suspected abnormalities. The advantage of CVS is that the results are available early in pregnancy, so that termination, if elected, can occur earlier in the pregnancy and the obstetric complications of termination are fewer.

The risk of CVS is somewhat higher than that of amniocentesis, though both are relatively safe. Between 0.5% and 1% of pregnancies are lost as a complication of CVS, whereas less than one in 300 amniocenteses result in fetal loss. Some centers offer "early amniocentesis," performed during gestational weeks 12-14; the magnitude of the risks is similar to that of CVS. These figures are lower than—but are in addition to—the 2-3% spontaneous abortion rate after the first trimester ends.

Indications for Prenatal Diagnosis

The indications for prenatal diagnosis are listed in [Table 41-7](#). A few deserve comment.

Most studies done for advanced maternal age will detect no chromosomal aberration, and the couple will be reassured by this news. However, it is always appropriate to emphasize that the average risk of producing a child with a defect evident at birth, such as a physical malformation or some inborn error of metabolism, is about 3%, and that the risk increases with the age of either parent. Simply examining the chromosomes reduces this risk minimally. On the other hand, unless one of the other indications is present, it is simply not possible to "screen" a pregnancy for most birth defects (neural tube defects being an exception).

Individuals contemplating pregnancy—especially those of Ashkenazic Jewish or other Caucasian ethnicity—should be offered screening for the most common mutations in the *CFTR* gene that cause cystic fibrosis. If both partners are detected as being carriers, prenatal diagnosis of a fetus would be an option for them.

A history for cytogenetic aberrations emphasizes a chromosomal defect in a parent, a family history of a chromosomal defect, or a previous child or conceptus with a defined or undefined chromosomal defect. The factors that render some couples susceptible to repeated episodes of aneuploidy are unclear, and routine prenatal testing is warranted once a defect has occurred.

Cytogenetic analysis of the fetus will of course give information about the sex chromosomes. Some couples do not desire advance knowledge of the sex of their child, and the person transmitting the results to the couple should always address this issue first. On the other hand, some couples *only* want to know the sex of the fetus and plan to terminate the pregnancy if the undesired sex is detected. Virtually no centers in the United States consider sex selection to be an appropriate indication for prenatal diagnosis.

The level of a-fetoprotein in maternal serum changes with gestational age, with the mother's medical status, and with abnormalities of the fetus. If the first two factors can be well controlled, the assay can be used to provide information about the fetus. Levels are expressed as multiples of the median value for a particular gestational age. Higher than normal levels are associated with open neural tube defects (the conditions for which the test was developed), recent or impending fetal demise, gastroschisis, and fetal renal disease. Extremely high levels are highly specific for fetal anomalies—a level three times the median increases 20-fold the risk of meningomyelocele or anencephaly. Low a-fetoprotein levels in maternal serum are associated with fetal trisomy, especially Down's syndrome; the reason for this association remains unclear. The addition of two other analytes in maternal serum—human chorionic gonadotropin (hCG) and unconjugated estriol (uE3)—to the assay for a-fetoprotein (to produce the "triple screen") enhances by several times the ability to detect a fetus with trisomy 21 and trisomy 18. Measuring in the first trimester both serum pregnancy-associated plasma protein A and the translucency of the fetal neck by ultrasound—followed by routine triple screening in the second trimester—improves the rate of detection of Down's syndrome to about 85% while reducing false-positives to about 1%. A positive result on any of these screening protocols for trisomy should be followed by offering the woman amniocentesis to confirm the diagnosis.

NEOPLASIA: CHROMOSOMAL & DNA ANALYSIS

Studies of both chromosomes and nucleic acids support Boveri's 1914 hypothesis that cancer is caused by a change in genetic material at the cellular level. Two classes of genes have been discovered that function in neoplastic transformation.

Oncogenes arise from preexisting normal genes (proto-oncogenes) that have been altered by both viral and nonviral factors. As a result, the cells synthesize either normal proteins in inappropriate amounts or proteins that are aberrant in structure and function. Many of these proteins are cellular growth factors or receptors for growth factors. The net result of oncogene activation is unregulated cell division. Mutations that activate oncogenes virtually always arise in somatic cells and are not usually inherited. Although some oncogenes are more likely to be activated in certain tumors, in general the same mutations may be found in neoplasia arising in different cells and tissues.

Tumor suppressor genes can be viewed as the antithesis of oncogenes. Their normal function is to suppress transformation; mutation in both alleles is necessary to obliterate this important function. The first mutant allele at any tumor suppressor gene might arise spontaneously or might be inherited; mutation in the other allele (the "second hit") virtually always arises spontaneously, but by any of a number of molecular mechanisms. These genes show considerably more tumor specificity than do oncogenes; however, while some specific mutations are necessary for certain tumors to arise, no loss of single tumor suppressor function is sufficient. Clearly, a person who inherits one copy of a mutant tumor suppressor gene is at increased risk that in some susceptible cell, at some time during life, the function of that gene will be lost. This susceptibility is inherited as an autosomal dominant trait. For example, mutation in one allele of the *P53* locus results in the Li-Fraumeni syndrome (151623), in which susceptibility before age 45 years to sarcomas and other tumors occurs in males and females in successive generations. Inherited mutations in this locus also increase the risk that a second tumor will develop following radiation or chemotherapy for the first tumor, suggesting that the initial treatment may induce a "second hit" in a *P53* locus in another tissue. However, inheriting a *P53* mutation is not a guarantee that cancer will develop at an early age; much more needs to be learned about the pathogenesis of neoplasia before the genetic counseling of families with a molecular predisposition to cancer is clarified. *BRCA1*, a gene that predisposes women to breast (114480) and ovarian cancer, is another example of a tumor suppressor gene. Women who inherit one mutant allele of *BRCA1* have on average, a 60-80% lifetime risk of developing breast cancer, and the average age of tumor detection is in the fifth decade. Their risk of developing ovarian cancer is 34-45%. For both females and males with certain mutations in *BRCA1*, the risks of colon and pancreatic cancer are increased severalfold over that of the general population.

In selected cases, a patient's DNA can be analyzed for the presence of a mutated gene and thereby assess that individual's risk for developing a tumor. Examples are retinoblastoma (189200), certain forms of Wilms' tumor (194070), breast cancer (114489), and familial colon cancer (114500). To illustrate how noninvasive and sensitive the methodology has become, it is possible to analyze stool for the presence of mutations in tumor suppressor genes that might indicate the presence of a clinically undetected adenocarcinoma of the colon. The analysis—not yet in general use—depends on the ability of the polymerase chain reaction to amplify minute quantities of the mutant DNA present in epithelial cells shed from the tumor.

A third class of genes that predispose to malignancy has been discovered in the past few years. So-called **mutator genes** have joined oncogenes and tumor suppressor genes as risk factors. Mutator genes normally function to repair damage to DNA that occurs from environmental insults such as exposure to carcinogens and ultraviolet irradiation. When a mutator gene is mutated itself, DNA damage accumulates and eventually affects oncogenes and tumor suppressor genes, thereby making cancer more likely. Hereditary nonpolyposis colon cancer (HNPCC) is one familial syndrome due to mutations in one or another of the five mutator genes identified thus far (*MSH2* and *MLH1* being the most commonly responsible for HNPCC).

This exciting work on the molecular nature of oncogenesis was preceded by years of study of the cytogenetics of tumors. Indeed, the retinoblastoma tumor suppressor gene was ultimately isolated because a small number of patients with this tumor have a constitutive deletion of chromosome 13 where this gene maps. Other chromosomal aberrations have been found to be highly characteristic of—or even specific for—certain tumors ([Table 41-8](#)). Detection of one of these cytogenetic aberrations can thus aid in diagnosis.

Hematologic malignancies are especially amenable to study because of the relative ease of performing cytogenetic analysis. Such malignancies are associated with over 100 specific chromosomal rearrangements, chiefly translocations. Most of these rearrangements are restricted to a specific type of cancer ([Table 41-9](#)), and the remainder occur with many cancers.

In the leukemias, the chromosomal aberration is the basis of one of the subclassifications of the disease. When cytogenetic information is combined with the histologic classification, it is possible to define subsets of patients in which response to therapy, clinical course, and prognosis are predictable. If at the time of diagnosis there are no chromosomal changes in the bone marrow cells, the survival time is longer than if any or all of the bone marrow cells have abnormal cytogenetic characteristics. As secondary chromosomal changes occur, the leukemia becomes more aggressive, often associated with drug resistance and a reduced chance for complete or prolonged remission. The least ominous chromosomal change is numerical alteration without morphologic abnormality.

Less cytogenetic information is available for lymphomas and premalignant hematologic disorders than for leukemia. In Hodgkin's disease, studies have been limited by the low yield of dividing cells and the low number of clear-cut aneuploid clones, so that complete chromosomal analyses with banding are available for far fewer patients with Hodgkin's disease than for any other type of lymphoma. In Hodgkin's disease, the modal chromosomal number tends to be triploid or tetraploid. About one-third of the samples have a 14q+ chromosome. In non-Hodgkin's lymphomas, high-resolution techniques of banding detect abnormalities in 95% of cases. Cytogenetic findings are now being correlated with the immunologic and histologic features and with prognosis.

In Burkitt's lymphoma, a solid tumor of B cell origin, 90% of patients have a translocation between the long arm of chromosome 8 and the long arm of chromosome 14, with chromosomal breakage sites being at or near immunoglobulin and oncogene loci.

Instability of chromosomes also predisposes to the development of some malignancies. In certain autosomal recessive diseases such as ataxia-telangiectasia, Bloom's syndrome, and Fanconi's anemia, the cells have a tendency to **genetic instability**, ie, to chromosomal breakage and rearrangement in vitro. These diseases are associated with a fairly high incidence of neoplasia, particularly leukemia and lymphoma.

Some chromosomal aberrations, better known for their effect on phenotype, also predispose to tumors. For example, patients with Down's syndrome (trisomy 21) have a 20-fold increase in the risk of leukemia; 47,XXY males (Klinefelter's syndrome) have a 30-fold increase in the risk of breast cancer; and XY phenotypic females have a heightened risk of developing ovarian cancer, primarily gonadoblastoma.

The indications for cytogenetic analysis of neoplasia continue to evolve. Not all tumors require study. However, in cases of tumors of unclear type (especially leukemias and lymphomas), with a strong family history of early neoplasia, or for certain tumors associated with potential generalized chromosomal defects (present in nonneoplastic cells), cytogenetic analysis should be strongly considered.

■ SELECTED GENETIC DISORDERS

ACUTE INTERMITTENT PORPHYRIA (176000)

Essentials of Diagnosis

- Unexplained abdominal crisis, generally in young women.
- Acute peripheral or central nervous system dysfunction.
- Recurrent psychiatric illnesses.
- Hyponatremia.
- Porphobilinogen in the urine during an attack.

General Considerations

Though there are several different types of porphyrias, the one with the most serious consequences and the one that usually presents in adulthood is acute intermittent porphyria, which is inherited as an autosomal dominant, though it remains clinically silent in the majority of patients who carry the trait. Those who develop clinical illness are usually women, with symptoms beginning in the teens or 20s, but in rare cases onset can begin after menopause. The disorder is caused by deficiency of porphobilinogen deaminase activity, leading to increased excretion of aminolevulinic acid and porphobilinogen in the urine. The diagnosis may be elusive if not specifically considered. The characteristic abdominal pain may be due to abnormalities in autonomic innervation in the gut. In contrast to other forms of porphyria, cutaneous photosensitivity is absent in acute intermittent porphyria. Attacks are precipitated by numerous factors, including drugs and intercurrent infections. Harmful and relatively safe drugs for use in treatment are listed in [Table 41-10](#). Hyponatremia may be seen, due in part to inappropriate release of antidiuretic hormone, though gastrointestinal loss of sodium in some patients may contribute.

Clinical Findings

A. Symptoms and Signs

Patients show intermittent abdominal pain of varying severity, and in some instances it may so simulate acute abdomen as to lead to exploratory laparotomy. Since the origin of the abdominal pain is neurologic, there is absence of fever and leukocytosis. Complete recovery between attacks is usual. Any part of the nervous system may be involved, with evidence for autonomic and peripheral neuropathy. Peripheral neuropathy may be symmetric or asymmetric and mild or profound; in the latter instance, it can even lead to quadriplegia with respiratory paralysis. Other central nervous system manifestations include seizures, psychosis, and abnormalities of the basal ganglia. Hyponatremia may further cause or exacerbate central nervous system manifestations.

B. Laboratory Findings

Often there is profound hyponatremia. The diagnosis can be confirmed by demonstrating an increased amount of porphobilinogen in the urine during an acute attack. Freshly voided urine is of normal color but may turn dark upon standing in light and air.

Most families have a different mutation in the porphobilinogen deaminase gene causing acute intermittent porphyria. With some effort in research laboratories, mutations can be discovered and used for presymptomatic and prenatal diagnosis.

Prevention

Avoidance of factors known to precipitate attacks of acute intermittent porphyria—especially drugs (sulfonamides and barbiturates, or drugs listed in [Table 41-10](#))—can reduce morbidity. Starvation diets also cause attacks and so must be avoided.

Treatment

Treatment with a high-carbohydrate diet diminishes the number of attacks in some patients and is a reasonable empirical gesture considering its benignity. Acute attacks may be life-threatening and require prompt diagnosis, withdrawal of the inciting agent (if possible), and treatment with analgesics and intravenous glucose and hematin. A minimum of 300 g of carbohydrate per day should be provided orally or intravenously. Electrolyte balance requires close attention. Hematin therapy is still evolving and should be undertaken with full recognition of adverse consequences, especially phlebitis and coagulopathy. The intravenous dosage is up to 4 mg/kg once or twice daily.

ALKAPTONURIA (203500)

Alkaptonuria is caused by a recessively inherited deficiency of the enzyme homogentisic acid oxidase. This acid derives from metabolism of both phenylalanine and tyrosine and is present in large amounts in the urine throughout the patient's life. An oxidation product accumulates slowly in cartilage throughout the body, leading to degenerative joint disease of the spine and peripheral joints. Indeed, examination of patients in the third and fourth decades shows a slight darkish blue color below the skin in areas overlying cartilage, such as in the ears, a phenomenon called "ochronosis." In some patients, a more severe hyperpigmentation can be seen in the sclera, conjunctiva, and cornea. Accumulation of metabolites in heart valves can lead to aortic or mitral stenosis. A predisposition to coronary artery disease may also be present. While the syndrome causes considerable morbidity, life expectancy is reduced only modestly. Symptoms are more often attributable to spondylitis with back pain, leading to a clinical picture difficult to distinguish from that of ankylosing spondylitis, though on radiographic assessment the sacroiliac joints are not fused in alkaptonuria.

The diagnosis is established by demonstrating homogentisic acid in the urine, which turns black spontaneously on exposure to the air; this reaction is particularly noteworthy if the urine is alkaline or when alkali is added to a specimen. Molecular analysis of the homogentisic acid oxidase gene, recently mapped to chromosome 3, is not necessary for diagnosis.

Treatment of the arthritis is similar to that for other arthropathies. Though in theory rigid dietary restriction might reduce accumulation of the pigment, this has not proved to be of practical benefit.

DOWN'S SYNDROME (190685)

Down's syndrome is usually diagnosed at birth on the basis of the typical facial features, hypotonia, and single palmar crease. Several serious problems that may be evident at birth or may develop early in childhood include duodenal atresia, congenital heart disease (especially atrioventricular canal defects), and leukemia. The intestinal and cardiac anomalies usually respond to surgery, and the leukemia generally responds to conservative management. Intelligence varies across a wide spectrum. Many people with Down's syndrome do well in sheltered workshops and group homes, but few achieve full independence in adulthood. An Alzheimer-like dementia usually becomes evident in the fourth or fifth decade and, for those who survive childhood, accounts for a reduced life expectancy. Studies addressing the risk and severity of dementia in relation to the apolipoprotein E genotype have had conflicting results. Cytogenetic analysis should always be performed—even though most patients will have simple trisomy for chromosome 21—to detect unbalanced translocations; such patients may have a parent with a balanced translocation, and there will be a substantial recurrence risk of Down's syndrome in future offspring.

Many pregnancies carrying a fetus with Down's syndrome can be detected in the early second trimester through screening maternal serum for a-fetoprotein and certain hormones ("triple screen") and by detecting increased nuchal thickness on fetal ultrasound.

The risk of bearing a child with Down's syndrome increases exponentially with the age of the mother at conception and begins a marked rise after age 35. By age 45 years, a mother has one chance in 40 of having an affected child. The risk of other conditions associated with trisomy also increases, because of the increased predisposition of older oocytes to nondisjunction during meiosis. There is virtually no risk of trisomy associated with increased paternal age. However, older men do have an increased risk of fathering a child with a new autosomal dominant condition. But because there are so many distinct conditions, the chance of fathering an offspring with any given one is extremely small.

FRAGILE X MENTAL RETARDATION (309550)

This X-linked condition accounts for more cases of mental retardation in males than any condition except Down's syndrome; about one in 2000 males is affected. The first marker for this condition was a small gap, or fragile site, evident near the tip of the long arm of the X chromosome. Subsequently, the condition was found to be due to expansion of a trinucleotide repeat (CGG) near a gene called *FMR1*. All individuals have some CGG repeats in this location, but as the number increases beyond 52, the chances of further expansion during spermatogenesis or oogenesis increase. Being born with one *FMR1* allele with 200 or more repeats results in mental retardation in virtually all men and about 60% of women. The more repeats, the greater the likelihood that further expansion will occur during gametogenesis; this results in **anticipation**, in which the disorder can worsen from one generation to the next. Affected (heterozygous) women show no physical signs other than early menopause, but they may have learning difficulties or frank retardation. Affected males show macroorchidism (enlarged testes) after puberty, large ears and a

prominent jaw, a high-pitched voice, and mental retardation. Some show evidence of a mild connective tissue defect, with joint hypermobility and mitral valve prolapse.

DNA diagnosis for the number of repeats has supplanted cytogenetic analysis for both clinical and prenatal diagnosis. This should be done on any male or female who has unexplained mental retardation.

GAUCHER'S DISEASE (230800)

Gaucher's disease is inherited as an autosomal recessive. A deficiency of β -glucocerebrosidase causes an accumulation of sphingolipid within phagocytic cells throughout the body. Anemia and thrombocytopenia are common and may be symptomatic; both are due primarily to hypersplenism, but marrow infiltration with Gaucher cells may contribute. Cortical erosions of bones, especially the vertebrae and femur, are due to local infarctions, but the mechanism is unclear. Episodes of bone pain (termed "crises") are reminiscent of those in sickle cell disease. A hip fracture in a patient with a palpable spleen—especially in a Jewish person of Eastern European origin—suggests the possibility of Gaucher's disease. Bone marrow aspirates reveal typical Gaucher cells, which have an eccentric nucleus and PAS-positive inclusions, along with wrinkled cytoplasm and inclusion bodies of a fibrillar type. In addition, the serum acid phosphatase is elevated. Definitive diagnosis requires the demonstration of deficient glucocerebrosidase activity in leukocytes.

Two uncommon forms of Gaucher's disease, called type II and type III, involve neurologic accumulation of sphingolipid and a variety of neurologic problems. Type II is of infantile onset and has a poor prognosis.

Over 200 mutations have been found to cause Gaucher's disease, and some are highly predictive of the neuronopathic forms. Thus, mutation detection, especially in a young person, is of potential value. Only four mutations in glucocerebrosidase account for more than 90% of the disease among Ashkenazic Jews, in whom the carrier frequency is 1:15.

Until recently, treatment has been supportive and has included splenectomy for thrombocytopenia secondary to platelet sequestration. The production of a recombinant form of the enzyme glucocerebrosidase (imiglucerase) for intravenous administration on a regular basis now permits a reduction in total body stores of glycolipid and improvement in orthopedic and hematologic manifestations. Unfortunately, the neurologic manifestations of types II and III have not improved with enzyme replacement therapy. The major drawback is the exceptional cost of imiglucerase, which can exceed \$350,000 per year for a severely affected patient. Administration of less enzyme (30 units/kg per month) is effective for most adults and reduces the cost to about \$100,000-150,000 annually.

HOMOCYSTINURIA (236200)

Homocystinuria in its classic form is caused by cystathionine β -synthase deficiency and exhibits an autosomal recessive pattern of inheritance. This results in extreme elevations of plasma and urinary homocystine levels, a basis for diagnosis of this disorder. Homocystinuria is similar in certain superficial aspects to Marfan's syndrome, since patients may show a similar body habitus and ectopia lentis is almost always present. However, mental retardation is often present, and the cardiovascular events are those of repeated venous and arterial thromboses whose precise cause remains obscure. Life expectancy is reduced, especially in untreated and pyridoxine-unresponsive patients; myocardial infarction, stroke, and pulmonary embolism are the most common causes of death. This condition is diagnosed in some states by newborn screening for hypermethioninemia; however, pyridoxine-responsive infants may not be detected. The diagnosis should be suspected in patients in the second and third decades of life who show evidence of arterial or venous thromboses and have no other risk factors. Although many mutations have been identified in the cystathionine β -synthase gene, amino acid analysis of plasma remains the most appropriate diagnostic test. Patients should be studied after they have been off folate or pyridoxine supplementation for at least 1 week. The plasma should be separated promptly from the fresh venous blood specimen.

About one-half of patients have a form of cystathionine β -synthase deficiency that improves biochemically and clinically through pharmacologic doses of pyridoxine and folate. For these patients, treatment from infancy can prevent retardation and the other clinical problems. Patients who are pyridoxine-nonresponders must be treated with dietary reduction in methionine and supplementation of cysteine, also from infancy. The vitamin betaine is also useful in reducing plasma methionine levels by facilitating a metabolic pathway that bypasses the defective enzyme. Patients who have suffered venous thrombosis should be anticoagulated, but there are no studies to support prophylactic use of warfarin or antiplatelet agents.

HOMOCYSTEINE & ARTERIAL OCCLUSIVE DISEASE (603174)

Over the past 5 years, considerable evidence has accumulated to support the 20-year-old observation that patients with clinical and angiographic evidence of coronary artery disease tend to have higher levels of plasma homocysteine than controls without coronary artery disease. The relationship has been extended to cerebrovascular and peripheral vascular diseases. Although this effect was initially thought to be due at least in part to heterozygotes for cystathionine β -synthase deficiency (see above), in fact there is little evidence for this. Rather, the major factor leading to hyperhomocysteinemia is folate deficiency. Pyridoxine (vitamin B₆) and vitamin B₁₂ are also important in the metabolism of methionine, and deficiency of any of these vitamins can lead to accumulation of homocysteine. A number of genes influence utilization of these vitamins and can predispose to deficiency. For example, having one—and especially two—copies of an allele that causes thermolability of methylene tetrahydrofolate reductase predisposes to elevated fasting homocysteine levels. However, both nutritional and most genetic deficiencies of these vitamins can be corrected by dietary supplementation of folic acid and, if serum levels are low, vitamins B₆ and B₁₂. In the United States, cereal grains are now fortified with folic acid. Studies are ongoing to determine the long-term utility of routine vitamin supplementation in people at risk for arterial occlusive disease, but many workers in this field recommend, at a minimum, taking 1 mg of folic acid per day. Because patients with end-stage renal disease tend to have marked hyperhomocysteinemia and low serum folate, 5 mg of folic acid per day seems warranted.

Relatively few laboratories currently provide highly reliable assays for homocysteine. Processing of the specimen is crucial to obtain accurate results. The plasma must be separated within 30 minutes; otherwise, blood cells release the amino acid and the measurement will then be artificially elevated.

KLINEFELTER'S SYNDROME

Boys with an extra X chromosome are normal in appearance before puberty; thereafter, they have disproportionately long legs and arms, a female escutcheon, gynecomastia, and small testes. Infertility is due to azoospermia; the seminiferous tubules are hyalinized. The diagnosis is often not made until a couple is evaluated for inability to conceive. Mental retardation is somewhat more common than in the general population. Many men with Klinefelter's syndrome have learning problems. The risk of breast cancer is much higher in men with Klinefelter's syndrome than in 46,XY men, as is the risk of diabetes mellitus.

Treatment with testosterone after puberty is advisable but will not restore fertility. However, men with Klinefelter's syndrome have had mature sperm aspirated from their testes and injected into oocytes, resulting in fertilization. After the blastocysts were implanted into the uterus of a partner, "natural" children resulted.

MARFAN'S SYNDROME (154700)

- Disproportionately tall stature, thoracic deformity, and joint laxity or contractures.
- Ectopia lentis and myopia.
- Aortic dilation and dissection.
- Mitral valve prolapse.

General Considerations

Marfan's syndrome, a systemic connective tissue disease, is inherited as an autosomal dominant. It is characterized by abnormalities of the skeletal system, ocular system, and cardiovascular system. Spontaneous pneumothorax, dural ectasia, and striae atrophicae can also occur. Of most concern is disease of the ascending aorta, which is associated with a dilated aortic root. Histology of the aorta shows diffuse medial abnormalities. Aortic and mitral valve leaflets are also abnormal and mitral regurgitation may be present as well, often with elongated chordae tendineae, which on occasion may rupture.

Clinical Findings

A. Symptoms and Signs

Affected patients are typically tall, with particularly long arms, legs, and digits (arachnodactyly). However, there can be wide variability in the clinical presentation. Commonly, joint dislocations and pectus excavatum are found. Ectopia lentis may lead to severe myopia and retinal detachment. Mitral valve prolapse is seen in about 85% percent of patients. Aortic root dilation with aortic regurgitation or dissection with rupture can occur. To diagnose Marfan's syndrome, people with an affected relative need features in at least two systems. People with no family history need features in the skeletal system, two other systems, and one of the major criteria of ectopia lentis, dilation of the aortic root, or aortic dissection. Patients with homocystinuria due to cystathionine synthase deficiency also have dislocated lenses; tall, disproportionate stature; and thoracic deformity. They tend to have below normal intelligence, stiff joints, and a predisposition to arterial and venous occlusive disease. Males with Klinefelter's syndrome do not show the typical ocular or cardiovascular features of Marfan's syndrome and are generally sporadic occurrences in the family.

B. Laboratory Findings

Mutations in the fibrillin gene on chromosome 15 cause Marfan's syndrome. Nonetheless, no simple laboratory test is available to support the diagnosis in questionable cases because related conditions may also be due to defects in fibrillin.

Prevention

There is prenatal and presymptomatic diagnosis for patients in whom the molecular defect in fibrillin has been found and for large enough families in whom linkage analysis using polymorphic markers around the fibrillin gene can be performed.

Treatment

Children with Marfan's syndrome require regular ophthalmologic surveillance to correct visual acuity and thus prevent amblyopia, and annual orthopedic consultation for diagnosis of scoliosis at an early enough stage so that bracing might delay progression. Patients of all ages require echocardiography at least annually to monitor aortic diameter and mitral valve function. All patients should use standard endocarditis prophylaxis. Chronic β-adrenergic blockade, titrated to individual tolerance but enough to produce a negative inotropic effect (atenolol, 1-2 mg/kg), retards the rate of aortic dilation. Restriction from vigorous physical exertion protects from aortic dissection. Prophylactic replacement of the aortic root with a composite graft when the diameter reaches 50-55 mm (normal: < 40 mm) prolongs life. A procedure to spare the patient's aortic valve and replace just the aneurysmal sinuses of Valsalva is showing promise and would also avoid the need for life-long anticoagulation.

Prognosis

People with Marfan's syndrome who are untreated commonly die in the fourth or fifth decade from aortic dissection or congestive heart failure secondary to aortic regurgitation. However, because of earlier diagnosis, lifestyle modifications, beta-adrenergic blockade, and prophylactic aortic surgery, life expectancy has increased by several decades in the past 25 years.

42. Diagnostic Testing & Medical Decision Making - *C. Diana Nicoll, MD, PhD, MPA, & Michael Pignone, MD, MPH*

■ INTRODUCTION

The clinician's main task is to make reasoned decisions about patient care despite incomplete clinical information and uncertainty about clinical outcomes. While data elicited from the history and physical examination are often sufficient for making a diagnosis or for guiding therapy, more information may be required. In these situations, clinicians often turn to diagnostic tests for help.

■ BENEFITS; COSTS & RISKS

When used appropriately, diagnostic tests can be of great assistance to the clinician. Tests can be helpful for **screening**, ie, to identify risk factors for disease and to detect occult disease in asymptomatic persons. Identification of risk factors may allow early intervention to prevent disease occurrence, and early detection of occult disease may reduce disease morbidity and mortality through early treatment. Optimal screening tests meet the criteria listed in [Table 42-1](#).

Tests can also be helpful for **diagnosis**, ie, to help establish or exclude the presence of disease in symptomatic persons. Some tests assist in early diagnosis after onset of symptoms and signs; others assist in developing a differential diagnosis; others help determine the stage or activity of disease.

Finally, tests can be helpful in **patient management**. Tests can help (1) evaluate the severity of disease, (2) estimate prognosis, (3) monitor the course of disease (progression, stability, or resolution), (4) detect disease recurrence, and (5) select drugs and adjust therapy.

When ordering diagnostic tests, clinicians should weigh the potential benefits against the potential costs and disadvantages. Some tests carry a risk of morbidity or mortality—eg, cerebral angiogram leads to stroke in 1% of cases. The potential discomfort associated with tests such as colonoscopy may deter some patients from completing a diagnostic work-up. The result of a diagnostic test may mandate further testing or frequent follow-up—eg, a patient with a positive fecal occult blood test may incur significant cost, risk, and discomfort during follow-up colonoscopy.

Furthermore, a false-positive test may lead to incorrect diagnosis or further unnecessary testing. Classifying a healthy patient as diseased based on a falsely positive diagnostic test can cause psychologic distress and may lead to risks from unnecessary or inappropriate therapy. A diagnostic or screening test may identify cases of disease that would not otherwise have been recognized and that would not have affected the patient. For example, early-stage low-grade prostate cancer detected by PSA screening in an 84-year-old man with known severe congestive heart failure will probably not become symptomatic or require treatment during his lifetime.

The costs of diagnostic testing must always be understood and considered. Total costs may be high, or cost-effectiveness may be unfavorable. An individual test such as MRI of the head can cost more than \$1400, and diagnostic tests as a whole account for approximately one-fifth of health care expenditures in the USA. Even relatively inexpensive tests may have poor cost effectiveness if they produce very small health benefits.

■ PERFORMANCE OF DIAGNOSTIC TESTS

TEST PREPARATION

Factors affecting both the patient and the specimen are important. The most crucial element in a properly conducted laboratory test is an appropriate specimen.

Patient Preparation

Preparation of the patient is important for certain tests—eg, a fasting state is needed for optimal glucose and triglyceride measurements; posture and sodium intake must be strictly controlled when measuring renin and aldosterone levels; and strenuous exercise should be avoided before taking samples for creatine kinase determinations, since vigorous muscle activity can lead to falsely abnormal results.

Specimen Collection

Careful attention must be paid to patient identification and specimen labeling. Knowing when the specimen was collected may be important. For instance, aminoglycoside levels cannot be interpreted appropriately without knowing whether the specimen was drawn just before ("trough" level) or after ("peak" level) drug administration. Drug levels cannot be interpreted if they are drawn during the drug's distribution phase (eg, digoxin levels drawn during the first 6 hours after an oral dose). Substances that have a circadian variation (eg, cortisol) can be interpreted only in the context of the time of day the sample was drawn.

During specimen collection, other principles should be remembered. Specimens should not be drawn above an intravenous line, as this may contaminate the sample with intravenous fluid. Excessive tourniquet time will lead to hemoconcentration and an increased concentration of protein-bound substances such as calcium. Lysis of cells during collection of a blood specimen will result in spuriously increased serum levels of substances concentrated in cells (eg, lactate dehydrogenase and potassium). Certain test specimens may require special handling or storage (eg, blood gas specimens). Delay in delivery of specimens to the laboratory can result in ongoing cellular metabolism and therefore spurious results for some studies (eg, low serum glucose).

■ TEST CHARACTERISTICS

[Table 42-2](#) lists the general characteristics of useful diagnostic tests. Most of the principles detailed below can be applied not only to laboratory and radiologic tests but also to elements of the history and physical examination.

Accuracy

The accuracy of a laboratory test is its correspondence with the true value. An inaccurate test is one that differs from the true value even though the results may be reproducible ([Figures 42-1A](#) and [1B](#)). In the clinical laboratory, accuracy of tests is maximized by calibrating laboratory equipment with reference material and by participation in external quality control programs.

Precision

Test precision is a measure of a test's reproducibility when repeated on the same sample. An imprecise test is one that yields widely varying results on repeated measurements ([Figure 42-1B](#)). The precision of diagnostic tests, which is monitored in clinical laboratories by using control material, must be good enough to distinguish clinically relevant changes in a patient's status from the analytic variability of the test. For instance, the manual white blood cell differential count is not precise enough to detect important changes in the distribution of cell types, because it is calculated by subjective evaluation of a small sample (100 cells). Repeated measurements by different technicians on the same sample result in widely different results. Automated differential counts are more precise because they are obtained from machines that use objective physical characteristics to classify a much larger sample (10,000 cells).

Reference Range

Reference ranges are method- and laboratory-specific. In practice, they often represent test results found in 95% of a small population presumed to be healthy; by definition, then, 5% of healthy patients will have an abnormal test result ([Figure 42-2](#)). Slightly abnormal results should be interpreted critically—they may be either truly abnormal or falsely abnormal. The practitioner should also be aware that the more tests ordered, the greater the chance of obtaining a falsely abnormal result. For a healthy person subjected to 20 independent tests, there is a 64% chance that one test result will lie outside the reference range ([Table 42-3](#)). Conversely, values within the reference range may not rule out the actual presence of disease since the reference range does not establish the distribution of results in patients with disease.

It is important to consider also whether published reference ranges are appropriate for the patient being evaluated, since some ranges depend on age, sex, weight,

diet, time of day, activity status, or posture. For instance, the reference ranges for hemoglobin concentration are age- and sex-dependent. [Table 2](#) of the Appendix contains the reference ranges for commonly used chemistry and hematology tests. Test performance characteristics such as sensitivity and specificity are needed to interpret results and are discussed below.

Interfering Factors

The results of diagnostic tests can be altered by external factors, such as ingestion of drugs; and internal factors, such as abnormal physiologic states.

External interferences can affect test results in vivo or in vitro. In vivo, alcohol increases γ -glutamyl transpeptidase, and diuretics can affect sodium and potassium concentrations. Cigarette smoking can induce hepatic enzymes and thus reduce levels of substances such as theophylline that are metabolized by the liver. In vitro, cephalosporins may produce spurious serum creatinine levels due to interference with a common laboratory method of analysis.

Internal interferences result from abnormal physiologic states interfering with the test measurement. As an example, patients with gross lipemia may have spuriously low serum sodium levels if the test methodology used includes a step in which serum is diluted before sodium is measured. Because of the potential for test interference, clinicians should be wary of unexpected test results and should investigate reasons other than disease that may explain abnormal results, including laboratory error.

Sensitivity & Specificity

Clinicians should use measures of test performance such as sensitivity and specificity to judge the quality of a diagnostic test for a particular disease. Test **sensitivity** is the likelihood that a diseased patient has a positive test. If all patients with a given disease have a positive test (ie, no diseased patients have negative tests), the test sensitivity is 100%. Generally, a test with high sensitivity is useful to exclude a diagnosis because a highly sensitive test will render few results that are falsely negative. To exclude infection with the AIDS virus, for instance, a clinician might choose a highly sensitive test such as the HIV antibody test.

A test's **specificity** is the likelihood that a healthy patient has a negative test. If all patients who do not have a given disease have negative tests (ie, no healthy patients have positive tests), the test specificity is 100%. A test with high specificity is useful to confirm a diagnosis, because a highly specific test will have few results that are falsely positive. For instance, to make the diagnosis of gouty arthritis, a clinician might choose a highly specific test, such as the presence of negatively birefringent needle-shaped crystals within leukocytes on microscopic evaluation of joint fluid.

To determine test sensitivity and specificity for a particular disease, the test must be compared against an independent "gold standard" test that defines the true disease state of the patient. For instance, the sensitivity and specificity of the ventilation-perfusion scan for pulmonary emboli are obtained by comparing the results of scans with the gold standard, pulmonary arteriography. Application of the gold standard examination to patients with positive scans establishes specificity. Failure to apply the gold standard examination following negative scans may result in an overestimation of sensitivity, since false negatives will not be identified. However, for many disease states (eg, pancreatitis), an independent gold standard test either does not exist or is very difficult or expensive to apply—and in such cases reliable estimates of test sensitivity and specificity are sometimes difficult to obtain.

Sensitivity and specificity can also be affected by the population from which these values are derived. For instance, many diagnostic tests are evaluated first using patients who have severe disease and control groups who are young and well. Compared with the general population, this study group will have more results that are truly positive (because patients have more advanced disease) and more results that are truly negative (because the control group is healthy). Thus, test sensitivity and specificity will be higher than would be expected in the general population, where more of a spectrum of health and disease is found. Clinicians should be aware of this **spectrum bias** when generalizing published test results to their own practice.

Test sensitivity and specificity depend on the threshold above which a test is interpreted to be abnormal ([Figure 42-3](#)). If the threshold is lowered, sensitivity is increased at the expense of lowered specificity. If the threshold is raised, sensitivity is decreased while specificity is increased.

[Figure 42-4](#) shows how test sensitivity and specificity can be calculated using test results from patients previously classified by the gold standard as diseased or nondiseased.

The performance of two different tests can be compared by plotting the sensitivity and (1 minus the specificity) of each test at various reference range cutoff values. The resulting **receiver operator characteristic (ROC) curve** will often show which test is better; a clearly superior test will have an ROC curve that always lies above and to the left of the inferior test curve, and, in general, the better test will have a larger area under the ROC curve. For instance, [Figure 42-5](#) shows the ROC curves for prostate-specific antigen (PSA) and prostatic acid phosphatase (PAP) in the diagnosis of prostate cancer. PSA is a superior test because it has higher sensitivity and specificity for all cutoff values.

■ USE OF TESTS IN DIAGNOSIS & MANAGEMENT

The value of a test in a particular clinical situation depends not only on the test's sensitivity and specificity but also on the probability that the patient has the disease before the test result is known (**pretest probability**). The results of a useful test will substantially change the probability that the patient has the disease (**posttest probability**). [Figure 42-4](#) shows how posttest probability can be calculated from the known sensitivity and specificity of the test and the estimated pretest probability of disease (or disease prevalence).

The pretest probability of disease has a profound effect on the posttest probability of disease. As demonstrated in [Table 42-4](#), when a test with 90% sensitivity and specificity is used, the posttest probability can vary from 8% to 99% depending on the pretest probability of disease. Furthermore, as the pretest probability of disease decreases, it becomes more likely that a positive test result represents a false positive.

As an example, suppose the clinician wishes to calculate the posttest probability of prostate cancer using the PSA test and a cut-off value of 4 ug/L. Using the data shown in [Figure 42-5](#), sensitivity is 90% and specificity is 60%. The clinician estimates the pretest probability of disease given all the evidence and then calculates the posttest probability using the approach shown in [Figure 42-4](#). The pretest probability that an otherwise healthy 50-year-old man has prostate cancer is equal to the prevalence of prostate cancer in that age group (probability = 10%) and the posttest probability after a positive test is only 20—ie, even though the test is positive, there is still an 80% chance that the patient does not have prostate cancer ([Figure 42-6A](#)). If the clinician finds a prostate nodule on rectal examination, the pretest probability of prostate cancer rises to 50% and the posttest probability using the same test is 69% ([Figure 42-6B](#)). Finally, if the clinician estimates the pretest probability to be 98% based on a prostate nodule, bone pain, and lytic lesions on spine x-rays, the posttest probability using PSA is 99% ([Figure 42-6C](#)). This example illustrates that pretest probability has a profound effect on posttest probability and that tests provide more information when the diagnosis is truly uncertain (pretest probability about 50%) than when the diagnosis is either unlikely or nearly certain.

■ ODDS-LIKELIHOOD RATIOS

Another way to calculate the posttest probability of disease is to use the odds-likelihood approach. Sensitivity and specificity are combined into one entity called the likelihood ratio (LR).

LR = $\frac{\text{Probability of result in diseased persons}}{\text{Probability of result in nondiseased persons}}$

When test results are dichotomized, every test has two likelihood ratios, one corresponding to a positive test (LR⁺) and one corresponding to a negative test (LR⁻):

$$LR^+ = \frac{\text{Probability that test is positive in diseased persons}}{\text{Probability that test is positive in nondiseased persons}} = \frac{\text{Sensitivity}}{1 - \text{Specificity}}$$

$$LR^- = \frac{\text{Probability that test is negative in diseased persons}}{\text{Probability that test is negative in nondiseased persons}} = \frac{1 - \text{Sensitivity}}{\text{Specificity}}$$

For continuous measures, multiple likelihood ratios can be defined to correspond to ranges of results. (See [Table 42-5](#) for an example.)

Lists of likelihood ratios can be found in some textbooks, journal articles, and computer programs (see [Table 42-6](#) for sample values). Likelihood ratios can be used to make quick estimates of the usefulness of a contemplated diagnostic test in a particular situation. The simplest method for calculating posttest probability from pretest probability and likelihood ratios is to use a nomogram ([Figure 42-7](#)). The clinician places a straightedge through the points that represent the pretest probability and the likelihood ratio and then reads the posttest probability where the straightedge crosses the posttest probability line.

A more formal way of calculating posttest probabilities uses the likelihood ratio as follows:

$$\text{Pretest odds} \times \text{Likelihood ratio} = \text{Posttest odds}$$

To use this formulation, probabilities must be converted to odds, where the odds of having a disease are expressed as the chance of having the disease divided by the chance of not having the disease. For instance, a probability of 0.75 is the same as 3:1 odds ([Figure 42-8](#)).

To estimate the potential benefit of a diagnostic test, the clinician first estimates the pretest odds of disease given all available clinical information and then multiplies the pretest odds by the positive and negative likelihood ratios. The results are the **posttest odds**, or the odds that the patient has the disease if the test is positive or negative. To obtain the posttest probability, the odds are converted to a probability ([Figure 42-8](#)).

For example, if the clinician believes that the patient has a 60% chance of having a myocardial infarction (pretest odds of 3:2) and the creatine kinase MB test is positive ($LR^+ = 32$), then the posttest odds of having a myocardial infarction are

$$\frac{3}{2} \times 32 = \frac{96}{2} \text{ or } 48:1 \text{ odds} \left(\frac{\frac{48}{1}}{\frac{48}{1} + 1} = \frac{48}{48 + 1} = 98\% \text{ probability} \right)$$

If the CKMB test is negative ($LR^- = 0.05$), then the posttest odds of having a myocardial infarction are

$$\frac{3}{2} \times 0.05 = \frac{0.15}{2} \text{ odds} \left(\frac{\frac{0.15}{2}}{\frac{0.15}{2} + 1} = \frac{0.15}{0.15 + 2} = 7\% \text{ probability} \right)$$

Sequential Testing

To this point, the impact of only one test on the probability of disease has been discussed, whereas during most diagnostic workups, clinicians obtain clinical information in a sequential fashion. To calculate the posttest odds after three tests, for example, the clinician might estimate the pretest odds and use the appropriate likelihood ratio for each test:

$$\text{Pretest odds} \times LR_1 \times LR_2 \times LR_3 = \text{Posttest odds}$$

When using this approach, however, the clinician should be aware of a major assumption: the chosen tests or findings must be **conditionally independent**. For instance, with liver cell damage, the aspartate aminotransferase (AST) and alanine aminotransferase (ALT) enzymes may be released by the same process and are thus not conditionally independent. If conditionally dependent tests are used in this sequential approach, an inaccurate posttest probability will result.

Threshold Approach to Decision Making

A key aspect of medical decision making is the selection of a treatment threshold, ie, the probability of disease at which treatment is indicated. [Figure 42-9](#) shows a possible way of identifying a treatment threshold by considering the value (utility) of the four possible outcomes of the treat/don't treat decision.

Use of a diagnostic test is warranted when its result could shift the probability of disease across the treatment threshold. For example, a clinician might decide to treat with antibiotics if the probability of streptococcal pharyngitis in a patient with a sore throat is greater than 25% ([Figure 42-10A](#)). If, after reviewing evidence from the history and physical examination, the clinician estimates the pretest probability of strep throat to be 15%, then a diagnostic test such as throat culture ($LR^+ = 7$) would be useful only if a positive test would shift the posttest probability above 25%. Use of the nomogram shown in [Figure 42-7](#) indicates that the posttest probability would be 55% ([Figure 42-10B](#)); thus, ordering the test would be justified as it affects patient management. On the other hand, if the history and physical examination had suggested that the pretest probability of strep throat was 60%, the throat culture ($LR^- = 0.33$) would be indicated only if a negative test would lower the posttest probability below 25%. Using the same nomogram, the posttest probability after a negative test would be 33% ([Figure 42-10C](#)). Therefore, ordering the throat culture would not be justified as it does not affect patient management.

This approach to decision making is now being applied in the clinical literature.

Kohn MA et al: What white blood cell count should prompt antibiotic treatment in a febrile child? Tutorial on the importance of disease likelihood to the interpretation of diagnostic tests. *Med Decis Making* 2001;21:479. [PMID: 11760105]

Solomon DH et al: The rational clinical examination. Does this patient have a torn meniscus or ligament of the knee? Value of the physical examination. *JAMA* 2001;286:1610. [PMID: 11585485]

Decision Analysis

Up to this point, the discussion of diagnostic testing has focused on test characteristics and methods for using these characteristics to calculate the probability of disease in different clinical situations. Although useful, these methods are limited because they do not incorporate the many outcomes that may occur in clinical medicine or the values that patients and clinicians place on those outcomes. To incorporate outcomes and values with characteristics of tests, decision analysis can be used.

The basic idea of decision analysis is to model the options in a medical decision, assign probabilities to the alternative actions, assign values (utilities) to the various outcomes, and then calculate which decision gives the greatest value. To complete a decision analysis, the clinician would proceed as follows: (1) Draw a decision tree showing the elements of the medical decision. (2) Assign probabilities to the various branches. (3) Assign values (utilities) to the outcomes. (4) Determine the expected utility (the product of probability and utility) of each branch. And (5) select the decision with the highest expected utility.

[Figure 42-11](#) shows a decision tree where the decision to be made is whether to treat without testing, perform a test and then treat based on the test result, or perform no tests and give no treatment. The clinician begins the analysis by building a decision tree showing the important elements of the decision. Once the tree is built, the clinician assigns probabilities to all the branches. In this case, all the branch probabilities can be calculated from (1) the probability of disease before the test (pretest probability), (2) the chance of a positive test if the disease is present (sensitivity), and (3) the chance of a negative test if the disease is absent (specificity). Next, the clinician assigns utility values to each of the outcomes.

After the expected utility is calculated for each branch of the decision tree, by multiplying the utility of the outcome by the probability of the outcome, the clinician can identify the alternative with the highest expected utility.

Although time-consuming, decision analysis can help to structure complex clinical problems and to make difficult clinical decisions.

Evidence-Based Medicine

Evidence-based medicine stresses the use of evidence from clinical research—rather than intuition and pathophysiologic reasoning—as a basis for clinical decision making. Evidence-based medicine relies on the identification of methodologically sound evidence, critical appraisal of research studies, and the dissemination of accurate and useful summaries of evidence to inform clinical decision making. Systematic reviews can be used to summarize evidence for dissemination, as can evidence-based synopses of current research. Systematic reviews often use meta-analysis—statistical techniques to combine evidence from different studies to produce a more precise estimate of the effect of an intervention or the accuracy of a test.

Clinical practice guidelines are systematically developed statements intended to assist practitioners and patients in making decisions about health care. Clinical algorithms and practice guidelines are now ubiquitous in medicine. Their utility and validity depend on the quality of the evidence that shaped the recommendations, on their being kept current, and on their acceptance and appropriate application by clinicians. While some clinicians are concerned about the effect of guidelines on professional autonomy and individual decision making, many organizations are trying to use compliance with practice guidelines as a measure of quality of care.

•

Figure 42-3. Hypothetical distribution of test results for healthy and diseased individuals. The position of the "cutoff point" between "normal" and "abnormal" (or "negative" and "positive") test results determines the test's sensitivity and specificity. If point "A" is the cutoff point, the test would have 100% sensitivity but low specificity. If point "C" is the cutoff point, the test would have 100% specificity but low sensitivity. For many tests, the cutoff point is determined by the reference range, ie, the range of test results that are within 2 SD of the mean of test results for healthy individuals (point "B"). In some situations, the cutoff is altered to enhance either sensitivity or specificity.

43. Information Technology in Patient Care: The Internet, Telemedicine, & Clinical Decision Support - *Justin Graham, MD, MS, & Rick Kulkarni, MD*

INTRODUCTION

The use of computer systems and communication tools to enhance and improve medical practice, education, and research has increased exponentially in the past 30 years. Yet it is only recently that clinicians have begun to accept information technology as a means of improving patient care. This is due in part to substantial advances in component technologies: processors and memory, networks, and software. More importantly, health care workers and their patients have grown more familiar with computers in other occupational, commercial, and recreational applications. Therefore, an increasing number of clinicians apply these tools to the practice of medicine. Modern medicine is very information-intensive. Clinicians regularly synthesize the vast, rapidly growing body of medical literature with detailed, ongoing patient evaluations. They communicate the resulting reams of data to their patients and to other clinicians. Never before has information technology been better suited to assist in these tasks. Modern information systems offer the promise of unprecedented quality, innovation, and efficiency in the delivery of health care. But there are both old pitfalls and new perils to be avoided.

The complex technical and theoretical details underlying medical informatics and computer science are beyond the scope of this chapter. What follows is a brief introduction to topics and resources of general interest in this field, offered to help clinicians care for their patients as information technology becomes an integral part of the patient-clinician relationship.

THE INTERNET IN CLINICAL PRACTICE

The contemporary Internet encompasses a wide array of communication modalities. The dominant component of the Internet continues to be the World Wide Web. The Web's popularity derives from its ability to rapidly transmit both text and graphics to a user's computer screen through standard browser applications (eg, Microsoft Internet Explorer, Netscape Navigator).

Despite the Web's dominance, other forms of communication on the Internet continue to be vital to the medium's success in facilitating communication. Electronic mail (e-mail) is a text-based form of communication employed by most Internet users in a "store-and-forward" fashion (ie, not processed immediately by the recipient). File transfer protocol (FTP) permits rapid transfer of files from one computer to another through the Internet. User groups make possible congregation and communication between individuals with similar interests.

The individual clinician's interaction with the Internet depends on his or her personal requirements and expectations. Simple store-and-forward modes of communication such as e-mail simplify exchanges with patients and colleagues. The Web allows clinicians to review useful information such as clinical knowledge and patient-related material through hospital electronic records at the point of need. Many clinicians are increasingly turning to the Web to meet their accreditation requirements for continuing education. Most academic institutions offer faculty and staff e-mail accounts and access to the Web that can be used without charge.

Activities such as keeping up to date with current events in medicine, learning from electronic journals, and interacting with an institution's Web site for professional activities all require the use of browser software in order to access the Web. Several high-quality medical news Web sites (eg, CNN Health, Doctor's Guide) and an increasing number of online medical journals offering direct access to current and archived issues have made the Internet a valuable resource for physicians. Active participation in online medical communities providing access to searchable reference material and discussion groups (eg, eMedicine.com, MDConsult) add significantly to the overall experience.

Clinicians may consider taking further advantage of the Web by constructing a clinical practice Web site. Although the details of programming and implementing a Web site are complex, the process itself can be straightforward and achievable if the legal implications and the scope of the project are appropriately addressed. Offering clinical information to patients or engaging in the transmission of patient-related health information on the Web requires consideration of potential legal pitfalls. The transfer of health-related information is strictly regulated by federal agencies and federal legislation. Privacy and security standards established by the Centers for Medicaid and Medicare Services (CMS) and rules currently being implemented through the Health Insurance Portability and Accountability Act (HIPAA) must also be considered. (See Legal Aspects of Medical Informatics, below.) Providing medical content can be construed as formal medical advice. General patient education material and online recommendations should be followed by instructions directing patients to first discuss any suggested lifestyle or medication changes with a physician prior to adoption. In addition, the prudent physician should review previously published guidelines on responding to unsolicited e-mail requests for medical guidance. (See Patient-Clinician Electronic Communication, below.)

The scope of the clinical practice Web site should also be established prior to embarking on its construction. Programming a small Web site composed of several standard HTML (Hypertext Markup Language) "Web pages" can be accomplished by the individual clinician without a significant expenditure of time spent in learning computer code. Several off-the-shelf HTML editors have greatly simplified HTML programming by providing intuitive, user-friendly work environments. The actual installation of the Web pages onto a computer that "serves" content to the general Internet community can be accomplished by locating an Internet Service Provider (ISP). Professional assistance is recommended for advanced Web activities such as interacting with online databases and implementing interactive Web pages (e.g., submission forms, online applications).

INFORMATION RELIABILITY & QUALITY ASSESSMENT

Today's Internet offers a varied and extensive collection of Web sites devoted to the dissemination of health-related information. These Web sites provide a constantly expanding repository of information previously inaccessible to most clinicians and their patients. Continuing concerns with Web sites offering health-related information are these sites also frequently offer poor control related to the accuracy, timeliness, and reliability of the posted information.

Finding useful health-related information on the Internet can be a time-consuming process for the clinician unfamiliar with Internet search strategies. Even for those who are more experienced, locating reliable and useful information depends on one's ability to assemble a short list of potentially useful Web sites and then navigate to those sites to assess their usefulness.

A better strategy for the busy clinician is either to refer to established online compendiums of medical knowledge (eg, MDConsult, eMedicine.com) or to take advantage of Web sites that compile and review medical content offered on the Internet. Compilation Web sites will often apply a core set of reviewing criteria to all of the primary sites they review and rate. The criteria should be based on publisher accountability and applied to all health content Web sites. [Table 43-1](#) sets forth an example of a core set of standards.

Several review services provide rating criteria as well as seals of approval that individual Web sites can apply for and display to indicate compliance with established codes of conduct. An excellent example is the Geneva-based Health on the Net Foundation. Other Web sites such as the Current Medical Diagnosis & Treatment Companion Web Page (CMDT-CWP) offer stand-alone reviews and categorical ratings of hundreds of health care-related Web sites without requiring any display of seals of approval. [Table 43-2](#) is an example of a well-constructed rating system currently in use on the CMDT-CWP.

LEGAL ASPECTS OF MEDICAL INFORMATICS

Today's health care environment takes advantage of the improved efficiencies of electronic data exchange using Internet technologies for a variety of clinical and administrative purposes. Specific examples include electronic medical records (EMRs) to improve access to clinical records both at a given institution and between hospitals, inter-institutional clinical research collaborative efforts, and off-site access protocols for making patient information available to providers and third-party organizations (eg, insurance companies). The advantages of electronic transfer of information for efficiency and accuracy are undeniable. An important consideration when utilizing Internet technology for any purpose when clinical information is exchanged is the potential for compromise of sensitive patient information. Although significant strides toward acceptable levels of security were made over the past several years through CMS and other organizations, continued concerns regarding the integrity of existing privacy and security measures at both government and third-party institutional levels led to the enactment of the HIPAA in 1998. The act went into full effect in April 2003. It represented a landmark change in the way health care information was exchanged and processed. Calling for standardization of electronic health data and requiring protection of confidentiality and security, the act imposes severe civil and criminal penalties on those in violation (up to 10 years in prison or fines of \$250,000 (or both) for knowingly misusing identifiable health care data). The act affects virtually every organization that deals with health data, including medical centers, provider groups, HMOs, insurance companies, pharmacies, and physician offices. HIPAA states that the burden of maintaining a secure electronic health information environment and complying with federally mandated regulations for the secure transmission of patient-related health care information between health care providers and other third-party organizations falls primarily on the health information management specialists at the health care organization providing clinical care to the patient. Administrative and information technology staffs of the health care organizations are thus charged with the responsibility for implementing security authentication for information systems, standardizing electronic health transactions, creating unique identifiers for patients, providers, and health plans, and safeguarding the security and confidentiality of all patient-identifiable data. (See [Table 43-3](#))

The individual hospital- or clinic-based physician must become familiar with the general principles of electronic security to prevent accidental compromise of sensitive information—if only to avoid being held civilly or criminally liable for inadvertent violations. Clinicians should familiarize themselves with their designated local HIPAA Privacy Officer as well as published privacy and confidentiality policies for the organization. Under HIPAA rules, patients must provide explicit consent (eg, signed authorization) for the transmission of any protected health care information that is disclosed for nonroutine health care delivery purposes such as clinical research or marketing. Patients have the right under HIPAA rules and procedures to access their medical records for the purpose of reviewing and requesting changes; for requesting restricted access; and for determining whether there has been unauthorized disclosure outside the context of routine health care operations. (See [Table 43-4](#))

PATIENT-CLINICIAN ELECTRONIC COMMUNICATION

Although clinicians have been communicating with their patients by e-mail for several years, this aspect of the patient-provider relationship has come under scrutiny. Electronic communication can extend and complement personal encounters, improve compliance and access to care, and increase the involvement of patients in their own care. However, the nature of e-mail creates legal, ethical, and practical considerations that must be respected by patients and providers alike.

E-mail is more permanent than oral communication and more spontaneous than letters and other written communications. It is by its nature self-documenting. E-mail can be duplicated or forwarded with the press of a button, and copies may linger on intermediate or back-up computer systems long after both the sender and receiver have deleted the originals. It can be easily altered, with or without attribution, by the sender, the recipient, or a third party. E-mail lends itself readily to detailed instructions as well as attachments and links to other information sources.

Electronic communication is well suited for communicating administrative information, medication or dressing instructions, patient education materials, routine laboratory results, appointment reminders, and prescription refills. It can augment home monitoring of a variety of treatment plans, such as diabetic diets or smoking cessation programs. Providers can easily make general announcements to an entire patient practice about issues such as vacation coverage, influenza vaccine availability, or changes in referral procedures ([Table 43-5](#)). This new mode of communication should certainly enhance the patient-clinician relationship—although, admittedly, there are few controlled clinical trial reports on outcomes.

E-mail imposes the same legal and ethical obligations that inform other kinds of doctor-patient communication. Providers have a duty to respond promptly to patient inquiries and to maintain strict confidentiality regardless of the technology involved. The very nature of e-mail complicates these issues and presents unfamiliar considerations such as source verification and technical failure. Thus, some experts have advocated obtaining formal informed consent from patients before exchanging e-mails. Providers ought at least come to agreement with their patients about basic policies for exchanges of these messages ([Tables 43-6](#) and [43-7](#)).

Some clinicians have expressed concern that once their e-mail addresses become widely available, they will be deluged by messages from individuals with whom they have no preexisting relationship. Studies have not found e-mail from unfamiliar patients to be burdensome. However, there is currently no consensus on the physician's duty in this situation. Additionally, there may be legal consequences to providing advice to patients who are out of state or abroad and thus possibly beyond the scope of the physician's license. At minimum, physicians should post electronic communication policies addressing unsolicited communication wherever their e-mail addresses can be found.

Many organizations are exploring ways other than e-mail to engage their patients electronically. Secure Web-based communication systems and other Internet technologies are being developed that avoid some of the privacy and security pitfalls of standard e-mail. Some payers and health plans are even considering providing clinician reimbursement for these kinds of online encounters.

INTERACTIVE FORUMS

Informal consultations among clinicians have been common, but limited to the offices and conference rooms of specific health care settings or, periodically, academic meetings. The Internet and its dramatic reduction in barriers to communication has made these activities continuous and far-reaching.

Many online discussion groups are available for health care providers with similar interests ([Table 43-8](#)). Almost all function as electronic bulletin boards, where individuals leave new messages or comments relevant to ongoing discussion "threads" (topics).

Newsgroups (also called Usenet newsgroups) are one of the oldest applications of the Internet, predating the World Wide Web, although today the Web provides a convenient Usenet interface. There are tens of thousands of newsgroups organized in nested series with names like "sci.med.prostate.bph" or "alt.support.crohns-colitis." Newsgroups are open to the general public, are usually unmoderated, and are subject to little or no information quality control. There are many ways to access newsgroups, but perhaps the easiest is to browse through them at <http://groups.google.com>.

Web-based forums are usually adjuncts to specific Web sites. They frequently require registration demonstrating appropriate credentials (eg, medical license number), and moderators often monitor postings for veracity and relevance. Thus, Web-based forums generally carry discussions of higher quality among fewer participants.

Mailing lists are discussions delivered directly by e-mail. Any comment posted to the ongoing dialogue is instantly sent to every subscriber throughout the world. Mailing lists can be moderated or unmoderated, private or public, and may have as few as two or as many as tens of thousands of subscribers. High-volume lists, which can average hundreds of postings each day, can be received using digest mode, which gathers the day's postings into a single e-mail message. Subscribing usually involves sending an e-mail message to an address containing "listserv" or "majordomo" with the text containing "Subscribe" followed by the name of the list in question (eg, Stroke-L or Lymenet-L).

The Internet's closest approximation to a face-to-face conversation takes place in chatrooms, where participants take turns typing text visible to the whole group as the discussion unfolds. More advanced chatrooms allow participants to "whisper" private messages to one another. Although—as with everywhere on the Internet—it is impossible to verify the identities of those with whom one is communicating, quality chatrooms provide moderators, discussants, or attendants responsible for guiding discussions and omitting noncontributing participants. Most chatrooms of interest to health care providers are hosted by medical Web sites.

Instant messaging applications such as Yahoo Messenger or AOL Instant Messenger have recently gained popularity. These applications allow real-time, synchronous text chat and file exchange with other online users such as patients and other clinicians. Users of these systems should remember that they are not secure and do not provide suitable privacy for discussion of confidential matters.

TELEMEDICINE

Telemedicine has been defined as "the use of electronic information and communications technologies to provide and support health care when distance separates the participants." The first example was the telephone. The first video telemedicine application was tested in the 1960s by neurologists and psychiatrists in Nebraska.

Telemedicine applications of the past 20 years have relied mainly on interactive video to connect patients and referring clinicians in remote locations with specialists in urban tertiary care centers. Using studio or home video recording equipment, visual and audio information is conveyed either by physical transportation of videotape or other recording media or by more sophisticated, specially designed video conferencing networks.

As broad-bandwidth (high transmission rate) networks have become available, "store-and-forward" telemedicine has become more commonplace, using multimedia e-mail and Web technology to forward medical images, audio, medical records, and laboratory results. By combining these data with real-time synchronous consultations, consultants can now provide comprehensive evaluations from anywhere in the world.

The next generation of telemedicine applications will expand the remote clinician's capabilities beyond diagnosis to therapeutic interventions. Telesurgery, remote psychotherapy, and virtual "home visits" to manage chronic medical problems are all in early development. Remote monitoring of chronic medical conditions using networked medical devices such as blood pressure cuffs or blood glucose monitors has become increasingly popular. Multiple Web sites attest to these and even more innovative uses of telemedicine for clinicians to explore ([Table 43-9](#)).

Telemedicine applications have several limitations. The peer-reviewed literature discussing telemedicine is currently largely limited to pilot projects and short-term outcomes; the few rigorous studies performed to date suggest the efficacy of teleradiology, telepsychiatry, telenursing, transfer of echocardiographic images, and electronic consultations with specialists. Secondly, given the ease of transmission and duplication of digital information, confidentiality and security must be safeguarded. Although information transfer ignores geographic boundaries, medical licensure does not—especially in the United States, where several states have limited the interstate practice of medicine. Liability and malpractice are thorny and untested issues, as the practice of telemedicine presents a new form of the patient-caregiver relationship and associated hazards, such as technical failures leading to altered or suboptimal data. Finally, health care payer policy is lagging behind the technology.

Medicare and other insurers will reimburse telemedicine visits that meet a very restrictive set of criteria. Consultative "store-and-forward" teleradiology is usually reimbursed, as are certain consultations, office visits, individual psychotherapy, and pharmacologic management sessions when they involve interactive audio and video. Triage, diagnosis, and advice are not covered by video, just as they are excluded from coverage when performed by telephone.

CLINICAL DECISION SUPPORT SYSTEMS

Computers and artificial intelligence systems have played a role in improving the quality of health care delivery to patients for several decades. One specific aspect of their contribution has been in the area of clinical decision support. Advances in enabling technology (eg, the Internet) have led to the dissemination of clinical decision support modalities both for the practicing physician as well as for the individual patient.

In contrast to general clinical information sources such as up-to-date clinical references (eg, medical journals or electronic textbooks), computer-based decision support systems directly assist the clinician in making a decision about a specific patient. These applications incorporate individual patient characteristics into a computerized knowledge base to generate patient-specific assessments or recommendations.

Clinical judgment is dependent on information gathering, accurate assessment of probabilities, and problem-solving skills. Clinicians draw upon their personal knowledge base, accumulated over years of experience, to recognize patterns, anticipate outcomes, and reason heuristically. (Heuristic reasoning uses rules of thumb, eg, "Chest pain in an older man is a myocardial infarction until proved otherwise."). Health care providers, while adept at these tasks, are subject to limitations and prejudices inherent to humans. Information overload can overwhelm clinicians, forcing them to ignore relevant data. Clinicians are also prone to several human cognitive biases that can hamper decision-making (see [Table 43-10](#)).

Free from human limitations, clinical decision support systems offer an adjunct to the traditional patient care model. They have made possible the sharing of expert knowledge and problem-solving skills from institution to institution in a reliable and reproducible manner. Clinicians can also learn to improve their own decision-making skills by using these systems for feedback, evaluation, and simulations.

Clinical decision support systems perform a variety of functions from providing feedback to actions taken by clinicians to initiating communication between providers upon encountering unusual data. Specific examples of the types of logic used by clinical decision support systems in addition to topical examples are provided in [Table 43-11](#).

Clinical decision support systems save lives and reduce costs. Inpatient order entry systems continue to routinely result in double-digit percentage reductions in costs of patient care without negative effects on outcomes. Drug family checking systems reduce the frequency of adverse drug events by up to 55%. Time-based reminders for preventive care activities increase the percentage of patients who are up-to-date with recommended adult preventive testing schedules, and automated e-mails increase interprovider communication and satisfaction. Hospital-based providers have accepted use of clinical decision support systems in their daily practice, and such systems are moving also into mainstream clinical practice. Clinicians must investigate how these innovative and rationally developed technologies can be most effective for their specific situations.

PERSONAL DIGITAL ASSISTANTS (HANDHELDS)

Personal digital assistants (PDAs; handhelds) are pocket-sized computing devices used primarily for personal information management. The defining feature of handhelds is their ability to synchronize with a personal computer. The benefits of synchronization include minimization of accidental information loss, ease of information input, and transfer of online information into the device.

The devices are designed for limited data input. Feasible activities on the limited screen size include recording expenses, writing memos, and e-mail composition. Large data entry tasks and image composition are not realistic on the devices themselves but must be accomplished through synchronization of the device with a computer. Additional applications available for the devices included file transfer and backup utilities, investment applications, mapping and navigation tools, digital imagery, and games. Plug-in modules have transformed handhelds in various other devices from cameras to audio players to voice recorders. Higher-end models feature wireless connectivity and integrated cellular functionality, permitting their user to access information on the Web and send and receive e-mail as well as pages.

Clinicians will find handhelds to be particularly useful. To begin, clinicians may take full advantage of the personal information management features discussed in the preceding paragraphs. The usefulness of handhelds for clinicians is significantly extended beyond this basic functionality through the development of proprietary clinical applications. Specific examples of such functionality are outlined in [Table 43-12](#).

Clinical calculators perform a variety of pertinent clinical functions such as medication calculations (eg, intravenous antibiotic and pressor drip calculations), clinical parameter calculations (eg, fractional excretion of sodium and free water deficit) and physiology calculators (eg, caloric converters, pregnancy estimated date of confinement). Medical databases include collections of useful information on such topics as microbial diseases, immunization schedules, and interpretation of laboratory tests. Drug references provide easy access to comprehensive databases on adult and pediatric drug dosing, regimens, contraindications, adverse reactions, pregnancy and lactation, and mode of metabolism or excretion. Finally, information management applications provide extended functionality through innovative patient charting and clinical management software, procedure and case log, and electronic prescription generators.

MEDICAL CODING & TERMINOLOGY

Medical classification systems are tools used for bringing semantic and conceptual order to the chaos inherent in the enormously complex practice of medicine. Once thought to be the domain of data analysts and bureaucrats, disease coding and classification have increasingly become important for clinicians to understand. Large epidemiologic studies rely exclusively on disease coding for patient selection and stratification. Political and economic public health decisions are frequently made on the basis of data collected via specialized classification systems. However, disease coding can intrude on the patient-physician relationship if it is allowed to dictate reimbursements, elements of the clinical encounter, documentation, and appropriateness of testing and treatment.

One of the most influential classification systems in use today is the World Health Organization's International Classification of Diseases ([Table 43-13](#)). It is currently in its tenth formal revision (ICD-10), though many institutions have not yet upgraded from ICD-9. It divides all of medicine into 21 "chapters," with titles like Diseases of the Digestive System, or External Causes of Morbidity and Mortality. Each chapter is subdivided into blocks, categories, and subcategories, to allow increasing level of detail—nearly 8000 in all. Categorization is inconsistent and incomplete: code outlines can be derived from anatomy, etiology, or epidemiology and frequently end with the category "not elsewhere classified" (NEC) or "not otherwise specified" (NOS). Although ICD was originally designed for epidemiology and health statistics, clinical modifications (ICD-10-CM) have been created that contain more clinical detail for use with billing, medical review, and reimbursement, raising the number of categories to 50,000. So while ICD-10 may have categories that correspond loosely to the level of information found on a death certificate, ICD-10-CM is able to categorize the

fine detail found in that patient's hospital chart.

In an attempt to correlate diagnosis with cost of treatment, the United States Health Care Finance Administration created Diagnosis Related Groups (DRG) ([Table 43-13](#)). There are about 500 DRG codes in 23 Major Diagnostic Categories, derived to simplify adult inpatient Medicare billing, each corresponding to a patient's principal diagnosis or procedure and associated with a standardized cost. These correlations can be used to help determine an institution's case-mix or a population's relative severity of illness. Many different ICD codes may fall under a single DRG code—as long as the diseases they represent incur similar inpatient expenses.

There are many other coding systems, each designed for a different purpose ([Table 43-13](#)). Current Procedural Terminology (CPT) is a listing of descriptive terms and identifying codes created by the American Medical Association for reporting medical services and procedures—again for billing. The Systematized Nomenclature of Medicine (SNOMED) is a general purpose nomenclature designed to encompass all events in the medical record; unlike CPT, it is intended not for billing but for the standardization of databases, trials, and comparative information. Medical Subject Headings (MeSH) are devised by librarians at the National Library of Medicine to create a loose hierarchy for structuring the medical literature.

Most coding systems are created with very specific purposes in mind, and they usually succeed. However, problems occur when they are applied to tasks for which they were unintended.

Table 43-6. Provider strategies for management of electronic communication.¹

Use password-protected workstations, digital signatures and encryption for all messages when readily available.
Print all messages, with replies and confirmation of receipt, and place in patient's permanent medical record.
Double-check all "To:" fields prior to sending messages.
Configure automatic reply to acknowledge receipt of messages.
Send a new message to inform patient of completion of request.
Maintain a mailing list of patients, but do not send group mailings where recipients are visible to each other. Use blind copy feature in software.
Create template banner headings and footers giving explicit instructions about how to escalate communication to telephone calls and office visits.
Never forward a patient's message or patient-identifiable information to a third party without the express permission of the patient.
Perform at least weekly backups of mail onto long-term storage.
Commit policy decisions to writing and electronic form.
Avoid anger, sarcasm, harsh criticism, and libelous references to third parties in messages.

Table 43-7. Suggested elements of a patient-provider agreement for electronic communication.¹

Establish turnaround time for messages and expressly state that e-mail is not for urgent matters or emergencies.
Provide instructions on how and when to escalate to phone calls, office appointments, and emergency room visits.
Agree on privacy issues and who, besides the addressee, will read messages. Make specific reference to office staff, covering providers, and third-party consultations.
Inform patients about the possibility of electronic eavesdropping by patients' own employers, Internet service providers, and others, such as family, who have access to the same computers or e-mail account.
Establish types of transactions (prescription refill, appointment scheduling, etc) and sensitivity of subject matter (HIV, mental health, etc) permitted over e-mail.
Instruct patients to put category of transaction in subject line of message for filtering: "prescription," "appointment," "medical advice," "billing question."
Request that patients put their name and patient identification number in the body of the message.
Ask that patients use autoreply feature to acknowledge reading provider's message.
Describe how messages will be incorporated into the permanent medical record.

Table 43-11. Functional classes and examples of clinical decision support systems.

Class	Function	Examples
Feedback	Provide feedback by responding to an action taken by the clinician or to new data entered into the system	Drug family checking results in alerts on allergies, drug-drug interactions, and other patient-specific conflicts Parameter checking looks for dosing errors and other parameter discrepancies in patient-specific scenarios (eg, gentamicin dosing in renal failure) Redundant utilization checking alerts physicians to duplicate test orders
Data organization	Organization and presentation of disparate data into logical, intuitive schemas at the point-of-need	Aggregate data trending observes key indicators for large numbers of patients over time (eg, emergence of antibiotic resistance patterns)
Proactive information	Provision of information to the clinician at the point-of-need (eg, clinical pathway on pneumonia when patient with pneumonia being admitted to hospital)	Template and order sets can be provided appropriate to given situations
Intelligent actions	Automation of routine and repeated tasks for the clinician on a regular time schedule (eg, provision of all new laboratory values on current patient list every morning)	Rule-based event detection allows users to create logical rules to be checked when triggering events occur (eg, check glucose level in hyponatremia) Time-based checks to post reminders when expected transactions have not occurred (eg, warfarin order not filled by 8:00 PM)
Communication	Alert clinician and other providers who need to know about unusual data (eg, test results) or communications regarding specific patients	Parameter alerts provide clinicians with key information on panic values Automated e-mails send information to clinicians when provider-patient encounters occur (eg, e-mail to primary doctor when patient evaluated in the emergency department)
Expert advice	Diagnostic and therapeutic advice using a comprehensive knowledge base and a problem-solving method, such as probabilistic reasoning, neural nets, or heuristic rules.	Differential diagnosis and suggestions for further testing generated from patient-specific data. Reducing uncertainty in test interpretation (eg, probability of pulmonary embolism given patient demographics and indeterminate V/Q scan)

44. Complementary & Alternative Medicine - *Ellen F. Hughes, MD, PhD, Bradly P. Jacobs, MD, MPH, & Brian M. Berman, MD*

Introduction

The use of complementary and alternative medicine has become common in the United States. To maintain effective clinician-patient communication and ensure responsible clinical practice, it is important that clinicians learn the theory, practice, and scientific evidence associated with these therapies. This chapter provides an overview of four alternative medicine therapies: herbal medicine, nonherbal dietary supplements, acupuncture, and homeopathy.

Background

In 1998 a survey by Eisenberg estimated that over 40% of Americans made more than 600 million visits to alternative medicine practitioners and spent over \$27 billion for their services. These visits exceeded the total number of visits to all United States primary care physicians, and the out-of-pocket expenditures were about the same as what the American public pays for all physician services.

Common reasons for seeking this care include acute musculoskeletal strain and conditions such as back pain, anxiety, depression, insomnia, chronic pain, and addiction. A 1998 survey by Astin identified the following predictors for Americans who use this category of care: higher education, poorer health status, having had an experience that caused a change in worldview, a holistic orientation toward life, and identification with a cultural group that has a commitment to women's rights, environmentalism, spirituality, and personal growth psychology.

Of patients using alternative medicine, only 4% use it exclusively. The majority combine it with conventional medicine because they perceive the combination to be superior to either option used alone. In one recent telephone survey, complementary therapies were judged by patients to be more effective for treating headache and back pain, but conventional therapy was considered superior for treatment of hypertension.

Within the conventional medical paradigm, efforts are being made to understand this phenomenon. Most medical schools now offer elective courses, and many are integrating information about these therapies into their required curricula. Special interest groups to discuss the role of alternative medicine have been organized in the Association of American Medical Colleges, the Society of Teachers of Family Medicine, and the American Public Health Association. Private and public hospitals are providing outpatient and inpatient clinical services for people seeking such care. Funding for biomedical research in this field has increased dramatically. The National Institutes of Health established the Office of Alternative Medicine in 1992 with an annual budget of \$2 million; in 1998, its role was expanded as the National Center for Complementary and Alternative Medicine (NCCAM). A total of more than \$200 million has been budgeted by NIH for research in the field in fiscal year 2003-2004. In 1998, *JAMA* and its ten affiliated *Archives* journals published theme issues including more than 80 articles pertaining to the field.

In 1996, the state of Washington passed legislation requiring insurance companies to reimburse policyholders for all services provided as alternative medicine. Recognizing the large public demand for these services, many United States health insurance companies have expanded benefit packages to include such services for an additional premium. According to data from early 2001, statutory licensure of practitioners exists for chiropractors in all 50 states, for acupuncturists in 42 states, for massage therapists in 25 states, for practitioners of naturopathic medicine in 11 states, and for homeopathic practitioners in 3 states. Insurance coverage is mandated for the costs of chiropractic medicine in 42 states and for costs of acupuncture in 7 states.

The National Institutes of Health classifies the complementary and alternative modalities into five major categories: (1) alternative medical systems (traditional Oriental medicine, acupuncture, Ayurveda, naturopathy, homeopathy, Native American healing, Tibetan medicine, etc); (2) mind-body interventions (meditation, certain uses of hypnosis, dance, art and music therapy, spiritual healing, and prayer); (3) biologic-based therapies (herbal medicines and dietary supplements, special diets, and orthomolecular medicine); (4) manipulative and body-based methods (chiropractic, massage, the Feldenkrais method, other "body work" systems, and aspects of osteopathic medicine such as craniosacral work); and (5) energy therapies (reiki, therapeutic touch, qigong, magnets, and other methods of affecting the "bioelectric field" of the body).

■ HERBAL MEDICINES

Epidemiology

The use of herbs for medicinal purposes has increased dramatically over the past decade. Herbal products are used by one out of three Americans at an annual total cost of more than \$4 billion, but fewer than half of those individuals discuss the matter with a conventional health care provider. Consumers hold strong views about the efficacy of the supplements they take. Seventy percent state that they would continue to take their favorite supplement even if a government study claimed it was not effective.

In the 1850s, 80% of medicines in the *United States Pharmacopeia* were derived from plants. Today, approximately 20-30% of the drugs listed in *USP Dictionary* are plant-derived—important examples include atropine, colchicine, digoxin, and many antineoplastic agents.

Herbal medicines have been dispensed for centuries by traditional herbalists who have been involved with their cultivation and preparation as well as assessment of their potency. At present, most herbal products are commercially cultivated, processed in unregulated environments, and sold over-the-counter without the counseling of a qualified health practitioner.

Regulatory Issues

In 1994, the United States Congress passed the Dietary Supplement and Health Education Act (DSHEA). This act limited regulatory control over dietary supplements and herbs. DSHEA classifies vitamins, minerals, herbs, and amino acids as nutritional or dietary supplements. Under DSHEA, supplements can be marketed without proof of safety or efficacy as long as no claim is made for their use in the diagnosis, treatment or cure, or prevention of disease. Manufacturers can, however, make "structure and function" claims that a product enhances a normal body function or state such as thinking, mood, or immune function. For example, saw palmetto can be marketed to support urinary tract health but not to treat benign prostatic hyperplasia. In contrast to prescription drugs, the FDA must first prove that a herbal preparation is *unsafe* before it can order that a product be taken off the market.

Quality Assurance

Since there are no regulations mandating that herbal manufacturers follow strict quality assurance guidelines, consumers have no guarantee of the safety and efficacy of the products they purchase. They cannot be certain that the plant was accurately identified; that the product is free of microbial, pesticide, and heavy metal contamination; or that all batches will contain the same ingredients in the same strengths. Indeed, a 17-fold difference in the amount of active ingredient was found when six national brands of St. John's wort were tested off the shelf.

The situation is different in Germany, where there is some regulation of herbal medicines. The German Federal Health Agency Commission E was formed in the 1970s to investigate and assess the safety and efficacy of herbal products. More than 400 monographs were produced on 350 herbal preparations, many of which are now available in an expanded English version. Since the United States has no such regulatory system, patients are advised to follow certain guidelines when considering whether to use herbal medicines ([Table 44-1](#)).

Product Formulations & Standardization

Herbal formulations include liquids (extracts, tinctures, infusions, and decoctions) and fresh, dried, and powdered preparations. The potency of herbs varies widely depending on which part of the plant is used, where it is cultivated, and what variations there may be in growing conditions and methods of preparation.

To ensure a consistent percentage of the primary active ingredients across batches and brand names, standardized extracts have been developed. Since multiple constituents may have pharmacologic activity, determining the active ingredients for standardization purposes can be a difficult task. The European scientific community has played a significant role in producing and investigating high-quality standardized extracts that contain consistent quantities of marker compounds (ideally, the active ingredients). This work has laid the foundation for conducting phase 2 and phase 3 clinical trials. The quality of research in the field is improving, but most herbal remedies have not been evaluated in controlled clinical trials.

Safety of Herbal Medicines

Although many medicinal herbs are relatively safe, some have significant toxicity. Herbs themselves can have unanticipated effects such as hepatotoxicity as seen with chaparral and germander. Ma-huang contains ephedrine and is sold as a component of many weight loss products and in a banned euphoriant called "herbal ecstasy." Over 800 cases of adverse events associated with Ma-huang have been reported to the FDA. (See Ephedra in the specific herbs section for details.) Herbal products may also be intentionally adulterated with prescription drugs or contaminated with harmful substances such as pesticides or heavy metals. Prescription drugs such as prednisone, NSAIDs, antibiotics, and testosterone have been detected in imported Chinese patent medicines. An estimated 15 million adults in 1997 took herbal medicines concurrently with prescription medications, creating a potential risk for adverse drug-herb or drug-supplement interactions. Patients taking St. John's wort along with the drugs indinavir or cyclosporine have lower blood levels of these prescription medicines. St. John's wort has the capacity to induce the cytochrome P450 system, which can lead to increased metabolism (ie, lower blood levels) of prescription medicines that are processed by this system such as warfarin, theophylline, and birth control pills. Proving that a side effect experienced by a patient taking a dietary supplement is caused by that supplement is often difficult. Practitioners should take a detailed history from the patient and, if possible, obtain a sample of the product to facilitate further analysis if needed. All suspected adverse events should be reported to the FDA's Medwatch Program (<http://www.fda.gov/medwatch>), although it is estimated that fewer than 1% are actually reported.

REVIEW OF THE EVIDENCE FOR SELECTED HERBAL MEDICINES

Table 44-2 provides an overview of selected herbal medicines.

St. John's Wort (*Hypericum perforatum*)

St. John's wort is used in the treatment of mild to moderate depression. Multiple constituents identified as potential active ingredients include naphthodianthrone, flavonoids, and xanthones. Most preparations are standardized to hypericin content (a naphthodianthrone), but recent data indicate that there are other active ingredients as well, including hyperforin. The highest concentration of active ingredients is found in the flowering tops. The precise mechanisms of action are not known. Irreversible MAO-inhibitory activity noted in vitro has not been observed in vivo. Other postulated mechanisms include selective inhibition of serotonin, ?-aminobutyrate, norepinephrine, and dopamine reuptake in the central nervous system.

Over the past two decades, St. John's wort has been studied in approximately 3000 patients with mild to moderate depression. Most of the 30 randomized controlled clinical trials, systematic reviews, and meta-analyses have shown that it is more effective than placebo and as effective as tricyclic agents for the treatment of mild to moderate depression. In Linde's review of 23 randomized controlled trials with 1757 subjects, hypericin-treated patients did significantly better than those receiving placebo (OR = 2.7; 95% CI, 1.8-4.0) and as well as those receiving antidepressants such as imipramine 50-75 mg/d, maprotiline 75 mg/d, desipramine 100-150 mg/d, and amitriptyline 30 mg/d (OR = 1.1; 95% CI, 0.9-1.3). Side effects occurred in over 50% of patients taking conventional antidepressants compared with 20% of patients taking St. John's wort. A Cochrane Collaboration systematic analysis of 27 randomized controlled trials with almost 2300 patients confirmed Linde's earlier findings. A review of commonly used herbs by Ernst also concludes that St. John's wort is effective in treating mild to moderate depression. In contrast, two recent studies conclude that St. John's wort is no more effective than placebo in the treatment of major depressive symptoms. In one trial, 340 patients with major depression were randomized to receive St. John's wort, sertraline, or placebo. After 8 weeks of treatment, no differences were observed—using the Hamilton and Beck depression scales—in patients taking St. John's wort, the SSRI, or placebo. In contrast, a recent meta-analysis of three randomized, placebo-controlled, double-blind, multicenter trials of St. John's wort for mild to moderate depression using a Schwabe Hypericum extract concluded that St. John's root was more effective than placebo. St. John's wort is generally well tolerated. Side effects are not common and include mild headache, photosensitivity, gastrointestinal upset, and restlessness. Patients are advised to avoid taking St. John's wort in addition to prescription antidepressants, as there have been case reports of serotonin syndrome. St. John's wort also induces the cytochrome P450 system (isozyme CYP3A4), which may lower the blood levels of other drugs that are metabolized by this system (eg, ethinyl estradiol, warfarin, cyclosporine, and indinavir). Several cases of cardiac and renal organ rejection have been reported in patients whose previously stable level of cyclosporine was lowered after initiation of St. John's wort. Of further concern is that this herb-drug interaction may persist even after St. John's wort is discontinued. A 40% decrease in serum levels of the chemotherapeutic agent irinotecan noted in five patients taking concurrent St. John's wort persisted for 3 weeks after St. John's wort was discontinued.

Garlic

Garlic is one of the most popular herbal remedies and is available in fresh, dried, and powdered forms. The German Federal Health Agency Commission E and the European Scientific Cooperative on Phytotherapy have approved garlic for the treatment of hyperlipidemia and atherosclerosis. Allicin, the ingredient believed responsible for garlic's therapeutic benefit and odor, is highly unstable. Both heat and acid destroy the enzyme allinase, which is necessary to produce allicin, and for that reason garlic is best ingested raw. Garlic is also available over-the-counter in multiple formulations. The best-studied form is an enteric-coated capsule of dehydrated garlic. Freeze-drying helps retain most of the active ingredients found in raw garlic. Enteric coating permits allicin to be released in the small intestine, thereby enhancing absorption and reducing the breath odor. Over-the-counter preparations are frequently standardized to yield 0.6% allicin, but allicin yield among powdered preparations varies as much as 230-fold in brands used in trials. This lack of standardization may contribute to inconsistent results in dozens of clinical trials.

Garlic appears to have small effects on cholesterol and very minimal effect on blood pressure and none on glucose levels. The mechanisms of action believed responsible for the lipid-lowering effect include inhibition of HMG-CoA reductase and 14a-demethylase. A systematic review by Ackerman funded by the Agency for Health Care Policy and Research identified 36 randomized controlled trials on the use of garlic for the treatment of cardiovascular risk factors. Among the 26 trials evaluating hyperlipidemia, small but statistically significant reductions (16 mg/dL) were found for total cholesterol at 3 months among patients treated with garlic compared with placebo. Among the eight trials with outcomes at 6 months, no significant reductions in lipids were seen with garlic compared with placebo. In a qualitative review of antithrombotic effects, a modest and short-term effect was identified. Because garlic has some activity against platelet activation, there is a

theoretical risk of increased bleeding, but there is insufficient evidence to determine a causal association. Effects on glucose and blood pressure were absent to minimal in studies reviewed.

Silagy and Neil reviewed 16 randomized controlled clinical trials representing 952 patients for the treatment of hyperlipidemia with garlic. They found approximately 12% reduction in total cholesterol and triglycerides with doses of 600-900 mg/d of a freeze-dried preparation. This dose was equivalent to one-half to one clove of raw garlic per day. They also performed a meta-analysis of garlic for the treatment of hypertension and found a pooled mean blood pressure reduction of 8 mm Hg systolic and 5 mm Hg diastolic between groups. A more recent meta-analysis of 13 randomized controlled trials by Stevenson showed less of a lipid-lowering effect of garlic. Total cholesterol decreased approximately 6%; analyses of trials limited to high quality found no difference in cholesterol levels between garlic and diet control.

Garlic is well tolerated and apparently safe for chronic use. In addition to the well-known breath and body odor, common side effects include gastrointestinal upset, nausea, and flatulence.

A more than 50% reduction in blood levels of saquinavir after garlic supplementation was reported recently. The mechanism of action of this significant herb-drug interaction may be induction of the cytochrome P450 system by the herb, as has been noted also with St. John's wort. Garlic supplementation causes a decrease in platelet aggregation, but the clinical significance of this observation is not clear.

Ginkgo

The dried leaf of the ginkgo tree has been used medicinally for thousands of years. More than 400 studies over the past 30 years have investigated ginkgo's ability to improve blood flow in a variety of conditions, including memory impairment, dementia, peripheral vascular disease, and tinnitus. The German Commission E has approved a standardized form of ginkgo leaf extract (Egb761) for the treatment of cognitive impairment and intermittent claudication. Multiple pharmacologically active compounds have been isolated from ginkgo, including flavonoid glycosides and terpene lactones (ginkgolides). The flavonoids have antioxidant and free radical scavenging ability. The terpene lactones (especially ginkgolide B) have platelet-activating factor antagonist activity. In addition, ginkgo extracts activate certain central neurotransmitters, including the cholinergic system, which may contribute to their beneficial effects on memory and cognition. Egb761—the formulation that has been studied most extensively—is standardized to contain 24% flavonoid glycosides and 6% terpene lactones.

A 1998 review identified 50 trials that assessed ginkgo's efficacy on cognitive function in the elderly. Because the vast majority of trials did not require a definitive diagnosis of dementia or Alzheimer's disease, only four trials involving 424 patients met study entry criteria for meta-analysis. Results showed a modest improvement in cognitive function when compared with the placebo group—comparable to the effect of donepezil on dementia. The longest of these studies (1 year) showed stabilization of cognitive and functional abilities in 309 demented patients treated with Egb761 compared with placebo, with no differences in adverse outcomes. There is conflicting evidence about ginkgo's ability to enhance memory in healthy individuals. A recent trial reported no benefits of taking 120 mg/d of ginkgo for 6 weeks on multiple measures of memory and concentration in 230 healthy older subjects. Earlier smaller studies suggest that 240 mg/d for up to 6 weeks may be helpful in enhancing memory in healthy individuals. The NIH has recently funded investigators at the University of Pittsburgh to determine whether ginkgo taken over 5 years can prevent or delay the development of dementia in 3000 patients 75 years of age or older.

In general, ginkgo is well tolerated in healthy adults at recommended doses for up to 6 months. Allergic skin reactions, gastrointestinal disturbances, and headache occur in fewer than 2% of patients. There are theoretical concerns about a risk of increased bleeding because antiplatelet activating factor activity has been demonstrated in vitro. Several cases of increased bleeding have been reported (two patients were also taking aspirin or warfarin). Although no bleeding complications have been reported in any clinical trials and causality has not been clearly established, caution should be exercised when combining ginkgo with anticoagulants.

Ginkgo has also been evaluated for its effect on intermittent claudication. In a recent meta-analysis of eight randomized, placebo-controlled, double-blinded trials involving 418 patients, there was a modest treatment effect in the increase of pain-free walking distance in favor of ginkgo over placebo. There is insufficient evidence to support ginkgo's efficacy in treating tinnitus, acute mountain sickness, premenstrual syndrome, or vertigo.

Echinacea

Echinacea ranks among the top-selling herbs in the United States, accounting for more than \$300 million in sales annually. In the 1920s, echinacea tincture was a popular anti-infective agent until the discovery of antibiotics. Three of nine echinacea species are currently used for the treatment and prevention of upper respiratory infections. Above-ground parts and roots of *Echinacea purpurea* and the roots of *E pallida* and *E angustifolia* are used for medicinal purposes. Several active ingredients have been identified, including polysaccharides, glycoproteins, alkaloids, and flavonoids. In vitro and animal studies suggest that these ingredients cause stimulation of the immune system (natural killer cells, macrophages, and cytokine activity) and that they possess anti-inflammatory, free radical-scavenging, and antiviral activity.

Two high-quality systematic reviews have evaluated 13 double-blind, randomized, controlled trials of echinacea for prevention or treatment of the common cold. The quality of most clinical trials has been limited by use of multiple products and doses (including formulations containing multiple herbs) and the lack of rigorous methodology. In both reviews, there was modest benefit of echinacea compared with placebo for the acute treatment of upper respiratory infections. Subjects reported reduced symptoms or shortened duration of a viral upper respiratory tract when the herb was started within several days after onset of cold symptoms and continued for 8-10 days. In contrast, an encapsulated mixture of unrefined *Echinacea purpurea* and *Echinacea angustifolia* provided no detectable benefit and caused no harm in healthy college students who had the common cold compared with placebo. There is not sufficient evidence to support the use of echinacea to prevent upper respiratory infections. Four large European trials of echinacea for that purpose showed positive trends but no statistically significant efficacy of the herb compared with placebo. Similar findings were reported in a recent double-blind trial of 117 adults who were challenged with rhinovirus after taking a United States echinacea product or placebo for 2 weeks.

In general, echinacea is well tolerated, with few reported adverse events. Rare allergic reactions have been reported (especially in patients with ragweed allergies), and there was a single case of recurrent erythema nodosum. The German Commission E recommends that patients who are pregnant, have autoimmune disease, or who are immunocompromised not take echinacea because of its immune-stimulating effects. The Commission also recommends that its use be limited in others to less than 4 weeks. The data supporting these recommendations are not clear.

Kava

Kava is prepared from the dried rhizome of the *Piper methysticum* plant. Traditionally, it was used to prepare a ceremonial drink in the South Pacific islands. Its present-day uses include the treatment of anxiety, stress, and insomnia. The active ingredients (kavapyrones) have central muscle-relaxing properties and anticonvulsant activity. The precise anxiolytic mechanism of action is not fully understood but may involve enhanced binding of γ -aminobutyric acid in the central nervous system.

A recent systematic review and meta-analysis of seven German randomized, double-blind, placebo-controlled trials concluded that kava was more effective than placebo in relieving anxiety. The longest study involved 101 German outpatients randomized to kava or placebo for 6 months. Compared with placebo, kava-treated patients had progressively lower Hamilton anxiety scale scores at 3 and 6 months. In two shorter trials, kava also relieved acute anxiety more effectively than placebo. In one study, 59 patients were given two doses of kava prior to surgery. In the second study, 20 women were given kava for 1 week while awaiting the results of a breast biopsy. In one head-to-head 6-week European study—there was no placebo group—kava was as effective in relieving anxiety in 172 patients as oxazepam, 5 mg three times daily, or bromazepam, 3 mg three times daily.

Kava has been well tolerated in clinical trials. Fewer than 2.3% of patients report gastrointestinal complaints, drowsiness, tremor, headache, or allergic skin reactions. There are several case reports of patients feeling sedated, disoriented, or ataxic after consuming high doses of kava (or kava in combination with alcohol or prescription drugs that act on the central nervous system). These include two "driving under the influence" arrests of patients who had consumed 8-16 cups of a kava beverage. Kava may have dopamine antagonist properties. Three patients using European kava preparations developed extrapyramidal dystonic reactions or worsening Parkinson's disease. A reversible kava dermatopathy (dry, flaky, yellow skin, ataxia, partial hearing loss, and weight loss) has been reported in South Pacific Islanders who consume kava at doses 100 times higher than recommended.

In November 2001, the German government reported 29 cases of hepatitis, cirrhosis, and liver failure possibly associated with the use of kava. Although 18 of these reports were in patients who were also taking medications with known or potential liver toxicity, one case involved a previously healthy 50-year-old man who was not taking prescription medications or alcohol who required a liver transplant. As a result, kava products have been taken off the market in Switzerland and Germany. Warnings about possible hepatic toxicity have been issued to patients with acute or chronic liver disease.

Ginseng

Ginseng root has been used for medicinal purposes in Asia for over 2000 years. There are three major forms of ginseng in use today. *Panax ginseng*, known as Asian ginseng, is commonly used in the United States. *Panax quinquefolius*, known as American ginseng, is cultivated in the United States and exported to China. *Eleutherococcus senticosus*, known as Siberian ginseng, is not a member of the panax genus. The German Commission E monograph on ginseng root approves its use as "a tonic to counteract weakness and fatigue, as a restorative for declining stamina and impaired concentration, and as an aid to convalescence." Extracts are made from dried roots and contain ginsenosides. Over 25 ginsenosides have been isolated, each with unique and sometimes oppositional effects on the cardiovascular, central nervous, and immune systems. The mechanisms of action have not been clearly delineated.

There is an extensive body of scientific literature on this subject, with over 4000 books and papers published. Multiple indications have been studied using different ginseng species, often with poor methodologic rigor. One European study identified 57 randomized controlled trials of ginseng in the world's literature, but only 16 studies were of good enough quality to be included in their systematic review. Insufficient evidence was available to support or refute the use of ginseng for any of the purported indications, including improvement of physical performance, cognitive functioning, and quality of life. One recent study suggests that American ginseng may attenuate postprandial glycemia in both normal and diabetic subjects.

Ginseng is well tolerated, with few adverse effects. A recent systematic review of adverse reactions reports that the incidence is similar in ginseng monopreparations and placebo. Possible drug interactions have been reported between *P. ginseng* and warfarin, phenelzine, calcium channel blockers, digoxin, and alcohol. Earlier reports of "ginseng abuse syndrome" and other toxicities are now attributed to adulterants found in earlier unregulated over-the-counter ginseng products. Indeed, 13 out of 21 ginseng products recently evaluated for quality and purity failed because they contained unacceptable levels of pesticides or heavy metals or inadequate concentrations of ginsenosides.

Saw Palmetto

Traditionally, the fruit of the dwarf palm tree (*Serenoa repens*) was used by Native Americans for urinary complaints. Saw palmetto is now widely used to treat benign prostatic hyperplasia. In some European countries, herbal medicine is first-line therapy for that problem. Saw palmetto lipophilic extract is prepared from the berries of this palm indigenous to the southeastern United States. The principal active ingredients are sterols and free fatty acids. The mechanism of action is unclear; but there is evidence for inhibition of 5 α -reductase activity and dihydrotestosterone binding at the androgen receptor.

A recent systematic review of saw palmetto extracts for the treatment of benign prostatic hyperplasia identified 21 randomized controlled trials involving 3139 patients. Although most studies were of short duration (mean of 9 weeks) and included small numbers of patients, symptoms and flow rates improved in men taking saw palmetto relative to those taking placebo. Saw palmetto produced similar improvement in urinary symptoms and flow compared with finasteride and is associated with fewer adverse effects. (Erectile dysfunction occurred in 4.9% of those taking finasteride versus 1.1% in those taking saw palmetto.) In two large, well-designed trials, saw palmetto extract appears to be as effective as finasteride. Two small European studies suggest that the herb is slightly less effective than prazosin and alfuzosin, an alpha-adrenergic antagonist not available in the United States. A recent 6-month double-blind, placebo-controlled trial of 44 men showed slightly (not statistically significant) greater reduction in prostatic hyperplasia symptoms in those taking a herbal blend containing saw palmetto, nettle root, pumpkin seed, and lemon bioflavonoid extracts and beta-carotene. Prostate biopsies taken before and after treatment demonstrated a decrease in the percentage of epithelium in the transition zone of the prostate from 17.8% to 10.7% ($P < .01$) in saw palmetto-treated men versus no change in the placebo group.

This herb is very well tolerated by most patients for up to 3-5 years, with only mild and rare gastrointestinal symptoms being reported. Saw palmetto has not been shown to reduce prostate size or lower the serum level of prostate-specific antigen. No herb-drug interactions have been reported. Saw palmetto was one of eight ingredients in PC-SPEs, a popular herbal product used by many men with prostate cancer. PC SPEs was withdrawn from the market when it was found to be contaminated with the prescription drugs diethylstilbestrol and warfarin. The University of California at San Francisco is conducting a randomized controlled trial funded by the NIH to evaluate the long-term efficacy of this herb for benign prostatic hyperplasia.

Ephedra (Ma-huang)

The dried young stems of *Ephedra sinica* have been used for thousands of years in traditional Oriental medicine to treat respiratory disorders, especially bronchospasm and congestion. Ephedra is widely marketed for its stimulant and appetite suppressant effects (alone or in combination with caffeine-like herbs). Ephedra's alkaloids are

structurally similar to amphetamines. Sympathomimetic side effects include tremors, severe hypertension, seizures, and arrhythmias. These may lead to myocardial infarction, stroke, and death. Over 800 cases of adverse events, including more than 20 deaths, have been reported to the FDA. Samenuk et al reviewed 926 cases of possible Ma-huang toxicity reported between 1995 and 1997. In 37 patients, use of this herb was temporally related to stroke, myocardial infarction, or sudden death. Underlying heart disease was not a prerequisite for adverse events, and the toxic effects were not limited to massive doses. A report from the House Committee on Government Reform documents 13,000 adverse events reported to the largest manufacturer of ephedra products, Metabolife. Products containing ephedra accounted for 64% of all reported adverse effects to United States poison control centers from herbs, even though they represented only 0.82% of herbal product sales. The relative risk of an adverse reaction in persons using ephedra compared with other herbs was extremely high, ranging from 100 for kava to 720 for ginkgo biloba. The FDA has advised patients with hypertension, glaucoma, seizure disorders, and coronary artery disease to avoid using this product. It is contraindicated also in patients with anxiety, mania, or thyroid disease and in those taking other stimulants or who are pregnant. Because it may increase steroid clearance, it may reduce the effectiveness of prednisone. The recommended maximum daily dose of ephedra is 24 mg.

■ DIETARY SUPPLEMENTS

Sales of dietary supplements have increased dramatically over the past decade. The Dietary Supplement Health Education Act of 1994 has made it possible for manufacturers to sell dietary supplements directly to the public without FDA approval or oversight. Consequently, in the United States, there are no quality assurance regulations that pertain to these products. Reports of adulteration and contamination are available, but the magnitude of this problem remains unknown. Furthermore, there have been several reports of the dose printed on the label being different from the actual dose provided. (See section on herbal medicines, above, for further details on regulatory and quality assurance issues and advice for patients to follow when purchasing these products.) [Table 44-3](#) provides an overview of selected dietary supplements commonly used in the United States today.

S-Adenosylmethionine (SAME)

S-Adenosylmethionine is an endogenous compound that serves as a methyl group donor for hundreds of compounds, including neurotransmitters, fatty acids, nucleic acids, proteins, and membrane phospholipids. Endogenous production is dependent on vitamin B₁₂ and folic acid metabolism. Primary uses of the drug are the treatment of depression, osteoarthritis, alcoholic liver disease, and migraine headaches. Originally discovered in the 1950s, SAME was not synthesized as a stable compound that could be made commercially available until the 1970s. It is available by prescription throughout Europe. The mechanism of action is unclear for most conditions. Based on clinical trial data from over 22,000 patients, SAME is well-tolerated and safe. Side effects include nausea, flatulence, headache, and anxiety. A phase 4 open-label clinical trial involving over 20,000 patients followed for 8 weeks found that 87% of the cohort reported good to very good tolerance with SAME. There are no significant drug-herb interactions, although a case of serotonin syndrome in a patient taking SAME with clomipramine has been reported.

Early studies suggesting that SAME may be helpful in treating depression were limited by short duration and poor methodology. SAME may affect multiple neurotransmitters; increased levels of serotonin, 5-hydroxyindoleacetic acid, and dopamine as well as inhibition of norepinephrine reuptake have been noted after SAME administration. A meta-analysis published in 1994 identified 11 trials comparing SAME with tricyclic antidepressants and 13 trials comparing either oral or parenteral formulations of SAME with placebo. SAME was found to be as effective as tricyclic antidepressants and superior to placebo in the treatment of depression. Furthermore, SAME was better-tolerated and had a more rapid onset of clinical effect than tricyclic antidepressants. Two recent multicenter trials of SAME versus imipramine report that both oral and intramuscular preparations of SAME are as effective as the tricyclic agent in reducing depression and with fewer side effects, though neither study was placebo-controlled. No head-to-head trials have compared SAME with selective serotonin reuptake inhibitors. SAME appears to have analgesic and anti-inflammatory properties and was studied extensively in the 1980s for the treatment of osteoarthritis. The mechanism of action for these effects is unknown. Although many early studies used a parenteral form of SAME, only an oral formulation is available in the United States, and it is expensive (\$50-\$150 per month) and has poor bioavailability. A recent review of 11 randomized controlled trials (1418 patients) comparing SAME with placebo or NSAIDs for osteoarthritis concluded that SAME was as effective as NSAIDs in reducing pain and functional limitation and better-tolerated. Compared with placebo, SAME was more effective in improving functional limitations and did not differ in adverse events.

Studies of alcohol-fed baboons suggest that SAME increases glutathione levels and attenuates liver injury. There is some evidence that SAME increases glutathione levels in humans as well. Investigators performed a multicenter clinical randomized, double-blind, placebo-controlled trial involving 123 patients with alcoholic liver cirrhosis treated with SAME or placebo for 2 years. Combined mortality and liver transplantation rate was 30% in the placebo group compared with 16% in the SAME group ($P = .08$). When Child class C subjects ($n = 8$) were excluded, respective rates were 29% and 12% ($P = .03$). This study provides support for SAME supplementation in alcoholic liver disease.

Dehydroepiandrosterone (DHEA)

DHEA and its sulfate ester, DHEAS, are secreted by the adrenal cortex. In healthy individuals there is a 25% decrease in serum DHEA levels per decade until age 70, when levels are at 20-30% of lifetime peak levels. Low DHEA levels have been reported in people who are critically ill, suffering from major burns, or depressed and in premenopausal women with breast cancer. Low levels with advanced age and in conditions of stress have been cited in the popular press as evidence that DHEA supplementation would be beneficial.

The mechanism of action of DHEA remains unknown. Preliminary evidence suggests that DHEA supplementation might be useful in depression, dysthymia, systemic lupus erythematosus, and adrenal insufficiency.

Animal studies suggest that DHEA and DHEAS have excitatory effects on the central nervous system, which may account for their influence on mood and sense of well-being. A 6-week clinical trial randomized 22 subjects with major depression to DHEA or placebo and found DHEA to be superior as measured by a 50% reduction from baseline using the Hamilton Depression Scale. Another study by Bloch found similar improvements using multiple well-validated instruments for the treatment of midlife dysthymia in a randomized double-blind crossover pilot study involving 15 patients.

Low DHEA levels in men and women with systemic lupus erythematosus suggest that DHEA may play a causative role. One hundred women with active, mild to moderate SLE were randomized to 200 mg/d oral DHEA or placebo for 24 weeks. DHEA was well tolerated, significantly reduced the number of SLE flares, and improved patients' global assessment of disease activity. Women with adrenal insufficiency have unmeasurable DHEA serum levels. Treatment with DHEA in a 4-month randomized, double-blinded, placebo-controlled crossover study was associated with improvements in mood, well-being, and libido.

Side effects of DHEA include acne, deepening of the voice, and facial hair growth, but no serious adverse events have been reported. The long-term effects of DHEA supplementation remain unknown. The safety issue of most concern is that DHEA—as a potent precursor of sex steroids—may increase the risk of estrogen- or androgen-dependent malignancies. Therefore, if supplementation is used, patients should be monitored closely. Furthermore, patients at high-risk for prostate, ovarian, breast, or uterine cancer should be counseled against DHEA supplementation.

Glucosamine & Chondroitin

Glucosamine and chondroitin have been used in Europe alone and in combination to treat osteoarthritis since the 1980s. These compounds are substrates for the production of articular cartilage. Glucosamine stimulates the production of glycosaminoglycans, leading to increased synthesis of cartilage. Chondroitin may help maintain articular fluid viscosity, inhibit enzymes that break down cartilage, and stimulate cartilage repair. Glucosamine is prepared commercially from crustacean shells. Chondroitin is extracted from bovine tissues such as cow trachea.

A meta-analysis by McAlindon and coworkers identified 15 randomized, double-blind, placebo-controlled trials involving 1710 patients with knee or hip osteoarthritis. Summary estimates found glucosamine and chondroitin to have moderate to large effects for treating osteoarthritis symptoms. Most trials were of poor to fair quality, and publication bias probably exaggerated the benefits. However, at least a modest degree of efficacy can perhaps be assumed. A Cochrane Review of 16 double-blind, randomized controlled trials of glucosamine for osteoarthritis showed that glucosamine was superior to placebo.

Glucosamine not only reduces the symptoms of osteoarthritis but may also slow the progression of the disease. Reginster and coworkers randomized 212 patients with osteoarthritis of the knee to receive either 1500 mg/d of glucosamine or placebo. After 3 years, patients taking glucosamine reported a 24% reduction in symptoms versus a 10% increase in the placebo group. X-rays revealed that the treatment patients experienced a loss of only 0.06 mm joint space versus 0.31 mm in the placebo group after 3 years. Glucosamine was very well-tolerated and did not elevate serum glucose levels. Similar results were found in 200 patients with mild to moderate knee osteoarthritis who were randomized to glucosamine sulfate or placebo for 3 years. Patients in the glucosamine group had greater pain relief and less joint space narrowing on x-ray. Several negative trials have been reported in patients with more severe arthritis and in those taking other forms of glucosamine. No drug-herb interactions have been reported. An NIH-funded multicenter trial is under way to evaluate glucosamine and chondroitin sulfate (alone and in combination) in more than 1000 patients compared with celecoxib and placebo. In summary, clinical trial literature suggests that glucosamine with or without chondroitin is well tolerated, safe, and effective in the treatment of osteoarthritis, with fewer side effects than NSAIDs.

Coenzyme Q₁₀ (Ubidecarenone)

Coenzyme Q₁₀ (also known as ubiquinone-10) is a lipid-soluble endogenous provitamin that resides in the lipid layer of the mitochondria. It plays a crucial role in oxidative phosphorylation for ATP production and is necessary for the basic functioning of all cells. It has also been observed to have effects on membrane stabilization, free radical scavenging, and calcium-dependent slow channels. Coenzyme Q₁₀ levels decrease with age. Deficiencies have been observed among patients with congestive heart failure, renal failure, male infertility, periodontal disease, and Parkinson's disease and in those taking HMG-CoA reductase inhibitors and other prescription medications (diabetes medications, beta-blockers, diuretics, and antidepressants).

Studies of coenzyme Q₁₀ for the prevention and treatment of cardiovascular disease have had mixed results. In some parts of Russia, Europe, and Japan, coenzyme Q₁₀ is part of standard therapy for congestive heart failure. Earlier trials in patients with congestive heart failure demonstrated fewer disease exacerbations, reduced hospitalizations, improved ejection fraction, and more favorable quality of life measurements. A 1999 study showed that coenzyme Q₁₀ had no effect on ejection fraction, hemodynamic parameters, or quality of life. A more recent study of 55 patients with class III and class IV congestive heart failure receiving standard medical therapy also showed no benefit of coenzyme Q₁₀ on ejection fraction, peak oxygen consumption, or exercise duration. Other studies have evaluated coenzyme Q₁₀ for acute myocardial infarction, angina, diabetes, hypertension, and periodontal disease. Preliminary research suggests that coenzyme Q₁₀ levels are low in hypertensive patients and that supplementation may result in small decreases in blood pressure. Well-designed, long-term clinical trials are needed to verify its usefulness in treating hypertension. Although several medical conditions are associated with coenzyme Q₁₀ deficiency, there is insufficient evidence to support or refute the use of coenzyme Q₁₀ to improve outcomes for any particular condition.

Because coenzyme Q₁₀ is lipophilic, it is often formulated with vegetable oil or vitamin E to enhance its absorption. Its bioavailability is also enhanced when it is taken with meals, especially fat-rich foods. No serious adverse events have been reported with coenzyme Q₁₀ use, and it is generally well tolerated. No significant drug-herb interactions have been reported, but coenzyme Q₁₀ is chemically similar to vitamin K and so may reduce the effectiveness of warfarin. Although coenzyme Q₁₀ supplementation appears to be safe, it is relatively expensive.

■ ACUPUNCTURE

In acupuncture, certain locations on the surface of the body are stimulated, often with needles, to treat illness and promote health. Practitioners trained in Oriental medicine believe that a vital energy called chi (pronounced "chee") circulates in the body through 12 main pathways called meridians. Each meridian is named after a particular organ or "official," but the term actually relates to the energetic function more than the structure or anatomy of the organ. There are both surface and internal projections for each meridian. The surface projections contain sites called acupuncture points. Oriental medicine practitioners insert needles into these points to influence the body's chi to restore health.

History

The earliest reference to acupuncture can be traced to a text on Chinese medicine called *The Yellow Emperor's Classic of Internal Medicine* (the *Huang Ti Nei Ching*), which dates from the second century BC. This text is often referenced to support the authenticity of a particular practice or theory and is used as part of the curriculum in training colleges. Acupuncture spread through much of Asia and by the sixteenth century Jesuit missionaries had brought the practice to Europe. As early as 1912, William Osler described its use in the first edition of *The Principles and Practice of Medicine*. "For lumbago," he wrote, "acupuncture is, in acute cases, the most efficient treatment." Research and enthusiasm in the United States grew dramatically in 1971 when James Reston wrote an article describing his experience with acupuncture for postoperative analgesia after undergoing an appendectomy while in China.

Mechanism of Action

Acupuncture for analgesia stimulates the muscle's small-diameter nerve fibers that enter the dorsal horn of the spinal cord. An impulse is then sent to other levels within the spinal cord, the midbrain, and the hypothalamic-pituitary system, which then release neurotransmitters that cause analgesia. Therefore, when practitioners place a needle in the region of pain, all three centers are activated to provide an analgesic effect. When practitioners place needles in locations distant from the pain site, only the midbrain and hypothalamic-pituitary systems are activated. Although this theory implies that sham acupuncture may be as effective as real acupuncture, experimentally induced acute pain studies in animals and humans have consistently shown that real point stimulation is far superior to sham. These conflicting findings have prevented sham acupuncture from being widely accepted as an appropriate control. The 1998 NIH Consensus Statement on Acupuncture strongly recommends that future acupuncture research focus on finding such a control. A study of functional brain MRI imaging of healthy volunteers identified preferential activation of the

hypothalamus and nucleus accumbens and deactivation of the rostral part of the anterior cingulate cortex, amygdala, and hippocampal complex among patients receiving active needling compared with minimally stimulated controls. Chronic pain studies, however, have shown less consistent results.

Despite extensive histologic studies, investigators have been unable to identify unique anatomic structures or physiologic effects at acupuncture points. Despite these shortcomings, our understanding of the mechanism of action of acupuncture for the treatment of pain is superior to our understanding of the mechanism of action for many drugs in widespread use today.

Training, Licensure, & Regulation

Acupuncture educational programs are accredited by the Accreditation Commission for Acupuncture and Oriental Medicine (ACAOM). Typical acupuncture training for nonphysicians in the United States requires completion of an accredited 4-year (2500 hours) master's degree training program. In order to become a licensed acupuncturist (LAc), one must pass a national and, frequently, state board examination. Although many states do not require physicians to obtain additional training, most states require a minimum of 200 hours of training in an accredited program. There are currently over 10,000 licensed acupuncture practitioners and 3000 physician acupuncturists in the United States. In 22 of the 42 states that license, register, or certify acupuncturists, these practitioners are permitted to work independently.

Clinical Practice

In the United States and Europe, Oriental medicine-trained practitioners conduct a comprehensive multisystem history, observation, and physical examination during the initial consultation. Examination consists of palpation of the abdomen and selected acupuncture points; examination of the tongue to assess color, shape, and coating; and palpation of the pulse along the wrist at three locations on both arms to assess its quality, rhythm, and strength. Treatment by the **classic acupuncture method** is based on the belief that each patient presents with a unique constellation of symptoms and signs. What this means is that ten patients presenting with migraine headaches may receive ten different treatments. Western-style practitioners will conduct a conventional examination and include variable components of the Oriental medicine approach depending on the individual's depth of training. Treatment is based on the **formula acupuncture method**, which utilizes a fixed combination of acupuncture points for a given medical diagnosis such that a cohort of migraine sufferers will be treated in the same way.

Treatment involves inserting four to fifteen needles at selected acupuncture points for 10-30 minutes—though certain schools leave the needles in place for only a few seconds to minutes. Needles are approximately 37-gauge, stainless steel, and disposable. Needles are stimulated with electricity, heat, or manually. Follow-up consultations last from 20 minutes to 45 minutes.

Patients can expect to see the practitioner weekly or biweekly for 4-10 weeks, followed by less frequent visits as the condition improves.

Adverse Events

In current practice in the United States and Europe, acupuncture is generally considered safe, associated with a very low incidence of adverse events. Precautions useful for avoiding serious adverse events are listed in [Table 44-4](#). The most frequent problems are vasovagal or sedating reactions such as presyncope, syncope, and drowsiness. These are easily prevented by having the patient lie flat on the table, monitoring patients during the initial visit, and permitting the patient to remain in the office until a normal state of awareness is achieved. Serious complications in the literature over the past 30 years have been due to the reuse of needles between patients, leading to transmission of infection such as hepatitis B and C or HIV, and needling the thorax in patients with emphysema, leading to pneumothorax. There have also been case reports of unusual serious adverse events, including endocarditis in patients with prosthetic heart valves who had small indwelling needles in place for several days, cardiac tamponade after needling directly over the heart, spinal cord trauma from deep insertion or migration of cut or broken retained needles, and pacemaker malfunction during acupuncture with electrical stimulation.

Most surveys estimate that the frequency of adverse events is 1:100,000 to 1:10,000. A 14-year review of the world literature identified 193 complications and concluded that acupuncture is generally safe except for patients with emphysema, in whom the risk of pneumothorax is significant. Another review identified 300 complications reported in the literature over a 30-year period. With more than 10 million acupuncture visits in the United States annually, the frequency approximates one per million visits.

CLINICAL USES OF ACUPUNCTURE

In the United States, acupuncture is frequently used to treat acute non-life-threatening conditions or chronic conditions that conventional medicine is unable to treat effectively ([Table 44-5](#)). What follows is a survey of some conditions for which patients frequently seek acupuncture care.

Stroke Rehabilitation

A 2001 systematic review of randomized controlled trials of acupuncture for stroke rehabilitation identified nine trials, including 538 subjects meeting study entry criteria. Six of out nine trials found acupuncture superior to control interventions, but study quality was poor. These findings suggest that acupuncture appears promising for the treatment of stroke, but studies of high quality are needed to confirm these preliminary findings.

Park J et al: Effectiveness of acupuncture for stroke: a systematic review. *J Neurol* 2001;248:558. [PMID: 11517996]

Chronic Pain

A 1989 meta-analysis of randomized controlled trials of acupuncture for chronic pain identified 14 trials meeting study entry criteria with five studies on low back pain, five studies on head and neck pain, and three studies on other types of chronic pain. Only two studies used inert medical placebo, with the remainder using sham acupuncture, transcutaneous electrical nerve stimulation (TENS), or continued standard medical care. Heterogeneity was present across trials as well as in all subgroups. With this limitation, the overall risk difference was statistically significant in favor of acupuncture ($P < .01$). In sensitivity analyses, individualized treatments (classic acupuncture) were superior to placebo; however, standardized treatments (formula acupuncture) were not more effective than placebo. Overall, although this review concluded that acupuncture was superior to control group intervention, serious methodologic issues were present. A criterion-based review of 51 controlled trials of acupuncture for the treatment of chronic pain found 24 trials reporting results favoring acupuncture. Using a 100-point quality scale, only 11 trials scored at least 50 points. The investigators concluded that poor study quality made it impossible to arrive at definitive conclusions.

Overall, there is some evidence suggesting benefit of acupuncture for persons with chronic pain when compared with placebo and insufficient evidence to suggest acupuncture is superior to standard medical care or sham acupuncture. The ability to make definitive recommendations regarding efficacy for chronic pain is hampered by poor methodologic study quality, which includes possible insufficient frequency and duration of acupuncture treatments.

Ezzo J: Is acupuncture effective for the treatment of chronic pain? A systematic review. *Pain* 2000;86:217. [PMID: 10812251]

Patel M et al: A meta-analysis of acupuncture for chronic pain. *Int J Epidemiol* 1989;18:900. [PMID: 2695475]

Low Back Pain

Ernst et al performed a meta-analysis on acupuncture in the treatment of low back pain and identified 30 trials, of which nine met inclusion criteria involving 377 patients. The summary odds ratio was 2.3 (95% CI, 1.3-4.1) favoring acupuncture compared with various control groups. Subgroup analysis limited to four trials using sham acupuncture as the control group found real and sham acupuncture to have similar effectiveness. Investigators concluded that acupuncture is an effective treatment for low back pain; however, larger studies using sham acupuncture are needed to distinguish between the specific effects of treatment at correct acupuncture points and the nonspecific effects of needling.

Van Tulder et al performed a systematic review using 11 randomized controlled trials on acupuncture for low back pain—none of which studied acute back pain. The quality of the studies was poor, and pooled analyses were not performed because of heterogeneity across trials. Overall, the reviewers found acupuncture equally effective as trigger point injection, TENS, and sham acupuncture. More recently, Smith performed a systematic review on acupuncture as a treatment for chronic neck and back pain that included 13 randomized controlled trials, five of which reported positive results. Studies with better methodologic quality were more likely to show negative results.

In summary, the literature is contradictory, with results from a meta-analysis favoring acupuncture and results from a systematic review finding no clear evidence for effectiveness. There is insufficient evidence on which to base a claim that acupuncture is superior to inert placebo or standard medical care for the treatment of low back pain.

Osteoarthritis

A systematic review performed by Ernst in 1998 found 13 trials that met study entry criteria. The majority of trials used formula acupuncture. Seven of the 13 trials reported positive results; however, overall the methodologic quality was poor. Among randomized trials, five out of ten were positive. When sham acupuncture was used as the control group, only one out of five trials were positive. The reviewers concluded that acupuncture was not clearly superior to control interventions and that the literature was of poor quality.

A methodologically rigorous randomized controlled trial involved 73 patients treated for 12 weeks with acupuncture or conventional care. Subjective scores were recorded using the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) and the Lequesne Index. Acupuncture was superior to control intervention based on the WOMAC and Lequesne scores. No adverse events were reported. Investigators concluded that acupuncture for osteoarthritis appeared safe and effective when compared with standard care.

Ezzo and colleagues performed a more recent 2001 systematic review of acupuncture for osteoarthritis of the knee. Seven trials assessed 393 patients on the outcomes of pain, function, global improvement, and imaging. For pain and function, limited support was found for the efficacy of acupuncture over a wait list control or treatment as usual. For pain, real acupuncture was more effective than sham acupuncture. For level of function, however, real acupuncture was not found to be more effective than sham acupuncture.

In conclusion, there is limited evidence suggesting that acupuncture is more effective than conventional care alone. An NIH-funded multicenter randomized controlled trial currently under way at the University of Maryland will more definitively assess efficacy and long-term outcomes.

Acute Dental Pain

The NIH consensus development statement on acupuncture states, "There is evidence of efficacy for postoperative dental pain." A review in 1999 identified 16 controlled trials of acupuncture for the treatment of acute dental pain. Among the eight randomized and at least partially blinded trials, seven showed benefit. Among the seven trials using sham control, six showed benefit. Subsequent to this review, a randomized, double-blind, placebo acupuncture-controlled trial involving 39 patients evaluated acupuncture for the treatment of postsurgical dental pain. Controls experienced a similar tap sensation next to the acupuncture sites to produce a noticeable sensation; however, needle insertion was not performed. Patients receiving acupuncture scored more favorably than controls on multiple outcomes. There is thus sufficient evidence to recommend the use of acupuncture as effective adjunctive treatment for the treatment of acute dental pain. Multiple studies have demonstrated its efficacy when compared with sham acupuncture.

Lao L et al: Evaluation of acupuncture for pain control after oral surgery: a placebo-controlled trial. Arch Otolaryngol Head Neck Surg 1999;125:567. [\[PMID: 10326816\]](#)

Headache

Melchart et al performed a systematic review in 2002 to evaluate the treatment of acupuncture for recurrent headaches. That group identified 26 randomized and quasi-randomized trials involving 1151 subjects in which 16 trials studied migraine headaches, six studied tension headaches, and 4 studied mixed headaches. Of the 16 trials that used sham acupuncture, 8 found real acupuncture superior to sham acupuncture and four found a trend in favor of real acupuncture. Two trials found no difference between groups, and two trials were uninterpretable. In the remaining 10 trials, control groups varied, and conflicting results were reported. Overall, investigators felt there was evidence that acupuncture is effective in the treatment of recurrent headaches; however, more research is needed to ascertain which headaches would be most responsive to acupuncture treatment.

Melchart D et al: Acupuncture for idiopathic headache. Cochrane Database Syst Rev 2001;(1):CD001218. [\[PMID: 11279710\]](#)

Melchart D et al: Acupuncture for recurrent headaches: a systematic review of randomized controlled trials. Cephalalgia 1999;19:779. [\[PMID: 10595286\]](#)

Asthma

Linde performed a systematic review of randomized and possibly randomized clinical trials that evaluated the effects of acupuncture for the treatment of asthma. Seven trials met study entry criteria, including 174 participants. All trials compared real acupuncture with sham acupuncture. Among the three trials that measured postexpiratory flow rates, there was no difference between the real and sham acupuncture groups. The authors conclude that there is insufficient evidence that acupuncture has a significant treatment effect for people with asthma. No research has evaluated the efficacy of acupuncture as part of a comprehensive treatment program. Among trials reporting positive results, benefit was primarily identified in subjective rather than objective measures. Because asthma can be a life-threatening condition for which effective standard medical therapy exists, acupuncture should be used only as an adjunct to conventional therapy.

Martin performed a systematic review and meta-analysis from 11 randomized controlled trials. Trials compared acupuncture at real and placebo points with outcome measures consisting of at least one of the following: peak expiratory flow rate, forced expiratory volume in one second (FEV₁), and vital capacity. Studies in which bronchoconstriction was experimentally induced showed a significant effect favoring real acupuncture. Overall, no evidence for an effect of acupuncture in reducing asthma was found; however, methodologic shortcomings such as small sample size may have precluded identifying statistically significant differences between groups.

Nausea & Vomiting

Based on multiple randomized controlled trials, there is strong evidence demonstrating effectiveness of acupuncture in the treatment of pregnancy-induced, chemotherapy-induced, and postoperative nausea and vomiting. One review identified 33 trials using a particular acupuncture point (P6) for treatment of nausea and vomiting. None of the four trials in which acupuncture was given while the patient was under general anesthesia demonstrated a positive effect. Among the remaining 29 trials, 27 identified real acupuncture as being more effective than sham acupuncture or placebo control. In subgroup analyses, all five studies evaluating acupuncture for cancer chemotherapy-induced nausea and vomiting were positive. Six out of seven studies for pregnancy-induced symptoms were positive. Among trials in which acupuncture was performed while the subjects were not under general anesthesia, 16 out of 17 studies of treatment for postoperative nausea and vomiting were positive. In sensitivity analyses, 11 out of the 12 high-quality trials involving over 2000 patients identified acupuncture as superior to control. A subsequent review on studies of treatment for postoperative nausea and vomiting reported acupuncture to be equivalent to first-line antiemetics in preventing early and late vomiting. The NIH consensus development panel on acupuncture stated, "There is clear evidence that needle acupuncture is efficacious for adult postoperative and chemotherapy induced nausea and vomiting and probably for the nausea of pregnancy."

Lee A et al: The use of nonpharmacologic techniques to prevent postoperative nausea and vomiting: a meta-analysis. Anesth Analg 1999;88:1362. [\[PMID: 10357346\]](#)

Vickers AJ: Can acupuncture have specific effects on health? A systematic review of acupuncture antiemesis trials. J R Soc Med 1996;89:303. [PMID: 8758186]

Nicotine, Heroin, Cocaine, & Alcohol Addiction

There is good evidence suggesting that acupuncture is not effective in maintaining abstinence from nicotine addiction. Systematic reviews have identified multiple trials of sufficient quality to determine that there is no evidence to support its use. In a randomized trial comparing electroacupuncture and sham control for nicotine withdrawal symptoms, there was no difference in nicotine withdrawal symptoms or abstinence rates at day 14. The NIH consensus development statement acupuncture states, "There is evidence that acupuncture does not demonstrate efficacy for cessation of smoking."

Despite insufficient evidence to support its use, auricular acupuncture is in widespread use throughout American drug treatment facilities. A recent large, randomized placebo-controlled study of auricular acupuncture for alcohol dependence found no significant effects above results achieved for conventional treatment alone. Although heroin, alcohol, and cocaine addiction studies have frequently reported positive outcomes, serious methodologic flaws are present. For example, an 8-week clinical trial showed patients assigned to acupuncture were significantly more likely to remain abstinent from cocaine use. However, analyses did not adjust for the 50% versus 20% dropout rate in the acupuncture and relaxation groups, respectively. A randomized controlled, single-blind trial conducted in six community-based clinics in the United States found that acupuncture was not more effective than needle insertion control or relaxation alone in reducing cocaine use. Until scientifically rigorous studies can demonstrate efficacy, acupuncture should not be used as monotherapy in the treatment of these addictions.

Avants SK et al: A randomized controlled trial of auricular acupuncture for cocaine dependence. Arch Intern Med 2000;160:2305. [PMID: 10927727]

■ HOMEOPATHY

Christian F.S. Hahnemann is credited with devising the system of homeopathy in 1790. Three main principles of homeopathy include the "law of similars," the use of dilute concentrations of medicines, and "potentization." The second and third principles remain the most controversial for many scientists and conventionally trained physicians.

The law of similars is also known as the principle of "like cures like"; it is derived from the observation that a homeopathic medicine when given to a healthy volunteer will produce a constellation of symptoms similar to those it will cure in an ill patient. Since the 1800s, the process of testing medicines on healthy volunteers to record the symptoms provoked (known as "provings") has been recorded and compiled to create several materia medicas. A randomized double-blind crossover trial was performed to evaluate whether homeopathic substances can bring about symptoms different from observation and placebo. Investigators report an insignificant tendency to report more symptoms when taking belladonna 30CH compared with control arms. However, there was no indication that symptoms were different between groups or compared with baseline presentations.

The second principle—the use of dilute concentrations of medicine—entails serially diluting and "succussing" (shaking) a substance to concentrations in which there is little probability of any molecules remaining in solution. Homeopathic physicians assert that these remedies remain pharmacologically active and allude to allergy desensitization and immunization as sharing similar approaches to homeopathy in that both use low doses of potentially toxic substances to achieve beneficial clinical effects.

Potentization is based on the claim that once a medicine is at low concentration, the more dilute the solute the more potent the effect.

The World Health Organization states that homeopathy is the second most used medical system internationally, with over \$1 billion in expenditures for such therapy. Twenty to 30 percent of French and German physicians use homeopathy in clinical practice. In Great Britain, five homeopathic hospitals are part of the National Health System, and over 30% of generalists use homeopathy. In the United States, there are more than 500 physicians and 5000 nonphysicians using homeopathy in clinical practice, and 2.5 million Americans currently use homeopathic medicines—of which two-thirds are self-prescribed—spending more than \$250 million annually.

Mechanisms of Action

Although there are several mechanisms under investigation, none are well validated.

Adverse Events

Given the low concentration of homeopathic medicines, the probability of adverse events is remote. However, adverse events have been reported from ingestion of large quantities of remedies containing heavy metals. Indirect adverse events may occur—eg, if children do not receive immunizations because certain homeopathic physicians advise parents against this practice.

Training, Licensure, & Regulation

Homeopathic educational programs are accredited by the Council for Homeopathic Education. There are two levels of training for homeopaths. The Primary Care Certificate in Homeotherapeutics requires 60-100 hours of course work and passage of a written examination. The more advanced level, the Diplomate in Homeotherapeutics (Dht), requires an additional 3 years of clinical practice. There is comprehensive homeopathic training which involves 3 or more years of part-time to full-time study. Nonphysicians may practice homeopathy within the scope of practice of their specific profession. The American Board of Homeotherapeutics governs certification for physicians; the Homeopathic Association of Naturopathic Physicians governs naturopaths; and the Council for Homeopathic Certification governs all other practitioners. BR>

The *Homeopathic Pharmacopoeia of the United States* was included in the original Food and Drug Act of 1938, which classified these medicines as drugs. Currently, the Food and Drug Administration considers these medicines as nonprescription products. Unlike the practice in Great Britain and Europe, there is little oversight of the manufacturing of these products.

Clinical Encounter

The initial consultation takes about 1-1½ hours, with significant time spent on obtaining a detailed history. Attention is given to the physical, mental, and emotional symptoms, overall personality type, and any internal or external factors that influence the presenting symptoms, such as emotions, wind, season of the year, and reactions to different foods. The symptom inventory is then matched to an appropriate remedy taken from the materia medica. Follow-up visits may last for a few minutes to 40 minutes. During the follow-up visit, the practitioner determines if there has been improvement in symptoms, no change, or aggravation of symptoms. The latter scenario, if transient, is viewed as the first sign of recovery.

Clinical Uses

Homeopathic physicians are trained to treat a broad range of conditions in the primary care and specialty setting. In clinical practice, however, practitioners frequently treat patients with chronic conditions that conventional medicine cannot adequately address, including arthritis, allergies, autoimmune diseases, or non-life-threatening acute conditions such as viral infections or minor trauma. Parents may take their children to homeopathic physicians for recurrent conditions such as otitis media and allergies with the goal of avoiding repetitive antibiotic, steroid, or chronic conventional medications.

Research

Over 180 controlled trials and over ten reviews have been published on the effects of homeopathy compared with placebo. The majority of trials are published in non-English language journals and are frequently not listed in Medline. A few methodologically rigorous reviews have been published in English ([Table 44-6](#)). The majority of systematic reviews have pooled trials on homeopathy regardless of the medical condition being treated. These reviews have found that patient outcomes in homeopathic treatment groups were superior to placebo group outcomes. Since many of the trials do not provide in-depth reports on the treatment encounter, it remains unclear whether these positive effects are specific to the homeopathic remedy itself or to nonspecific effects that occur as part of the treatment encounter. Since few trials have been independently replicated, there is insufficient evidence to determine if treatment effects found for a single medical condition are reproducible by independent investigators.

A 1997 systematic review identified 89 double-blind or randomized placebo-controlled trials and found the overall combined odds ratio was 2.45 (95% CI, 2.0-2.9) favoring patients in the homeopathy-treated group. Analyses restricted to high-quality studies found similar statistically significant results with an odds ratio of 1.66 (95% CI, 1.3-2.1); this effect persisted after adjustment for publication bias. Pooled analysis of four multicenter trials by the same investigator evaluating the effects of

Galphimia glauca for seasonal allergies found an odds ratio of 2.0 (95% CI, 1.5-2.7) for improvement in ocular and nasal symptoms at 4 weeks.

A meta-analysis conducted in 2000 identified 118 randomized controlled clinical trials of which 16 satisfied inclusion criteria. Investigators reported that patients receiving homeopathic remedies compared with placebo were significantly more likely to have improved treatment outcomes ($P = .00003$); however, analyses limited to the five high-quality studies revealed only a trend for improvement ($P = .08$). Overall, there is some evidence that homeopathy is more effective than placebo; however, multiple high-quality studies of individual conditions are needed to validate these findings.

Table 44-1. Advice to patients using herbal medicines.

Communication

Discuss use of all therapies with your primary care provider.

Product quality

Manufacturers are not required to submit evidence to the FDA or any regulatory body to demonstrate product safety, effectiveness, or quality. Ask your primary care provider, a pharmacist, or a trained herbalist regarding the specific herbs you are using. Use herbs that are standardized to contain a specific quantity of the active ingredients. Select formulations that have been studied in clinical trials. Select formulations produced by larger companies—they are more likely to ensure product quality in order to protect their reputations.

Labeling

It should state the common and scientific names of herb(s). It should state the concentration or dose of the herb(s) and provide instructions on dose and frequency. It should state that the product is "standardized" to contain a certain amount of the active ingredient(s). It should state the methods used to ensure product quality. It should state the name and address of the manufacturer. It should state the batch or lot number and the expiration date. It should list potential side effects and interactions.

Pregnancy

Few herbs have been studied for safety during pregnancy. Seek advice from your primary care provider before using herbs during pregnancy.

Interactions

Discuss with your primary care provider the safety profile and interactions that may occur when combining herbs and when taking herbs plus drugs.

Reporting

Report any adverse reactions to your state poison control program or the FDA.

	Leading Indications	Active Constituents	Mechanism of Action	Standardized Complex	Dosage	Level of Evidence ¹ and Effect Size ²
Echinacea (purple coneflower)	1. Treatment of URIs 2. Prevention of URIs	Isobutylamides, chicoric acid, polyenes, alkaloids, and alkylamides	Immunostimulant, phagocytosis, cytokines (IL-1, TNF, IFN)	Fresh-pressed juice of <i>E. purpurea</i> with 2.4% β-1,2-fructofuranosides, in 20% ethanol solute	300 mg, or 3 mL q3-4 h	1. B: small 2. C
Ephedra	1. Weight loss 2. Stimulant	Ephedrine alkaloids	Sympathomimetic		Max: 8 mg/dose; 24 mg/d	1. C: small 2. B: dose-dependent
Garlic (<i>Allium sativum</i>)	1. Cholesterol 2. Hypertension 3. Coronary artery disease	Allicin	1. HMG CoA-reductase, 14a-demethylase 2. Unclear 3. Antiplatelet effects	Allicin 0.6-1.3%	600-900 mg qd	1. B: small 2. C: small 3. C
<i>Ginkgo biloba</i> (EGB 761, GBE)	1. Dementia 2. Claudication	Flavonoid glycosides, terpenes such as ginkgolide B	PAF inhibition, antioxidant, membrane stabilization	24% flavonoid glycoside	60 mg tid	1. A: moderate 2. A: small
Asian ginseng (<i>Panax ginseng</i>)	Stamina, aphrodisiac, fertility, "tonic," "energy-booster," "adaptogen"	Ginsenosides	Unclear	> 2% ginsenosides	200-600 mg qd extract; 1-2 g crude drug	C Multiple studies but few for any given indication.
Kava (<i>Piper methysticum</i>)	Anxiety	Kava lactones	May modulate GABA binding	30-55% kava lactones in USA	70 mg bid-tid kava lactones	B: moderate
St. John's wort (<i>Hypericum perforatum</i>)	1. Depression: mild to moderate 2. Depression: major	Naphodianthrone (such as hypericum or hyperforin), flavonoids, and xanthones	May modulate neurotransmitters (serotonin, NE, GABA)	Hypericin 0.3% or hyperforin, 3%	300 mg tid	1. A: moderate. 2. B: no better than placebo
Saw palmetto (<i>Serenoa repens</i>)	Benign prostatic hypertrophy	Sterols, free fatty acids	5a-Reductase inhibition; inhibition of DHT binding to androgen receptor	85-95% sterols and fatty acids	160 mg bid	B: moderate

¹Level of evidence: A, good evidence; B, some evidence; C, insufficient evidence
²Effect size: none, small, moderate, large
³Safety: I, generally safe; II, relatively safe; III, insufficient evidence; IV, may be harmful; V, clear evidence of harm.
⁴Average range of costs in retail drug stores.

CoA = coenzyme A, DHT = dihydrotestosterone, GABA = gamma-aminobutyric acid, GI = gastrointestinal, HMG = hydroxymethylglutaric acid, IFN = interferon, IL = interleukin, MI = prostate-specific antigen, TNF = tumor necrosis factor,

Table 1. Therapeutic drug monitoring.^{1, 2}

Drug	Effective Concentrations	Half-Life (hours)	Dosage Adjustment	Comments
Amikacin	Peak: 20-30 µg/mL; trough: < 10 µg/mL	2-3 ? in uremia	? in renal dysfunction	Concomitant kanamycin or tobramycin therapy may give falsely elevated amikacin results by immunoassay.
Amitriptyline	160-240 ng/mL	9-46		Drug is highly protein-bound. Patient-specific decrease in protein binding may invalidate quoted range of effective concentration.
Carbamazepine	4-12 µg/mL	10-15		Induces its own metabolism. Metabolite 10,11-epoxide exhibits 13% cross-reactivity by immunoassay.
Cyclosporine	150-400 mg/mL (ng/L) whole blood	6-12	Need to know specimen and methodology used	Cyclosporine is lipid-soluble (20% bound to leukocytes; 40% to erythrocytes; 40% in plasma, highly bound to lipoproteins). Binding is temperature-dependent, so whole blood is preferred to plasma or serum as specimen. High-performance liquid chromatography (HPLC) or monoclonal fluorescence polarization immunoassay measures cyclosporine reliably; polyclonal fluorescence polarization immunoassays cross-react with metabolites, so the therapeutic range used with those assays is higher. Anticonvulsants and rifampin increase metabolism. Erythromycin, ketoconazole, and calcium channel blockers decrease metabolism.
Desipramine	100-250 ng/mL	13-23		Drug is highly protein-bound. Patient-specific decrease in protein binding may invalidate quoted range of effective concentration.
Digoxin	0.8-2 ng/mL	42 ? in uremia, CHF	? in renal dysfunction, CHF, hypothyroidism ? in hyperthyroidism	Bioavailability of digoxin tablets is 50-90%. Specimen must not be drawn within 6 hours of dose. Dialysis does not remove a significant amount. Hypokalemia potentiates toxicity. Digitalis toxicity is a clinical and not a laboratory diagnosis. Digibind (digoxin-specific antibody) therapy of digoxin overdose can interfere with measurement of digoxin levels depending on the digoxin assay. Elimination reduced by quinidine, verapamil, and amiodarone.
Ethosuximide	40-100 µg/mL	Child: 30 Adult: 50		Levels used primarily to assess compliance. Toxicity is rare and does not correlate well with plasma concentrations.
Gentamicin	Peak: 4-8 µg/mL; trough: < 2 µg/mL	2-5 ? in uremia (7.3 on dialysis)	? in renal dysfunction	Draw peak specimen 30 minutes after end of infusion. Draw trough just before next dose. In uremic patients, carbenicillin may decrease gentamicin half-life from 46 hours to 22 hours.
Imipramine	180-350 ng/mL	10-16		Drug is highly protein-bound. Patient-specific decrease in protein binding may invalidate quoted range of effective concentration.
Lidocaine	1-5 µg/mL	1.8 ? in uremia, CHF; ? in cirrhosis	? in CHF, liver disease	Levels increased with cimetidine therapy. CNS toxicity common in the elderly.
Lithium	0.7-1.5 meq/L	22 ? in uremia	? in renal dysfunction	Thiazides and loop diuretics may increase serum lithium levels.
Methotrexate		8.4 ? in uremia	? in renal dysfunction	7-Hydroxymethotrexate cross-reacts 1.5% in immunoassay. To minimize toxicity, leucovorin should be continued if methotrexate level is > 0.1 µmol/L at 48 hours after start of therapy. Methotrexate > 1 µmol/L at > 48 hours requires an increase in leucovorin rescue therapy.
Nortriptyline	50-140 ng/mL	18-44		Drug is highly protein-bound. Patient-specific decrease in protein binding may invalidate quoted range of effective concentration.
Phenobarbital	10-30 µg/mL	86 ? in cirrhosis	? in liver disease	Metabolized primarily by the hepatic microsomal enzyme system. Many drug-drug interactions.
Phenytoin	10-20 µg/mL; 5-10 µg/mL in uremia, hypoalbuminemia	Dose-dependent		Metabolite cross-reacts 10% in immunoassay. Metabolism is capacity-limited. Increase dose cautiously when level approaches therapeutic range, since new steady-state level may be disproportionately higher. Drug is very highly protein-bound; protein binding is decreased in uremia and hypoalbuminemia.
Primidone	5-10 µg/mL	8		Phenobarbital cross-reacts 0.5%. Metabolized to phenobarbital. Primidone/phenobarbital ratio > 1:2 suggests poor compliance.
Procainamide	4-8 µg/mL	3 ? in uremia	? in renal dysfunction	30% of patients with plasma levels of 12-16 µg/mL have electrocardiographic changes; 40% of patients with plasma levels of > 16 µg/mL have severe toxicity.
Quinidine	1-4 µg/mL	7 ? in CHF; ?in liver disease	? in liver disease, CHF	Effective concentration is lower in chronic liver disease and nephrosis, where binding is decreased.
Salicylate	150-300 µg/mL	Dose-dependent		
Theophylline	5-20 µg/mL	9	? in CHF, cirrhosis, and with cimetidine	Caffeine cross-reacts 10%. Elimination is increased 1 1/2 - 2 times in smokers. 1,3-Dimethyl uric acid metabolite increased in uremia and, because of cross-reactivity, may cause an apparent slight increase in serum theophylline.
Tobramycin	Peak: 5-10 µg/mL; trough: < 2 mg/mL	2-3; ? in uremia	? in renal dysfunction	Tobramycin, kanamycin, and amikacin may cross-react in immunoassay.
Valproic acid	55-100 µg/mL	13-19		95% protein-bound. Decreased binding in uremia and cirrhosis.
Vancomycin	Trough: 5-15 µg/mL	6 ? in uremia	? in renal dysfunction	Toxicity in uremic patients leads to irreversible deafness. Keep peak level < 30-40 µg/mL to avoid toxicity.

? = unchanged; ?e redcrease(d); ? = decrease(d); CHF = congestive heart failure.

¹Modified and reproduced, with permission, from Nicoll D et al: *Pocket Guide to Diagnostic Tests*, 4th ed. McGraw-Hill, 2004.

²Use red-topped tube (not marbled) for therapeutic drug monitoring. In general, the specimen should be drawn just before the next dose (trough).

Ammonia (NH ₃)	Plasma	18-60 µg/dL	0.59	11-35 µmol/L	Green
Amylase	Serum	20-110 units/L (laboratory-specific)	0.02	0.33-1.83 µkat/L (laboratory-specific)	Marbled
Angiotensin-converting enzyme (ACE)	Serum	12-35 units/L (method-dependent)	16.67	< 590 nkat/L (method-dependent)	Marbled
Antithrombin III (AT III)	Plasma	84-123% (qualitative) 22-39 mg/dL (quantitative)			Blue
a ₁ -Antitrypsin ³ Serum	110-270 mg/dL	0.01	1.1-2.7 g/L	Marbled	
Aspartate aminotransferase (AST, SGOT, GOT)	Serum	0-35 units/L (laboratory-specific)	0.02	0-0.58 µkat/L (laboratory-specific)	Marbled
Basophil count	Whole blood	0.01-0.12 × 10 ⁹ /L			Lavender
Bilirubin	Serum	Total: 0.1-1.2 mg/dL Direct (conjugated to glucuronide): 0.1-0.4 mg/dL Indirect (unconjugated): 0.1-0.7 mg/dL	17.10	2-21 µmol/L < 7 µmol/L < 12 µmol/L	Marbled
Blood urea nitrogen (BUN)	Serum	8-20 mg/dL	0.36	2.9-7.1 mmol/L	Marbled
C-peptide	Serum	0.8-4.0 ng/mL	1.00	0.8-4.0 µg/L	Marbled (fasting)
Calcitonin	Plasma	Male: < 90 pg/mL Female: < 70 pg/mL	1.00	Male: < 90 ng/L Female: < 70 ng/L	Green
Calcium (Ca ²⁺)	Serum	8.5-10.5 mg/dL Panic: < 6.5 or > 13.5 mg/dL	0.25	2.1-2.6 mmol/L	Marbled
Calcium (ionized)	Serum	4.6-5.3 mg/dL	0.25	1.15-1.32 mmol/L	Marbled
Calcium (U _{Ca})	Urine	100-300 mg/d	0.025	2.5-7.5 mmol/d	Urine bottle containing hydrochloric acid
Carbon dioxide, partial pressure (PCO ₂)	Whole blood	32-48 mm Hg	0.13	4.26-6.38 kPa	Heparinized syringe
Carbon dioxide (CO ₂), total (bicarbonate)	Serum	22-28 meq/L Panic: < 15 or > 40 meq/L	1.00	22-28 mmol/L Panic: < 15 or > 40 mmol/L	Marbled
Carboxyhemoglobin (HbCO)	Whole blood	< 9% of total hemoglobin (Hb)	0.01	< 0.09 fraction of total hemoglobin	Lavender
Carcinoembryonic antigen (CEA)	Serum	0-2.5 ng/mL	1.00	0-2.5 µg/L	Marbled
CD4 T cell count	Whole blood	359-1725 cells/µL			Lavender (CBC and differential and % CD4 required)
Ceruloplasmin	Serum	20-35 mg/dL (laboratory-specific)	10.00	200-350 mg/L	Marbled
Chloride (Cl ⁻)	Serum	98-107 meq/L	1.00	98-107 mmol/L	Marbled
Cholesterol	Serum	Desirable: < 200 mg/dL Borderline: 200-239 mg/dL High risk: > 240 mg/dL	0.03	Desirable: < 5.2 mmol/L Borderline: 5.2-6.1 mmol/L High risk: > 6.2 mmol/L	Marbled
Chorionic gonadotropin, β-subunit (β-hCG), quantitative	Serum	Males and nonpregnant females: undetectable or < 5 mU/mL	1.00	Males and nonpregnant females: undetectable or < 5 units/L	Marbled
Complement C3	Serum	64-166 mg/dL	10.00	640-1660 mg/L	Marbled
Complement C4	Serum	15-45 mg/dL	10.00	150-450 mg/L	Marbled
Complement CH50	Plasma or serum	22-40 units/mL (laboratory-specific)			Marbled
Cortisol	Plasma or serum	8:00 AM: 5-20 µg/dL	27.59	140-550 nmol/L	Marbled, lavender, or green
Cortisol (urinary free)	Urine	10-110 µg/24 h	2.76	30-300 nmol/d	Urine bottle containing boric acid
Creatine kinase (CK)	Serum	32-267 units/L (method-dependent)	0.02	0.53-4.45 µkat/L (method-dependent)	Marbled
Creatine kinase MB (CKMB)	Serum	< 16 units/L or < 4% of total CK (laboratory-specific) Mass units: 0-7 µg/L	0.04	< 0.27 µkat/L	Marbled
Creatinine (Cr)	Serum	0.6-1.2 mg/dL	83.3	50-100 µmol/L	Marbled
Creatinine clearance (Cl _{Cr})	See Collection column.	Adults: 90-140 mL/min/1.73 m ² BSA	0.017	1.5-2.3 mL/s/1.73 m ² BSA	Carefully timed 24-hour urine and simultaneous serum or plasma creatinine sample

Cryoglobulins	Serum	< 0.12 mg/dL			Marbled at 37 °C
Eosinophil count	Whole blood	0.4-0.5 × 10 ⁹ /L			Lavender
Erythrocyte count (RBC count)	Whole blood	4.2-5.6 × 10 ⁶ /μL	1.00	4.2-5.6 × 10 ¹² /L	Lavender
Erythrocyte sedimentation rate	Whole blood	Male: < 10 mm/h Female: < 15 mm/h (laboratory-specific)		Same	Lavender
Erythropoietin (EPO)	Serum	5-20 mU/mL	1.00	5-20 units/L	Marbled
Ethanol	Serum	mg/dL Legal "driving under the influence" in many states is defined as > 80 mg/dL (> 17 mmol/L)	0.217	mmol/L	Marbled
Factor VIII assay	Plasma	40-150% of normal (varies with age)			Blue
Fecal fat	Stool	Random: < 60 droplets of fat per high-power field 72-hour: < 7 g/d			Qualitative: Random stool sample Quantitative: 72-hour collection following 2-day dietary fat regimen
Ferritin	Serum	Male: 16-300 ng/mL Female: 4-161 ng/mL	1.00	Male: 16-300 μg/L Female: 4-161 μg/L	Marbled
α-Fetoprotein (AFP)	Serum	0-15 ng/mL	1.00	0-15 μg/L	Marbled
Fibrin D-dimers	Plasma	Negative			Blue
Fibrinogen (functional)	Plasma	175-433 mg/dL Panic: < 75 mg/dL	0.01	1.75-4.3 g/L	Blue
Folic acid (red cells)	Whole blood	165-760 ng/mL	2.27	370-1720 nmol/L	Lavender
Follicle-stimulating hormone (FSH)	Serum	Female: Follicular phase 4-13 mU/mL Luteal phase 2-13 mU/mL Midcycle 5-22 mU/mL Postmenopausal 30-138 mU/mL Male: 1-10 mU/mL (laboratory-specific)	1.00	Female: 4-13 units/L 2-13 units/L 5-22 units/L 30-138 units/L Male: 1-10 units/L (laboratory-specific)	Marbled
Free erythrocyte protoporphyrin (FEP)	Whole blood	< 35 μg/dL (method-dependent)			Lavender
Fructosamine	Serum			1.6-2.6 mmol/L	Marbled
Gamma-glutamyltranspeptidase (GGT)	Serum	9-85 units/L (laboratory-specific)	0.02	0.15-1.42 μkat/L (laboratory-specific)	Marbled
Gastrin	Serum	< 100 pg/mL (laboratory-specific)	1.00	< 100 ng/L	Marbled
Glucose	Serum	60-110 mg/dL Panic: < 40 or > 500 mg/dL	0.055	3.3-6.1 mmol/L	Marbled (fasting)
Glucose-6-phosphatedehydrogenase (G6PD) screen	Whole blood	5-14 units/g Hb	0.02	0.1-0.28 μkat/L	Green or blue
Glutamine	CSF	6-16 mg/dL Panic: > 40 mg/dL	0.07	0.1-0.28 mmol/L	Collect CSF in a plastic tube
Glycated (glycosylated)hemoglobin (HbA _{1c})	Serum	3.9-6.9% (method-dependent)			Lavender
Growth hormone (GH)	Serum	0-5 ng/mL	1.00	0-5 μg/L	Marbled
Haptoglobin	Serum	46-316 mg/dL	0.01	0.5-3.2 g/L	Marbled
HDL cholesterol	Serum	Male: 27-67 mg/dL Female: 34-88 mg/dL	0.026	0.7-1.73 mmol/L 0.88-2.28 mmol/L	Marbled
<i>Helicobacter pylori</i> antibody	Serum	Negative			Marbled
Hematocrit (Hct)	Whole blood	Male: 39-49% Female: 35-45% (age-dependent)	0.01	Male: 0.39-0.49 Female: 0.35-0.45	Lavender
Hemoglobin A _{1c} (See Glycated Hemoglobin)	Serum				
Hemoglobin A ₂ (HbA ₂)	Whole blood	1.5-3.5% of total hemoglobin	0.01	0.015-0.035	Lavender
Hemoglobin electrophoresis	Whole blood	HbA: > 95% HbA ₂ : 1.5-3.5%			Lavender, blue, or green
Hemoglobin, fetal (HbF)	Whole blood	Adult: < 2% (varies with age)			Lavender, blue, or green
Hemoglobin, total (Hb)	Whole blood	Male: 13.6-17.5 g/dL Female: 12.0-15.5 g/dL Panic: = 7 g/dL (age-dependent)	10.00	Male: 136-175 g/L Female: 120-155 g/L	Lavender
Hemosiderin	Urine	Negative			Urine container
HIV viral load	Plasma	Negative			Lavender
β-Hydroxybutyrate	Serum	0.5-3 mg/dL	0.096	0.05-0.3 mmol/L	Marbled
5-Hydroxyindoleacetic acid (5-HIAA)	Urine	2-8 mg/24 h	5.23	10-40 μmol/d	Urine bottle containing hydrochloric acid
IgG index	Serum and CSF	0.29-0.59 ratio			Marbled and glass or plastic tube for CSF
Immunoglobulins (Ig)	Serum	IgA: 78-367 mg/dL IgG: 583-1761 mg/dL IgM: 52-335 mg/dL	0.01	IgA: 0.78-3.67 g/L IgG: 5.83-17.6 g/L IgM: 0.52-3.35 g/L	Marbled
Insulin, immuno-reactive	Serum	6-35 μU/mL	7.18	42-243 pmol/L	Marbled
Insulin-like growth factor-1	Plasma	123-463 ng/mL (age- and sex-dependent)	1.0	123-463 μg/L	Lavender
Iron (Fe ²⁺)	Serum	50-175 μg/dL	0.18	9-31 μmol/L	Marbled
Iron-binding capacity, total (TIBC)	Serum	250-460 μg/dL	0.18	45-82 μmol/L	Marbled
Lactate dehydrogenase (LDH)	Serum	88-230 units/L (laboratory-specific)	0.02	1.46-3.82 μkat/L (laboratory-specific)	Marbled
Lactate dehydrogenase(LDH) isoenzymes	Serum	LDH ₁ /LDH ₂ : < 0.85			Marbled

Lactic acid (lactate)	Venous blood	0.5-2.0 meq/L	1.00	0.5-2.0 mmol/L	Gray
LDL cholesterol	Serum	< 130 mg/dL	0.026	< 3.37 mmol/L	Marbled
Lead (Pb)	Whole blood	Child: < 25 µg/dL Adult: < 40 µg/dL	0.05	Child: < 1.21 µmol/L Adult: < 1.93 µmol/L	Navy
Lecithin/sphingomyelin (L/S) ratio	Amniotic fluid	> 2.0 (method-dependent)			Collect in a plastic tube
Leukocyte alkaline phosphatase (LAP)	Whole blood	40-130 Based on 0 to 4+ rating of 100 PMNs stained for alkaline phosphatase			Green
Leukocyte (white bloodcell) count, total (WBC count)	Whole blood	3.4-10 × 10 ³ /µL Panic: < 1.5 × 10 ³ /µL	1.00	3.4-10 × 10 ⁹ /L	Lavender
Lipase	Serum	0-160 units/L (laboratory-specific)	0.02	0-2.66 µkat/L (laboratory-specific)	Marbled
Luteinizing hormone(LH)	Serum	Female: Follicular phase 1-18 mU/mL Luteal phase 0.4-20 mU/mL Midcycle 24-105 mU/mL Postmenopausal 15-62 mU/mL Male: 1-10 mU/mL (laboratory-specific)	1.00	1-18 units/L 0.4-20 units/L 24-105 units/L 15-62 units/L Male: 1-10 units/L (laboratory-specific)	Marbled
Lymphocyte count	Whole blood	0.8-3.5 × 10 ⁹ /L			Lavender
Magnesium (Mg ²⁺)	Serum	1.8-3.0 mg/dL Panic: < 0.5 or > 4.5 mg/dL	0.41	0.75-1.25 mmol/L	Marbled
Mean corpuscular hemoglobin (MCH)	Whole blood	26-34 pg			Lavender
Mean corpuscular hemoglobin concentration (MCHC)	Whole blood	31-36 g/dL	10.00	310-360 g/L	Lavender
Mean corpuscular volume (MCV)	Whole blood	80-100 fL			Lavender
Metanephrines	Urine	0.3-0.9 mg/24 h	5.46	1.6-4.9 µmol/d	Urine bottle containing hydrochloric acid
Methemoglobin (MetHb)	Whole blood	< 1% of total hemoglobin	0.01	< 0.01 fraction of total hemoglobin	Lavender
Methylmalonic acid	Serum	0-0.05 mg/L	8.475	0-0.4 µmol/L	Marbled
Monocyte count	Whole blood	0.2-0.8 × 10 ⁹ /L			Lavender
Neutrophil count	Whole blood	2.2-8.6 × 10 ⁹ /L			Lavender
Osmolality	Serum	275-293 mosm/kg H ₂ O Panic: < 240 or > 320 mosm/kg H ₂ O	1.00	275-293 mmol/kg H ₂ O	Marbled
	Urine	Random: 100-900 mosm/kg H ₂ O	1.00	Random: 100-900 mmol/kg H ₂ O	Urine container
Oxygen, partial pressure (Po ₂)	Whole blood	83-108 mm Hg	0.13	11.04-14.36 kPa	Heparinized syringe
Parathyroid hormone (PTH)	Serum	Intact PTH: 11-54 pg/mL (laboratory-specific)	0.11	Intact PTH: 1.2-5.7 pmol/L (laboratory-specific)	Marbled
Partial thromboplastin time, activated (PTT)	Plasma	25-35 seconds (rangevaries) Panic: = 60 seconds			Blue
pH	Whole blood	Arterial: 7.35-7.45 Venous: 7.31-7.41			Heparinized syringe
Phosphorus	Serum	2.5-4.5 mg/dL Panic: < 1.0 mg/dL	0.32	0.8-1.45 mmol/L	Marbled
Platelet count (Plt)	Whole blood	150-450 × 10 ³ /µL Panic: < 25 × 10 ³ /mL	1.00	150-450 × 10 ⁹ /L Panic: < 25 × 10 ⁹ /L	Lavender
Platelet-associated IgG	Whole blood	Negative			Yellow (17 mL of blood)
Porphobilinogen (PBG)	Urine	Negative			
Potassium (K ⁺)	Serum	3.5-5.0 meq/L Panic: < 3.0 or > 6.0 meq/L	1.00	3.5-5.0 mmol/L	Marbled
Prolactin (PRL)	Serum	< 20 ng/mL	1.00	< 20 µg/L	Marbled
Prostate-specific antigen (PSA)	Serum	0-4 ng/mL	1.00	0-4 µg/L	Marbled
Protein C	Plasma	71-176%			Blue
Protein electrophoresis	Serum	Adults: Albumin: 3.3-4.7 g/dL α ₁ : 0.1-0.4 g/dL α ₂ : 0.3-0.9 g/dL β ₂ : 0.7-1.5 g/dL ?: 0.5-1.4 g/dL	10.00	33-47 g/L 1-4 g/L 3-9 g/L 7-15 g/L 5-14 g/L	Marbled
Protein S (antigen)	Plasma	76-178%			Blue
Protein, total	Plasma or serum	6.0-8.0 g/dL	10.00	60-80 g/L	Marbled
Prothrombin time (PT)	Whole blood	11-15 seconds Panic: = 30 seconds (laboratory-specific) INR (international normalized ratio):1.0; 2-3.5 or warfarin: 2-3.5 Panic: > 6			Blue
Red blood cell count	Whole blood	4.7-6.1 × 10 ⁹ /L			Lavender
Red cell volume	Whole blood	25-35 mL/kg			Green

Renin activity (PRA)	Plasma	High-sodium diet (75-150 meq Na ⁺ /d): Supine: 0.2-2.3 ng/mL/h Standing: 1.3-4.0 ng/mL/h Low-sodium diet (30-75 meq Na ⁺ /d): Standing: 4.0-7.7 ng/mL/h			Lavender
Reptilase clotting time	Plasma	13-19 seconds			Blue
Reticulocyte count	Whole blood	33-137 × 10 ³ /μL	1.00	33-137 × 10 ⁹ /L	Lavender
Russell's viper venom clotting time (dilute) (RVVT)	Plasma	24-37 seconds			Blue
Salicylate (aspirin, others)	Serum	20-30 mg/dL Panic: > 35 mg/dL	10.00	200-300 mg/L	Marbled
Sodium (Na ⁺)	Serum	135-145 meq/L Panic: < 125 or > 155 meq/L	1.00	135-145 mmol/L	Marbled
Testosterone	Serum	Male: 3.0-10.0 ng/mL Female: 0.3-0.7 ng/mL	3.47	Male: 10-35 nmol/L Female: 1.0-2.4 nmol/L	Marbled
Thrombin time	Plasma	24-35 seconds (laboratory-specific)			Blue
Thyroglobulin	Serum	3-42 ng/mL	1.00	3-42 μg/L	Marbled
Thyroid-stimulating hormone (TSH)	Serum	0.4-6 μU/mL	1.00	0.4-6 mU/L	Marbled
Thyroid-stimulating hormone receptorantibody (TSH-R Ab [stim])	Serum	< 130% of basal activity. Based on cAMP generation in thyroid cell tissue culture.			
Thyroxine, free (FT ₄)	Serum	9-24 pmol/L (varies with method)			Marbled
Thyroxine (T ₄), total	Serum	5-11 μg/dL	12.80	64-142 nmol/L	Marbled
Thyroxine index, free (FT ₄ I)	Serum	6.5-12.5			Marbled
Transferrin	Serum	190-375 mg/dL	0.01	1.9-3.75 g/L	Marbled
Triglycerides	Serum	< 165 mg/dL	0.01	< 1.65 g/L	Marbled (fasting)
Triiodothyronine (T ₃), total	Serum	95-190 ng/dL	0.015	1.5-2.9 nmol/L	Marbled
Troponin-I (cTnI)	Serum	< 1.5 ng/mL			Marbled
Uric acid	Serum	Male: 2.4-7.4 mg/dL Female: 1.4-5.8 mg/dL	59.48	Male: 140-440 μmol/L Female: 80-350 μmol/L	Marbled
Vanillylmandelic acid (VMA)	Urine	2-7 mg/24 h	5.05	10-35 μmol/d	Urine bottle containing hydrochloric acid
Vitamin B ₁₂	Serum	140-820 pg/mL	0.74	100-600 pmol/L	Marbled
Vitamin B ₁₂ absorption test (Schilling test)	24-hour urine	Excretion of > 8% of administered dose			Urine bottle
Vitamin D, 25-hydroxy (25[OH]D)	Serum or plasma	10-50 ng/mL	2.5	25-125 nmol/L	Marbled or green
Vitamin D, 1,25-dihydroxy (1,25[OH] ₂ D)	Serum or plasma	20-76 pg/mL	2.4	48-182 pmol/L	Marbled or green
White blood cell count	Whole blood	4.8-10.8 × 10 ⁹ /L	1.00		Lavender

¹The reference ranges given here in conventional units and in SI units are from several large medical centers. Always use the reference ranges provided by your clinical laboratory, since ranges may be method-dependent.

²Reference: Young DS: Implementation of SI units for clinical laboratory data. Ann Intern Med 1987;106:114; JAMA Instructions for Authors, JAMA 1997;278:74.

³Also called a₁-antiprotease in some clinical contexts.

• **Location In Book:**

- CURRENT MEDICAL DIAGNOSIS & TREATMENT - 43rd Ed. (2004)
Appendix: Therapeutic Drug Monitoring & Laboratory Reference Ranges - C. Diana Nicoll, MD, PhD, MPA
Table 2. Reference ranges for commonly used tests.

•

Table 3. Commonly Used Specimen Collection Tubes

Color	Tube Contents	Typical Use
Lavender	EDTA	Complete blood count
Marbled	Serum separator	Serum chemistry tests
Red	None	Blood banking (serum); therapeutic drug monitoring
Blue	Citrate	Coagulation studies
Gray	Inhibitor of glycolysis (sodium fluoride)	Lactic acid
Green	Heparin	Plasma studies
Yellow	Acid citrate	HLA typing
Navy	Trace metal free	Trace metals (eg, lead)
