The use of "counterforce" straps (bands worn distal to the elbow, over the bulk of the forearm musculature), intended to decrease the forces transmitted to the elbow during activity, are inadequate substitutes for rest. NSAIDs are effective in mild cases. Symptoms that persist after 2 weeks of conservative therapy usually respond either to infiltration of triamcinolone, 10-20 mg mixed with 1-2 mL of 1% lidocaine, around the involved epicondyle—or to physiotherapy. Results are quicker with corticosteroid injections but longer-lasting with physiotherapy. After the pain and tenderness have subsided, patients may begin a physical therapy program involving daily stretching of the flexor and extensor tendons. There are anecdotal reports of dramatic relief with operative treatment.

3. Patellofemoral Syndrome

Patellofemoral syndrome is among the most common causes of knee complaints in primary care medicine, particularly among adolescent and young adult patients. The syndrome frequently gives rise to the chief complaint of anterior knee pain. The belief that furrowing and roughening of the cartilage on the patella's posterior surface cause the syndrome (chondromalacia patellae) is erroneous. This finding is common, rarely leads to symptomatology, and requires no intervention. A variety of injuries or anatomic abnormalities predispose patients to irregular patellar movements, however, leading to the patellofemoral syndrome. Such predisposing conditions include imbalance of quadriceps strength, patella alta, recurrent patellar subluxation, direct trauma to the patella, and meniscal injuries. For most of these causes, the therapeutic approach is similar.

Clinical Findings

Patients frequently have difficulty localizing the source of their complaint but generally confirm that the pain is in the front of the knee, around or underneath the patella. Questions regarding specific precipitants of the pain may be useful in establishing the diagnosis. For example, because of the flexion load, patients have difficulty going up or down staircases. Another characteristic symptom is the positive "theater" sign: after remaining seated for a prolonged period, patients describe extreme discomfort with their first few steps after rising. The symptoms improve with further walking. Finally, patients with patellofemoral syndrome often complain of crepitus, joint locking, or sensations of joint instability, all of which lack anatomic explanations.

The physical examination is less useful than the history in establishing the diagnosis, but a significant number of patients have characteristic physical findings. In particular, when the knee is held in slight flexion, gentle pressure against the patella as the patient contracts the quadriceps muscles may reproduce the symptoms. In some cases, with the knee extended and the quadriceps relaxed, the typical pain may be reproduced by digital pressure under the medial or lateral border of the patella, with side-to-side movement of the bone. Inflammatory findings on examination are incompatible with the diagnosis of patellofemoral syndrome and suggest other disorders.

Treatment

Therapy includes avoidance of flexion loads and strengthening of the quadriceps. Referral to a physical therapist is helpful in educating the patient about home exercises. Many patients learn that the most effective therapy is bicycling, with the seat high enough to permit nearly full knee extension with each cycle. Although most cases respond to these interventions and even resolve altogether, some persist for years. Even in the latter, conservative therapy remains the rule; operation is rarely indicated.

4. Overuse Syndromes of the Knee

Runners—particularly those who overtrain, fail to stretch prior to running, or do not attain the proper level of conditioning before starting a running program—may develop a variety of painful overuse syndromes of the knee. Most of these conditions are forms of tendinitis or bursitis that can be diagnosed on examination. The most common conditions include anserine bursitis, the iliotibial band syndrome, and popliteal and patellar tendinitis.

Clinical Findings

Symptoms resulting from all of these conditions worsen as the patient continues to run and often require cessation of the activity. Anserine bursitis results in pain medial and inferior to the knee joint over the medial tibia. The iliotibial band syndrome and popliteal tenosynovitis may be difficult to differentiate, because the popliteus tendon inserts into the lateral femoral condyle underneath the iliotibial band. Both conditions result in pain on the lateral side of the knee. Patellar tendinitis, a cause of anterior knee discomfort, typically occurs at the tendon's insertion into the patella rather than at its more inferior insertion.

All of these diagnoses are confirmed by palpation at the relevant sites around the knee. None is associated with joint effusions or other signs of synovitis.

Treatment

Rest and abstention from the associated physical activities for a period of days to weeks are essential. Once pain has subsided, a program of gentle stretching (particularly prior to resuming exercise) may prevent recurrence. Corticosteroid with lidocaine injections may be useful when intense discomfort is present, but caution must be employed when injecting corticosteroids into the region of a tendon.

5. Medial Meniscus Injuries

Tears of the medial meniscus are the most common knee injuries encountered in primary care. Because the medial meniscus is firmly tethered to the underlying tibia, injuries to the medial meniscus occur ten times more commonly than injuries to the lateral meniscus. Both result from a twisting action exerted on the knee joint while the foot is in a weight-bearing position.

Clinical Findings

The injury is heralded by a tearing or popping sensation followed by severe pain. Occasionally, meniscal tears result from seemingly minor trauma. In contrast to ligamentous injuries, in which hemorrhage causes immediate swelling, effusions associated with meniscal injuries accumulate over hours and are typically worse on the day following the injury. Several days after resolution (full or partial), the patient may experience joint locking or instability, recurrent swelling with activity, and pain. The sensation of locking, which may result from mechanical blockage by a fragment of torn meniscus, more commonly results from "pseudolocking" caused by muscle spasm and swelling.

Joint effusion is usually present, frequently accompanied by a ballottable patella. Tenderness may be localized to the medial joint line, and range of motion in the knee may be restricted. In patients without an acutely painful, swollen knee, McMurray's test may suggest the diagnosis. This test is performed with the patient supine and the hip and knee in full flexion. The examiner has one hand on the involved knee and the other on the ipsilateral foot. As the foot is externally rotated, the examiner extends the patient's knee. The presence of a "snap" (palpable or audible) suggests a medial meniscus lesion. MRI is now the optimal test for confirming the diagnosis if plain films exclude other conditions.

Treatment

Initial management is conservative, with elevation of the joint and application of a compression dressing and ice. Weight bearing should be minimized for the first few days after the injury but may be resumed slowly thereafter. The patient should perform quadriceps-strengthening exercises under the instruction of a physical therapist. Surgery is reserved for patients with symptoms that recur upon resumption of normal activities or for patients with irreducible locking caused by mechanical problems.

6. Ankle Sprains

Ankle sprains are among the most common of all sports injuries. Most sprains involve the lateral ligament complex, particularly the anterior talofibular ligament. In more severe injuries, the calcaneofibular ligament may also be involved. If both of these ligaments are ruptured, the injury results in significant joint instability and is classified as a grade III (severe) sprain. (Grades I and II correspond to mild and moderate injuries, respectively.) This section reviews only the type of ankle sprain resulting from inversion (varus) injuries, which account for 85% of all sprains.

Clinical Findings

Varus sprains include a spectrum of severity, ranging from slight loss of function to injuries in which the swelling is prompt, the pain prominent, and weight-bearing impossible. A history of hearing a "pop" at the time of injury is frequently associated with the latter.

Hemorrhage resulting from torn ligaments and damaged peroneal muscle tendons may cause substantial ecchymosis. Tenderness is typically present at the site of injury, and the associated swelling may be considerable. Stability of the anterior talofibular and calcaneofibular ligaments should be assessed with the "anterior drawer" sign: With the foot held in slight plantar flexion, the examiner cups the patient's heel with one hand and the patient's shin with the other. The examiner then applies gentle anterior force in the plane of the patient's foot. Excessive anterior motion of the foot constitutes a positive test (grade III sprain). Plain radiographs exclude associated bony injury.

Treatment

Most ankle sprains—even grade III—are treated identically. The acronym "RICE" (rest, ice, compression, elevation) applies more accurately to ankle sprains than to any other injury. Early application of a compression dressing is essential to control swelling and provide stability to the traumatized joint. Weight bearing should be minimal, with liberal use of crutches. Elevation of the ankle for several days hastens functional recovery by diminishing pain and swelling, and ice is also helpful (alternating 30 minutes on, 30 minutes off). The ice should be applied on top of the compression dressing and not against the skin both because close apposition of the dressing to the skin is critical to control swelling and because direct application of ice is uncomfortable and even deleterious to the skin. Referral to a physical therapist may expedite recovery. Patients should be informed that symptoms from lateral ankle sprains may take weeks or months to resolve, and that this period will be prolonged by premature attempts to bear weight on the injured ankle. Surgical repairs of ruptured lateral ligaments provide excellent outcomes but are usually necessary only in cases of chronically unstable joints.

7. Plantar Fasciitis

The most common cause of foot pain in outpatient medicine is plantar fasciitis, which results from constant strain on the plantar fascia at its insertion into the medial tubercle of the calcaneus. Although certain inflammatory disorders such as the seronegative spondyloarthropathies predispose patients to enthesopathies, the majority of cases occur in patients with no associated disease. Most occur as the result of excessive standing and improper footwear.

Clinical Findings

Patients with plantar fasciitis report severe pain on the bottoms of their feet in the morning—the first steps out of bed in particular—but the pain subsides after a few minutes of ambulation.

The diagnosis may be confirmed by palpation over the plantar fascia's insertion on the medial heel. Radiographs have no role in the diagnosis of this condition—heel spurs frequently exist in patients without plantar fasciitis, and most symptomatic patients do not have heel spurs.

Treatment

Treatment consists of imposing an interval of days without prolonged standing and the use of arch supports. Arch supports give relief by requiring the arches to bear more of the patient's weight, thus unloading the plantar entheses. NSAIDs may provide some relief. In severe cases, a corticosteroid with lidocaine injection (small volume—no more than a total of 1.5 mL) directly into the most tender area on the sole of the foot is helpful. Rare patients require release of the plantar fascia from its attachment site at the os calcis.

■ AUTOIMMUNE DISEASES

The autoimmune disorders are a protean group of acquired diseases in which genetic factors appear to play a role. They have in common widespread immunologic and inflammatory alterations of connective tissue.

These illnesses share certain clinical features, and differentiation among them is often difficult because of this. Common findings include synovitis, pleuritis, myocarditis, endocarditis, pericarditis, peritonitis, vasculitis, myositis, skin rash, alterations of connective tissues, and nephritis. Laboratory tests may reveal Coombs-positive hemolytic anemia, thrombocytopenia, leukopenia, immunoglobulin excesses or deficiencies, antinuclear antibodies (which include antibodies to many nuclear constituents, including DNA and extractable nuclear antigen), rheumatoid factors, cryoglobulins, false-positive serologic tests for syphilis, elevated muscle enzymes, and alterations in serum complement.

Some of the laboratory alterations that occur in this group of diseases (eg, false-positive serologic tests for syphilis, rheumatoid factor) occur in asymptomatic individuals. These changes may also be demonstrated in certain asymptomatic relatives of patients with connective tissue diseases, in older persons, in patients using certain drugs, and in patients with chronic infectious diseases.

RHEUMATOID ARTHRITIS

Essentials of Diagnosis

- Prodromal systemic symptoms of malaise, fever, weight loss, and morning stiffness.
- Onset usually insidious and in small joints; progression is centripetal and symmetric; deformities common.
- Radiographic findings: juxta-articular osteoporosis, joint erosions, and narrowing of the joint spaces.
- Rheumatoid factor usually present.
- Extra-articular manifestations: subcutaneous nodules, pleural effusion, pericarditis, lymphadenopathy, splenomegaly with leukopenia, and vasculitis.

General Considerations

Rheumatoid arthritis is a chronic systemic inflammatory disease of unknown cause, chiefly affecting synovial membranes of multiple joints. The disease has a wide clinical spectrum with considerable variability in joint and extra-articular manifestations. The prevalence in the general population is 1-2%; female patients outnumber males almost 3:1. The usual age at onset is 20-40 years, although rheumatoid arthritis may begin at any age. Susceptibility to rheumatoid arthritis is genetically determined. Most patients have a class 2 human leukocyte antigen (HLA) with an identical five-amino-acid sequence. Although rheumatoid arthritis was once considered to be a relatively benign disorder that could be kept in check by slowly adding layers of treatment, it is now known to be a disease with such a strong tendency to shorten life and cause severe disability that early and aggressive treatment—often with drugs used in combination—is preferred.

The pathologic findings in the joint include chronic synovitis with pannus formation. The pannus erodes cartilage, bone, ligaments, and tendons. In the acute phase, effusion and other manifestations of inflammation are common. In the late stage, organization may result in fibrous ankylosis; true bony ankylosis is rare. In both acute and chronic phases, inflammation of soft tissues around the joints may be prominent and is a significant factor in joint damage.

The microscopic findings most characteristic of rheumatoid arthritis are those of the subcutaneous nodule. This is a granuloma with a central zone of fibrinoid necrosis, a surrounding palisade of radially arranged elongated connective tissue cells, and a periphery of chronic granulation tissue. Pathologic alterations indistinguishable from those of the subcutaneous nodule are occasionally seen in the myocardium, pericardium, endocardium, heart valves, visceral pleura, lungs, sclera, dura mater, spleen, and larynx as well as in the synovial membrane, periarticular tissues, and tendons. Nonspecific pericarditis and pleuritis are found in 25-40% of patients at autopsy. Additional nonspecific lesions associated with rheumatoid arthritis include inflammation of small arteries, pulmonary fibrosis, mononuclear cell infiltration of skeletal muscle and perineurium, and hyperplasia of lymph nodes. Secondary amyloidosis occurs less frequently since the advent of multiple therapies.

Clinical Findings

A. Symptoms and Signs

The clinical manifestations of rheumatoid disease are highly variable. The onset of articular signs of inflammation is usually insidious, with prodromal symptoms of malaise, weight loss, and vague periarticular pain or stiffness. Less often, the onset is acute, triggered by infection, surgery, trauma, emotional strain, or the postpartum period. There is characteristically symmetric joint swelling with associated stiffness, warmth, tenderness, and pain. Stiffness persisting for over 30 minutes is prominent in the morning and subsides during the day; its duration is a useful indicator of activity of disease. Stiffness may recur after daytime inactivity and may be much more severe after strenuous activity. Although any joint may be affected in rheumatoid arthritis, the proximal interphalangeal and metacarpophalangeal joints of the fingers as well as the wrists, knees, ankles, and toes are most often involved. Monarticular disease is occasionally seen early. Synovial cysts and rupture of tendons may occur. Entrapment syndromes are not unusual—particularly of the median nerve at the carpal tunnel of the wrist. Palmar erythema is noted occasionally, as are tiny hemorrhagic infarcts in the nail folds or finger pulps, which are signs of vasculitis. Twenty percent of patients have subcutaneous nodules, most commonly situated over bony prominences but also observed in the bursas and tendon sheaths; these occur in seropositive patients, as do most other extra-articular manifestations. A small number of patients have splenomegaly and lymph node enlargement. Low-grade fever, anorexia, weight loss, fatigue, and weakness often persist; chills are rare. After months or years, deformities may occur; the most common are ulnar deviation of the fingers, boutonniere deformity (hyperextension of the distal interphalangeal joint with flexion of the proximal interphalangeal joint), "swan-neck" deformity (flexion of the distal interphalangeal with extension of the proximal interphalangeal joint), and valgus deformity of the knee. Atrophy of skin or muscle is common. Dryness of the eyes, mouth, and other mucous membranes is found especially in advanced disease (see Sjogren's Syndrome). Other ocular manifestations include episcleritis and scleromalacia, the latter due to scleral nodules and capable of causing retinal detachment. Pericarditis and pleural disease, when present, are frequently silent clinically. Aortitis is a rare late complication that can result in aortic regurgitation or rupture and is usually associated with evidence of rheumatoid vasculitis elsewhere in the body.

B. Laboratory Findings

Serum protein abnormalities are often present. Rheumatoid factor, an IgM antibody directed against the Fc fragment of IgG, is present in the sera of more than 75% of patients. High titers of rheumatoid factor are commonly associated with severe rheumatoid disease. Titers may also be significantly elevated in a number of diverse conditions, including syphilis, sarcoidosis, infective endocarditis, tuberculosis, leprosy, and parasitic infections; in advanced age; and in asymptomatic relatives of patients with autoimmune diseases. Antinuclear antibodies are demonstrable in 20% of patients, though their titers are lower than in systemic lupus erythematosus.

During both the acute and chronic phases, the erythrocyte sedimentation rate and the gamma globulins (most commonly IgM and IgG) are typically elevated. A moderate hypochromic normocytic anemia is common. The white cell count is normal or slightly elevated, but leukopenia may occur, often in the presence of splenomegaly (eg, Felty's syndrome). The platelet count is often elevated, roughly in proportion to the severity of overall joint inflammation. Joint fluid examination is valuable, reflecting abnormalities that are associated with varying degrees of inflammation. (See [Tables 20-1](#) and [20-2](#).)

C. Imaging

Of all the laboratory tests, x-ray changes are the most specific for rheumatoid arthritis. X-rays, however, are not sensitive in that most of those taken during the first 6 months are read as normal. The earliest changes occur in the wrists or feet and consist of soft tissue swelling and juxta-articular demineralization. Later, diagnostic changes of uniform joint space narrowing and erosions develop. The erosions are often first evident at the ulnar styloid and at the juxta-articular margin, where the bony surface is not protected by cartilage. Diagnostic changes also occur in the cervical spine, with C1-2 subluxation, but these changes usually take many years to develop. The value of MRI in early diagnosis is not established.

Differential Diagnosis

The differentiation of rheumatoid arthritis from other diseases of connective tissue can be difficult. However, certain clinical features are helpful. Rheumatic fever is characterized by the migratory nature of the arthritis, an elevated antistreptolysin titer, and a more dramatic and prompt response to aspirin; carditis and erythema marginatum may occur in adults, but chorea and subcutaneous nodules virtually never do. Butterfly rash, discoid lupus erythematosus, photosensitivity, alopecia, high titer to anti-DNA, renal disease, and central nervous system abnormalities point to the diagnosis of systemic lupus erythematosus. Degenerative joint disease (osteoarthritis) is not associated with constitutional manifestations, and the joint pain is characteristically relieved by rest, in contrast to the morning stiffness of

rheumatoid arthritis. Signs of articular inflammation, prominent in rheumatoid arthritis, are usually minimal in degenerative joint disease. Osteoarthritis—in contrast to rheumatoid arthritis—spares the wrist and the metacarpophalangeal joints. While in the early years gouty arthritis is almost always intermittent and monarticular, in later years it can become a chronic polyarticular process that mimics rheumatoid arthritis. Gouty tophi can at times resemble rheumatoid nodules. The early history of intermittent monoarthritis and the presence of synovial urate crystals are distinctive features of gout. Septic arthritis can be distinguished by chills and fever, demonstration of the causative organism in joint fluid, and the frequent presence of a primary focus elsewhere, eg, gonococcal arthritis. Septic arthritis can complicate rheumatoid arthritis and should be considered whenever a patient with rheumatoid arthritis has one joint inflamed out of proportion to the rest. Lyme disease typically involves only one joint, most commonly the knee, and is associated with positive serologic tests (see [Chapter 34](#)). Human parvovirus B19 infection in adults can occasionally mimic rheumatoid arthritis. The mean age at onset is 35-37; arthralgias are much more prominent than arthritis; and rash—on the cheeks, torso, or extremities—is common. The patients are rheumatoid factor-negative, do not have erosions, and have IgM antibodies to human parvovirus B19 infection. Polymyalgia rheumatica occasionally causes polyarthralgias in patients over age 50, but these patients remain rheumatoid factor-negative and have chiefly proximal muscle pain and stiffness. A variety of cancers produce paraneoplastic syndromes, including polyarthritis. One form is hypertrophic pulmonary osteoarthropathy most often produced by lung and gastrointestinal carcinomas, characterized by a rheumatoid-like arthritis associated with clubbing, periosteal new bone formation, and a negative rheumatoid factor. Diffuse swelling of the hands with palmar fasciitis occurs in a variety of cancers, especially ovarian carcinoma.

Treatment

A. Basic Program (Nonpharmacologic Management)

The primary objectives in treating rheumatoid arthritis are reduction of inflammation and pain, preservation of function, and prevention of deformity. Patient satisfaction and the success of therapy depend on how effectively the clinician utilizes the nonpharmacologic measures outlined in the following paragraphs.

1. Education and emotional factors—The clinician should explain the disease, describe its fluctuations, and involve the patient and family in decisions about therapy.

2. Physical and occupational therapies—Physical and occupational therapists understand nonpharmacologic treatments of arthritis (described below) and can effectively teach them. The therapist can develop a program the patient can follow at home, with only periodic monitoring.

3. Systemic rest—The amount of systemic rest required depends upon the presence and severity of inflammation. Complete bed rest may be desirable in patients with profound systemic and articular inflammation, as can occur in rheumatoid arthritis, systemic lupus erythematosus, or psoriatic arthritis. With mild inflammation, 2 hours of rest each day may suffice. In general, rest should be continued until significant improvement is sustained for at least 2 weeks; thereafter, the program may be liberalized. However, the increase of physical activity must proceed gradually and with appropriate support for any involved weight-bearing joints.

4. Articular rest—Decrease of articular inflammation may be expedited by articular rest. Relaxation and stretching of the hip and knee muscles, to prevent flexion contractures, can be accomplished by having the patient lie in the prone position for 15 minutes several times daily. Sitting in a flexed position for prolonged periods is a poor form of joint rest. Appropriate adjustable supports provide rest for inflamed weight-bearing joints, relieve spasm, and may reduce deformities, soft tissue contracture, or instability of the ligaments. The supports must be removable to permit daily range of motion and exercise of the affected extremities (see below).

5. Exercise—Exercises are designed to preserve joint motion, muscular strength, and endurance. Initially, for inflammatory disease, passive range of motion and isometric exercises (such as straight leg raising) are best tolerated. The buoyancy of water permits maximum isotonic and isometric exercise with no more stress on joints than active range of motion exercises. Although ideal for arthritic patients, the cost of hydrotherapy often precludes its use. As tolerance for exercise increases and the activity of the disease subsides, progressive resistance exercises may be introduced. Patients should follow the general rule of eliminating any exercise that produces increased pain 1 hour after the exercise has ended.

6. Heat and cold—These are used primarily for their muscle-relaxing and analgesic effects. Radiant or moist heat is generally most satisfactory. The ambulatory patient will find warm tub baths convenient. Exercise may be better performed after exposure to heat. Some patients derive more relief of joint pain from local application of cold.

7. Assistive devices—Patients with significant hip or knee arthritis may benefit from having a raised toilet seat, a gripping bar, or a cane. Patients hold the cane in the hand opposite to the affected knee or hip, thus leaning away from the affected joint. Crutches or walkers may be needed for patients with more extensive disease.

8. Splints—Splints may provide joint rest, reduce pain, and prevent contracture, but certain principles should be adhered to.

a. Night splints of the hands or wrists (or both) should maintain the extremity in the position of optimum function. The elbow and shoulder lose motion so rapidly that other local measures and corticosteroid injections are usually preferable to splints.

b. The best "splint" for the hip is prone-lying for several hours a day on a firm bed. For the knee, prone-lying may suffice, but splints in maximum tolerated extension are frequently needed. Ankle splints are of the simple right-angle type.

c. Splints should be applied for the shortest period needed, should be made of lightweight materials for comfort, and should be easily removable for range-of-motion exercises once or twice daily to prevent loss of motion.

d. Corrective splints, such as those for overcoming knee flexion contractures, should be used under the guidance of a clinician familiar with their proper use.

Note: Avoidance of prolonged sitting or knee pillows may decrease the need for splints.

9. Weight loss—For overweight patients, achieving ideal body weight will reduce the wear and tear placed on arthritic joints of the lower extremities.

B. Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

The first drug used to treat rheumatoid arthritis is an NSAID. These agents have analgesic and anti-inflammatory effects but are believed not to be capable of preventing erosions or altering progression of the disease. A number of NSAIDs are available, including aspirin, ibuprofen, fenoprofen, naproxen, tolmetin, sulindac, meclofenamate sodium, piroxicam, flurbiprofen, diclofenac, oxaprozin, nabumetone, etodolac, ketoprofen, celecoxib, rofecoxib, and valdecoxib.

NSAIDs work in arthritis by the same mechanism that causes side effects: inhibition of cyclooxygenase, the enzyme that converts arachidonic acid to prostaglandins. Although prostaglandins play important roles in promoting inflammation and pain, they also help maintain homeostasis in several organs—especially the stomach, where prostaglandin E serves as a local hormone responsible for gastric mucosal cytoprotection. The discovery that cyclooxygenase (COX) exists in two isomers—COX-1 (which is expressed continuously in many cells and is responsible for the salutary effects of prostaglandins) and COX-2 (which is induced by cytokines and expressed in inflammatory tissues)—was initially of little practical consequence since all traditional NSAIDs inhibit both isomers. However, selective COX-2 inhibitors (celecoxib, rofecoxib, and valdecoxib) are FDA-approved for the treatment of osteoarthritis and rheumatoid arthritis. Compared with traditional NSAIDs, COX-2 inhibitors are just as effective for treating rheumatoid arthritis and less likely to cause clinically significant upper gastrointestinal events (eg, obstruction, perforation, hemorrhage, or ulceration). Rheumatoid arthritis patients taking rofecoxib for 9 months are about half as likely as those taking naproxen to develop important gastrointestinal complications. Thus, 41 patients treated with rofecoxib rather than naproxen for 1 year would prevent one gastrointestinal event.

In terms of efficacy, all NSAIDs appear equivalent. Anecdotes suggest that indomethacin is more effective than other NSAIDs for ankylosing spondylitis (see below). For rheumatoid arthritis, no NSAID is convincingly more effective than another.

For traditional NSAIDs that inhibit both COX-1 and COX-2, gastrointestinal side effects, such as gastric ulceration, perforation, and gastrointestinal hemorrhage, are the most common serious side effects. The overall rate of bleeding with NSAID use is low (1:6000 users or less) but is increased by chronic use, concomitant corticosteroids or anticoagulants, the presence of rheumatoid arthritis, history of peptic ulcer disease or alcoholism, and age over 70. Twenty-five percent of all hospitalizations and deaths from peptic ulcer disease result from traditional NSAID therapy. Each year, 1:1000 patients with rheumatoid arthritis will require hospitalization for NSAID-related gastrointestinal bleeding or perforation. Although all traditional NSAIDs can cause massive gastrointestinal bleeding, the risk may be higher with indomethacin and piroxicam, probably because these drugs preferentially inhibit COX-1 in the stomach.

There are two approaches to reducing the gastrointestinal toxicity of NSAIDs. One approach is to use a COX-2 inhibitor. The other approach is to use a traditional NSAID and add either a proton pump inhibitor (eg, omeprazole 20 mg daily), famotidine 40 mg twice daily, or misoprostol. The expense of these medications dictates that their use should be reserved for patients with risk factors for NSAID-induced gastrointestinal toxicity (noted above). Carafate, antacids, and ranitidine either do not work or do not work as well as omeprazole. The efficacy of misoprostol is limited by its poor tolerance; 20% of patients cannot tolerate the diarrhea and bloating associated with full doses (200 ug four times daily). Giving smaller amounts of misoprostol (eg, 100 ug four times daily) or using less frequent dosing (eg, 200 ug twice daily) improves tolerance while reducing efficacy only modestly. Misoprostol is an abortifacient and is contraindicated in patients who are or might become pregnant. Patients who have recently recovered from an NSAID-induced bleeding gastric ulcer appear to be at high risk of rebleeding (about 5% in 6 months) when an NSAID—be it a COX-2 inhibitor or a traditional NSAID combined with a proton pump inhibitor—is reintroduced. NSAIDs can also affect the lower intestinal tract, causing perforation or aggravating inflammatory bowel disease.

Acute liver injury from NSAIDs is rare, occurring in about one out of every 25,000 patients using these agents. Having rheumatoid arthritis or taking sulindac may increase the risk. Minor transient increases in aminotransferase levels do not predict risk for NSAID-associated hepatotoxicity.

All of the NSAIDs, including aspirin and the COX-2 inhibitors, can produce renal toxicity, including interstitial nephritis, nephrotic syndrome, prerenal azotemia, and aggravation of hypertension. Hyperkalemia due to hyporeninemic hypoaldosteronism may also be seen. The risk of renal toxicity is low but is increased by age over 60, a history of renal disease, congestive heart failure, ascites, and diuretic use. COX-2 inhibitors appear to cause as much nephrotoxicity as traditional NSAIDs.

All NSAIDs except the nonacetylated salicylates and the COX-2 inhibitors interfere with platelet function and prolong bleeding time. For all older NSAIDs except aspirin, the effect on bleeding time resolves as the drug is cleared. Aspirin irreversibly inhibits platelet function, so the bleeding time effect resolves only as new platelets are made. COX-2 inhibitors, which differ from other NSAIDs in not inhibiting platelet function, do not increase the risk of bleeding with surgical procedures as most NSAIDs do. Whether this lack of platelet inhibition with COX-2 inhibitors increases the risk of myocardial infarction or thrombosis is not yet clear. Patients requiring low-dose aspirin who are not compliant have a greater risk of developing a thrombotic event while taking a "coxib" than while taking a traditional NSAID. Whether combination therapy with low-dose aspirin and a coxib maintains the gastrointestinal advantage of selective COX-2 inhibitors is not yet known.

Although groups of patients with rheumatoid arthritis respond similarly to NSAIDs, individuals may respond differently—an NSAID that works for one patient may not work for another. Thus, if the first NSAID chosen is not effective after 2-3 weeks of use, another should be tried.

C. Additional Drugs

Disease-modifying antirheumatic drugs (DMARDs) should be started as soon as the diagnosis of rheumatoid disease is certain.

1. Methotrexate—Many now believe that methotrexate is the treatment of choice for patients with rheumatoid arthritis who fail to respond to NSAIDs. Methotrexate is generally well-tolerated and often produces a beneficial effect in 2-6 weeks—compared with the 2- to 6-month onset of action for drugs such as gold, penicillamine, and antimalarials. The usual initial dose is 7.5 mg of methotrexate orally once weekly. If the patient has tolerated methotrexate but has not responded in 1 month, the dose can be increased to 15 mg orally once per week. The maximum dose is approximately 20 mg/wk. The most frequent side effects are gastric irritation and stomatitis. If needed to minimize gastrointestinal toxicity, methotrexate can be administered by subcutaneous or intramuscular injection. A severe, potentially life-threatening interstitial pneumonitis occurs rarely and usually responds to cessation of the drug and institution of corticosteroids. Hepatotoxicity with fibrosis and cirrhosis is another important toxic effect that appears to be very rare, with a risk of approximately 1:1000 after 5 years of methotrexate therapy. Still, methotrexate is contraindicated in a patient with any form of chronic hepatitis. Diabetes, obesity, and renal disease increase the risk of hepatotoxicity. Liver function tests should be monitored every 4-8 weeks, along with the CBC, serum creatinine, and serum albumin. Heavy alcohol use increases the hepatotoxicity, so patients should be advised not to drink. In a patient with no risk factors for hepatotoxicity, liver biopsy is not needed initially but is performed if aminotransferase levels are elevated, despite dosage reduction, in 6 out of 12 monthly determinations or if the serum albumin falls below normal. Cytopenia due to bone marrow suppression and infection are other important potential problems. The risk of developing cytopenia is much higher in patients with a serum creatinine of 2 mg/dL or higher. Side effects, including hepatotoxicity, may be reduced by prescribing either daily folate (1 mg) or weekly leucovorin calcium (2.5-5 mg taken 24 hours after the dose of methotrexate). To date, methotrexate has not been proved to increase the risk of malignancy. The combination of methotrexate and other folate antagonists, such as trimethoprim-sulfamethoxazole, should be used cautiously, since pancytopenia can result. Probenecid should also be avoided since it increases methotrexate drug levels and toxicity.

2. Tumor necrosis factor inhibitors—Inhibitors of tumor necrosis factor (TNF) are fulfilling the aim of targeted therapy for rheumatoid arthritis and are now frequently added to the treatment of patients who have not responded adequately to methotrexate. TNF inhibitors work faster than methotrexate and may replace that drug as the remitting agent of first choice. TNF is a cytokine that activates lymphocytes and leukocytes and is greatly increased in the synovial fluid of patients with rheumatoid arthritis; two inhibitors are in use. The first is etanercept, a soluble recombinant TNF receptor:Fc fusion protein (administered at a dosage of 25 mg subcutaneously twice weekly). The second is infliximab, an anti-TNF antibody that is administered at a dosage of 3-10 mg/kg intravenously initially and then repeated after 2, 6, 10, and 14 weeks. Each drug produces substantial improvement in over 60% of patients. Etanercept is usually very well tolerated. Minor irritation at injection sites is the most common side effect. Rarely, patients develop nonrecurrent leukopenia. Since TNF may play a physiologic role in combating infection, there has been concern that TNF inhibitors increase the risk of developing infections. Infliximab very likely multiplies fourfold the risk of tuberculosis. Screening for latent tuberculosis is now recommended before TNF blockers are initiated. It is prudent to discontinue TNF blockers when a patient develops fever or other manifestations of a clinically important infection. Multiple sclerosis-like attacks have been reported rarely in patients taking TNF inhibitors, but the importance of this association has not yet been determined. Infliximab can rarely cause anaphylaxis and induce anti-DNA antibodies. Concomitant use of methotrexate appears to enhance the clinical response to infliximab and to prevent development of neutralizing antibodies to the drug (which is a hybrid human-mouse antibody). Because both drugs cost more than \$10,000 per year, many insurers do not cover their cost unless the patient has a definite diagnosis of rheumatoid arthritis and has failed methotrexate.

3. Antimalarials—Hydroxychloroquine sulfate is the antimalarial agent most often used against rheumatoid arthritis. It should be reserved for patients with mild disease, since only 25-50% will respond and in some of those cases only after 3-6 months of therapy. The advantage of hydroxychloroquine is its comparatively low toxicity, especially at a dosage of 200-400 mg/d. The most important reaction, pigmentary retinitis causing visual loss, is rare at this dose. Ophthalmologic examinations every 6-12 months are required when this drug is employed for long-term therapy. Other reactions include neuropathies and myopathies of both skeletal and cardiac muscle, which usually improve when the drug is withdrawn.

4. Corticosteroids—Corticosteroids usually produce an immediate and dramatic anti-inflammatory effect in rheumatoid arthritis, and they may be able to slow the rate of bony destruction. However, the problem of untoward reactions resulting from prolonged use greatly limits its long-term efficacy. BR>Corticosteroids may be used on a short-term basis to tide patients over acute disabling episodes, to facilitate other treatment measures (eg, physical therapy), or to manage serious extra-articular manifestations (eg, pericarditis, perforating eye lesions). They may also be indicated for active and progressive disease that does not respond favorably to conservative management and when there are contraindications to or therapeutic failure of methotrexate, gold salts, or other disease-modifying agents.

No more than 10 mg of prednisone or equivalent per day is appropriate for articular disease. Many patients do reasonably well on 5-7.5 mg daily. (The use of 1 mg tablets is to be encouraged.) When the steroids are to be discontinued, they should be phased out gradually on a planned schedule appropriate to the duration of treatment. All patients receiving chronic corticosteroid therapy should take measures to prevent osteoporosis.

Intra-articular corticosteroids may be helpful if one or two joints are the chief source of difficulty. Intra-articular triamcinolone, 10-40 mg depending on the size of the joint to be injected, may be given for symptomatic relief, but no more often than four times a year.

5. Sulfasalazine—This drug is a second-line agent for rheumatoid arthritis. It is usually introduced at a dosage of 0.5 g twice daily and then increased each week by 0.5 g until the patient improves or the daily dose reaches 3 g. Side effects, particularly neutropenia and thrombocytopenia, occur in 10-25% and are serious in 2-5%. Sulfasalazine also causes hemolysis in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Patients taking sulfasalazine should have complete blood counts monitored every 2-4 weeks for the first 3 months, then every 3 months.

6. Leflunomide—Leflunomide, a pyrimidine synthesis inhibitor, is also FDA-approved for treatment of rheumatoid arthritis. It can be used alone or combined with methotrexate. Administration is started at a dosage of 100 mg/d for 3 days followed by a maintenance dosage of 20 mg daily. The most frequent side effects are diarrhea, rash, reversible alopecia, and hepatotoxicity. Some patients experience dramatic unexplained weight loss. The drug is carcinogenic, teratogenic, and has a half-life of 2 weeks. Thus, it is contraindicated in premenopausal women or in men who wish to father children.

7. Azathioprine—This agent, like methotrexate, is an antimetabolite that is effective for severe rheumatoid arthritis not responsive to gold or antimalarials. The usual initial dose is 1 mg/kg, gradually increased as needed to a maximum of 2.5-3 mg/kg. Its potential for severe toxicity, including immunosuppression complicated by opportunistic infection, restricts its use.

8. Minocycline—Minocycline is more effective than placebo for rheumatoid arthritis. It is reserved for early, mild cases, since its efficacy is modest, and it works better during the first year of rheumatoid arthritis. The mechanism of action is not clear, but tetracyclines do have anti-inflammatory properties, including the ability to inhibit destructive enzymes such as collagenase. The dosage of minocycline is 200 mg/d. Adverse effects are uncommon except for dizziness, which occurs in about 10%.

9. Gold salts and penicillamine—Gold and penicillamine are now very rarely used.

10. Combination therapy—Combination therapy can be considered for patients who have failed to respond to individual agents. The combination of methotrexate, hydroxychloroquine, and sulfasalazine appears more effective than methotrexate alone. The combination of cyclosporine (2.5-5 mg/kg/d) plus methotrexate also appears more effective than methotrexate alone.

D. Other Therapies

Anakinra, a recombinant form of human IL-1 receptor antagonist, may be given to adult patients who have failed one or more DMARDs. Anakinra can be used alone or in combination with DMARDs other than TNF-blocking agents. This agent must be administered daily by subcutaneous injection. Since anakinra has been associated with an increased incidence of serious infection, it should be discontinued whenever suggestive symptoms develop.

The efficacy of removing rheumatoid factor by performing apheresis and passing the patient's plasma over a Prosorba column containing staphylococcal protein A (which binds rheumatoid factor) has been demonstrated in short-term studies.

Dietary modification, especially supplementation with n-3 fatty acids in doses of 2.5-3 g/d, has been helpful to some patients, as has oral administration of collagen from articular cartilage.

E. Surgical Measures

See section on Some Orthopedic Procedures for Arthritic Joints at the end of this chapter.

Course & Prognosis

Determining the best initial treatment is difficult because patients suspected of having rheumatoid arthritis can follow two widely divergent courses. Of all patients who present with polyarthritis that appears to be (but probably is not) rheumatoid arthritis, 50-75% experience remission within 2 years. These patients are often negative for rheumatoid factor, have good functional status even during disease activity, and are commonly seen in community practices but rarely in academic centers. Clearly, conservative therapy makes good sense for this patient population.

For patients whose joint symptoms persist beyond 2 years the outcome is not so favorable. Patients in this group die, on average, 10-15 years earlier than people without rheumatoid arthritis. In fact, for patients who have persistent symptoms and poor functional status, the mortality curve resembles that for stage IV Hodgkin's disease or triple-vessel coronary artery disease. The most common causes of death are infection, heart disease, respiratory failure, renal failure, and gastrointestinal disease. Factors that identify those at particular risk of early death include positive rheumatoid factor, poor functional status, more than 30 inflamed joints, and extra-articular manifestations (eg, rheumatoid lung disease). These patients, then, need aggressive therapy and probably need it early, since extensive bone damage can occur during the first 2 years.

Since some patients with polyarthritis will remit and others will sustain substantial damage within the first 2 years, a guidepost for early decisions about aggressive treatment is needed. Patients who have poly-arthritis lasting more than 12 weeks are those at greatest risk of having persistent disease and are appropriate candidates for aggressive therapy. Although genetic risk factors for developing rheumatoid arthritis have been identified, it has not been possible in this way to consistently identify those patients needing aggressive therapy.

ADULT STILL'S DISEASE

Still's disease is considered a variant of rheumatoid arthritis in which high spiking fevers are much more prominent, especially at the outset, than arthritis. This syndrome also occurs in adults. Most adults are in their 20s or 30s; onset after age 60 is rare. The fever is dramatic, often spiking to 40 °C, associated with sweats and chills, and then plunging to several degrees below normal. Many patients initially complain of sore throat. An evanescent salmon-colored nonpruritic rash, chiefly on the chest and abdomen, is a characteristic feature. However, the rash can easily be missed since it often appears only with the fever spike. Many patients also have lymphadenopathy and pericardial effusions. Joint symptoms are mild or absent in the beginning, but a destructive arthritis, especially of the wrists, may develop months later. Anemia and leukocytosis, with white blood counts sometimes exceeding 40,000/uL, are the rule. Ferritin levels are often exceptionally high in adult Still's disease—for reasons that are not clear. Although the diagnosis requires exclusion of other causes of fever, the diagnosis of adult Still's disease is strongly suggested by the fever pattern, sore throat, and the classic rash. About half of the patients respond to high-dose aspirin (eg, 1 g three times daily) or other NSAIDs, and half require prednisone, sometimes in doses greater than 60 mg/d. About one-third of patients have recurrent episodes.

SYSTEMIC LUPUS ERYTHEMATOSUS

Essentials of Diagnosis

- Occurs mainly in young women.
- Rash over areas exposed to sunlight.
- Joint symptoms in 90% of patients. Multiple system involvement.
- Depression of hemoglobin, white blood cells, platelets.
- Serologic findings: antinuclear antibodies (100%), anti-native DNA antibodies (approximately two-thirds), and low serum complement levels (particularly during disease flares).

General Considerations

Systemic lupus erythematosus (SLE) is an inflammatory autoimmune disorder that may affect multiple organ systems. Many of its clinical manifestations are secondary to the trapping of antigen-antibody complexes in capillaries of visceral structures or to autoantibody-mediated destruction of host cells (eg, thrombocytopenia). The clinical course is marked by spontaneous remission and relapses. The severity may vary from a mild episodic disorder to a rapidly fulminant, life-threatening illness.

The prevalence of SLE is influenced by many factors, including gender, race, and genetic inheritance. About 85% of patients are women. Sex hormones appear to play some role, since most cases develop after menarche and before menopause. Among the patients who develop SLE during childhood or after the age of 50, the gender distribution is more equal. Race is also a factor, as SLE occurs in 1:1000 white women but in 1:250 black women. Familial occurrence of SLE has been repeatedly documented, and the disorder is concordant in 25-70% of identical twins. If a mother has SLE, her daughters' risk of developing the disease is 1:40 and her sons' risk is 1:250. Aggregation of serologic abnormalities (positive antinuclear antibody) is seen in asymptomatic family members, and the prevalence of other rheumatic diseases is increased among close relatives of patients. The importance of specific genes in SLE is emphasized by the high frequency of certain HLA haplotypes, especially DR2 and DR3, and null complement alleles.

Before making a diagnosis of SLE, it is imperative to ascertain that the condition has not been induced by a drug. A host of pharmacologic agents have been implicated as causing a lupus-like syndrome, but only a few cause the disorder with appreciable frequency ([Table 20-8](#)). Procainamide, hydralazine, and isoniazid are the best-studied drugs. While antinuclear antibody tests and other serologic findings become positive in many persons receiving these agents, clinical manifestations occur in only a few.

Four features of drug-induced lupus separate it from SLE: (1) the sex ratio is nearly equal; (2) nephritis and central nervous system features are not ordinarily present; (3) hypocomplementemia and antibodies to native DNA are absent; and (4) the clinical features and most laboratory abnormalities often revert toward normal when the offending drug is withdrawn.

The diagnosis of SLE should be suspected in patients having a multisystem disease with serologic positivity (eg, antinuclear antibody, false-positive serologic test for syphilis). Differential diagnosis includes rheumatoid arthritis, vasculitis, scleroderma, chronic active hepatitis, acute drug reactions, polyarteritis, and drug-induced

lupus.

The diagnosis of SLE can be made with reasonable probability if 4 of the 11 criteria set forth in [Table 20-9](#) are met. These criteria should be viewed as rough guidelines that do not supplant clinical judgment in the diagnosis of SLE.

Clinical Findings

A. Symptoms and Signs

The systemic features include fever, anorexia, malaise, and weight loss. Most patients have skin lesions at some time; the characteristic "butterfly" rash affects fewer than half of patients. Other cutaneous manifestations are discoid lupus, typical fingertip lesions, periungual erythema, nail fold infarcts, and splinter hemorrhages. Alopecia is common. Mucous membrane lesions tend to occur during periods of exacerbation. Raynaud's phenomenon, present in about 20% of patients, often antedates other features of the disease.

Joint symptoms, with or without active synovitis, occur in over 90% of patients and are often the earliest manifestation. The arthritis is seldom deforming; erosive changes are almost never noted on radiographs. Subcutaneous nodules are rare.

Ocular manifestations include conjunctivitis, photophobia, transient or permanent monocular blindness, and blurring of vision. Cotton-wool spots on the retina (cytoid bodies) represent degeneration of nerve fibers due to occlusion of retinal blood vessels.

Pleurisy, pleural effusion, bronchopneumonia, and pneumonitis are frequent. Restrictive lung disease is often demonstrated.

The pericardium is affected in the majority of patients. Cardiac failure may result from myocarditis and hypertension. Cardiac arrhythmias are common. Atypical verrucous endocarditis of Libman-Sacks is usually clinically silent but occasionally can produce acute or chronic valvular incompetence—most commonly mitral regurgitation—and can serve as a source of emboli.

Mesenteric vasculitis occasionally occurs in SLE and may closely resemble polyarteritis nodosa, including the presence of aneurysms in medium-sized blood vessels. Abdominal pain (particularly postprandial), ileus, peritonitis, and perforation may result.

Neurologic complications of SLE include psychosis, organic brain syndrome, seizures, peripheral and cranial neuropathies, transverse myelitis, and strokes. Severe depression and psychosis are sometimes exacerbated by the administration of large doses of corticosteroids. Several forms of glomerulonephritis may occur, including mesangial, focal proliferative, diffuse proliferative, and membranous (see [Chapter 22](#)). Some patients may also have interstitial nephritis. With appropriate therapy, the survival rate even for patients with serious renal disease (proliferative glomerulonephritis) is favorable.

B. Laboratory Findings

([Tables 20-10](#), [20-11](#), and [19-4](#).) SLE is characterized by the production of many different autoantibodies, some of which produce specific laboratory abnormalities (eg, hemolytic anemia). Antinuclear antibody tests are sensitive but not specific for systemic lupus—ie, they are positive in virtually all patients with lupus but are positive also in many patients with nonlupus conditions such as rheumatoid arthritis, various forms of hepatitis, and interstitial lung disease. Antibodies to double-stranded DNA and to Sm are specific for systemic lupus but not sensitive, since they are present in only 60% and 30% of patients, respectively. Depressed serum complement—a finding suggestive of disease activity—often returns toward normal in remission. Anti-double-stranded DNA antibody levels also correlate with disease activity in some patients; anti-Sm levels do not.

Three types of antiphospholipid antibodies occur ([Table 20-11](#)). The first causes the biologic false-positive tests for syphilis; the second is the lupus anticoagulant, which despite its name is a risk factor for venous and arterial thrombosis and miscarriage. It is most commonly identified by prolongation of the activated partial thromboplastin time, an in vitro phenomenon related to antibody reacting to phospholipid in the test materials. Anticardiolipin antibodies are the third type of antiphospholipid antibodies. In many cases, the "anticardiolipin antibody" appears to be directed at a serum cofactor (β_2 -glycoprotein-I) rather than at phospholipid itself. A primary **antiphospholipid antibody syndrome** is diagnosed in patients who have recurrent venous or arterial occlusions, recurrent fetal loss, or thrombocytopenia in the presence of antiphospholipid antibodies but without other features of SLE. Livedo reticularis, skin ulcers, mental status changes, and mitral regurgitation are also noted.

Abnormality of urinary sediment is almost always found in association with renal lesions. Showers of red blood cells, with or without casts, and mild proteinuria are frequent during exacerbation of the disease; these usually abate with remission.

Treatment

Some patients with SLE have a benign form of the disease requiring only supportive care and need little or no medication. Emotional support, as described for rheumatoid arthritis, is especially important for patients with lupus. Patients with photosensitivity should be cautioned against sun exposure and should apply a protective lotion to the skin while out of doors. Skin lesions often respond to the local administration of corticosteroids. Minor joint symptoms can usually be alleviated by rest and NSAIDs. Every drug that may have precipitated the condition should be withdrawn if possible.

Antimalarials (hydroxychloroquine) may be helpful in treating lupus rashes or joint symptoms that do not respond to NSAIDs. When these are used, the dose should not exceed 400 mg/d, and biannual monitoring for retinal changes is recommended. Drug-induced neuropathy and myopathy may be erroneously ascribed to the underlying disease. The androgenic steroid danazol may be effective therapy for thrombocytopenia not responsive to corticosteroids. Dehydroepiandrosterone (DHEA) appears to have a therapeutic role comparable to that of the antimalarial agents in the treatment of SLE, but its side effects (particularly acne) are troubling to some patients.

Corticosteroids are required for the control of certain complications. (Systemic steroids are not usually given for minor arthritis, skin rash, leukopenia, or the anemia associated with chronic disease.) Glomerulonephritis, hemolytic anemia, pericarditis or myocarditis, alveolar hemorrhage, central nervous system involvement, and thrombotic thrombocytopenic purpura all require corticosteroid treatment and often other interventions as well. Forty to 60 mg of prednisone is often needed initially; however, the lowest dose of corticosteroid that controls the condition should be employed. Central nervous system lupus may require higher doses of corticosteroids than are usually given; however, steroid psychosis may mimic lupus cerebritis, in which case reduced doses are appropriate. In lupus nephritis, sequential studies of serum complement and antibodies to DNA often permit early detection of disease exacerbation and thus prompt increase in corticosteroid therapy. Such studies also allow for lowering the dosage of the drugs and withdrawing them when they are no longer needed. Immunosuppressive agents such as cyclophosphamide, mycophenolate mofetil, and azathioprine are used in cases resistant to corticosteroids. Cyclophosphamide improves renal survival. Overall patient survival, however, is no better than in the prednisone-treated group. Very close follow-up is needed to watch for potential side effects when immunosuppressants are employed; these agents should be administered by physicians experienced in their use. In recent years, mycophenolate mofetil has been employed in place of cyclophosphamide in the treatment of SLE nephritis in some patients. For patients with the antiphospholipid syndrome—the presence of antiphospholipid antibodies and compatible clinical events—intensive anticoagulation is the treatment of choice. One tested approach is to use warfarin with a target INR of > 3.0.

Course & Prognosis

The prognosis for patients with systemic lupus appears to be considerably better than older reports implied. From both community settings and university centers, 10-year survival rates exceeding 85% are routine. In most patients, the illness pursues a relapsing and remitting course. Corticosteroids, often needed in doses of 40 mg/d or more during severe flares, can usually be tapered to low doses (10-15 mg/d) during disease inactivity. However, there are some in whom the disease pursues a virulent course, leading to serious impairment of vital structures such as lung, heart, brain, or kidneys, and the disease may lead to death. With improved control of lupus activity and with increasing use of corticosteroids and immunosuppressive drugs, the mortality and morbidity patterns in lupus have changed. Infections—especially with opportunistic organisms—have become the leading cause of death, followed by active SLE, chiefly due to renal or central nervous system disease. Although such manifestations are more likely to be seen in the early phases of the illness, one must be alert to the possibility of their occurrence at any time. Accelerated atherosclerosis, attributed in part to corticosteroid use, has been responsible for a rise in late deaths due to myocardial infarction. With more patients living longer, it has become evident that avascular necrosis of bone, affecting most commonly the hips and knees, is responsible for substantial morbidity. Still, the outlook for most patients with SLE has become increasingly favorable.

SYSTEMIC SCLEROSIS (SCLERODERMA)

Essentials of Diagnosis

- Diffuse thickening of skin, with telangiectasia and areas of increased pigmentation and depigmentation.
- Raynaud's phenomenon and antinuclear antibodies are present in virtually all patients.
- Systemic features of dysphagia, hypomotility of gastrointestinal tract, pulmonary fibrosis, and cardiac and renal involvement.

General Considerations

Systemic sclerosis is a chronic disorder characterized by diffuse fibrosis of the skin and internal organs. The causes of systemic sclerosis are not known, but autoimmunity, fibroblast dysregulation, graft-versus-host disease from fetal lymphocytes retained in the maternal circulation, and occupational exposure to silica have been implicated. Symptoms usually appear in the third to fifth decades, and women are affected two to three times as frequently as men.

Two forms of systemic sclerosis are generally recognized: limited (80% of patients) and diffuse (20%). Two bedside clues help distinguish the two subsets. First, in the CREST syndrome, hardening of the skin (scleroderma) is limited to the face and hands, whereas in diffuse scleroderma the skin changes also involve the trunk and proximal extremities. Second, tendon friction rubs, especially frequent over the wrists, ankles, and knees, occur uniquely (but not universally) in diffuse scleroderma. In general, patients with CREST syndrome have better outcomes than those with diffuse disease, largely because patients with limited disease rarely develop renal failure or interstitial lung disease. Curiously, however, patients with limited disease are more liable to develop digital ischemia and pulmonary hypertension. Gastrointestinal and cardiac disease also tend to be more severe and more rapidly progressive in diffuse scleroderma.

Clinical Findings

A. Symptoms and Signs

Most frequently, the disease makes its appearance in the skin, although visceral involvement may precede the cutaneous features. Polyarthralgia and Raynaud's phenomenon (present in 90% of patients) are early manifestations. Subcutaneous edema, fever, and malaise are common. With time the skin becomes thickened and hidebound, with loss of normal folds. Telangiectasia, pigmentation, and depigmentation are characteristic. Ulceration about the fingertips and subcutaneous calcification are seen. Dysphagia due to esophageal dysfunction is common and results from abnormalities in motility and later from fibrosis. Fibrosis and atrophy of the gastrointestinal tract cause hypomotility, and malabsorption results from bacterial overgrowth. Large-mouthed diverticula occur in the jejunum, ileum, and colon. Diffuse pulmonary fibrosis and pulmonary vascular disease are reflected in restrictive lung physiology and low diffusing capacities. Cardiac abnormalities include pericarditis, heart block, myocardial fibrosis, and right heart failure secondary to pulmonary hypertension. Scleroderma renal crisis, resulting from obstruction of smaller renal blood vessels, is a marker for a poor outcome even though many cases can now be treated effectively with angiotensin-converting enzyme inhibitors.

B. Laboratory Findings

Mild anemia is often present. Among patients with severe renal disease, the peripheral blood smear can show findings consistent with a microangiopathic hemolytic anemia (because of mechanical damage to red cells from diseased small vessels). Elevation of the sedimentation rate is unusual. Proteinuria and cylindruria appear in association with renal involvement. Antinuclear antibody tests are nearly always positive, frequently in high titers ([Tables 20-10](#) and [19-4](#)). The scleroderma antibody (SCL-70) directed against topoisomerase III is found in one-third of patients with diffuse systemic sclerosis and in 20% of those with CREST syndrome; an anticentromere antibody is seen in 50% of those with CREST syndrome and in 1% of individuals with diffuse systemic sclerosis ([Tables 20-10](#) and [19-4](#)). Although present in only a minority of patients with diffuse systemic sclerosis, anti-Scl-70 antibodies may portend a poor prognosis, with a high likelihood of serious internal organ involvement (eg, interstitial lung disease). Anticentromere antibodies are highly specific for limited systemic sclerosis, but they also occur occasionally in overlap syndromes. Other scleroderma autoantibodies and their clinical associations are those directed against RNA polymerases (anti-RNAP I, II, III), associated with diffuse skin changes, cardiac and renal involvement, and increased mortality; and antibodies to B23, associated with pulmonary hypertension.

Differential Diagnosis

Several diseases with principally cutaneous manifestations may mimic systemic sclerosis in their skin findings. These disorders include morphea and limited systemic sclerosis, two diseases often categorized as forms of "localized" scleroderma. These disorders are generally limited to circumscribed areas of the skin and usually have excellent outcomes. Morphea is associated with lavender plaques, typically located over the trunk. Linear scleroderma may be associated with atrophy of underlying muscle and bone and may cause deformities that are both cosmetically and functionally disabling.

Eosinophilic fasciitis is a rare disorder presenting with skin changes that resemble diffuse systemic sclerosis. The inflammatory abnormalities, however, are limited to the fascia rather than the dermis and epidermis. Patients with eosinophilic fasciitis are further distinguished from those with systemic scleroderma by the presence of peripheral blood eosinophilia, the absence of Raynaud's phenomenon, the good response to prednisone, and an increased risk of developing aplastic anemia.

The eosinophilia-myalgia syndrome was first noted in patients who ingested tryptophan, an essential amino acid that was sold as an over-the-counter remedy for insomnia and premenstrual symptoms—until banned by the Food and Drug Administration. Weeks to months after beginning ingestion, affected patients developed a syndrome of severe generalized myalgias, and cutaneous abnormalities ranging from hives to generalized swelling and induration of the arms and legs. Peripheral eosinophilia (> 1000/uL) is characteristic. Other common clinical manifestations have included pulmonary symptoms, fever, myopathy, lymphadenopathy, and ascending polyneuropathy. Besides eosinophilia, laboratory features include mild elevations of aldolase with normal creatine kinase levels and, frequently, positive ANA tests. Full-thickness biopsies may reveal features of systemic sclerosis, evidence of fasciitis or myositis, or small vessel vasculitis. While some patients improve after discontinuing tryptophan, others progress and require corticosteroid therapy, which is not always effective. Deaths have been reported, especially from neurologic involvement. Patients presenting with systemic sclerosis or an eosinophilic fasciitis-like syndrome should be asked about tryptophan use.

Treatment

Treatment of systemic sclerosis is symptomatic and supportive. There is currently no medication that is known to alter the underlying disease process. However, interventions for management of specific organ manifestations of this disease have improved substantially. Severe Raynaud's syndrome may respond to calcium channel blockers, eg, long-acting nifedipine, 30-120 mg/d, or to losartan, 50 mg/d. Intravenous iloprost, a prostacyclin analog that causes vasodilation and platelet inhibition, is moderately effective in healing digital ulcers. Patients with esophageal disease should take medications in liquid or crushed form. Esophageal reflux can be reduced and scarring prevented by avoiding late-night meals, elevating the head of the bed, and using antacids and H₂ blockers. Proton pump inhibitors (eg, omeprazole, 20-40 mg/d) are the only drugs that achieve near-complete inhibition of gastric acid production, and they are remarkably effective for refractory esophagitis. Patients with delayed gastric emptying maintain their weight better if they eat small, frequent meals and remain upright for at least 2 hours after eating. Octreotide, a somatostatin analog, helps some patients with bacterial overgrowth and pseudo-obstruction. Malabsorption due to bacterial overgrowth also responds to antibiotics, eg, tetracycline, 500 mg four times daily. The hypertensive crises associated with systemic sclerosis renal crisis must be treated early and aggressively (in the hospital) with angiotensin-converting enzyme inhibitors, eg, captopril, 37.5-75 mg/d in three divided doses. Prednisone has little or no role in the treatment of scleroderma. Cyclophosphamide, a drug with many important side effects, may improve severe interstitial lung disease. Bosentan, an endothelin receptor antagonist, improves exercise capacity and cardiopulmonary hemodynamics in patients with pulmonary hypertension.

The 9-year survival rate in scleroderma averages approximately 40%. The prognosis tends to be worse in those with diffuse scleroderma, in blacks, in males, and in older patients. In most cases, death results from renal, cardiac, or pulmonary failure. Those who do not develop severe internal organ involvement in the first 3 years do much better, with 72% surviving at least 9 years. Breast and lung cancer may be more common in patients with scleroderma.

IDIOPATHIC INFLAMMATORY MYOPATHIES (POLYMYOSITIS & DERMATOMYOSITIS)

Essentials of Diagnosis

- Bilateral proximal muscle weakness.
- Characteristic cutaneous manifestations in dermatomyositis (Gottron's papules, heliotrope rash).
- Diagnostic tests: elevated creatine kinase and other muscle enzymes, muscle biopsy, electromyography.
- Increased risk of malignancy, particularly in adult dermatomyositis.
- Inclusion body myositis can mimic polymyositis but is less responsive to treatment.

General Considerations

Polymyositis and dermatomyositis are systemic disorders of unknown cause whose principal manifestation is muscle weakness. Although their clinical presentations (aside from the presence of certain skin findings in dermatomyositis, some of which are pathognomonic) and treatments are similar, the two diseases are pathologically quite distinct. They affect persons of any age group, but the peak incidence is in the fifth and sixth decades of life. Women are affected twice as commonly as men, and the diseases (particularly polymyositis) also occur more often among blacks than whites. There is an increased risk of malignancy, particularly in adult patients with dermatomyositis. Indeed, up to one patient in four with dermatomyositis has an occult malignancy. Malignancies may be evident at the time of presentation with the muscle disease but may not be detected until months afterward in some cases. Rare patients with dermatomyositis have skin disease without overt muscle involvement, a condition termed "dermatomyositis sine myositis."

Clinical Findings

A. Symptoms and Signs

Polymyositis may begin abruptly, but the usual presentation is one of gradual and progressive muscle weakness. The weakness chiefly involves proximal muscle groups of the upper and lower extremities as well as the neck. Leg weakness (eg, difficulty in rising from a chair or climbing stairs) typically precedes arm symptoms. In contrast to myasthenia gravis, polymyositis and dermatomyositis do not cause facial or ocular muscle weakness. Pain and tenderness of affected muscles occur in one-fourth of cases, but these are rarely the chief complaints. About one-fourth of patients have dysphagia. In contrast to scleroderma, which affects the smooth muscle of the lower esophagus and can cause a "sticking" sensation below the sternum, polymyositis or dermatomyositis involves the striated muscles of the upper pharynx and can make initiation of deglutition difficult. Muscle atrophy and contractures occur as late complications of advanced disease. Clinically significant myocarditis is uncommon even though there is often CK-MB elevation. Patients who are bed-bound from myositis should be screened for respiratory muscle weakness that can be severe enough to cause CO₂ retention and to require mechanical ventilation.

In dermatomyositis, the characteristic rash is dusky red and may appear in malar distribution mimicking the classic rash of SLE. Erythema also occurs over other areas of the face, neck, shoulders, and upper chest and back ("shawl sign"). Periorbital edema and a purplish (heliotrope) suffusion over the eyelids are typical signs. Periungual erythema, dilations of nail-bed capillaries, and scaly patches over the dorsum of proximal interphalangeal and metacarpophalangeal joints (Gottron's sign) are highly suggestive.

A subset of patients with polymyositis and dermatomyositis develop the "antisynthetase syndrome," a group of findings including inflammatory arthritis, Raynaud's phenomenon, interstitial lung disease, and often severe muscle disease associated with certain autoantibodies (eg, anti-Jo1 antibodies).

B. Laboratory Findings

Measurement of serum levels of muscle enzymes, especially creatine kinase and aldolase, is most useful in diagnosis and in assessment of disease activity. Anemia is uncommon. The sedimentation rate is not appreciably elevated in half of the patients. Rheumatoid factor is found in a minority of patients. Antinuclear antibodies are present in many patients, and anti-Jo-1 antibodies are seen in the subset of patients who have associated interstitial lung disease ([Tables 20-10](#) and [19-4](#)). Chest radiographs are usually normal, though interstitial fibrosis is occasionally seen. Electromyographic abnormalities consisting of polyphasic potentials, fibrillations, and high-frequency action potentials are helpful in establishing the diagnosis. None of the studies are specific. The search for an occult malignancy should begin with a history and physical examination, supplemented with a complete blood count, comprehensive biochemical panel, serum protein electrophoresis, and urinalysis, and should include age- and risk-appropriate cancer screening tests. If these evaluations are unrevealing, then a more invasive or extensive laboratory evaluation is probably not cost-effective. No matter how extensive the initial screening, some malignancies will not become evident for months after the initial presentation.

C. Muscle Biopsy

Biopsy of clinically involved muscle is the only specific diagnostic test. The pathology findings in polymyositis and dermatomyositis are distinct. Although both include lymphoid inflammatory infiltrates, the findings in dermatomyositis are localized to perivascular regions and there is evidence of humoral and complement-mediated destruction of microvasculature associated with the muscle. In addition to its vascular orientation, the inflammatory infiltrate in dermatomyositis centers on the interfascicular septa and is located around, rather than in, muscle fascicles. In contrast, the pathology of polymyositis characteristically includes endomysial infiltration of the inflammatory infiltrate. Owing to the sometimes patchy distribution of pathologic abnormalities, however, false-negative biopsies sometimes occur in both disorders.

Differential Diagnosis

Muscle inflammation may occur as a component of SLE, systemic sclerosis, or Sjogren's syndrome. In those cases, associated findings usually permit the precise diagnosis of the primary condition.

Inclusion body myositis, because of its tendency to mimic polymyositis, is a common cause of "treatment-resistant polymyositis." In contrast to the epidemiologic features of polymyositis, however, the typical inclusion body myositis patient is white, male, and over the age of 50. The onset of inclusion body myositis is even more insidious than that of polymyositis or dermatomyositis (eg, occurring over years rather than months), and asymmetric distal motor weakness is common in inclusion body myositis. Inclusion body myositis is less likely to respond to therapy and is associated with characteristic pathologic findings evident on frozen section or electron microscopy.

Most endocrine diseases can be associated with proximal muscle weakness. This is particularly true for hyper- and hypothyroidism, and the latter is associated also with elevations of creatinine phosphokinase. Patients with polymyalgia rheumatica are over the age of 50 and—in contrast to patients with polymyositis—have pain but no objective weakness. Disorders of the peripheral and central nervous systems (eg, chronic inflammatory polyneuropathy, multiple sclerosis, myasthenia gravis, Eaton-Lambert disease and amyotrophic lateral sclerosis) can produce weakness but are distinguished by characteristic symptoms and neurologic signs and often by distinctive electromyographic abnormalities. Many drugs, including corticosteroids, alcohol, clofibrate, penicillamine, tryptophan, and hydroxychloroquine, can produce proximal muscle weakness. Chronic use of colchicine at doses as low as 0.6 mg twice a day in elderly patients with mild to moderate renal insufficiency can produce a mixed neuropathy-myopathy that mimics polymyositis. The weakness and muscle enzyme elevation reverse with cessation of the drug. HMG-CoA reductase inhibitors, which are frequently used to treat hypercholesterolemia, can cause myopathy and rhabdomyolysis. Although only about 0.1% of patients taking a statin drug alone develop myopathy, concomitant administration of other drugs (especially gemfibrozil, cyclosporine, niacin, and itraconazole) increases the risk. Polymyositis can occur as a complication of HIV or HTLV-I infection and with zidovudine therapy as well.

Treatment

Most patients respond to corticosteroids. Often a daily dose of 40-60 mg or more of prednisone is required initially. The dose is then adjusted downward according to the response of sequentially observed serum levels of muscle enzymes. Long-term use of steroids is often needed, and the disease may recur or reemerge when they are withdrawn. Patients with an associated neoplasm have a poor prognosis, although remission may follow treatment of the tumor; steroids may or may not be effective in these patients. In patients resistant or intolerant to corticosteroids, therapy with methotrexate or azathioprine may be helpful. Intravenous immune globulin has also been shown to be effective for dermatomyositis resistant to prednisone.

OVERLAP (OR MIXED) CONNECTIVE TISSUE DISEASE

Not infrequently, patients have features of more than one rheumatic disease. Special attention has been drawn to patients who have overlapping features of SLE, systemic sclerosis, and polymyositis. Initially, these patients were thought to have a distinct entity ("mixed connective tissue disease") defined by a specific autoantibody to ribonuclear protein (RNP). With time in many patients, the manifestations evolve to one predominant disease, such as scleroderma, and many patients with antibodies to RNP have clear-cut SLE. Therefore, "overlap connective tissue disease" is the preferred designation for patients having features of different rheumatic diseases.

SJOGREN'S SYNDROME

Essentials of Diagnosis

- Ninety percent of patients are women; the average age is 50 years.
- Dryness of eyes and dry mouth (sicca components) are the most common features; they occur alone or in association with rheumatoid arthritis or other connective

tissue disease.

- Rheumatoid factor and other autoantibodies common.
- Increased incidence of lymphoma.

General Considerations

Sjogren's syndrome, an autoimmune disorder, is the result of chronic dysfunction of exocrine glands in many areas of the body. It is characterized by dryness of the eyes, mouth, and other areas covered by mucous membranes and is frequently associated with a rheumatic disease, most often rheumatoid arthritis. The disorder is predominantly a disease of women, in a ratio of 9:1, with greatest incidence between age 40 and 60 years.

Disorders with which Sjogren's syndrome is frequently associated include rheumatoid arthritis, SLE, primary biliary cirrhosis, scleroderma, polymyositis, Hashimoto's thyroiditis, polyarteritis, and interstitial pulmonary fibrosis. When Sjogren's syndrome occurs without rheumatoid arthritis, HLA-DR2 and -DR3 antigens are present with increased frequency.

Clinical Findings

A. Symptoms and Signs

Keratoconjunctivitis sicca results from inadequate tear production caused by lymphocyte and plasma cell infiltration of the lacrimal glands. Symptoms include burning, itching, ropy secretions, and impaired tear production during crying. Parotid enlargement, which may be chronic or relapsing, develops in one-third of patients. Dryness of the mouth (xerostomia) leads to difficulty in speaking and swallowing and to severe dental caries. There may be loss of taste and smell. Desiccation may involve the nose, throat, larynx, bronchi, vagina, and skin.

Systemic manifestations include dysphagia, pancreatitis, pleuritis, obstructive lung disease (in the absence of smoking), neuropsychiatric dysfunction, and vasculitis; they may be related to the associated diseases noted above. Renal tubular acidosis (type I, distal) occurs in 20% of patients. Chronic interstitial nephritis, which may result in impaired renal function, may be seen. A glomerular lesion is rarely observed but may occur secondary to associated cryoglobulinemia.

B. Laboratory Findings

Laboratory findings include mild anemia, leukopenia, and eosinophilia. Rheumatoid factor is found in 70% of patients. Heightened levels of serum immunoglobulins, antinuclear antibodies, and antibodies against RNA, salivary gland, lacrimal duct, and thyroid may be noted. Antibodies against the cytoplasmic antigens SS-A and SS-B (also called Ro and La, respectively) are often present in Sjogren's syndrome ([Tables 20-10](#) and [19-4](#)). When SS-A antibodies are present, extraglandular manifestations of Sjogren's syndrome are far more common.

Useful ocular diagnostic tests include the Schirmer test, which measures the quantity of tears secreted. Lip biopsy, a simple procedure, is the only specific diagnostic technique and has minimal risk; if lymphoid foci are seen in accessory salivary glands, the diagnosis is confirmed. Biopsy of the parotid gland should be reserved for patients with atypical presentations such as unilateral gland enlargement.

Treatment & Prognosis

Treatment is symptomatic and supportive. Artificial tears applied frequently will relieve ocular symptoms and avert further desiccation. The mouth should be kept well lubricated. Sipping water frequently or using sugar-free gums and hard candies usually relieves dry mouth symptoms. Pilocarpine (5 mg four times daily) and the acetylcholine derivative cevimeline (30 mg three times daily) may improve xerostomia symptoms. Atropinic drugs and decongestants decrease salivary secretions and should be avoided. A program of oral hygiene is essential in order to preserve dentition. If there is an associated rheumatic disease, its treatment is not altered by the presence of Sjogren's syndrome.

The disease is usually benign and may be consistent with a normal life span; it is influenced mainly by the nature of the associated disease. The patients (3-10% of the total Sjogren's population) at greatest risk of developing lymphoma have severe dryness, marked parotid gland enlargement, splenomegaly, vasculitis, peripheral neuropathy, anemia, and mixed monoclonal cryoglobulinemia.

RHABDOMYOLYSIS

Defined strictly, rhabdomyolysis is necrosis of skeletal muscle and may be encountered in a wide variety of clinical settings, alone or in concert with other disorders of muscle. When the term "rhabdomyolysis" is employed without being otherwise defined, physicians ordinarily think of the syndrome of crush injury to muscle, associated with myoglobinuria, renal insufficiency, markedly elevated creatine kinase levels and, frequently, multiorgan failure as a consequence of other complications of the trauma. Renal insufficiency in myoglobinuria is caused by tubular damage resulting from filtered myoglobin postinjury and is nearly always associated with hypovolemia. Experimental models of severe rhabdomyolysis in which blood volume and pressure are maintained ordinarily are not associated with acute tubular necrosis. From a practical point of view, however, many patients who suffer crush injuries are indeed volume-contracted, and oliguric renal failure is encountered routinely.

Vigorous fluid resuscitation, mannitol, and urine alkalinization are suggested early in the course, but it is not clear that the outcome is affected by these measures. On occasion, oliguric tubular necrosis may be converted to a nonoliguric variety, and—though the prognosis for recovery of renal function and mortality is the same—many clinicians believe it is easier to care for nonoliguric disease, since hyperkalemia and pulmonary edema are less important concerns.

In addition to crush injuries, prolonged immobility, particularly after drug overdose or intoxication and commonly associated with exposure hypothermia, may be associated with rhabdomyolysis. Often there is little evidence for muscle injury on external examination of these patients—and specifically, neither myalgia nor myopathy present. The clue to muscle necrosis in such individuals may be a urinary dipstick testing positive for blood in the absence of red cells in the sediment. This false-positive finding is due to myoglobinuria, which results in a positive reading for blood. Such an abnormality is investigated by serum creatine kinase determination. Other studies elevated in rhabdomyolysis include ALT and LDH—and once again, these studies may be obtained for other reasons, such as suspected liver disease or hemolysis. When disproportionately elevated, it is prudent to establish that they are not of muscle origin by confirming them with CK determination.

A number of other causes of rhabdomyolysis are encountered, and the statin group of drugs for treatment of hyperlipidemia are common offenders (see above). A simple intramuscular injection may cause some elevation of CK, and acute alcoholic intoxication is also culpable on rare occasions. For the most part, however, rhabdomyolysis is seen with concomitant myopathy, though the term rhabdomyolysis refers only to a test abnormality. Certain types of myopathies—notably the endocrine myopathies associated with hyperthyroidism and hypercortisolism—are not associated with muscle enzyme elevation.

■ VASCULITIS SYNDROMES

The vasculitis syndromes are a heterogeneous group of disorders characterized by the pathologic features of inflammation and necrosis of blood vessels. The causes of most forms of vasculitis are not known. Infection is important in the pathogenesis of some forms of vasculitis. In polyarteritis nodosa, 10-30% of patients have evidence of hepatitis B or C. Most patients with mixed cryoglobulinemia are infected with hepatitis C. Infective endocarditis and syphilis can be associated with vasculitis, and cases of herpes zoster are in rare instances followed by central nervous system vasculitis. Drug reactions—especially to penicillins, sulfonamides, and allopurinol—can produce serum sickness associated with vasculitis. No common pathogenic link has been identified for these disorders, though the deposition of immune complexes in the vascular system occurs in many.

Although there are multiple forms of vasculitis, including primary and secondary forms, only the major forms of primary vasculitis are discussed in detail here.

POLYARTERITIS NODOSA & MICROSCOPIC POLYANGIITIS

Essentials of Diagnosis

- Microscopic polyangiitis may involve small blood vessels (capillaries, arterioles, venules) as well as medium-sized vessels. Classic polyarteritis nodosa involves only medium-sized vessels, but substantial overlap occurs.
- Clinical findings depend on the arteries involved.
- Common symptoms of both disorders include fever and other constitutional symptoms, abdominal pain, livedo reticularis, mononeuritis multiplex, anemia, and an elevated sedimentation rate.
- Classic polyarteritis nodosa is often associated with hypertension but spares the lung.
- Ten to 30 percent of polyarteritis nodosa cases are associated with hepatitis B or C.
- Microscopic polyangiitis is frequently associated with antineutrophil cytoplasmic antibodies (ANCA), pulmonary hemorrhage, and glomerulonephritis.

General Considerations

Polyarteritis nodosa was the first form of vasculitis recognized (in 1866). For many years, all forms of inflammatory vascular disease were termed "polyarteritis nodosa." In recent decades, numerous subtypes of vasculitis have been recognized, greatly narrowing the spectrum of vasculitis called polyarteritis nodosa. Currently, the term is reserved for a medium-sized necrotizing arteritis that has a predilection for involving peripheral nerves, mesenteric vessels (including renal arteries), heart, and brain but the capability of involving most organs. Microscopic polyangiitis, as its name implies, is the term given to nongranulomatous vasculitis involving small blood vessels. It is often associated with ANCAs that produce a p-ANCA pattern on immunofluorescence testing and are directed against myeloperoxidase, a constituent of neutrophil granules. Because microscopic polyangiitis may involve medium-sized as well as small blood vessels, its spectrum overlaps that of polyarteritis nodosa. Although the causes of polyarteritis and microscopic polyangiitis are not usually known, chronic hepatitis B or C causes 10-30% of cases of polyarteritis. In a minority of cases, microscopic polyangiitis appears to be induced by reactions to medications, particularly propylthiouracil, hydralazine, allopurinol, penicillamine, and sulfasalazine.

Clinical Findings

A. Symptoms and Signs

The clinical onset is usually insidious, with fever, malaise, weight loss, and other symptoms developing over weeks to months. Pain in the extremities is often a prominent early feature caused by arthralgia, myalgia (particularly affecting the calves), or neuropathy. The combination of mononeuritis multiplex (with the most common finding being foot-drop) and features of a systemic illness is one of the earliest specific clues to the presence of an underlying vasculitis. Polyarteritis and microscopic polyangiitis are among the forms of vasculitis most commonly associated with vasculitic neuropathy.

A wide variety of findings suggesting vasculitis of small blood vessels may develop in microscopic polyangiitis. These include palpable purpura and numerous other signs of cutaneous vasculitis; hematuria, proteinuria, and red blood cell casts in the urine; and pulmonary hemorrhage. The renal lesion is a segmental, necrotizing glomerulonephritis, often with localized intravascular coagulation. The pathologic findings in the lung are typically those of capillaritis.

In polyarteritis nodosa, the typical findings reflect the involvement of deeper, medium-sized blood vessels. Skin findings often include livedo reticularis, subcutaneous nodules, and skin ulcers. Digital gangrene is not an unusual occurrence. Involvement of the renal arteries leads to a renin-mediated hypertension (much less characteristic of vasculitides involving smaller blood vessels). For unclear reasons, classic polyarteritis nodosa seldom involves the lung.

Abdominal pain—particularly diffuse periumbilical pain precipitated by eating—is common to both polyarteritis nodosa and microscopic polyangiitis. Nausea and vomiting are frequently associated. Infarction compromises the function of major viscera and may lead to acalculous cholecystitis or appendicitis. Some patients present dramatically with an acute abdomen caused by mesenteric vasculitis and gut perforation or with hypotension resulting from rupture of a microaneurysm in the liver, kidney, or bowel.

Subclinical cardiac involvement is common in polyarteritis nodosa, and overt cardiac dysfunction occasionally occurs (eg, myocardial infarction secondary to coronary vasculitis, or myocarditis).

B. Laboratory Findings

The sedimentation rate is almost always elevated, often strikingly so. Most patients have a slight anemia, and leukocytosis is common. Three-fourths of patients with microscopic polyangiitis are ANCA-positive (usually with antibodies directed against myeloperoxidase, causing a p-ANCA pattern on immunofluorescence testing). Patients with classic polyarteritis nodosa are ANCA-negative. Serologic tests for hepatitis B or C are positive in 10-30% of patients with polyarteritis nodosa.

C. Biopsy and Angiography

The diagnosis of both of these disorders requires confirmation with either a tissue biopsy or, in the case of polyarteritis nodosa, an angiogram. Biopsies of symptomatic sites (eg, nerve, muscle, lung, or kidney) have high sensitivities and specificities. The least invasive tests should usually be obtained first, but biopsy of an involved organ is essential. If performed by experienced physicians, tissue biopsies normally have high benefit-risk ratios because of the importance of establishing the diagnosis. Patients suspected of having polyarteritis nodosa—eg, on the basis of mesenteric ischemia or new-onset hypertension occurring in the setting of a systemic illness—may be diagnosed by the angiographic finding of aneurysmal dilations in the renal, mesenteric, or hepatic arteries. Angiography must be performed cautiously in patients with baseline renal dysfunction.

Treatment

For polyarteritis nodosa, corticosteroids in high doses (up to 60 mg of prednisone daily) may control fever and constitutional symptoms and heal vascular lesions. Pulse methylprednisolone (eg, 1 g intravenously daily for 3 days) may be necessary for patients who are critically ill at presentation. Immunosuppressive agents, especially cyclophosphamide, appear to improve the survival of patients when given with steroids. Some patients who have polyarteritis nodosa associated with hepatitis B may respond to a short course of prednisone, accompanied by lamivudine (100 mg/d) and plasmapheresis (three times a week for up to 6 weeks).

In microscopic polyangiitis, patients are more likely to require cyclophosphamide because of the urgency in treating pulmonary hemorrhage and glomerulonephritis. Cyclophosphamide may be administered either in an oral daily fashion or via intermittent (usually monthly) intravenous pulses. Cyclophosphamide doses should be decreased in the setting of significant renal dysfunction.

Prognosis

Without treatment, the 5-year survival rate in these disorders is poor—on the order of 20%. With appropriate therapy, remissions are possible in many cases and the 5-year survival rate has improved to 60-90%. Poor prognostic factors are renal insufficiency, proteinuria, gastrointestinal ischemia, central nervous system disease, and cardiac involvement. Relapses following disease remissions may occur in both disorders but are more common in microscopic polyangiitis (up to 35%). For polyarteritis nodosa associated with hepatitis B, the likelihood of chronic disease may be higher.

POLYMYALGIA RHEUMATICA & GIANT CELL ARTERITIS

Essentials of Diagnosis

- Giant cell arteritis is characterized by headache, jaw claudication, polymyalgia rheumatica, visual abnormalities, and a markedly elevated ESR.
- The hallmark of polymyalgia rheumatica is pain and stiffness in shoulders and hips lasting 1 month without other explanation.

General Considerations

Polymyalgia rheumatica and giant cell arteritis probably represent a spectrum of one disease: Both affect the same population (patients over the age of 50), show preference for the same HLA haplotypes, and show similar patterns of cytokines in blood and arteries. Polymyalgia rheumatica and giant cell arteritis also frequently coexist. The important differences between the two conditions are that polymyalgia rheumatica alone does not cause blindness and responds to low-dose (10-20 mg/d) prednisone therapy, whereas giant cell arteritis can cause blindness and large artery complications and requires high-dose therapy (40-60 mg/d).

Clinical Findings

A. Polymyalgia Rheumatica

Polymyalgia rheumatica is a clinical diagnosis based on pain and stiffness of the shoulder and pelvic girdle areas, frequently in association with fever, malaise, and weight loss. It can occur in the absence of giant cell arteritis. Anemia and a markedly elevated sedimentation rate are almost always present. Because of the stiffness and pain in the shoulders, hips, and lower back, patients have trouble combing their hair, putting on a coat, or getting up out of a chair. In contrast to polymyositis, polymyalgia rheumatica does not cause muscular weakness. A few patients have joint swelling, particularly of the knees, wrists, and sternoclavicular joints. The differential diagnosis of malaise, anemia, and a markedly elevated sedimentation rate includes rheumatic diseases such as rheumatoid arthritis, other forms of vasculitis, multiple myeloma and other malignant disorders, and chronic infections such as bacterial endocarditis.

B. Giant Cell Arteritis

Giant cell arteritis is a systemic panarteritis affecting medium-sized and large vessels in patients over the age of 50. The condition is also called temporal arteritis, since that artery is frequently involved, as are other extracranial branches of the carotid artery. About 50% of patients with giant cell arteritis also have polymyalgia rheumatica. The classic symptoms suggesting that a patient has arteritis are headache, scalp tenderness, visual symptoms, jaw claudication, or throat pain. The temporal artery is usually normal on physical examination but may be nodular, enlarged, tender, or pulseless. Blindness results from occlusive arteritis of the posterior ciliary branch of the ophthalmic artery. The ischemic optic neuropathy of giant cell arteritis may produce no funduscopic findings for the first 24-48 hours after the onset of blindness. Asymmetry of pulses in the arms, a murmur of aortic regurgitation, or bruits heard near the clavicle resulting from subclavian artery stenoses identify patients in whom giant cell arteritis has affected the aorta or its major branches. Large vessel involvement, particularly thoracic aortic aneurysms, occurs in approximately 15% of patients with giant cell arteritis, sometimes years after the diagnosis. Forty percent of patients with giant cell arteritis have nonclassic symptoms at presentation, chiefly respiratory tract problems (most frequently dry cough), mononeuritis multiplex (most frequently with painful paralysis of a shoulder), or fever of unknown origin. Giant cell arteritis accounts for 15% of all cases of fever of unknown origin in patients over the age of 65. The fever can be as high as 40 °C and is frequently associated with rigors and sweats. In contrast to patients with infection, patients with giant cell arteritis and fever usually have normal white blood cell counts (before prednisone is started). Thus, in an older patient with fever of unknown origin, a very high erythrocyte sedimentation rate, and a normal white blood count, giant cell arteritis must be considered even in the absence of specific features such as headache or jaw claudication. In some cases, instead of having the well-known symptom of jaw claudication, patients complain of vague pain affecting other locations, including the tongue, nose, or ears. Indeed, unexplained head or neck pain in an older patient may signal the presence of giant cell arteritis.

C. Laboratory Findings

An elevated ESR, with a median result of about 65 mm/h, occurs in more than 90% of patients with polymyalgia rheumatica or giant cell arteritis. Other acute phase reactants such as C-reactive protein are also elevated. Interleukin-6 may be the most sensitive serologic indicator of disease activity yet described, but routine clinical testing for this cytokine is not widely available. Most patients also have a mild normochromic, normocytic anemia and thrombocytosis. The alkaline phosphatase (liver source) is elevated in 20% of patients with giant cell arteritis.

Treatment

A. Polymyalgia Rheumatica

Patients with isolated polymyalgia rheumatica are treated with prednisone, 10-20 mg/d. If the patient fails to experience a dramatic improvement within 72 hours, the diagnosis should be revisited. Within 1-2 months after beginning treatment, the patient's symptoms and laboratory abnormalities will resolve. The total duration of treatment varies considerably but ranges from 6 months to more than 2 years. Disease flares are common (50% or more) as prednisone is tapered.

B. Giant Cell Arteritis

The urgency of early diagnosis and treatment in giant cell arteritis relates to the prevention of blindness. Once blindness develops, it is usually permanent. Therefore, when a patient has symptoms and findings suggestive of temporal arteritis, therapy with prednisone, 60 mg daily, is initiated immediately, and temporal artery biopsy is promptly obtained. Although it is prudent to obtain a temporal artery biopsy as soon as possible after instituting treatment, diagnostic findings of giant cell arteritis may still be present 2 weeks (or even considerably longer) after starting corticosteroids. Typically, a positive biopsy shows inflammatory infiltrate in the media and adventitia with lymphocytes, histiocytes, plasma cells, and giant cells. An adequate biopsy specimen (2 cm in length) is essential, because the disease may be segmental. Unilateral temporal artery biopsies are positive in approximately 80-85% of patients; bilateral biopsies add 10-15% to the yield. Prednisone should be continued in a dosage of 60 mg/d for 1-2 months before tapering. When only the symptoms of polymyalgia rheumatica are present, temporal artery biopsy is not necessary.

In adjusting the dosage of steroid, the erythrocyte sedimentation rate is a useful but not absolute guide to disease activity. A common error is treating the ESR rather than the patient. The ESR often rises slightly as the prednisone is tapered, even as the disease remains quiescent. Because elderly individuals often have baseline ESRs that are outside the "normal" range, mild ESR elevations should not be an occasion for renewed treatment with prednisone in patients who are asymptomatic. Thoracic aortic aneurysms occur 17 times more frequently in patients with giant cell arteritis than in normal individuals. The aneurysms can develop at any time but typically occur 7 years after the diagnosis of giant cell arteritis is made.

WEGENER'S GRANULOMATOSIS

Essentials of Diagnosis

- Originally defined by the triad of upper respiratory tract disease, lower respiratory disease, and glomerulonephritis.
- Suspect if mild respiratory systems (eg, nasal congestion, sinusitis) are refractory to usual treatment.
- Pathology defined by the triad of small vessel vasculitis, granulomatous inflammation, and necrosis.
- Ninety percent of patients with severe, active disease have antineutrophil cytoplasmic antibodies (ANCA), usually directed against proteinase-3 (less commonly against myeloperoxidase).
- Renal disease often rapidly progressive without treatment.

General Considerations

Wegener's granulomatosis is a rare disorder (prevalence of three per 100,000) characterized by vasculitis of small arteries, arterioles, and capillaries, necrotizing granulomatous lesions of both upper and lower respiratory tract, and glomerulonephritis. Without treatment it is invariably fatal, most patients surviving less than a year after diagnosis. It occurs most commonly in the fourth and fifth decades of life and affects men and women with equal frequency.

Clinical Findings

A. Symptoms and Signs

The disorder usually develops over 4-12 months, with 90% of patients presenting with upper or lower respiratory tract symptoms or both. Upper respiratory tract symptoms can include nasal congestion, sinusitis, otitis media, mastoiditis, inflammation of the gums, or stridor due to subglottic stenosis. Since many of these symptoms are common, the underlying disease is not often suspected until the patient develops systemic symptoms or the original problem is refractory to treatment. The lung is affected initially in 40% and eventually in 80%, with symptoms including cough, dyspnea, and hemoptysis. Other early symptoms can include unilateral proptosis (from pseudotumor), red eye from scleritis, arthritis, purpura, and dysesthesia due to neuropathy. Renal involvement, which develops in three-fourths of the cases, may be subclinical until renal insufficiency is advanced. Fever, malaise, and weight loss are common.

Physical examination can be remarkable for congestion, crusting, ulceration, bleeding, and even perforation of the nasal mucosa. Destruction of the nasal cartilage with "saddle nose" deformity occurs late. Otitis media, proptosis, scleritis, episcleritis, and conjunctivitis are other common findings. Newly acquired hypertension, a frequent feature of polyarteritis nodosa, is rare in Wegener's granulomatosis.

Although limited forms of Wegener's granulomatosis have been described in which the kidney is spared initially, most untreated patients will develop renal disease. In such cases the urinary sediment invariably contains red cells, with or without white cells, and red cell casts. Renal biopsy discloses a segmental necrotizing glomerulonephritis with multiple crescents; this is characteristic but not diagnostic. Granulomas are observed in only 10% of renal biopsy specimens but are found much more commonly on lung biopsy.

B. Laboratory Findings

Most patients have slight anemia, mild leukocytosis, and an elevated erythrocyte sedimentation rate. Chest CT is more sensitive than chest radiography; lesions include infiltrates, nodules, masses, and cavities. Often the radiographs prompt concern about lung cancer. Hilar adenopathy is unusual in Wegener's granulomatosis; if present, sarcoidosis, tumor, or infection is more likely. Other common laboratory or radiographic abnormalities include hematuria, red blood cell casts, and sinus

destruction.

Histologic features of Wegener's granulomatosis include vasculitis, granulomatous inflammation, geographic necrosis, and acute and chronic inflammation. The full range of pathologic changes are usually evident only on thoracoscopic lung biopsy. Nasal biopsies often do not show vasculitis but may show chronic inflammation and other changes which, interpreted by an experienced pathologist, can serve as convincing evidence of the diagnosis.

Serum tests for antineutrophil cytoplasmic antibodies (ANCA) help in the diagnosis of Wegener's granulomatosis and related forms of vasculitis ([Tables 20-10](#) and [19-4](#)). Several different types of ANCA are recognized. The cytoplasmic pattern of immunofluorescence (c-ANCA), caused by antibodies to proteinase-3, a constituent of neutrophil granules, has a high specificity (> 90%) for Wegener's granulomatosis. In the setting of active disease, the sensitivity of c-ANCA is also reasonably high (= 70%). A substantial percentage of patients with "limited" Wegener's granulomatosis—disease that does not pose an immediate threat to life and is often confined to the respiratory tree—are ANCA-negative. Although ANCA testing may be very helpful when used properly, it does not eliminate the need in most cases for confirmation of the diagnosis by tissue biopsy. Furthermore, ANCA levels correlate erratically with disease activity, and changes in titer should not dictate changes in therapy in the absence of supporting clinical data. The perinuclear (p-ANCA) pattern is caused by antibodies to myeloperoxidase and is much less specific for Wegener's granulomatosis. Approximately 10-25% of patients with classic Wegener's granulomatosis have antibodies to myeloperoxidase. Owing to involvement of the same types of blood vessels, similar patterns of organ involvement, and the possibility of failing to identify granulomatous pathology on tissue biopsies because of sampling error, Wegener's granulomatosis is often difficult to differentiate from microscopic polyangiitis.

Atypical patterns of immunofluorescence—often mistaken for p-ANCA—occur frequently in patients with systemic lupus erythematosus and inflammatory bowel disease. Thus, all positive immunofluorescence assays for ANCA should be confirmed by enzyme immunoassays for the more specific autoantibodies against proteinase-3 and myeloperoxidase.

Treatment

Early treatment is crucial in prolonging life and preventing renal failure. While Wegener's granulomatosis may involve the sinuses or lung for months, once proteinuria or hematuria develops, progression to renal failure can be rapid (over several weeks). Remissions have been induced in up to 75% of patients treated with cyclophosphamide and prednisone, though half of these patients eventually suffer disease recurrences. The cyclophosphamide is best given daily by mouth; intermittent high-dose intravenous cyclophosphamide is less effective. Unfortunately, the traditional therapy of oral cyclophosphamide continued for 12 months after the patient achieves remission has resulted in severe toxicity, including a 2.4 times increased risk of all malignancies, a 33-fold increase in bladder cancer, and a 60% chance of ovarian failure. Methotrexate, 20-25 mg/wk, is a reasonable substitute for oral cyclophosphamide in patients who do not have immediately life-threatening disease. Another strategy to limit cyclophosphamide use is to employ the drug for about 3 months in order to induce remission and then switch to methotrexate. Trimethoprim-sulfamethoxazole (one double-strength tablet twice daily) is ineffective for life-threatening Wegener's disease; however, the drug may help maintain disease remissions. Trimethoprim-sulfamethoxazole and methotrexate are both folate antagonists; the combination can cause aplastic anemia and should be used with great care.

CRYOGLOBULINEMIA

Vasculitis secondary to cryoglobulinemia is uncommon but should be considered when patients present with palpable purpura and peripheral neuropathy. A proliferative glomerulonephritis that strongly resembles lupus nephritis may complicate cryoglobulinemia. Abnormal liver function tests, abdominal pain, and pulmonary disease may also occur. The diagnosis is based on a compatible clinical picture and a positive serum test for cryoglobulins. Type I cryoglobulins (monoclonal proteins that lack rheumatoid factor activity) are more commonly seen in lymphoproliferative disease. (Type I cryoglobulins usually cause hyperviscosity syndromes rather than vasculitis.) The diseases most commonly associated with cryoglobulinemic vasculitis are hepatitis C and connective tissues diseases, especially Sjogren's syndrome. Type II (monoclonal antibody with rheumatoid factor activity) and Type III (polyclonal antibody with rheumatoid factor activity) cryoglobulins cause vasculitis. Because 90% of cryoglobulinemia cases are associated with hepatitis C infections, the optimal approach to treatment is viral suppression with interferon-alpha with or without ribavirin. Pegylated forms of interferon alfa are also effective in cryoglobulinemia. Because immunosuppressive agents may facilitate viral replication, corticosteroids, cyclophosphamide, and other interventions (including plasmapheresis) should be reserved for organ-threatening complications.

Della Rossa A et al: Treatment of chronic hepatitis C infection with cryoglobulinemia. *Curr Opin Rheumatol* 2002;13: 231. [\[PMID: 11981318\]](#)

HENOC-SCHONLEIN PURPURA

Henoch-Schonlein purpura, the most common systemic vasculitis in children, occurs in adults as well. Typical features are palpable purpura, abdominal pain, arthritis, and hematuria. Pathologic features include leukocytoclastic vasculitis with IgA deposition. The cause is not known.

The purpuric skin lesions are typically located on the lower extremities but may also be seen on the hands, arms, trunk, and buttocks. Joint symptoms are present in the majority of patients, the knees and ankles being most commonly involved. Abdominal pain secondary to vasculitis of the intestinal tract is often associated with gastrointestinal bleeding. Hematuria signals the presence of a renal lesion that is usually reversible, although it occasionally may progress to renal insufficiency. Children tend to have more frequent and more serious gastrointestinal vasculitis, whereas adults more often suffer from renal disease. Biopsy of the kidney reveals segmental glomerulonephritis with crescents and mesangial deposition of IgA.

The disease is usually self-limited, lasting 1-6 weeks, and subsides without sequelae if renal involvement is not severe. Chronic courses with persistent or intermittent skin disease are more likely to occur in adults than in children. The efficacy of treatment is not well established.

Saulsbury FT: Henoch-Schonlein purpura. *Curr Opin Rheumatol* 2001;13:35. [\[PMID: 111489713\]](#)

RELAPSING POLYCHONDritis

This disease is characterized by inflammatory destructive lesions of cartilaginous structures, principally the ears, nose, trachea, and larynx. It may be associated either with other immunologic disorders such as SLE, rheumatoid arthritis, or Hashimoto's thyroiditis or with cancers, especially multiple myeloma. The disease, which is usually episodic, affects males and females equally. The cartilage is painful, swollen, and tender during an attack and subsequently becomes atrophic, resulting in permanent deformity. Biopsy of the involved cartilage shows inflammation and chondrolysis. Noncartilaginous manifestations of the disease include fever, episcleritis, uveitis, deafness, aortic insufficiency, and rarely glomerulonephritis. In 85% of patients, a migratory, asymmetric, and seronegative arthropathy occurs, affecting both large and small joints and the costochondral junctions.

Prednisone, 0.5-1 mg/kg/d, is often effective. Dapsone (100-200 mg/d) may also be effective, sparing the need for chronic high-dose corticosteroid treatment. Involvement of the tracheobronchial tree, leading to tracheomalacia, may lead to difficult management issues.

Letko E et al: Relapsing polychondritis: a clinical review. *Semin Arthritis Rheum* 2002;31:384. [\[PMID: 12077711\]](#)

BEHCET'S SYNDROME

Named after the Turkish dermatologist who first described it, this disease of unknown cause is characterized by recurrent oral and genital ulcers, uveitis, seronegative arthritis, and central nervous system abnormalities. Other features include ulcerative skin lesions, erythema nodosum, thrombophlebitis, and vasculitis. Arthritis occurs in about two-thirds of patients, most commonly affecting the knees and ankles. Keratitis, retinal vasculitis, and anterior uveitis (often with hypopyon—pus in the anterior chamber) are observed. The ocular involvement is often fulminant and may result in blindness. Involvement of the central nervous system, which may mimic multiple sclerosis radiologically, often results in serious disability or death. Findings include cranial nerve palsies, seizures, encephalitis, mental disturbances, and spinal cord lesions.

The clinical course may be chronic but is often characterized by remissions and exacerbations. Corticosteroids, azathioprine, chlorambucil, pentoxifylline, and cyclosporine have been used with beneficial results. Oral base corticosteroids may be of some help for oral ulcerations.

PRIMARY ANGIITIS OF THE CENTRAL NERVOUS SYSTEM

Primary angiitis of the central nervous system is a syndrome with several possible causes that produces small and medium-sized vasculitis limited to the brain and spinal cord. Biopsy-proved cases have predominated in men who present with a history of weeks to months of headaches, encephalopathy, and multifocal strokes. Systemic signs and symptoms are absent, and routine laboratory tests are usually normal. MRI of the brain is almost always abnormal, and the spinal fluid often reveals a mild lymphocytosis and a modest increase in protein level. Angiograms classically reveal a "string of beads" pattern produced by alternating segments of arterial narrowing and dilation. However, neither the MRI nor the angiogram appearance is specific for vasculitis. Many conditions, including vasospasm, can produce the same angiographic pattern as vasculitis. Definitive diagnosis requires a compatible clinical picture; exclusion of infection, neoplasm, or metabolic disorder or drug exposure (eg, cocaine) that can mimic primary angiitis of the central nervous system; and a positive brain biopsy. When a patient meeting the above criteria has a positive angiogram without a confirming biopsy, the diagnosis should be considered possible. Angiographically defined cases of central nervous system vasculopathy differ from biopsy-proved cases chiefly involving women who have had an abrupt onset of headaches and stroke (often in the absence of encephalopathy) with normal spinal fluid findings. Many patients who fit this clinical profile and have disease diagnosed by angiography (but not biopsy) probably have vasospasm rather than true vasculitis. Such cases may require shorter and less intensive courses of immunosuppression—or none at all—as opposed to those with biopsy-proved cases. The latter usually improve with prednisone therapy and may require cyclophosphamide.

■ SERONEGATIVE SPONDYLOARTHROPATHIES

The seronegative spondyloarthropathies are ankylosing spondylitis, psoriatic arthritis, Reiter's syndrome (also called reactive arthritis), and the arthritis associated with inflammatory bowel disease. These disorders are noted for onset usually before age 40, inflammatory arthritis of the spine or the large peripheral joints (or both), uveitis in a significant minority, the absence of autoantibodies in the serum, and a striking association with HLA-B27. Present in only 8% of normal whites and 3% of normal blacks, HLA-B27 is positive in 90% of patients with ankylosing spondylitis and 75% with Reiter's syndrome. HLA-B27 also occurs in 50% of the psoriatic and inflammatory bowel disease patients who have sacroiliitis. Patients with only peripheral arthritis in these latter two syndromes do not show an increase in HLA-B27.

That HLA-B27 itself (and not some other gene) confers susceptibility to these diseases has been demonstrated by experiments with transgenic rats. When the human HLA-B27 gene is expressed in rats, the animals develop a spinal and peripheral arthritis, psoriasiform nail and skin changes, and bowel inflammation. Thus, HLA-B27 is an important risk factor for the spondyloarthropathies. However, some patients with these disorders are HLA-B27-negative, and the great majority of HLA-B27-positive individuals do not develop spondyloarthropathies. The gene is therefore neither necessary nor sufficient to cause spondyloarthropathies.

Infection also appears to play a key role in some of the spondyloarthropathies, especially Reiter's syndrome, which characteristically develops days to weeks after bacterial dysentery or a nongonococcal sexually transmitted infection (see below). The interplay of susceptibility genes and environmental infections is demonstrated by the fact that the risk of developing Reiter's syndrome is 0.2% in the general population, 2% in the HLA-B27 individuals, and 20% in patients with HLA-B27 who become infected with salmonella, shigella, or enteric organisms. Despite these gains in our understanding of the importance of HLA-B27 and infection, the precise mechanism by which genes and infection cause spondyloarthropathy is not yet known.

ANKYLOSING SPONDYLITIS

Essentials of Diagnosis

- Chronic low backache in young adults.
- Progressive limitation of back motion and of chest expansion.
- Transient (50%) or permanent (25%) peripheral arthritis.
- Anterior uveitis in 20-25%.
- Diagnostic radiographic changes in sacroiliac joints.
- Accelerated erythrocyte sedimentation rate and negative serologic tests for rheumatoid factor.
- HLA-B27 usually positive but not helpful diagnostically.

General Considerations

Ankylosing spondylitis is a chronic inflammatory disease of the joints of the axial skeleton, manifested clinically by pain and progressive stiffening of the spine. The age at onset is usually in the late teens or early 20s. The incidence is greater in males than in females, and symptoms are more prominent in men, with ascending involvement of the spine more likely to occur.

Clinical Findings

A. Symptoms and Signs

The onset is usually gradual, with intermittent bouts of back pain that may radiate down the thighs. As the disease advances, symptoms progress in a cephalad direction and back motion becomes limited, with the normal lumbar curve flattened and the thoracic curvature exaggerated. Chest expansion is often limited as a consequence of costovertebral joint involvement. Radicular symptoms due to cauda equina fibrosis may occur years after onset of the disease. In advanced cases, the entire spine becomes fused, allowing no motion in any direction. Transient acute arthritis of the peripheral joints occurs in about 50% of cases, and permanent changes in the peripheral joints—most commonly the hips, shoulders, and knees—are seen in about 25%.

Spondylitic heart disease, characterized chiefly by atrioventricular conduction defects and aortic insufficiency, occurs in 3-5% of patients with long-standing severe disease. Anterior uveitis is associated in as many as 25% of cases and may be a presenting feature. Pulmonary fibrosis of the upper lobes, with progression to cavitation and bronchiectasis mimicking tuberculosis, may occur, characteristically long after the onset of skeletal symptoms. Constitutional symptoms similar to those of rheumatoid arthritis are absent in most patients.

B. Laboratory Findings

The erythrocyte sedimentation rate is elevated in 85% of cases, but serologic tests for rheumatoid factor are characteristically negative. Anemia may be present but is often mild. HLA-B27 is found in 90% of patients with ankylosing spondylitis. Because this antigen occurs in 8% of the healthy white population (and 4% of healthy blacks), it is not a specific diagnostic test.

C. Imaging

The earliest radiographic changes are usually in the sacroiliac joints. In the first few months of the disease process, the sacroiliac changes may be detectable only by CT scanning. Later, erosion and sclerosis of these joints are evident on plain radiographs. Involvement of the apophysial joints of the spine, ossification of the annulus fibrosus, calcification of the anterior and lateral spinal ligaments, and squaring and generalized demineralization of the vertebral bodies may occur in more advanced stages. The term "bamboo spine" has been used to describe the late radiographic appearance of the spinal column.

Additional radiographic findings include periosteal new bone formation on the iliac crest, ischial tuberosities and calcanei, and alterations of the pubic symphysis and sternomanubrial joint similar to those of the sacroiliacs. Radiologic changes in peripheral joints, when present, tend to be asymmetric and lack the demineralization and erosions seen in rheumatoid arthritis.

Differential Diagnosis

In contrast to ankylosing spondylitis, rheumatoid arthritis predominantly affects multiple, small, peripheral joints of the hands and feet. Rheumatoid arthritis also spares the sacroiliac joints, and has little effect on the rest of the spine except for C1-C2. Finally, rheumatoid arthritis is often associated with rheumatoid nodules and with rheumatoid factor, not with HLA-B27. The history and physical findings of ankylosing spondylitis serve to distinguish this disorder from other causes of low back pain such as disk disease, osteoporosis, soft tissue trauma, and tumors. The single most valuable distinguishing radiologic sign of ankylosing spondylitis is the appearance of the sacroiliac joints, although a similar pattern may be seen in Reiter's syndrome and in the arthritis associated with inflammatory intestinal diseases and psoriasis. In ankylosing hyperostosis (diffuse idiopathic skeletal hyperostosis [DISH], Forestier's disease), there is exuberant osteophyte formation. The osteophytes are thicker and more anterior than the syndesmophytes of ankylosing spondylitis, and the sacroiliac joints are not affected. The x-ray appearance of the sacroiliac joints in spondylitis should be distinguished from that in osteitis condensans ilii.

Ozgocmen S et al: Osteophyte-induced dysphagia: report of three cases. Joint Bone Spine 2002;69:226. [\[PMID: 12027318\]](#)

Treatment

A. Basic Program

The general principles of managing chronic arthritis (see above) apply equally well to ankylosing spondylitis. The importance of postural and breathing exercises should be stressed.

B. Drug Therapy

The nonsteroidal anti-inflammatory agents are employed in the treatment of this disorder. Of these, indomethacin appears to be the most effective, though it can be quite toxic. The dosage of indomethacin is usually 25-50 mg three times a day, but the smallest effective dose should be used. Indomethacin may produce a variety of untoward reactions, including headache, giddiness, nausea and vomiting, peptic ulcer, renal insufficiency, depression, and psychosis. Other NSAIDs are valuable alternatives and may be used as primary therapy. Sulfasalazine (1000 mg twice daily) is sometimes useful for the peripheral arthritis in patients with spondyloarthropathies but has little symptomatic effect on spinal and sacroiliac joint disease. Curiously, corticosteroids have minimal impact on the arthritis—particularly the spondylitis—of ankylosing spondylitis. Recent studies with tumor necrosis factor inhibitors demonstrate that these agents are highly effective in both the spinal and peripheral arthritis of ankylosing spondylitis. Either etanercept (25 mg subcutaneously twice a week) or infliximab (5 mg/kg every other month) is reasonable for patients whose symptoms are refractory to physical therapy and other interventions.

C. Physical Therapy

See above.

Prognosis

Almost all patients have persistent symptoms over decades; rare individuals experience long-term remissions. The severity of disease varies greatly, with about 10% of patients having work disability after 10 years. Developing hip disease within the first 2 years of disease onset presages a worse prognosis.

Khan MA: Update on spondyloarthropathies. Ann Intern Med 2002;136:896. [\[PMID: 12069564\]](#)

PSORIATIC ARTHRITIS

Essentials of Diagnosis

- Psoriasis precedes onset of arthritis in 80% of cases.
- Arthritis usually asymmetric, with "sausage" appearance of fingers and toes; resembles rheumatoid arthritis; rheumatoid factor is negative.
- Sacroiliac joint involvement common; ankylosis of the sacroiliac joints may occur.
- Radiographic findings: osteolysis; pencil-in-cup deformity; relative lack of osteoporosis; bony ankylosis; asymmetric sacroiliitis and atypical syndesmophytes.

General Considerations

In 15-20% of patients with psoriasis, arthritis coexists. The patterns or subsets of arthritis that may accompany psoriasis include the following:

1. Joint disease that resembles rheumatoid arthritis in which polyarthritis is symmetric. Usually, fewer joints are involved than in rheumatoid arthritis.
2. An oligoarticular form that may lead to considerable destruction of the affected joints.
3. A pattern of disease in which the distal interphalangeal joints are primarily affected. Early, this may be monarticular, and often the joint involvement is asymmetric. Pitting of the nails and onycholysis are frequently associated.
4. A severe deforming arthritis (arthritis mutilans) in which osteolysis is marked.
5. A spondylitic form in which sacroiliitis and spinal involvement predominate; 50% of these patients are HLA-B27-positive.

Clinical Findings

A. Symptoms and Signs

Although psoriasis usually precedes the onset of arthritis, arthritis precedes or occurs simultaneously with the skin disease in approximately 20% of cases. Arthritis is at least five times more common in patients with severe skin disease than in those with only mild skin findings. Occasionally, however, patients may have a single patch of psoriasis (typically hidden in the scalp, gluteal cleft, or umbilicus) and are unaware of its connection to the arthritis. Thus, a detailed search for cutaneous lesions is essential in patients with arthritis of new onset. Also, the psoriatic lesions may have cleared when arthritis appears—in such cases, the history is most useful in diagnosing previously unexplained cases of mono- or oligoarthritis. Nail pitting, a residue of previous psoriasis, is sometimes the only clue.

B. Laboratory Findings

Laboratory studies show an elevation of the sedimentation rate, but rheumatoid factor is not present. Uric acid levels may be high, reflecting the active turnover of skin affected by psoriasis. There is a correlation between the extent of psoriatic involvement and the level of uric acid, but gout is no more common than in patients without psoriasis. Desquamation of the skin may also reduce iron stores.

C. Imaging

Radiographic findings are most helpful in distinguishing the disease from other forms of arthritis. There are marginal erosions of bone and irregular destruction of joint and bone, which, in the phalanx, may give the appearance of a sharpened pencil. Fluffy periosteal new bone may be marked, especially at the insertion of muscles and ligaments into bone. Such changes will also be seen along the shafts of metacarpals, metatarsals, and phalanges. Paravertebral ossification occurs, which may be distinguished from ankylosing spondylitis by the absence of ossification in the anterior aspect of the spine.

Treatment

Treatment regimens are symptomatic. Nonsteroidal anti-inflammatory drugs are usually sufficient for mild cases. Corticosteroids are less effective in psoriatic arthritis than in other forms of inflammatory arthritis. In addition, they may exacerbate the skin disease during tapers. Antimalarials may also exacerbate psoriasis. In resistant cases, methotrexate may be helpful. For cases with disease that is refractory to methotrexate, etanercept or infliximab is usually effective for both arthritis and psoriatic skin disease. Successful treatment of the skin lesions (eg, by PUVA therapy) commonly—though not invariably—is accompanied by an improvement in peripheral articular symptoms.

Gladman DD: Current concepts in psoriatic arthritis. Curr Opin Rheumatol 2002;14:361. [\[PMID: 12118168\]](#)

REACTIVE ARTHRITIS

Essentials of Diagnosis

- Fifty to 80 percent of patients are HLA-B27-positive.
- Oligoarthritis, conjunctivitis, urethritis, and mouth ulcers most common features.
- Usually follows dysentery or a sexually transmitted infection.

General Considerations

Reactive arthritis (formerly called Reiter's syndrome) is a clinical tetrad of urethritis, conjunctivitis (or, less commonly, uveitis), mucocutaneous lesions, and aseptic arthritis. It occurs most commonly in young men, is associated with HLA-B27 in 80% of white patients and 50-60% of blacks, and often follows infection (see above).

Clinical Findings

A. Symptoms and Signs

Most cases of reactive arthritis develop within days or weeks after either a dysenteric infection (with shigella, salmonella, yersinia, campylobacter) or a sexually transmitted infection (with *Chlamydia trachomatis* or perhaps *Ureaplasma urealyticum*). Whether the inciting infection is sexually transmitted or dysenteric does not affect the subsequent manifestations but does influence the gender ratio: The ratio is 1:1 after enteric infections but 9:1 with male predominance after sexually transmitted infections.

Although affected joints are culture-negative, fragments of putative organisms have been identified by polymerase chain reaction studies on synovial fluid. The exact role of infection remains unclear.

The arthritis is most commonly asymmetric and frequently involves the large weight-bearing joints (chiefly the knee and ankle); sacroiliitis or ankylosing spondylitis is observed in at least 20% of patients, especially after frequent recurrences. Systemic symptoms including fever and weight loss are common at the onset of disease. The mucocutaneous lesions may include balanitis, stomatitis, and keratoderma blennorrhagicum, indistinguishable from pustular psoriasis. Involvement of the fingernails in Reiter's syndrome may also mimic psoriatic changes. Carditis and aortic regurgitation may occur. While most signs of the disease disappear within days or weeks, the arthritis may persist for several months or even years. Recurrences involving any combination of the clinical manifestations are common and are sometimes followed by permanent sequelae, especially in the joints.

B. Imaging

Radiographic signs of permanent or progressive joint disease may be seen in the sacroiliac as well as the peripheral joints.

Differential Diagnosis

Gonococcal arthritis can initially mimic reactive arthritis, but the marked improvement after 24-48 hours of antibiotic administration and the culture results distinguish the two disorders. Rheumatoid arthritis, ankylosing spondylitis, and psoriatic arthritis must also be considered.

The association of reactive arthritis and HIV has been debated, but evidence now indicates that it is equally common in sexually active men regardless of HIV status.

Treatment

NSAIDs have been the mainstay of therapy. Antibiotics given at the time of a nongonococcal sexually transmitted infection reduce the chance that the individual will develop this disorder. Tetracycline (250 mg four times daily) given for 3 months to patients with reactive arthritis associated with *C trachomatis* reduces the duration of symptoms. Tetracyclines have anti-inflammatory properties, so the response need not be attributed solely to an antimicrobial effect. Patients who fail NSAIDs and tetracycline may respond to sulfasalazine, 1000 mg twice daily. Anti-TNF agents (etanercept, infliximab) are reasonable therapies for patients with refractory disease.

Sieper J et al: Diagnosing reactive arthritis: role of clinical setting in the value of serologic and microbiologic assays. Arthritis Rheum 2002;46:319. [PMID: 11840434]

ARTHRITIS & INFLAMMATORY INTESTINAL DISEASES

One-fifth of patients with inflammatory bowel disease have arthritis, making it second only to anemia as the most common extraintestinal manifestation. Arthritis complicates Crohn's disease somewhat more frequently than it does ulcerative colitis. In both diseases, two distinct forms of arthritis occur. The first is peripheral arthritis—usually a nondeforming asymmetric oligoarthritis of large joints—in which the activity of the joint disease parallels that of the bowel disease. The arthritis usually begins months to years after the bowel disease, but occasionally the joint symptoms develop earlier and may be prominent enough to cause the patient to overlook intestinal symptoms. The second form of arthritis is a spondylitis that is indistinguishable by symptoms or x-ray from ankylosing spondylitis and follows a course independent of the bowel disease. About 50% of these patients are HLA-B27-positive.

Controlling the intestinal inflammation usually eliminates the peripheral arthritis. The spondylitis often requires NSAIDs, which need to be used cautiously since these agents may activate the bowel disease in a few patients. Range-of-motion exercises as prescribed for ankylosing spondylitis can be helpful.

About two-thirds of patients with Whipple's disease experience arthralgia or arthritis, most often an episodic, large-joint polyarthritis. The arthritis usually precedes the gastrointestinal manifestations by years. In fact, the arthritis resolves as the diarrhea develops. Thus, Whipple's disease should be considered in the differential diagnosis of unexplained episodic arthritis.

■ INFECTIOUS ARTHRITIS*

*Lyme disease is discussed in [Chapter 34](#).

NONGONOCOCCAL ACUTE BACTERIAL (SEPTIC) ARTHRITIS

Essentials of Diagnosis

- Sudden onset of acute arthritis, usually monarticular, most often in large weight-bearing joints and wrists.
- Previous joint damage or intravenous drug abuse common risk factors.
- Infection with causative organisms commonly found elsewhere in body.
- Joint effusions are usually large, with white blood counts commonly > 50,000/uL.

General Considerations

Nongonococcal acute bacterial arthritis is a disease of an abnormal host. The key risk factors are persistent bacteremia (eg, intravenous drug use, endocarditis) and damaged joints (eg, rheumatoid arthritis). *Staphylococcus aureus* is the most common cause of nongonococcal septic arthritis, followed by group A and group B streptococci. Gram-negative septic arthritis, once rare, has become more common, especially in intravenous drug abusers and in other immunocompromised hosts. *Escherichia coli* and *Pseudomonas aeruginosa* are the most common gram-negative isolates in adults.

The widespread use of arthroscopy and prosthetic joint surgery has also increased the frequency of septic arthritis. In the latter conditions, *Staphylococcus epidermidis* is the usual offending organism. Pathologic changes include varying degrees of acute inflammation, with synovitis, effusion, abscess formation in synovial or subchondral tissues, and, if treatment is not adequate, articular destruction.

Clinical Findings

A. Symptoms and Signs

The onset is usually sudden, with acute pain, swelling, and heat of one joint—most frequently the knee. Other commonly affected sites are the hip, wrist, shoulder, and ankle. Unusual sites, such as the sternoclavicular or sacroiliac joint, can be involved in intravenous drug abusers. Chills and fever are common but are absent in up to 20% of patients. Infection of the hip usually does not produce apparent swelling but results in groin pain greatly aggravated by walking.

B. Laboratory Findings

Blood cultures are positive in approximately 50% of patients. The leukocyte count of the synovial fluid exceeds 50,000/uL and often 100,000/uL, with 90% or more polymorphonuclear cells. Synovial fluid glucose is usually low. Gram stain of the synovial fluid is positive in 75% of staphylococcal infections and in 50% of gram-negative infections.

C. Imaging

Radiographs are usually normal early in the disease, but evidence of demineralization may be present within days of onset. Bony erosions and narrowing of the joint space followed by osteomyelitis and periostitis may be seen within 2 weeks.

Differential Diagnosis

The septic course with chills and fever, the acute systemic reaction, the joint fluid findings, evidence of infection elsewhere in the body, and the evidence of response to appropriate antibiotics are diagnostic of bacterial arthritis. Gout and pseudogout are excluded by the failure to find crystals on synovial fluid analysis. Acute rheumatic fever and rheumatoid arthritis commonly involve many joints; Still's disease may mimic septic arthritis, but laboratory evidence of infection is absent. Pyogenic arthritis may be superimposed on other types of joint disease, notably rheumatoid arthritis, and must be excluded (by joint fluid examination) in any apparent acute relapse of

the primary disease, particularly when a joint has been needled or when one is more strikingly inflamed than the others.

Treatment

Prompt systemic antibiotic therapy of any septic arthritis should be based on the best clinical judgment of the causative organism and the results of smear and culture of joint fluid, blood, urine, or other specific sites of potential infection. If the organism cannot be determined clinically, treatment should be started with bactericidal antibiotics effective against staphylococci, pneumococci, and gram-negative organisms.

Frequent (even daily) local aspiration is indicated when synovial fluid rapidly reaccumulates and causes symptoms. Immediate surgical drainage is reserved for septic arthritis of the hip, because that site is inaccessible to repeated aspiration. For most other joints, surgical drainage is used only if medical therapy fails over 2-4 days to improve the fever and the synovial fluid volume, white blood count, and culture results. Pain can be relieved with local hot compresses and by immobilizing the joint with a splint or traction. Rest, immobilization, and elevation are used at the onset of treatment. Early active motion exercises within the limits of tolerance will hasten recovery.

Prognosis

With prompt antibiotic therapy and no serious underlying disease, functional recovery is usually good. Five to 10 percent of patients with an infected joint die, chiefly from respiratory complications of sepsis. The mortality rate is 30% for patients with polyarticular sepsis. Bony ankylosis and articular destruction commonly also occur if treatment is delayed or inadequate.

GONOCOCCAL ARTHRITIS

Essentials of Diagnosis

- Prodromal migratory polyarthralgias.
- Tenosynovitis most common sign.
- Purulent monoarthritis in 50%.
- Characteristic skin rash.
- Most common in young women during menses or pregnancy.
- Symptoms of urethritis frequently absent.
- Dramatic response to antibiotics.

General Considerations

In contrast to nongonococcal bacterial arthritis, gonococcal arthritis usually occurs in otherwise healthy individuals. Host factors, however, influence the expression of the disease: Gonococcal arthritis is two to three times more common in women than in men, is especially common during menses and pregnancy, and is rare after age 40. Gonococcal arthritis is also common in male homosexuals, whose high incidence of asymptomatic gonococcal pharyngitis and proctitis predisposes them to disseminated gonococcal infection. Some of the signs of disseminated gonococcal infection may result from an immunologic reaction to nonviable fragments of the organism's cell wall; this may explain the frequent inability to culture organisms from skin and joint lesions. Recurrent disseminated gonococcal infection should prompt evaluation for a congenital deficiency of complement components, especially C7 and C8.

Clinical Findings

A. Symptoms and Signs

One to 4 days of migratory polyarthralgias involving the wrist, knee, ankle, or elbow is the most common initial course. Thereafter, two patterns emerge, one (60% of patients) characterized by tenosynovitis and the other (40%) by purulent monoarthritis, most frequently involving the knee. Less than half of patients have fever, and less than one-fourth have any genitourinary symptoms. Most patients will have asymptomatic but highly characteristic skin lesions that usually consist of two to ten small necrotic pustules distributed over the extremities, especially the palms and soles.

B. Laboratory Findings

The peripheral blood leukocyte count averages about 10,000 cells/uL and is elevated in less than one-third of patients. The synovial fluid white blood cell count, however, is typically over 50,000 cells/uL. The synovial fluid Gram stain is positive in one-fourth of cases and culture in less than half. Positive blood cultures are seen in 40% of patients with tenosynovitis and virtually never in patients with suppurative arthritis. Urethral, throat, and rectal cultures should be done in all patients, since they are often positive in the absence of local symptoms. Culturing *Neisseria gonorrhoeae* is facilitated by rapid transport to the microbiology laboratory, inoculation on appropriate media, and incubation in carbon dioxide.

C. Imaging

Radiographs are usually normal or show only soft tissue swelling.

Differential Diagnosis

Reactive arthritis can also produce acute monoarthritis in a young person but is distinguished by negative cultures, sacroiliitis, and failure to respond to antibiotics. Lyme disease involving the knee is less acute, does not show positive cultures, and may be preceded by known tick exposure and characteristic rash. The synovial fluid analysis will exclude gout, pseudogout, and nongonococcal bacterial arthritis. Rheumatic fever and sarcoidosis can produce migratory tenosynovitis but have other distinguishing features. Infective endocarditis with septic arthritis can mimic disseminated gonococcal infection.

Treatment

In most cases, patients suspected of having gonococcal arthritis should be admitted to the hospital to confirm the diagnosis, to exclude endocarditis, and to start treatment. While outpatient treatment has been recommended in the past, the rapid rise in gonococci resistant to penicillin makes initial inpatient treatment advisable. Approximately 4-5% of all gonococcal isolates produce a β -lactamase that confers penicillin resistance. An additional 15-20% of gonococcal species have chromosomal mutations that result in relative resistance to penicillin. Therefore, the current recommendations for initial treatment of gonococcal arthritis are to give ceftriaxone, 2 g intravenously daily (or cefotaxime, 1 g intravenously every 8 hours); levofloxacin, 400 mg daily, may be used for patients with beta-lactam allergies). Once improvement from parenteral antibiotics has been achieved for 24-48 hours, patients can be switched to oral cefixime, 400 mg orally twice daily, or levofloxacin 400 mg daily, to complete a 7- to 10-day course.

Prognosis

Generally, gonococcal arthritis responds dramatically in 24-48 hours after initiation of antibiotics so that daily joint aspirations are rarely needed. Complete recovery is the rule.

RHEUMATIC MANIFESTATIONS OF HIV INFECTION

Infection with human immunodeficiency virus (HIV) has been associated with various rheumatic disorders, most commonly arthralgias or Reiter's syndrome. More rarely myositis, psoriatic arthritis, Sjogren's syndrome, or vasculitis occur (see [Chapter 31](#)). It is possible that these disorders stem directly from HIV infection itself or from the many other infections that occur in immunodeficient patients. The rheumatic syndromes may follow the diagnosis of AIDS or may precede it by several months. Thus, coexistent HIV infection must be considered in patients presenting with reactive arthritis. The lower extremity joints, especially the knees and ankles, are most commonly affected. Often, as in classic Reiter's syndrome, Achilles tendon inflammation (enthesopathy) or knee peri-arthritis is a prominent and distinguishing feature. Many patients respond to NSAIDs, though a few are unresponsive and develop progressive deformities. In the era of highly active antiretroviral therapies, immunosuppressive medications can be used if necessary in HIV patients, though with reluctance and great caution.

Reveille JD: The changing spectrum of rheumatic disease in human immunodeficiency virus infection. Semin Arthritis Rheum 2000;30:147. [\[PMID: 1112428\]](#)

VIRAL ARTHRITIS

Arthritis may be a manifestation of many viral infections. It is generally mild and of short duration, terminating without lasting ill effects. Mumps arthritis may occur in the absence of parotitis. Rubella arthritis, which occurs more commonly in adults than in children, may appear immediately before, during, or soon after the disappearance of the rash. Its usual polyarticular and symmetric distribution mimics that of rheumatoid arthritis. However, the seronegative tests for rheumatoid factor and the rising rubella titers in convalescent serum help to confirm the diagnosis. Post-rubella vaccination arthritis may have its onset as long as 6 weeks following vaccination and occurs in all age groups. In adults, arthritis may follow infection with human parvovirus B19.

Transient polyarthritis may be associated with type B hepatitis and typically occurs before the onset of jaundice; it may occur in anicteric hepatitis as well. Urticaria or other types of skin rash may be present. Indeed, the clinical picture may be indistinguishable from that of serum sickness. Serum transaminase levels are elevated, and hepatitis B surface antigen is most often present. Serum complement levels are usually low during active arthritis and become normal after remission of arthritis. False-positive tests for rheumatoid factor, when present, disappear within several weeks. The arthritis is mild; it rarely lasts more than a few weeks and is self-limiting and without deformity. Hepatitis C infection may be associated with chronic polyarthralgia or polyarthritis that mimics rheumatoid arthritis.

■ INFECTIONS OF BONES

Direct microbial contamination of bones results from open fracture, surgical procedures, gunshot wounds, diagnostic needle aspirations, and therapeutic or self-administered drug injections.

Indirect or secondary infections are first noticed in other areas of the body and extend to bones by hematogenous routes.

ACUTE PYOGENIC OSTEOMYELITIS

Essentials of Diagnosis

- Fever and chills associated with pain and tenderness of involved bone.
- Aspiration of involved bone is usually diagnostic.
- Culture of blood or lesion tissue is essential for precise diagnosis.
- Erythrocyte sedimentation rate often extremely high (eg, > 100 mm/h).
- Radiographs early in the course are typically negative.

General Considerations

Osteomyelitis is a serious infection that is often difficult to diagnose and treat. Infection of bone occurs as a consequence of (1) hematogenous dissemination of bacteria, (2) invasion from a contiguous focus of infection, and (3) skin breakdown in the setting of vascular insufficiency.

Clinical Findings

A. Symptoms and Signs

1. Hematogenous osteomyelitis—Osteomyelitis resulting from bacteremia is a disease associated with sickle cell disease, intravenous drug users, or the elderly. Patients with this form of osteomyelitis often present with sudden onset of high fever, chills, and pain and tenderness of the involved bone. The site of osteomyelitis and the causative organism depend on the host. Among patients with hemoglobinopathies such as sickle cell anemia, osteomyelitis is caused by salmonellae ten times as often as by other bacteria. Intravenous drug users develop osteomyelitis most commonly in the spine. Although in this setting *S aureus* is most common, gram-negative infections, especially *P aeruginosa* and *serratia* species, are also frequent pathogens. Rapid progression to epidural abscess causing fever, pain, and sensory and motor loss is not uncommon. In older patients with hematogenous osteomyelitis, the most common sites are the thoracic and lumbar vertebral bodies. Risk factors for these patients include diabetes, intravenous catheters, and indwelling urinary catheters. These patients often have more subtle presentations, with low-grade fever and gradually increasing bone pain.

2. Osteomyelitis from a contiguous focus of infection—Prosthetic joint replacement, decubitus ulcer, neurosurgery, and trauma most frequently cause soft tissue infections that can spread to bone. *S aureus* and *S epidermidis* are the most common organisms. Localized signs of inflammation are usually evident, but high fever and other signs of toxicity are usually absent.

3. Osteomyelitis associated with vascular insufficiency—Patients with diabetes and vascular insufficiency are susceptible to developing a very challenging form of osteomyelitis. The foot and ankle are the most commonly affected sites. Infection originates from an ulcer or other break in the skin that is usually still present when the patient presents but may appear disarmingly unimpressive. Bone pain is often absent or muted by the associated neuropathy. Fever is also commonly absent. One of the best bedside clues that the patient has osteomyelitis is the ability to easily advance a sterile probe through a skin ulcer to bone.

B. Imaging and Laboratory Findings

The plain film is the most readily available imaging procedure to establish the diagnosis of osteomyelitis, but it can be falsely negative early. Early radiographic findings may include soft tissue swelling, loss of tissue planes, and periarticular demineralization of bone. About 2 weeks after onset of symptoms, erosion of bone and alteration of cancellous bone appear, followed by periostitis.

MRI, CT, and nuclear medicine bone scanning are more sensitive than conventional radiography. MRI is the most sensitive and is particularly helpful in demonstrating the extent of soft tissue involvement. Radionuclide bone scanning is most valuable when osteomyelitis is suspected but no site is obvious.

Identifying the offending organism is a crucial step in selection of antibiotic therapy. Bone biopsy for culture is required except in those with hematogenous osteomyelitis, who have positive blood cultures. Cultures from overlying ulcers, wounds, or fistulas are unreliable.

Differential Diagnosis

Acute hematogenous osteomyelitis should be distinguished from suppurative arthritis, rheumatic fever, and cellulitis. More subacute forms must be differentiated from tuberculosis or mycotic infections of bone and Ewing's sarcoma or, in the case of vertebral osteomyelitis, from metastatic tumor. When osteomyelitis involves the vertebrae, it commonly traverses the disk—a finding not observed in tumor.

Complications

Inadequate treatment of bone infections results in chronicity of infection, and this possibility is increased by delaying diagnosis and treatment. Extension to adjacent bone or joints may complicate acute osteomyelitis. Recurrence of bone infections often results in anemia, a markedly elevated erythrocyte sedimentation rate, weight loss, weakness, and, rarely, amyloidosis or nephrotic syndrome. Pseudoepitheliomatous hyperplasia, squamous cell carcinoma, or fibrosarcoma may occasionally arise in persistently infected tissues.

Treatment

Most patients require both debridement of necrotic bone and prolonged administration of antibiotics. Patients with vertebral body osteomyelitis and epidural abscess require urgent neurosurgical decompression. Depending on the site and extent of debridement, surgical procedures to stabilize, fill in, cover, or revascularize may be needed. Traditionally, in adults, antibiotics have been administered parenterally for at least 4-6 weeks. Oral therapy with quinolones (eg, ciprofloxacin, 750 mg twice daily) for 6-8 weeks has been shown to be as effective as standard parenteral antibiotic therapy for chronic osteomyelitis in adults with susceptible organisms. When treating osteomyelitis caused by *S aureus*, quinolones are usually combined with rifampin, 300 mg twice daily.

Prognosis

If sterility of the lesion is achieved within 2-4 days, a good result can be expected in most cases if there is no compromise of the patient's immune system. However, progression of the disease to a chronic form may occur. It is especially common in the lower extremities and in patients in whom circulation is impaired (eg, diabetics).

Kothari NA et al: Imaging of musculoskeletal infections. Radiol Clin North Am 2001;39:653. [PMID: 11549164]

MYCOTIC INFECTIONS OF BONES & JOINTS

Fungal infections of the skeletal system are usually secondary to a primary infection in another organ, frequently the lungs (see [Chapter 36](#)). Although skeletal lesions have a predilection for the cancellous portions of long bones and vertebral bodies, the predominant lesion—a granuloma with varying degrees of necrosis and abscess formation—does not produce a characteristic clinical picture.

Differentiation from other chronic focal infections depends upon culture studies of synovial fluid or tissue obtained from the local lesion. Serologic tests provide presumptive support of the diagnosis.

1. Candidiasis

Candidal osteomyelitis most commonly develops in debilitated, malnourished patients undergoing prolonged hospitalization for cancer, neutropenia, trauma, complicated abdominal surgical procedures, or intravenous drug use. Infected intravenous catheters frequently serve as a hematogenous source.

For susceptible candida species, fluconazole, 200 mg orally twice daily, is probably as effective as amphotericin B.

2. Coccidioidomycosis

Coccidioidomycosis of bones and joints is usually secondary to primary pulmonary infection. Arthralgia with periarticular swelling, especially in the knees and ankles, occurring as a nonspecific manifestation of systemic coccidioidomycosis, should be distinguished from actual bone or joint infection. Osseous lesions commonly occur in cancellous bone of the vertebrae or near the ends of long bones at tendinous insertions. These lesions are initially osteolytic and thus may mimic metastatic tumor or myeloma.

The precise diagnosis depends upon recovery of *Coccidioides immitis* from the lesion or histologic examination of tissue obtained by open biopsy. Rising titers of complement-fixing antibodies also provide evidence of the disseminated nature of the disease.

Itraconazole, 200 mg twice daily for 6-12 months, has become the treatment of choice for bone and joint coccidioidomycosis. Chronic infection is rarely cured with antifungal agents and may require operative excision of infected bone and soft tissue; amputation may be the only solution for stubbornly progressive infections. Immobilization of joints by plaster casts and avoidance of weight bearing provide benefit. Synovectomy, joint debridement, and arthrodesis are reserved for more advanced joint infections.

Bruno KM et al: Cryptococcal arthritis, tendinitis, tenosynovitis, and carpal tunnel syndrome: report of a case and review of the literature. *Arthritis Rheum* 2002;47:104. [PMID: [11932886](#)]

3. Histoplasmosis

Focal skeletal or joint involvement in histoplasmosis is rare and generally represents dissemination from a primary focus in the lungs. Skeletal lesions may be single or multiple and are not characteristic.

TUBERCULOSIS OF BONES & JOINTS

Essentials of Diagnosis

- A disease of children, the elderly, or those with HIV infection.
- In most cases, a single site of bone or joint is infected.
- Spine—especially lower thoracic—or knee most common sites.
- Chest radiographs abnormal in less than half.

General Considerations

Most tuberculous infections in the USA are caused by the human strain of *Mycobacterium tuberculosis* (see [Chapter 9](#)). Infection of the musculoskeletal system is caused by hematogenous spread from a primary lesion of the respiratory tract; it may occur shortly after primary infection or may be seen years later as a disease reactivation. Tuberculosis of the thoracic or lumbar spine (Pott's disease) usually occurs in the absence of extraspinal infection. It is a disease of children in developing nations and of the elderly in the United States. Tuberculosis of peripheral joints is almost always monarticular, with the knee the most common site. Extra-articular tuberculosis occurs in only 20%.

Clinical Findings

A. Symptoms and Signs

The onset of symptoms is generally insidious and not accompanied by general manifestations of fever, sweating, toxicity, or prostration. Pain may be mild at onset, is usually worse at night, and may be accompanied by stiffness. As the disease process progresses, limitation of joint motion becomes prominent because of muscle contractures and joint destruction. The knee is the most commonly involved peripheral joint. Symptoms of pulmonary tuberculosis may also be present.

Local findings during the early stages may be limited to tenderness, soft tissue swelling, joint effusion, and increase in skin temperature about the involved area. As the disease progresses without treatment, muscle atrophy and deformity become apparent. Abscess formation with spontaneous drainage externally leads to sinus formation. Progressive destruction of bone in the spine may cause a gibbus, especially in the thoracolumbar region.

B. Laboratory Findings

The precise diagnosis rests upon recovery of the acid-fast organism from joint fluid, pus, or tissue specimens. Biopsy of the bony lesion, synovium, or a regional lymph node may demonstrate the characteristic histopathologic picture of caseating necrosis and giant cells.

C. Imaging

There is a latent period between the onset of symptoms and the initial positive radiographic finding. The earliest changes of tuberculous arthritis are those of soft tissue swelling and distention of the capsule by effusion. Subsequently, bone atrophy causes thinning of the trabecular pattern, narrowing of the cortex, and enlargement of the medullary canal. As joint disease progresses, destruction of cartilage, both in the spine and in peripheral joints, is manifested by narrowing of the joint cleft and focal erosion of the articular surface, especially at the margins. Where the lesion is limited to bone, especially in the cancellous portion of the metaphysis, radiography may demonstrate single or multilocular cysts surrounded by sclerotic bone. With spinal tuberculosis, CT scanning is helpful in demonstrating paraspinal soft tissue extensions of the infection (eg, psoas abscess, epidural extension).

Differential Diagnosis

Tuberculosis of the musculoskeletal system must be differentiated from all subacute and chronic infections, rheumatoid arthritis, gout, and, occasionally, osseous dysplasia. In the spine, metastatic tumor may be suggested.

Complications

Destruction of bones or joints may occur in a few weeks or months if adequate treatment is not provided. Deformity due to joint destruction, abscess formation with spread into adjacent soft tissues, and sinus formation are common. Paraplegia is the most serious complication of spinal tuberculosis. As healing of severe joint lesions takes place, spontaneous fibrous or bony ankylosis follows.

Treatment (See also [Chapter 33](#).)

A. General Measures

General care is especially important when prolonged recumbency is necessary; skillful nursing care must be provided.

B. Chemotherapy

Because of the rise of resistant organisms, the new recommendation for treating bony tuberculosis is to begin with four drugs: isoniazid, 300 mg/d; rifampin, 600 mg/d; pyrazinamide, 25 mg/kg/d; and ethambutol, 15 mg/kg/d. If the isolate is sensitive to isoniazid and rifampin, the ethambutol can be stopped, with the pyrazinamide maintained for 2 months. Isoniazid and rifampin are continued for a total of 6 months. Cure without need for operation may be effected in most cases, even with extensive disease.

C. Surgical Measures

In acute infections where synovitis is the predominant feature, treatment can be conservative, at least initially. Immobilization by splint or plaster, aspiration, and chemotherapy may suffice to control the infection. Synovectomy may be valuable for less acute hypertrophic lesions that involve tendon sheaths, bursae, or joints.

Turgut M: Spinal tuberculosis (Pott's disease): its clinical presentation, surgical management, and outcome. A survey study on 694 patients. *Neurosurg Rev* 2001;24:8. [PMID: 11339471]

ARTHRITIS IN SARCOIDOSIS

The frequency of arthritis among patients with sarcoidosis is variously reported between 10% and 35%. It is usually acute in onset, but articular symptoms may appear insidiously and often antedate other manifestations of the disease. Knees and ankles are most commonly involved, but any joint may be affected. Distribution of joint involvement is usually polyarticular and symmetric. The arthritis is commonly self-limited, resolving after several weeks or months and rarely resulting in chronic arthritis, joint destruction, or significant deformity. Sarcoid arthropathy is often associated with erythema nodosum, but the diagnosis is contingent upon the demonstration of other extra-articular manifestations of sarcoidosis and, notably, biopsy evidence of noncaseating granulomas. In chronic arthritis, radiographs show typical changes in the bones of the extremities with intact cortex and cystic changes.

Treatment of arthritis in sarcoidosis is usually symptomatic and supportive. Colchicine may be of value. A short course of corticosteroids may be effective in patients with severe and progressive joint disease.

■ TUMORS & TUMOR-LIKE LESIONS OF BONE

Essentials of Diagnosis

- Persistent pain, swelling, or tenderness of a skeletal part.
- Pathologic ("spontaneous") fractures.
- Suspicious areas of bony enlargement, deformity, radiodensity, or radiolucency on x-ray.
- Histologic evidence of bone neoplasm on biopsy specimen.

General Considerations

Primary tumors of bone are relatively uncommon in comparison with secondary or metastatic neoplasms. They are, however, of great clinical significance because some grow rapidly and metastasize widely.

Although tumors of bone have been categorized classically as primary or secondary, there is some disagreement about which tumors are primary to the skeleton. Tumors of mesenchymal origin that reflect skeletal tissues (eg, bone, cartilage, and connective tissue) and tumors developing in bones that are of hematopoietic, nerve, vascular, fat cell, and notochordal origin should be differentiated from secondary malignant tumors that involve bone by direct extension or hematogenous spread. Because of the great variety of bone tumors, it is difficult to establish a satisfactory simple classification of bone neoplasms.

Clinical Findings

Persistent skeletal pain and swelling, with or without limitation of motion of adjacent joints or spontaneous fracture, are indications for prompt clinical, radiographic, laboratory, and possibly biopsy examination. Radiographs may reveal the location and extent of the lesion and certain characteristics that may suggest the specific diagnosis. The so-called classic radiographic findings of certain tumors (eg, punched-out areas of the skull in multiple myeloma, "sun ray" appearance of osteogenic sarcoma, and "onion peel" effect of Ewing's sarcoma), although suggestive, are not pathognomonic. Even a bone tumor's histologic characteristics, considered in isolation, provide incomplete information about the nature of the disease. The age of the patient, the duration of complaints, the site of involvement and the number of bones involved, and the presence or absence of associated systemic disease—as well as the histologic characteristics—must all be considered for proper management.

The possibility of benign developmental skeletal abnormalities, metastatic neoplastic disease, infections (eg, osteomyelitis), posttraumatic bone lesions, or metabolic disease of bone must always be kept in mind. If bone tumors occur in or near the joints, they may be confused with the various types of arthritis, especially monarticular arthritis.

Specific Bone Tumors

Tumors arising from osteoblastic connective tissue include osteoid osteoma and osteosarcoma. Osteoid osteomas are benign tumors of children and adolescents that should be surgically removed. Osteosarcoma, the most common malignancy of bone, typically occurs in an adolescent who presents with pain or swelling in a bone or joint (especially in or around the knee). Since the symptoms often appear to begin following a sports-related injury, accurate diagnosis may be delayed. Osteosarcoma can also develop in patients with Paget's disease of bone, enchondromatosis, fibrous dysplasia, or hereditary multiple exostoses. Osteosarcomas are treated by resection and chemotherapy, with 5-year survival rates improving from 15% in 1965 to 60% at this time. Fibrosarcomas, which are derived from nonosteoblastic connective tissue, have a prognosis similar to that of the osteogenic sarcomas. Tumors derived from cartilage include enchondromas, chondromyxoid fibromas, and chondrosarcomas. Histologic examination is confirmatory in this group, and the prognosis with appropriate curettement or surgery is generally good.

Other bone tumors include giant cell tumors (osteoclastomas), chondroblastomas, and Ewing's sarcoma. Of these, chondroblastomas are almost always benign. About 50% of giant cell tumors are benign, while the rest may be frankly malignant or recur after excision. Ewing's sarcoma, which affects children, adolescents, and young adults, has a 50% mortality rate in spite of chemotherapy, irradiation, and surgery.

Treatment

Although prompt action is essential for optimal treatment of certain bone tumors, accurate diagnosis is required because of the great potential for harm that may result from temporization, radical or ablative operations, or unnecessary irradiation.

Arndt C et al: Common musculoskeletal tumors of childhood and adolescence. *N Engl J Med* 1999;341:342. [PMID: 10423470]

NEUROGENIC ARTHROPATHY (CHARCOT'S JOINT)

Neurogenic arthropathy is joint destruction resulting from loss or diminution of proprioception, pain, and temperature perception. Although traditionally associated with tabes dorsalis, it is more frequently seen in diabetic neuropathy, syringomyelia, spinal cord injury, pernicious anemia, leprosy, and peripheral nerve injury. Prolonged administration of hydrocortisone by the intra-articular route may also cause Charcot's joint. As normal muscle tone and protective reflexes are lost, secondary degenerative joint disease ensues, resulting in an enlarged, boggy, painless joint with extensive cartilage erosion, osteophyte formation, and multiple loose joint bodies. Radiographic changes may be degenerative or hypertrophic in the same patient.

Treatment is directed against the primary disease; mechanical devices are used to assist in weight bearing and prevention of further trauma. In some instances, amputation becomes unavoidable.

Pakarinen TK: Charcot arthropathy of the diabetic foot. Current concepts and review of 36 cases. *Scand J Surg* 2002;91:195. [PMID: 12164523]

■ **OTHER RHEUMATIC DISORDERS**

RHEUMATIC MANIFESTATIONS OF CANCER

Rheumatologic syndromes may be the presenting manifestations for a variety of cancers. Dermatomyositis in adults, for example, is associated with cancer. Middle-aged or older patients with polyarthritis that mimics rheumatoid arthritis but is associated with new onset of clubbing and periosteal new bone formation should be suspected of having hypertrophic pulmonary osteoarthropathy, a disorder commonly associated with both malignant diseases (eg, lung and intrathoracic cancers) and nonmalignant ones (eg, cyanotic heart disease, cirrhosis, and lung abscess). Palmar fasciitis is characterized by bilateral palmar swelling and finger contraction and may be the first indication of cancer, particularly ovarian carcinoma. Palpable purpura due to leukocytoclastic vasculitis may be the presenting complaint in myeloproliferative disorders. Hairy cell leukemia can be associated with medium-sized vessel vasculitis such as polyarteritis nodosa. Acute leukemia can produce joint pains that are disproportionately severe in comparison to the minimal swelling and heat that are present. Leukemic arthritis complicates approximately 5% of cases. Rheumatic manifestations of myelodysplastic syndromes include cutaneous vasculitis, lupus-like syndromes, neuropathy, and episodic intense arthritis. Erythromelalgia, a painful warmth and redness of the extremities that (unlike Raynaud's) improves with cold exposure or with elevation of the extremity, is often associated with myeloproliferative diseases.

Abu-Shakra M et al: Cancer and autoimmunity: autoimmune and rheumatic features in patients with malignancies. Ann Rheum Dis 2001;60:433. [\[PMID: 11302861\]](#)

PALINDROMIC RHEUMATISM

Palindromic rheumatism is a disease of unknown cause characterized by frequent recurring attacks (at irregular intervals) of acutely inflamed joints. Periarticular pain with swelling and transient subcutaneous nodules may also occur. The attacks cease within several hours to several days. The knee and finger joints are most commonly affected, but any peripheral joint may be involved. Systemic manifestations other than fever do not occur. Although hundreds of attacks may take place over a period of years, there is no permanent articular damage. Laboratory findings are usually normal. Palindromic rheumatism must be distinguished from acute gouty arthritis and an atypical acute onset of rheumatoid arthritis. In some patients, palindromic rheumatism is a prodrome of rheumatoid arthritis.

Symptomatic treatment with NSAIDs is usually all that is required during the attacks. Hydroxychloroquine may be of value in preventing recurrences.

AVASCULAR NECROSIS OF BONE

Avascular necrosis of bone is a complication of corticosteroid use, trauma, SLE, pancreatitis, alcoholism, gout, sickle cell disease, and infiltrative diseases (eg, Gaucher's disease). The most commonly affected sites are the proximal and distal femoral heads, leading to hip or knee pain. Many patients with hip disease actually first present with pain referred to the knee. Physical examination will reveal that it is internal rotation of the hip—not movement of the knee—that is painful. Other commonly affected sites include the ankle, shoulder, and elbow. Initially, radiographs are often normal; MRI, CT scan, and bone scan are all more sensitive techniques. Treatment involves avoidance of weight bearing on the affected joint for at least several weeks. The value of surgical core decompression is controversial. Unfortunately, the natural history of avascular necrosis is usually progression of the bony infarction to cortical collapse, resulting in significant joint dysfunction. Total hip replacement is the usual outcome for all patients who are candidates for that procedure.

Pavelka K: Osteonecrosis. Baillieres Best Pract Res Clin Rheumatol 2000;14:399. [\[PMID: 10925752\]](#)

■ **SOME ORTHOPEDIC PROCEDURES FOR ARTHRITIC JOINTS**

Synovectomy

This procedure attempts to eliminate inflammation at a joint by surgically removing as much of the synovium as possible. The procedure has been performed most commonly in patients with rheumatoid arthritis who, despite medical therapy, have a persistent pannus of inflamed synovium (usually around a wrist or a knee). Patients with degenerative diseases do not have marked synovial inflammation and are not candidates for this procedure.

Unfortunately, synovium can regrow. Even in patients with rheumatoid arthritis, the long-term benefits of synovectomy remain unproved.

Arthroplasty

Realigning arthritic joints (arthroplasty) generally does not work as well as complete joint replacement, but it can defer the need for joint replacement. The typical candidate is an adult under 50 years of age who has severe osteoarthritis of one compartment of the knee (typically the medial compartment). Excising a wedge of femur will realign the patient's knee so as to shift weight to the compartment with normal cartilage and thereby eliminate or reduce the patient's pain.

Tendon Rupture

This is a fairly common complication in rheumatoid arthritis and requires immediate orthopedic referral. The most common sites are the finger flexors and extensors, the patellar tendon, and the Achilles tendon.

Arthrodesis

Arthrodesis (fusion) is being used less now than formerly, but a chronically infected, painful joint may be an indication for this surgical procedure.

Total Joint Arthroplasty

In the last 3 decades, remarkable progress has been made in the replacement of severely damaged joints with prosthetic materials. Although many different joints can be replaced, the largest experience and greatest success have been with hip and knee replacement. Indication for total joint arthroplasty is severe pain (usually including pain at rest) accompanied by loss of function and severe destruction of the joint on x-ray. Age is also a consideration, as the durability of artificial joints beyond 10-15 years is limited with older surgical techniques and unproved with newer techniques. Thus, patients over 65 are less likely than younger ones to face the challenge of revision.

Whatever the patient's age, success of the replacement depends upon the amount of physical stress to which the prosthetic components are subjected. Vigorous impact activity, even with the most advanced biomaterials and design, will result in failure of the prosthesis with time. Revision operations are technically more difficult, and the results may not be as good as with the primary procedure. The patient, therefore, must understand the limitations of joint replacement and the consequences of unrestrained joint usage.

A. Total Hip Arthroplasty

Hip replacement was originally designed for use in patients over 65 years of age with severe osteoarthritis. In these patients—usually less active physically—the prosthesis not only functioned well but outlasted the patients. Severe arthritis that fails to respond to conservative measures remains the principal indication for hip arthroplasty. Hip arthroplasty may also be indicated in younger patients severely disabled by painful hip disease (eg, rheumatoid arthritis), since in such cases it can be assumed that stress on the prosthetic joint will not be great. Contraindications to the operation include active infection and neurotrophic joint disease. Obesity is a relative contraindication. Serious complications may occur in about 1% of patients and include thrombophlebitis, pulmonary embolization, infection, and dislocation of the joint. Extensive experience has now been accumulated, and the short-term results are highly successful in properly selected patients. The long-term success has been limited by loosening of the prosthesis, a complication seen in 30-50% of patients 10 years after replacement with "first generation" techniques. Although loosening and periprosthetic osteolysis were blamed on the cement, second-generation cementing techniques for prosthetic hips have proved more durable than cementless hips in one out of four cases.

B. Total Knee Arthroplasty

The indications and contraindications for total knee arthroplasty are similar to those for hip arthroplasty. Results are slightly better in osteoarthritis patients than in those with rheumatoid arthritis. Complications are similar to those with hip arthroplasty. The failure rate of knee arthroplasty is slightly higher than that of hip arthroplasty.

Table 20-4. Origin of hyperuricemia.¹

Primary hyperuricemia

A. Increased production of purine:

- 1. Idiopathic.
- 2. Specific enzyme defects (eg, Lesch-Nyhan syndrome, glycogen storage diseases).

B. Decreased renal clearance of uric acid (idiopathic).

Secondary hyperuricemia

A. Increased catabolism and turnover of purine:

- 1. Myeloproliferative disorders.
- 2. Lymphoproliferative disorders.
- 3. Carcinoma and sarcoma (disseminated).
- 4. Chronic hemolytic anemias.
- 5. Cytotoxic drugs.
- 6. Psoriasis.

B. Decreased renal clearance of uric acid:

- 1. Intrinsic kidney disease.
- 2. Functional impairment of tubular transport:
 - a. Drug-induced (eg, thiazides, probenecid).
 - b. Hyperlacticacidemia (eg, lactic acidosis, alcoholism).
 - c. Hyperketoacidemia (eg, diabetic ketoacidosis, starvation).
 - d. Diabetes insipidus (vasopressin-resistant).
 - e. Bartter's syndrome.

21. Fluid & Electrolyte Disorders - Masafumi Fukagawa, MD, PhD, FJSIM, Kiyoshi Kurokawa, MD, MACP, & Maxine A. Papadakis, MD

APPROACH TO THE PATIENT

History & Physical Examination

Because fluid and electrolyte disorders may be asymptomatic or may cause only nonspecific symptoms, the clinician should never overlook abnormal values in routine laboratory studies. Evaluation of body fluid volume and effective circulating volume by weight and physical examination is essential to the diagnosis of this group of disorders.

Causes of changes in body fluid volume can usually be determined by the history and physical examination. **Volume overload** is manifested by an increase in weight and peripheral edema or ascites. Edema from local obstruction of venous return must be differentiated from systemic processes (congestive heart failure, cirrhosis, and nephrotic syndrome). A history of increased dietary sodium intake and use of medications that affect the renin-angiotensin system (angiotensin- converting enzyme inhibitors, prostaglandin synthesis inhibitors, mineralocorticoids, calcium channel blockers) should be sought. **Volume depletion** is characterized by weight loss, excessive thirst, and dry mucous membranes. The term **dehydration**, pure water deficit, should be distinguished from volume depletion, in which both water and salt are lost. There may be resting tachycardia, orthostatic hypotension, or shock. Causes include vomiting or diarrhea, diuretic use, renal disease, diabetes mellitus or diabetes insipidus, inadequate oral intake associated with altered mental status, and excessive insensible losses from sweating or fever.

Further Evaluation

Treatment of fluid and electrolyte disorders is based on (1) assessment of total body water and its distribution, (2) serum electrolyte concentrations, (3) urine electrolyte concentrations, and (4) serum osmolality. Serial changes in body weight constitute the best way of knowing if there has been an acute change in body water balance.

A. Body Water

[Table 21-1](#) shows the sex difference in total body water and the decrease in total body water that occurs with aging. Changes of total body water content are best evaluated by documenting changes in body weight. Two-thirds of total body water (40% of body weight) is intracellular fluid (ICF), while one-third (20% of body weight) is extracellular fluid (ECF). Water may be lost from either or both of the fluid compartments. Circulatory and neurologic symptoms, physical examination, and laboratory tests (serum and urine sodium, serum urea nitrogen, serum creatinine) can identify from which compartment fluid is lost.

One-fourth of extracellular fluid (5% of body weight) is retained within the blood vessels as plasma (effective circulating volume). Decreases of effective circulating volume may occur in the presence of either volume overload or volume depletion. Effective circulating volume may be assessed by physical examination (blood pressure, pulse rate, jugular vein dilation). In addition to the invasive measurement of central venous pressure or pulmonary wedge pressure, noninvasive measurement of the diameter of the inferior vena cava by ultrasonography may be useful for assessment of effective circulating volume.

B. Serum Electrolytes

[Table 21-2](#) shows the normal values for serum electrolytes. Electrolyte disorders may be suspected by considering the history and underlying disease and the medications the patient is taking.

C. Evaluation of Urine

Urinalysis provides information about underlying renal disorders. Samples also should be obtained for analysis of urine electrolyte abnormalities. An electrolyte concentration in urine is a useful indicator of renal handling of water and the electrolyte, ie, whether the kidney loses or preserves the electrolyte.

In addition to the total urine per day, a spot urine may be used. Simple concentration, or concentration per gram creatinine excretion, is usually sufficient for initial analysis. More precisely, fractional excretion is used. Fractional excretion (FE) of an electrolyte X is calculated using a random urine sample with simultaneously obtained serum samples for X and creatinine.

$$FEX(\%) = \frac{\text{Urine X/ Serum X}}{\text{Urine Cr/Serum Cr}} \times 100$$

D. Serum Osmolality

Serum osmolality (normally 285-295 mosm/kg) can be calculated from the following formula:

$$\text{Osmolality} = 2 (\text{Na}^+ \text{ meq/L}) + \frac{\text{Glucose mg/dL}}{18} + \frac{\text{BUN mg/dL}}{2.8}$$

(1 mosm of glucose equals 180 mg/L, and 1 mosm of urea nitrogen equals 28 mg/L.) Solute concentration is usually expressed in terms of osmolality. The number of particles in solution (ie, osmolytes; either molecules or ions) determines the number of milliosmoles. Each particle has a unit value of 1, so if a substance ionizes, each ion contributes the same amount as a nonionizable molecule. More importantly, permeability of the particle across the cell membrane determines if it acts as a physiologically active osmolyte. Only impermeable particles contribute to tonicity, and it is tonicity, not osmolality, that stimulates both thirst and ADH release. Substances that easily permeate cell membranes (eg, urea, ethanol) are not effective osmolytes and therefore do not cause shifting of fluid in body fluid compartments. For example, glucose in solution is nonionizable. Therefore, 1 mmol of glucose has an osmole concentration of 1 mosm/kg H₂O. One millimole of NaCl, however, forms two ions in water (one Na⁺ and one Cl⁻) and has an osmole concentration of roughly 2 mosm/kg H₂O. "Osmoles per kilogram of water" is *osmolality*; "osmoles per liter of solution" is *osmolality*. At the solute concentration of body fluids, the two measurements correspond so closely that they are interchangeable.

Clinical Implications

In many instances, electrolyte disorders are asymptomatic. However, patients may develop lethargy, weakness, confusion, delirium, and seizures, especially in the presence of an abnormal serum sodium concentration. Often these symptoms are mistaken for primary neurologic or metabolic disorders. Muscle weakness occurs in patients with severe hypokalemia, hyperkalemia, and hypophosphatemia; confusion, seizures, and coma may develop in those with severe hypercalcemia. Measurement of electrolytes (sodium, potassium, chloride, bicarbonate, calcium, magnesium, and phosphorus) is indicated for any patient with even vague neuromuscular symptoms.

Riggs JE: Neurologic manifestations of electrolyte disturbances. Neurol Clin 2002;20:157. [\[PMID: 11754308\]](#)

■ DISORDERS OF SODIUM CONCENTRATION

An abnormal serum sodium concentration does not necessarily imply abnormal sodium balance but rather abnormal water balance. Thus, most instances of abnormal sodium concentration are associated with abnormal serum osmolality. An abnormal sodium balance is often associated either with volume depletion or with edema formation.

HYPONATREMIA

Essentials of Diagnosis

- Extracellular fluid (ECF) volume and serum osmolality are important determinants of etiology.
- Most cases of hyponatremia result from water imbalance, not sodium imbalance.

General Considerations

Hyponatremia (defined as a serum sodium concentration less than 130 meq/L) is the most common electrolyte abnormality observed in a general hospitalized population, seen in about 2% of patients.

The initial approach to its investigation is the determination of serum osmolality ([Figure 21-1](#)).

The Urine Sodium

Measurement of urine sodium helps distinguish renal from nonrenal causes of hyponatremia. Urine sodium exceeding 20 meq/L is consistent with renal salt wasting (diuretics, ACE inhibitors, mineralocorticoid deficiency, salt-losing nephropathy). Urine sodium less than 10 meq/L or fractional excretion of sodium less than 1% (unless diuretics have been given) implies avid sodium retention by the kidney to compensate for extrarenal fluid losses from vomiting, diarrhea, sweating, or third-spacing, as with ascites.

Isotonic & Hypertonic Hyponatremia

Isotonic and hypertonic hyponatremia can be ruled out by determining serum osmolality, blood lipids, and blood glucose.

Isotonic hyponatremia can be seen with hyperlipidemia and hyperproteinemia. The marked increases in lipids (chylomicrons and triglycerides, but not cholesterol) and proteins (> 10 g/dL) occupy a disproportionately large portion of the plasma volume. Plasma osmolality remains normal because its measurement is unaffected by the lipids or proteins. A decreased volume of water results, so that the sodium concentration in total plasma volume is decreased. Because the sodium concentration in the plasma water is actually normal, hyperlipidemia and hyperproteinemia cause pseudohyponatremia. Most United States laboratories measure serum electrolytes using ion-specific electrodes and thus avoid misdiagnosis.

Hypertonic hyponatremia is most commonly seen with hyperglycemia. When blood glucose becomes acutely elevated, water is drawn from the cells into the extracellular space, diluting the serum sodium. The plasma sodium level falls 2 meq/L for every 100 mg/dL rise when the glucose concentration is between 200 and 400 mg/dL. If the glucose concentration is above 400 mg/dL, the plasma sodium concentration falls 4 meq/L for every 100 mg/dL rise in glucose. This dilutional hyponatremia is not pseudohyponatremia, since the sodium concentration does indeed fall. Infusion of hypertonic solutions containing osmotically active osmoles (eg, mannitol) may also cause hypertonic hyponatremia by drawing water to the extracellular space.

Hypotonic Hyponatremia

Hypotonic hyponatremia is true hyponatremia in a physiologic sense. Since the capacity of the kidney to excrete electrolyte-free water is potentially great—up to 20-30 L/d—in the presence of a normal GFR (100 L/d), electrolyte-free water intake must theoretically exceed 30 L/d for hyponatremia to develop.

Instead, in hypotonic hyponatremia, retention of electrolyte-free water nearly always occurs because of impaired excretion (renal failure, inappropriate ADH excess, etc).

A. Hypovolemic Hypotonic Hyponatremia

Hyponatremia with decreased extracellular fluid volume occurs in the setting of renal or extrarenal volume loss ([Figure 21-1](#)). Total body sodium is decreased. To maintain intravascular volume, antidiuretic hormone (ADH) secretion increases, and free water is retained. The drive to replenish intravascular volume overrides the need to sustain normal osmolality; losses of salt and water are replaced by water alone. The combination of low fractional excretion of sodium (< 0.5%) and low fractional urea clearance (< 55%) is the best way to predict improvement with saline therapy. Hyponatremia has been shown to develop in patients with intracranial diseases through renal sodium wasting. Unlike those with SIADH, these patients are hypovolemic, though plasma levels of ADH are inappropriately high for the osmolality. Observations in patients with subarachnoid hemorrhage suggest that the cerebral salt-wasting syndrome is caused by increased secretion of brain natriuretic peptide with suppression of aldosterone secretion.

Treatment consists of replacement of lost volume with isotonic or half-normal (0.45%) saline or lactated Ringer's infusion. The rate of correction must be adjusted to prevent permanent cerebral damage (see below). Corticosteroids can be used empirically if hypocortisolism is considered in the differential diagnosis. See Adrenocortical Hypofunction in [Chapter 26](#) for diagnosis (by means of the cosyntropin stimulation test) and treatment of hypocortisolism.

B. Euvolemic Hypotonic Hyponatremia

In this setting, determinations of urine osmolality ([Figure 21-1](#)) along with urine sodium are useful for appropriate diagnosis.

1. Clinical syndromes—

a. Syndrome of inappropriate ADH secretion (SIADH)—([Table 21-3](#).) Hypovolemia physiologically stimulates ADH secretion, so the diagnosis of SIADH is made only if the patient is euvolemic. In SIADH, increased ADH release occurs without osmolality-dependent or volume-dependent physiologic stimulation. Normal regulation of ADH release occurs from both the central nervous system and the chest via baroreceptors and neural input. It follows that the causes of SIADH are disorders affecting the central nervous system—structural, metabolic, psychiatric, or pharmacologic—or the lungs. Furthermore, some carcinomas, such as small cell lung carcinoma, synthesize ADH. Other states associated with SIADH include administration of drugs that either increase ADH secretion or potentiate its action. SIADH induced by selective serotonin (or epinephrine) reuptake inhibitors such as fluoxetine is fairly common in geriatric patients.

(1) Patterns of abnormal ADH secretion—

(a) *Random secretion*—ADH release is unrelated to osmoregulation. This pattern is seen in carcinomas and central nervous system diseases.

(b) *Reset osmostat*—This variant is characterized by ADH secretion appropriately suppressed at very low serum osmolalities but with ADH osmoregulation downset to a lower level of "normal." Therefore, ADH is secreted at a subnormal serum osmolality threshold (< 280 mosm/kg). Appropriate urinary dilution can be attained but at low serum osmolalities. This pattern is seen in the elderly, in patients with pulmonary processes, tuberculosis, or malnutrition. During pregnancy, the physiologic reset osmostat may suppress osmolality by about 10 mmol/kg of water.

(c) *Leak of ADH*—In conditions such as basilar skull fractures, low levels of ADH are "leaked" into the circulation despite hypo-osmolality. If serum osmolality rises to normal, ADH secretion increases appropriately and then continues to respond normally if osmolality further increases.

(2) *Clinical features*—SIADH is characterized by (1) hyponatremia; (2) decreased osmolality (< 280 mosm/kg) with inappropriately increased urine osmolality (> 150 mosm/kg); (3) absence of cardiac, renal, or liver disease; (4) normal thyroid and adrenal function (see [Chapter 26](#) for thyroid function tests and cosyntropin stimulation test); and (5) urine sodium usually over 20 meq/L. Natriuresis compensates for the slight increase in volume from ADH secretion. The mechanisms that regulate sodium excretion in response to increases in extracellular volume, such as suppression of the sympathetic nervous and renin-angiotensin systems and increased secretion of atrial natriuretic factor, are preserved and account for the increase in urinary sodium. The expansion of extracellular volume is not large enough to cause clinical hypervolemia, hypertension, or edema. Other changes frequently seen in SIADH include low blood urea nitrogen (BUN) (< 10 mg/dL) and hypouricemia (< 4 mg/dL), which are not only dilutional but result from increased urea and uric acid clearances in response to the volume-expanded state. A high BUN suggests a volume-contracted state, which excludes a diagnosis of SIADH.

b. Postoperative hyponatremia—Severe postoperative hyponatremia can develop in 2 days or less after elective surgery in healthy patients, especially premenopausal women. Most have received excessive postoperative hypotonic fluid in the setting of elevated ADH levels related to pain of surgery with continuing excretion of hypertonic urine. Similar mechanisms have been suspected for hyponatremia after colonoscopy. Patients awake normally from general anesthesia but within 2 days develop nausea, headache, seizures, and even respiratory arrest. Serum sodium levels may be less than 110 meq/L. Premenopausal women who develop hyponatremic encephalopathy are about 25 times more likely than menopausal women to die or to suffer permanent brain damage, suggesting a hormonal role in the pathophysiology of this disorder. Hyponatremia may also result from direct absorption of hypotonic irrigating fluids through veins during endometrial ablation or transurethral prostate resection. These patients can be symptomatic intraoperatively, with tremulousness, hypothermia, or hypoxia, or upon awakening from anesthesia, with headache, nausea, and vomiting.

c. Hypothyroidism—Hyponatremia is not commonly caused by hypothyroidism, but it can occur on occasion with serum sodium levels as low as 105 meq/L. Water retention is the cause, probably both from inappropriately elevated ADH levels and from nonhormonal alterations in the handling of water by the kidneys.

d. Psychogenic polydipsia and beer potomania—Marked excess free water intake (generally > 10 L/d) may produce hyponatremia. Euvolemia is maintained through the renal excretion of sodium. Urine sodium is therefore generally elevated (> 20 meq/L), but unlike SIADH, levels of ADH are suppressed. Urine osmolality is appropriately low (< 300 mosm/kg) as the increased free water is excreted. Hyponatremia from bursts of ADH occurs in manic-depressive patients with excess free water intake. Psychogenic polydipsia is observed in patients with psychologic problems, and these patients frequently take drugs interfering with water excretion. Similarly, excessive intake of beer, which contains very small amounts of sodium (< 5 meq/L), can cause severe hyponatremia in cirrhotic patients, who have elevated ADH and often decreased GFR.

e. Idiosyncratic diuretic reaction—In addition to hyponatremia developing from volume contraction due to diuretic therapy (see above), a less common diuretic-induced hyponatremia can occur in euvolemic patients, typically from thiazides. This syndrome is most often seen in healthy older women (over 70 years of

age) often after a few days of therapy. The mechanism for the hyponatremia appears to be a combination of excessive renal sodium loss and water retention.

f. Idiosyncratic ACE inhibitor reactions—ACE inhibitors can cause central polydipsia and increased antidiuretic hormone secretion, both of which result in severe, symptomatic hyponatremia. Angiotensin-converting enzyme does not block the conversion of angiotensin I to angiotensin II in the brain. Thus, angiotensin II converted in the brain stimulates thirst and ADH secretion.

g. Endurance exercise hyponatremia—Hyponatremia after endurance exercise (eg, triathlon events) may be caused by a combination of excessive fluid overload and continued ADH secretion. Reperfusion of the exercise-induced ischemic splanchnic bed causes delayed absorption of excessive quantities of hypotonic fluid ingested during exercise. Sustained elevation of ADH prevents water excretion in this setting. The retention of hypotonic fluid may be further exacerbated by NSAIDs frequently used by athletes.

h. Mineralocorticoid-responsive hyponatremia in the elderly—In a subgroup of elderly patients, hyponatremia does not resolve in response to water restriction even though they are euvoletic with high ADH levels. These patients may respond to fludrocortisone treatment.

2. Treatment—

a. Symptomatic hyponatremia—Symptomatic hyponatremia is usually seen in patients with serum sodium levels less than 120 meq/L. If there are central nervous system symptoms, hyponatremia should be rapidly treated at any level of serum sodium concentration.

(1) Rate and degree of correction—Central pontine myelinolysis may occur from osmotically induced demyelination due to overly rapid correction of serum sodium (an increase of more than 1 meq/L/h, or 25 meq/L within the first day of therapy). Hypoxic-anoxic episodes during hyponatremia may contribute to the demyelination. A reasonable approach is to increase the serum sodium concentration by no more than 1-2 meq/L/h and not more than 25-30 meq/L in the first 2 days; the rate should be reduced to 0.5-1 meq/L/h as soon as neurologic symptoms improve. The initial goal is to achieve a serum sodium concentration of 125-130 meq/L, guarding against overcorrection.

(2) Saline plus furosemide—Hypertonic (eg, 3%) saline with furosemide is indicated for symptomatic hyponatremic patients. If one administers 3% saline without a diuretic to a patient with SIADH, the serum sodium concentration increases temporarily, but euvoletic patients excrete the excess sodium. If one adds furosemide (0.5-1 mg/kg intravenously), however, the kidney cannot concentrate urine even in the presence of high levels of ADH. Infusion of 3% saline is accompanied by excretion of isotonic urine with a net loss of free water. The sodium concentration of 3% saline is 513 meq/L. In order to determine how much 3% saline to administer, a spot urinary Na^+ is determined after a furosemide diuresis has begun. The excreted Na^+ is replaced with 3% saline, empirically begun at 1-2 mL/kg/h and then adjusted based on urinary output and urinary sodium. For example, after administration of furosemide, urine volume may be 400 mL/h and sodium plus potassium excretion 100 meq/L. The excreted Na^+ plus K^+ is 40 meq/h, which is replaced with 78 mL/h of 3% saline (40 meq/h divided by 513 meq/L). Free water loss is about 1% of total body water. Therefore, an approximately 1% rise in plasma sodium concentration (1-1.5 meq/L/h) can be expected. Measurements of plasma sodium should be done approximately every 4 hours and the patient observed closely.

b. Asymptomatic hyponatremia—In asymptomatic hyponatremia, the correction rate of hyponatremia need be no more than 0.5 meq/L/h. No specific treatment is needed for patients with reset osmostats.

(1) Water restriction—Water intake should be restricted to 0.5-1 L/d. Gradual increase of serum sodium will occur over days.

(2) 0.9% saline—0.9% saline with furosemide may be used in asymptomatic patients whose serum sodium is less than 120 meq/L. Urinary sodium and potassium losses are replaced as above.

(3) Demeclocycline—Demeclocycline (300-600 mg twice daily) is useful for patients who cannot adhere to water restriction or need additional therapy; it inhibits the effect of ADH on the distal tubule. Onset of action may require 1 week, and concentrating may be permanently impaired. Therapy with demeclocycline in cirrhosis appears to increase the risk of renal failure.

(4) Fludrocortisone—Hyponatremia occurring as part of the cerebral salt-wasting syndrome can be treated with fludrocortisone.

(5) Selective vasopressin V2 antagonist—The renal effect of ADH on water excretion is mediated by the V2 receptor. Oral selective V2 antagonists have been in clinical trials and may be available for treatment of SIADH in the near future.

C. Hypervolemic Hypotonic Hyponatremia

Hyponatremia with increased extracellular fluid volume is seen when hyponatremia is accompanied by edema-associated disorders such as congestive heart failure, cirrhosis, nephrotic syndrome, and advanced renal disease (Figure 21-1). In congestive heart failure, total body sodium is increased, yet effective circulating volume is sensed as inadequate by baroreceptors. Increased ADH and aldosterone results, with retention of water and sodium.

The urine sodium concentration is generally less than 10 meq/L unless the patient has been taking diuretics.

Treatment

A. Water Restriction

The treatment of hyponatremia is that of the underlying condition (eg, improving cardiac output in congestive heart failure) and water restriction (to < 1-2 L of water daily).

B. Diuretics

To hasten excretion of water and salt, use of diuretics may be indicated. Since diuretics may worsen hyponatremia, the patient must be cautioned not to increase free water intake.

C. Hypertonic (3%) Saline

Hypertonic saline administration is dangerous in volume-overloaded states and is not routinely recommended. In patients with severe hyponatremia (serum sodium < 110 meq/L) and central nervous system symptoms, judicious administration of small amounts (100-200 mL) of 3% saline with diuretics may be necessary. Emergency dialysis should also be considered.

Hyponatremia in AIDS

Hyponatremia is seen in up to 50% of patients hospitalized for AIDS and in 20% of ambulatory AIDS patients, often associated with pneumonia and central nervous system processes. If hyponatremia is present at the time of hospital admission, it is just as likely to be due to hypovolemic gastrointestinal loss as to euvoletic SIADH. However, if hyponatremia develops after hospital admission, most patients have euvoletic SIADH. Infrequently, hypovolemic hyponatremia is due to adrenal insufficiency, isolated mineralocorticoid deficiency with hyporeninemic hypoaldosteronism, or an HIV-specific impairment in renal sodium conservation. Hyponatremia from adrenal insufficiency may coexist with hypokalemia—rather than hyperkalemia—if the patient also has diarrhea. Adrenal function can be tested with corticotropin stimulation to determine the adequacy of serum cortisol response (see Chapter 26). Patients with isolated hyporeninemic hypoaldosteronism have normal cortisol responses to corticotropin but have decreased serum aldosterone levels.

HYPERNATREMIA

- Occurs most commonly when water intake or water supplementation is inadequate, as in patients with altered mental status.
- Urine osmolality helps differentiate renal from nonrenal water loss.

General Considerations

An intact thirst mechanism usually prevents hypernatremia (> 145 meq/L). Thus, whatever the underlying disorder (eg, dehydration, lactulose or mannitol therapy, central and nephrogenic diabetes insipidus), excess water loss can cause hypernatremia only when adequate water intake is not possible, as with unconscious patients.

Rarely, excessive sodium intake may cause hypernatremia. Hypernatremia in primary aldosteronism is mild and usually does not cause symptoms. Hypernatremia in the presence of salt and water overload is uncommon but has been reported in very ill patients in the course of therapy.

Clinical Findings

A. Symptoms and Signs

When dehydration exists, orthostatic hypotension and oliguria are typical findings. Hyperthermia, delirium, and coma may be seen with severe hyperosmolality.

B. Laboratory Findings

1. Urine osmolality > 400 mosm/kg—Renal water-conserving ability is functioning.

- a. Nonrenal losses—Hypernatremia will develop if water ingestion fails to keep up with hypotonic losses from excessive sweating, exertional losses from the respiratory tract, or through stool water. Lactulose causes an osmotic diarrhea with loss of free water.
- b. Renal losses—While diabetic hyperglycemia can cause pseudohyponatremia (see above), progressive volume depletion from the osmotic diuresis of glycosuria can result in true hypernatremia. Osmotic diuresis can occur with the use of mannitol or urea.

2. Urine osmolality < 250 mosm/kg—A dilute urine with osmolality less than 250 mosm/kg with hypernatremia is characteristic of central and nephrogenic diabetes insipidus. Nephrogenic diabetes insipidus, seen with lithium or demeclocycline therapy, after relief of prolonged urinary tract obstruction, or with interstitial nephritis, results from renal insensitivity to ADH. Hypercalcemia and hypokalemia may be contributing factors when present.

Treatment

Treatment of hypernatremia is directed toward correcting the cause of the fluid loss and replacing water and, as needed, electrolytes. In response to increases in plasma osmolality, brain cells synthesize solutes—or idiogenic osmoles—which increase osmotic flow of water back into the brain cells to regulate their volume. This begins 4-6 hours after dehydration and takes several days to reach a steady state. If hypernatremia is too rapidly corrected, the osmotic imbalance may cause water to preferentially enter brain cells, causing cerebral edema and potentially severe neurologic impairment. Fluid therapy should be administered over a 48-hour period, aiming for a decrease in serum sodium of 1 meq/L/h (1 mmol/L/h). Potassium and phosphate may be added as indicated by serum levels; other electrolytes are also monitored frequently.

A. Choice of Type of Fluid for Replacement

1. Hypernatremia with hypovolemia—Severe hypovolemia should be treated with isotonic (0.9%) saline to restore the volume deficit and to treat the hyperosmolality, since the osmolality of isotonic saline (308 mosm/kg) is often lower than that of the plasma. This should be followed by 0.45% saline to replace any remaining free water deficit. Milder volume deficit may be treated with 0.45% saline and 5% dextrose in water.
2. Hypernatremia with euvoolemia—Water drinking or 5% dextrose and water intravenously will result in excretion of excess sodium in the urine. If GFR is decreased, diuretics will increase urinary sodium excretion but may impair renal concentrating ability, increasing the quantity of water that needs to be replaced.
3. Hypernatremia with hypervolemia—Treatment consists of providing water as 5% dextrose in water to reduce hyperosmolality, but this will expand vascular volume. Thus, loop diuretics such as furosemide (0.5-1 mg/kg) should be administered intravenously to remove the excess sodium. In severe renal insufficiency, hemodialysis may be necessary.

B. Calculation of Water Deficit

When calculating fluid replacement, both the deficit and the maintenance requirements should be added to each 24-hour replacement regimen.

1. Acute hypernatremia—In acute dehydration without much solute loss, free water loss is similar to the weight loss. Initially, 5% dextrose in water may be employed. As correction of water deficit progresses, therapy should continue with 0.45% saline with dextrose.
2. Chronic hypernatremia—Water deficit is calculated to restore normal osmolality for total body water. Total body water (TBW) (Table 21-1) correlates with muscle mass and therefore decreases with advancing age, cachexia, and dehydration and is lower in women than in men. Current TBW equals 0.4-0.6 of current body weight.

Volume to be replaced (in L) = Current TBW × $\frac{[Na^+] - 140}{140}$

DISORDERS OF POTASSIUM CONCENTRATION

HYPOKALEMIA

- Severe hypokalemia may induce dangerous arrhythmias and even rhabdomyolysis.
- Rule out intracellular potassium shifts.
- Assess urinary potassium excretion to rule out renal loss.
- When renal loss is suspected, evaluate mineralocorticoid action by urinary sodium and potassium excretion, TTKG, and plasma aldosterone level.

General Considerations

The total potassium content of the body is 50 meq/kg, more than 95% of which is intracellular. The plasma potassium concentration is maintained in a narrow range through two main regulating mechanisms: potassium shift between intracellular and extracellular compartments and modulation of renal potassium excretion. A deficit of 4-5 meq/kg exists for each 1 meq/L decrement in serum potassium concentration below a level of 4 meq/L.

Clinical Findings

A. Symptoms and Signs

Muscular weakness, fatigue, and muscle cramps are frequent complaints in mild to moderate hypokalemia. Smooth muscle involvement may result in constipation or ileus. Flaccid paralysis, hyporeflexia, hypercapnia, tetany, and rhabdomyolysis may be seen with severe hypokalemia (< 2.5 meq/L).

B. Laboratory Findings

The ECG shows decreased amplitude and broadening of T waves, prominent U waves, premature ventricular contractions, and depressed ST segments. Hypokalemia also increases the likelihood of digitalis toxicity. Thus, in patients with heart disease, hypokalemia induced by certain drugs such as β_2 -adrenergic agonists and diuretics may impose a substantial risk.

Pathophysiology & Diagnosis

Hypokalemia can occur as a result of shifting of potassium intracellularly from the extracellular space, extrarenal potassium loss (or insufficient potassium intake), or renal potassium loss ([Table 21-4](#)). Potassium uptake by the cell is stimulated by insulin in the presence of glucose. It is also facilitated by adrenergic beta-stimulation, whereas adrenergic alpha-stimulation blocks it. All of these effects are transient. Self-limited hypokalemia occurs in 50-60% of trauma patients, perhaps related to enhanced release of epinephrine. Profound hypokalemia due to barium intoxication has been reported that may also be the result of transport of potassium into cells. Hypokalemia in the presence of acidosis suggests profound potassium depletion and requires urgent treatment.

Aldosterone, which facilitates urinary potassium excretion through enhanced potassium secretion at the distal renal tubules, is the most important regulator of body potassium content. Urinary potassium concentration is low (< 20 meq/L) as a result of extrarenal fluid loss (eg, diarrhea, vomiting) and inappropriately high (> 40 meq/L) with urinary losses (eg, mineralocorticoid excess, Bartter's syndrome, Liddle's syndrome). Various genetic mutations that affect fluid and electrolyte metabolism, including disorders of potassium metabolism, have been reported recently ([Table 21-5](#)). Licorice-induced hypokalemia results from inhibition of 11β -hydroxysteroid dehydrogenase, which inactivates cortisol. Cortisol thus escapes degradation, binds to aldosterone receptors, and exerts aldosterone-like effects.

The transtubular $[K^+]$ gradient (TTKG) is a simple and rapid evaluation of net potassium secretion. TTKG is calculated as follows:

$$TTKG = \frac{\text{Urine } K^+ / \text{Plasma } K^+}{\text{Urine osm} / \text{Plasma osm}}$$

Hypokalemia with a TTKG > 4 suggests renal potassium loss with increased distal K^+ secretion. In such cases, plasma renin and aldosterone levels are helpful in differential diagnosis. The presence of nonabsorbed anions, including bicarbonate, also increases TTKG.

Magnesium is an important cofactor for potassium uptake and for maintenance of intracellular potassium levels. Loop diuretics (eg, furosemide) cause substantial renal potassium and magnesium losses. Magnesium depletion should be suspected in refractory hypokalemia despite potassium repletion.

Treatment

The safest way to treat mild to moderate deficiency is with oral potassium, and all potassium formulations are easily absorbed. Dietary potassium is almost entirely coupled to phosphate—rather than chloride—and is therefore not effective in correcting potassium loss associated with chloride depletion, such as from diuretics or vomiting. In the setting of abnormal renal function and mild to moderate diuretic dosage, 20 meq/d of oral potassium is generally sufficient to prevent hypokalemia, but 40-100 meq/d over a period of days to weeks is needed to treat hypokalemia and fully replete potassium stores.

Intravenous potassium replacement is indicated for patients with severe hypokalemia and for those who cannot take oral supplementation. For severe deficiency, potassium may be given through a peripheral intravenous line in a concentration that should not exceed 40 meq/L at rates of up to 40 meq/L/h. Continuous electrocardiographic monitoring is indicated, and the serum potassium level should be checked every 3-6 hours. Correct magnesium deficiency.

HYPERKALEMIA

Essentials of Diagnosis

- The ECG may show peaked T waves, widened QRS and biphasic QRS-T complexes or may be normal despite life-threatening hyperkalemia.
- Plasma potassium differentiates potassium leak from blood cells in cases of clotting, leukocytosis, and thrombocytosis from elevated serum potassium.
- Rule out extracellular potassium shift from the cells in acidosis and assess renal potassium excretion.

General Considerations

Many cases of hyperkalemia are spurious or associated with acidosis ([Table 21-6](#)). The common practice of repeatedly clenching and unclenching a fist during venipuncture may raise the potassium concentration by 1-2 meq/L by causing acidosis and consequent potassium loss from cells.

Intracellular potassium shifts to the extracellular fluid in hyperkalemia associated with acidosis. Serum potassium concentration rises about 0.7 meq/L for every decrease of 0.1 pH unit during acidosis. Potassium movement out of cells occurs primarily in metabolic acidosis due to the accumulation of minerals such as NH_4Cl or HCl. The inability of the chloride anion to permeate the cell membrane results in the transcellular exchange of H^+ for K^+ . Metabolic acidosis from organic acids (keto acids and lactic acid) does not induce hyperkalemia. Unlike the minerals, these organic acids easily permeate cell membranes and retard Na^+-K^+ ATPase. The hyperkalemia frequently observed in diabetic ketoacidosis is not due to the acidosis but to a combination of the hyperosmolality (the intracellular K^+ concentration of the dehydrated cell increases and K^+ diffuses extracellularly) and deficiencies of insulin, catecholamines, and aldosterone. Aminocaproic acid, a synthetic amino acid structurally related to lysine and arginine used for the prevention of operative blood loss, may induce shift of potassium. In the absence of acidosis, serum potassium concentration rises about 1 meq/L when there is a total body potassium excess of 1-4 meq/kg. However, the higher the serum potassium concentration, the smaller the excess necessary to raise the potassium levels further.

ACE inhibitors or angiotensin receptor blockers, commonly used in patients with congestive heart failure or renal insufficiency, may cause hyperkalemia. Simultaneous use of spironolactone increases the risk. Thiazide or loop diuretics may be effective in minimizing hyperkalemia.

Trimethoprim is structurally related to amiloride and triamterene, and all three drugs inhibit renal potassium excretion through suppression of sodium channels in the distal nephron. Serum potassium levels rise progressively over 4-5 days in patients treated with standard or high-dose trimethoprim (combined with sulfamethoxazole or dapson), especially if there is concurrent renal insufficiency. Over half of inpatients taking this drug have potassium levels over 5 meq/L, and 20% have marked hyperkalemia (> 5.5 meq/L). The potassium concentration returns to baseline after drug discontinuation.

In addition, it is of note that immunosuppressive drugs such as cyclosporine and tacrolimus can induce hyperkalemia in organ transplant recipients—and especially in kidney transplant patients. This is partly due to the suppression of basolateral Na^+-K^+ ATPase in principal cells.

Hyperkalemia is commonly seen in HIV-infected patients and has been attributed to impaired renal excretion of potassium due to the use of pentamidine or trimethoprim-sulfamethoxazole or to hyporeninemic hypoaldosteronism.

Clinical Findings

An elevated K⁺ concentration interferes with normal neuromuscular function to produce muscle weakness and, rarely, flaccid paralysis; abdominal distention and diarrhea may occur. Electrocardiography is not a sensitive method for detecting hyperkalemia, since nearly half of patients with a serum potassium level greater than 6.5 meq/L will not manifest electrocardiographic changes. Electrocardiographic changes in hyperkalemia include peaked T waves of increased amplitude, widening of the QRS, and biphasic QRS-T complexes. Inhibition of atrial depolarization despite normal conduction through usual pathways may occur. This sinoventricular rhythm resembles a junctional mechanism and occurs because of greater sensitivity of atrial myocytes to hyperkalemia than is the case for ventricular muscle cells. The heart rate may be slow; ventricular fibrillation and cardiac arrest are terminal events.

Treatment (Table 21-7)

One first confirms that the elevated level of serum K⁺ is genuine. Potassium concentration can be measured in plasma rather than in serum to avoid leakage of potassium out of cells into the serum of the blood sample in the course of clotting, which may be observed in thrombocytosis.

Treatment consists of withholding potassium and giving cation exchange resins by mouth or enema. Sodium polystyrene sulfonate, 40-80 g/d in divided doses, is usually effective. Emergent treatment of hyperkalemia is indicated if cardiac toxicity or muscular paralysis is present or if the hyperkalemia is severe (serum potassium > 6.5-7 meq/L) even in the absence of electrocardiographic changes. Insulin plus 10-50% glucose (5-10 g of glucose per unit of insulin) may be employed to deposit K⁺ with glycogen in the liver. Calcium may be given intravenously as an antagonist ion—but not when digoxin toxicity is suspected, since calcium may augment the deleterious effects of digoxin on the heart. Transcellular shifts of potassium can also be mediated by β₂-adrenergic stimulation. Albuterol, a nebulized β₂ agonist, is effective in decreasing serum potassium in patients on hemodialysis. For such patients, one or two standard doses of nebulized albuterol can reduce serum K⁺ 0.5-1 meq/L within 30 minutes after administration, and this effect is sustained for at least 2 hours. Albuterol and insulin are probably equally efficacious in lowering potassium in uremic patients, and the hypokalemic effects of coadministration of the two drugs (with glucose) are additive and appear not to constitute a hazard. Sodium bicarbonate can be given intravenously as an emergency measure in severe hyperkalemia; the increase in blood pH results in a shift of K⁺ into cells. Hemodialysis or peritoneal dialysis may be required to remove K⁺ in the presence of protracted renal insufficiency. Therapy of the precipitating event proceeds concurrently.

■ DISORDERS OF CALCIUM CONCENTRATION

Calcium constitutes about 2% of body weight, but only about 1% of the total body calcium is in solution in body fluid. In the plasma, only 50% of calcium is present as ionized calcium; the remainder forms a complex with protein—mostly albumin (40%)—or anions, including citrate, bicarbonate, and phosphate (10%). The normal total plasma (or serum) calcium concentration is 9-10.3 mg/dL. It is ionized calcium (normal: 4.7-5.3 mg/dL) which, under physiologic regulation, is necessary for muscle contraction and nerve function. When albumin is low, correction of serum calcium concentration is needed to accurately reflect the ionized calcium concentration. When albumin is low, serum Ca²⁺ concentration is depressed in a ratio of 0.8-1 mg of Ca²⁺ to 1 g of albumin.

Calcium-sensing protein, a receptor-like protein with the special function of detecting extracellular calcium ion concentrations, has been identified in parathyroid cells and in the kidney. Some diseases (eg, familial hypocalcemia and familial hypocalciuric hypercalcemia) associated with disturbed calcium metabolism are due to functional defects of this protein (Table 21-5).

HYPOCALCEMIA

- Often mistaken as a neurologic disorder.
- Check for insufficient action of PTH or vitamin D as well as magnesium depletion.

General Considerations

Development of hypocalcemia implies insufficient action of PTH or active vitamin D. Important causes of hypocalcemia are listed in Table 21-8.

The most common cause of hypocalcemia is renal failure, in which decreased production of active vitamin D₃ and hyperphosphatemia both play a role. (See Chapter 22.) Some cases of primary hypoparathyroidism are due to mutation of calcium-sensing protein in which inappropriate suppression of PTH release leads to hypocalcemia. Hypocalcemia in pancreatitis is also a marker for severe disease (see Chapter 15).

Clinical Findings

A. Symptoms and Signs

Hypocalcemia increases excitation of nerve and muscle cells, primarily affecting the neuromuscular and cardiovascular systems. Extensive spasm of skeletal muscle causes cramps and tetany. Laryngospasm with stridor can obstruct the airway. Convulsions can occur as well as paresthesias of lips and extremities and abdominal pain. Chvostek's sign (contraction of the facial muscle in response to tapping the facial nerve anterior to the ear) and Trousseau's sign (carpal spasm occurring after occlusion of the brachial artery with a blood pressure cuff for 3 minutes) are usually readily elicited. Prolongation of the QT interval (due to lengthened ST segment) predisposes to the development of ventricular arrhythmias. In chronic hypoparathyroidism, cataracts and calcification of basal ganglia of the brain may appear. (See Hypoparathyroidism, Chapter 26.)

B. Laboratory Findings

Serum calcium concentration is low (< 9 mg/dL). Serum phosphate is usually elevated in hypoparathyroidism or end-stage renal failure, whereas it is suppressed in early-stage renal failure or vitamin D deficiency.

Serum magnesium concentration is commonly low, and hypomagnesemia reduces both parathyroid hormone release and tissue responsiveness to parathyroid hormone, causing hypocalcemia. In respiratory alkalosis, total serum calcium is normal but ionized calcium is low. The ECG shows a prolonged QT interval.

Treatment*

*See also Chapter 26 for discussion of the treatment of hypoparathyroidism.

A. Severe, Symptomatic Hypocalcemia

In the presence of tetany, arrhythmias, or seizures, calcium gluconate 10% (10-20 mL) administered intravenously over 10-15 minutes is indicated. Because of the short duration of action, calcium infusion is usually required. Ten to 15 milligrams of calcium per kilogram body weight, or six to eight 10-mL vials of 10% calcium gluconate (558-744 mg of calcium), is added to 1 L of D₅W and infused over 4-6 hours. By monitoring the serum calcium level frequently (every 4-6 hours), the infusion

rate is adjusted to maintain the serum calcium level at 7-8.5 mg/dL.

B. Asymptomatic Hypocalcemia

Oral calcium (1-2 g) and vitamin D preparations ([Table 26-10](#)) are used. Calcium carbonate is well tolerated and less expensive than many other calcium tablets. The low serum Ca^{2+} associated with low serum albumin concentration does not require replacement therapy. If serum Mg^{2+} is low, therapy must include replacement of magnesium, which by itself usually will correct hypocalcemia.

Zivin JR et al: Hypocalcemia: a pervasive metabolic abnormality in the critically ill. Am J Kidney Dis 2001;37:689. [\[PMID: 11273867\]](#)

HYPERCALCEMIA

Essentials of Diagnosis

- Primary hyperparathyroidism and malignancy-associated hypercalcemia are the most common causes.
- Hypercalciuria usually precedes hypercalcemia.
- Low serum phosphate level may be suggestive of high PTH or PTHrP.

General Considerations

Important causes of hypercalcemia are listed in [Table 21-9](#). Primary hyperparathyroidism is the most common cause of hypercalcemia in ambulatory patients. Tumor production of PTH-related protein is the commonest paraneoplastic endocrine syndrome, accounting for most cases of hypercalcemia in inpatients. The neoplasm is clinically apparent in nearly all cases when the hypercalcemia is detected, and the prognosis is poor. Chronic hypercalcemia (over 6 months) or some manifestation such as nephrolithiasis suggests a benign cause. Primary hyperparathyroidism and malignancy account for 90% of all cases of hypercalcemia.

Milk-alkali syndrome, which had become rare with the advent of nonabsorbable antacid therapy for ulcer disease, should be considered as a cause of hypercalcemia with the current popularity of calcium ingestion for osteoporosis prevention. In the milk-alkali syndrome, massive calcium and vitamin D ingestion can cause hypercalcemic nephropathy. Because of the decreased GFR, retention of the alkali in the calcium antacid occurs and causes metabolic alkalosis, which can be worsened by the vomiting associated with this disorder.

Hypercalcemia also causes nephrogenic diabetes insipidus. Development of polyuria is mediated through activation of calcium-sensing receptors in collecting ducts. Volume depletion further worsens hypercalcemia.

Clinical Findings

A. Symptoms and Signs

Symptoms of hypercalcemia irrespective of cause are constipation and polyuria. The focus of the history and physical examination should be on the duration of the process of hypercalcemia and evidence for a neoplasm. Symptoms usually occur if the serum calcium is above 12 mg/dL and tend to be more severe if hypercalcemia develops acutely.

Interestingly, polyuria is absent in hypercalcemia in familial hypocalciuric hypercalcemia, in which function of calcium-sensing protein is altered in the kidney as well. A variety of neurologic symptoms also are observed. Stupor, coma, and azotemia may develop in severe hypercalcemia. Ventricular extrasystoles and idioventricular rhythm occur and can be accentuated by digitalis.

B. Laboratory Findings

A significant elevation of serum calcium is seen; the level must be interpreted in relation to the serum albumin level. The highest serum calcium levels (> 15 mg/dL) generally occur in malignancy. More than 200 mg/d of urinary calcium excretion suggests hypercalciuria; less than 100 mg/d, hypocalciuria. Hypercalciuric patients—such as those with malignancy or those receiving oral active vitamin D therapy—may easily develop hypercalcemia in case of volume depletion. Serum phosphate may or may not be low, depending on the cause.

The ECG shows a shortened QT interval. Measurements of PTH and PTH-related protein (PTHrP) help distinguish between hyperparathyroidism (elevated PTH) and malignancy-associated hypercalcemia (elevated PTHrP).

Treatment

Until the primary disease can be brought under control, renal excretion of calcium with resultant decrease in serum calcium concentration is promoted. Excretion of Na^+ is accompanied by excretion of Ca^{2+} .

The tendency in hypercalcemia is toward volume depletion from nephrogenic diabetes insipidus. Therefore, establishing euvolemia and inducing natriuresis by giving saline with furosemide is the emergency treatment of choice. In dehydrated patients with normal cardiac and renal function, 0.45% saline or 0.9% saline can be given rapidly (250-500 mL/h). Intravenous furosemide (20-40 mg every 2 hours) prevents volume overload and enhances Ca^{2+} excretion. Thiazides can actually worsen hypercalcemia (as can furosemide if inadequate saline is given). In the treatment of hypercalcemia of malignancy, bisphosphonates are safe and effective in more than 95% of patients and are the mainstay of treatment. In emergency cases, dialysis with low or no calcium dialysate may be needed. See [Chapter 40](#) for a discussion of the treatment of hypercalcemia of malignancy and [Chapter 26](#) for a discussion of the treatment of hypercalcemia of hyperparathyroidism.

■ DISORDERS OF PHOSPHORUS CONCENTRATION

Phosphate is important in the body as a constituent of bone and is crucial in cellular energy transfer and metabolism. Phosphate occupies 1% of body weight, and 80% of it is combined with calcium in bones and teeth. Only 10% is incorporated into a variety of organic compounds, and 10% is combined with proteins, lipids, carbohydrates, and other compounds in muscle and blood. Organic phosphate is the principal intracellular anion. In plasma, phosphate is mainly present as inorganic phosphate, and this fraction is very small ($< 0.2\%$ of total phosphate). However, body phosphate metabolism is regulated through plasma inorganic phosphate. Important determinants of plasma inorganic phosphate concentration are its intestinal absorption, renal excretion, and shift between the intracellular and extracellular spaces. Intestinal absorption of phosphate is facilitated by active vitamin D. Parathyroid hormone stimulates phosphate release from bone and suppresses proximal tubular reabsorption of phosphate, leading to hypophosphatemia and to bone phosphate store depletion if hypersecretion continues. Renal proximal tubular reabsorption of phosphate is decreased by volume expansion, glucocorticoid administration, and proximal tubular dysfunction, such as occurs in Fanconi's syndrome due to myeloma or other diseases. Growth hormone, on the other hand, augments proximal tubular reabsorption of phosphate. Recently, additional phosphaturic hormones such as phosphatonin, fibroblast growth factor 23, have been identified.

Cellular phosphatonin uptake is stimulated by various factors and conditions, including alkalemia, insulin, epinephrine, feeding, hungry bone syndrome, and accelerated cell proliferation.

Phosphorus metabolism and homeostasis are intimately related to calcium metabolism. See sections on metabolic bone disease in [Chapter 26](#).

HYPOPHOSPHATEMIA

Essentials of Diagnosis

- Severe hypophosphatemia may cause tissue hypooxygenation and even rhabdomyolysis.

- Renal loss of phosphate can be recognized by urinary phosphate excretion and more precisely by calculating TmP/GFR.
- PTH is one of the major factors that decrease TmP/GFR, leading to renal loss of phosphate.

General Considerations

Hypophosphatemia may occur in the presence of normal phosphate stores. Serious depletion of body phosphate stores may exist with low, normal, or high concentrations of phosphorus in serum. Leading causes of hypophosphatemia are listed in [Table 21-10](#).

In the presence of severe hypophosphatemia (1 mg/dL or less), affinity of hemoglobin for oxygen is increased through a decrease in the erythrocyte 2,3-diphosphoglycerate concentration. This impairs tissue oxygenation and thus cell metabolism, which underlies the effects of hypophosphatemia such as muscle weakness or even rhabdomyolysis.

Severe hypophosphatemia is common and multifactorial in alcoholic patients. In acute alcohol withdrawal, increased plasma insulin and epinephrine along with respiratory alkalosis promote intracellular shift of phosphate. Vomiting, diarrhea, and poor dietary intake contribute to hypophosphatemia. Chronic alcohol use results in a decrease in the renal threshold of phosphate excretion. This renal tubular dysfunction reverses after a month of abstinence. Patients with chronic obstructive pulmonary disease and asthma commonly have hypophosphatemia, attributed to xanthine derivatives causing shifts of phosphate intracellularly and the phosphaturic effects of beta-adrenergic agonists, loop diuretics, xanthine derivatives, and corticosteroids. Refeeding or glucose administration to phosphate-depleted patients may cause fatal hypophosphatemia.

Hypophosphatemia is a potent stimulator of 1 α -hydroxylation of vitamin D in the kidney to form active vitamin D. However, in oncogenic osteomalacia, which accompanies various mesenchymal tumors, activation of vitamin D is suppressed in spite of hypophosphatemia. This suppression may be due to overproduction of phosphatonin, which has been recently identified as fibroblast growth factor 23 (FGF23).

Clinical Findings

A. Symptoms and Signs

Acute, severe hypophosphatemia (0.1-0.2 mg/dL) can lead to acute hemolytic anemia with increased erythrocyte fragility, increased susceptibility to infection from impaired chemotaxis of leukocytes, and platelet dysfunction with petechial hemorrhages. Rhabdomyolysis, encephalopathy (irritability, confusion, dysarthria, seizures, and coma), and heart failure are uncommon but serious manifestations.

Chronic severe depletion may be manifested by anorexia, pain in muscles and bones, and fractures.

B. Laboratory Findings

Evaluation of urinary phosphate excretion is a useful clue to the diagnosis of hypophosphatemia. A spot urine with > 20 mg/dL of phosphate suggests renal phosphate loss. Tubular phosphate reabsorption can be assessed by the maximal tubular reabsorption rate (TmP/GFR).

$$\frac{\text{TmP}}{\text{GFR}} = \frac{\text{Serum Pi} - (\text{UPi} \times \text{UV})}{\text{GFR}}$$

where serum Pi = serum phosphate concentration

UPi = urine phosphate concentration

UV = urine volume

The normal range of TmP/GFR is 2.5-4.5 mg/dL; higher values indicate urinary phosphate loss. The main factors regulating TmP/GFR are PTH and phosphate intake. Increase of PTH or phosphate intake decreases TmP/GFR, so that more phosphate is excreted into the urine.

In addition to hypophosphatemia, evidence of anemia due to hemolysis may be present (eg, elevated serum lactate dehydrogenase). Rhabdomyolysis results in elevated serum creatine kinase (which contains mostly the MM fraction but also some MB fraction) and, in many cases, myoglobin in the urine. Other values vary according to the cause. Renal glycosuria and hypouricemia together with hypophosphatemia indicate Fanconi's syndrome. In chronic depletion, radiographs and biopsies of bones show changes resembling those of osteomalacia.

Treatment

Treatment is best directed toward prophylaxis by including phosphate in repletion and maintenance fluids. A rapid decline in calcium levels can occur with parenteral administration of phosphate; therefore, when possible, oral replacement of phosphate is preferable. For parenteral alimentation, 620 mg (20 mmol) of phosphorus is required for every 1000 nonprotein kcal to maintain phosphate balance and to ensure anabolic function. A daily ration for prolonged parenteral fluid maintenance is 620-1240 mg (20-40 mmol) of phosphorus. For asymptomatic hypophosphatemia (serum phosphorus 0.7-1 mg/dL), an infusion should provide 279-310 mg (9-10 mmol)/12 h until the serum phosphorus exceeds 1 mg/dL. Since the response to phosphate supplementation is not predictable, frequent monitoring of plasma and urine phosphate is necessary. A magnesium deficit often coexists and should be treated simultaneously. In administering phosphate-containing solutions, serum creatinine and calcium must be monitored to guard against hypocalcemia.

For oral use, phosphate salts are available in skim milk (approximately 1 g [33 mmol]/L). Tablets or capsules of mixtures of sodium and potassium phosphate may be given to provide 0.5-1 g (18-32 mmol) per day.

Contraindications to therapy with phosphate salts include hypoparathyroidism, renal insufficiency, tissue damage and necrosis, and hypercalcemia. When hyperglycemia due to any cause is treated, phosphate accompanies glucose into cells, and hypophosphatemia may ensue.

Subramian R et al: Severe hypophosphatemia: pathophysiologic implications, clinical presentations, and treatment. Medicine 2000;79:1. [\[PMID: 10670405\]](#)

HYPERPHOSPHATEMIA

Essentials of Diagnosis

- Renal failure is the most common cause.
- Hyperphosphatemia in the presence of hypercalcemia imposes a high risk of metastatic calcification.

General Considerations

Renal insufficiency is the main cause of hyperphosphatemia. Other causes are listed in [Table 21-11](#). Children normally have higher serum phosphate levels than adults.

Clinical Findings

A. Symptoms and Signs

The clinical manifestations are those of the underlying disorders (eg, chronic renal failure, hypoparathyroidism). Hyperphosphatemia in chronic renal failure leads to secondary hyperparathyroidism and renal osteodystrophy.

B. Laboratory Findings

In addition to elevated phosphate, other blood chemistry values are those characteristic of the underlying disease.

Treatment

Treatment is that of the underlying disease and of associated hypocalcemia if present. In acute and chronic renal failure, dialysis will reduce serum phosphate. Absorption of phosphate can be reduced by administration of calcium carbonate, 0.5-1.5 g three times daily with meals (500 mg tablets). This approach is preferred to

the traditional use of aluminum hydroxide because of concerns about aluminum toxicity. Another phosphate binder is sevelamer hydrochloride. Since this agent does not contain calcium or aluminum, it may be especially useful for patients with hypercalcemia or uremia.

■ **DISORDERS OF MAGNESIUM CONCENTRATION**

About 50% of total body magnesium exists in the insoluble state in bone. Only 5% is present as extracellular cation; the remaining 45% is contained in cells as intracellular cation. The normal plasma concentration is 1.5-2.5 meq/L, with about one-third bound to protein and two-thirds existing as free cation. Excretion of magnesium ion is via the kidney. Normally, about 3% of magnesium filtered by the glomerulus is excreted in urine.

Magnesium is an important activator ion, participating in the function of many enzymes involved in phosphate transfer reactions. Magnesium exerts physiologic effects on the nervous system resembling those of calcium. Magnesium acts directly upon the myoneural junction.

Altered concentration of Mg²⁺ in the plasma usually provokes an associated alteration of Ca²⁺. Hypermagnesemia suppresses secretion of parathyroid hormone with consequent hypocalcemia. Severe and prolonged magnesium depletion impairs secretion of PTH with consequent hypocalcemia. Hypomagnesemia may impair end-organ response to PTH as well.

HYPOMAGNESEMIA

- Serum concentration of magnesium may not be decreased even in the presence of magnesium depletion. Check urinary magnesium excretion if magnesium depletion is suspected.
- Causes neurologic symptoms, arrhythmias, and hypoparathyroidism.
- Impairs release of PTH.

General Considerations

Causes of hypomagnesemia are given in Table 21-12. Nearly half of hospitalized patients in whom serum electrolytes are ordered have unrecognized hypomagnesemia. Common causes include use of large volumes of intravenous fluids, diuretics, cisplatin in cancer patients (with concomitant hypokalemia), and administration of nephrotoxic agents such as aminoglycosides and amphotericin B. Molecular mechanisms of magnesium wasting have been revealed in some hereditary disorders.

Normomagnesemia does not exclude magnesium depletion because only 1% of total body magnesium is in the ECF. When magnesium depletion is suspected, urinary magnesium excretion should be checked.

Clinical Findings

A. Symptoms and Signs

Common symptoms are weakness, muscle cramps, and tremor. There is marked neuromuscular and central nervous system hyperirritability, with tremors, athetoid movements, jerking, nystagmus, and a positive Babinski response. There may be hypertension, tachycardia, and ventricular arrhythmias. Confusion and disorientation may be prominent features.

B. Laboratory Findings

Urinary excretion of magnesium exceeding 10-30 mg/d or a fractional excretion more than 2% indicates renal magnesium wasting. In calculating fractional excretion of magnesium, since only 30% is protein-bound, it follows that 70% of circulating magnesium is filtered by the glomerulus. In addition to hypomagnesemia, hypocalcemia and hypokalemia are often present. The ECG shows a prolonged QT interval, due to lengthening of the ST segment. Parathyroid hormone secretion is often suppressed (see Hypocalcemia, above).

Treatment

Treatment consists of the use of intravenous fluids containing magnesium as chloride or sulfate, 240-1200 mg/d (10-50 mmol/d) during the period of severe deficit, followed by 120 mg/d (5 mmol/d) for maintenance. Magnesium sulfate may also be given intramuscularly in a dosage of 200-800 mg/d (8-33 mmol/d) in four divided doses. Serum levels must be monitored and dosage adjusted to keep the concentration from rising above 2.5 mmol/L. K⁺ and Ca²⁺ may be required as well. Magnesium oxide, 250-500 mg by mouth two to four times daily, is useful for repleting stores in those with chronic hypomagnesemia. Hypokalemia and hypocalcemia of hypomagnesemia do not recover without magnesium supplementation.

Konrad M et al: Recent advances in molecular genetics of hereditary magnesium-losing disorders. J Am Soc Nephrol 2003;14:249. [PMID: 12506158]

HYPERMAGNESEMIA

- Almost always associated with renal insufficiency and a history of chronic intake of magnesium-containing drugs.

General Considerations

Magnesium excess is almost always the result of renal insufficiency and the inability to excrete what has been taken in from food or drugs, especially antacids and laxatives.

Clinical Findings

A. Symptoms and Signs

Muscle weakness, decreased deep tendon reflexes, mental obtundation, and confusion are characteristic manifestations. Weakness—even flaccid paralysis—and hypotension are noted. There may be respiratory muscle paralysis or cardiac arrest.

B. Laboratory Findings

Serum Mg²⁺ is elevated. In the common setting of renal insufficiency, concentrations of BUN and of serum creatinine, phosphate, and uric acid are elevated; serum K⁺ may be elevated. Serum Ca²⁺ is often low. The ECG shows increased PR interval, broadened QRS complexes, and peaked T waves, probably related to associated hyperkalemia.

Treatment

Treatment is directed toward alleviating renal insufficiency. Calcium acts as an antagonist to Mg^{2+} and may be given intravenously as calcium chloride, 500 mg or more at a rate of 100 mg (4.5 mmol)/min. Hemodialysis or peritoneal dialysis may be indicated.

Long-term use of magnesium containing drugs, such as magnesium hydroxylate and magnesium sulfate, should be avoided in patients with renal insufficiency.

■ HYPEROSMOLAR DISORDERS & OSMOLAR GAPS

HYPEROSMOLALITY WITH TRANSIENT OR NO SIGNIFICANT SHIFT IN WATER

Urea and alcohol are two substances that readily cross cell membranes and can produce hyperosmolality. Because of its permeant nature, urea has little effect on the shift of water across the cell membrane. Alcohol quickly equilibrates between intracellular and extracellular water, adding 22 mosm/L for every 1000 mg/L. This measured hyperosmolality does not produce symptoms by itself because of the equilibrium described, but in any case of stupor or coma in which measured osmolality exceeds that calculated from values of serum Na^+ and glucose and BUN, ethanol intoxication should be considered as a possible explanation of the discrepancy (osmolar gap). Toxic alcohol ingestion, particularly methanol or ethylene glycol, also causes an osmolar gap characterized by anion gap metabolic acidosis ([Chapter 39](#)).

The combination of anion gap metabolic acidosis and an osmolar gap exceeding 10 mosm/kg is not specific for toxic alcohol ingestion. Nearly half of patients with alcoholic ketoacidosis or lactic acidosis have similar findings, caused in part by elevations of endogenous glycerol, acetone, and acetone metabolites.

Delaney MF et al: Diabetic ketoacidosis and hyperglycemic hyperosmolar nonketotic syndrome. *Endocrinol Metab Clin North Am* 2000;29:683. [\[PMID: 11149157\]](#)

Magee MF et al: Management of decompensated diabetes. Diabetic ketoacidosis and hyperglycemic hyperosmolar syndrome. *Crit Care Clin* 2001;17:75. [\[PMID: 11219236\]](#)

HYPEROSMOLALITY ASSOCIATED WITH SIGNIFICANT SHIFTS IN WATER

Increased concentrations of solutes that do not readily enter cells produce a shift of water from the intracellular space to effect a true intracellular dehydration. Sodium and glucose are the solutes commonly involved. In these instances, the hyperosmolality does produce symptoms.

Clinical symptoms are mainly referred to the central nervous system. The severity of symptoms depends on the degree of hyperosmolality and rapidity of development. In acute hyperosmolality, symptoms of somnolence and confusion can appear when the osmolality exceeds 320-330 mosm/L, and coma, respiratory arrest, and death when it exceeds 340-350 mosm/L.

■ ACID-BASE DISORDERS

About 1 meq/L/kg/d of nonvolatile acid (H^+) is produced, together with volatile acid (CO_2), by whole body metabolism. Body fluid pH, however, remains relatively constant at about 7.40. This constancy of body fluid pH is achieved by removal of CO_2 and H^+ through lung and kidney, respectively.

In order to assess a patient's acid-base status, measurement of arterial pH, partial pressure of carbon dioxide (PCO_2), and plasma bicarbonate (HCO_3^-) is needed. Blood gas analyzers directly measure pH and PCO_2 , and the HCO_3^- value is calculated from the Henderson-Hasselbalch equation:

$$\text{pH} = 6.1 + \log \frac{\text{HCO}_3^-}{0.3 \times \text{Pco}_2}$$

The total venous CO_2 measurement is a more direct determination of HCO_3^- . Because of the dissociation characteristics of carbonic acid (H_2CO_3) at body pH, dissolved CO_2 is almost exclusively in the form of HCO_3^- , and for clinical purposes the total carbon dioxide content is equivalent (± 3 meq/L) to the HCO_3^- concentration:

If precise measurements of oxygenation are not needed or if oxygen saturation obtained from the pulse oximeter is adequate, venous blood gases generally provide useful information for assessment of acid-base balance and can be used interchangeably with arterial blood gases since the arteriovenous differences in pH and PCO_2 are small and relatively constant. Venous blood pH is usually 0.03-0.04 units lower than that of arterial blood, and venous blood PCO_2 is 7 or 8 mm Hg higher.

Calculated HCO_3^- concentration in venous blood is at most 2 meq/L higher than that of arterial blood. An important exception to the rule of interchangeability between arterial and venous blood gases for determination of acid-base balance is during cardiopulmonary arrest. In this setting, arterial pH may be 7.41 and venous pH 7.15, and arterial blood PCO_2 can be 32 mm Hg with a venous blood PCO_2 of 74 mm Hg.

Types of Acid-Base Disorders

There are two types of acid-base disorders: respiratory and metabolic. Primary respiratory disorders affect blood acidity by causing changes in PCO_2 , and primary metabolic disorders are caused by disturbances in the HCO_3^- concentration. The primary disturbances are usually accompanied by compensatory changes; however, even though these changes attenuate a pH shift from the normal value (7.40), they do not fully compensate for the primary acid-base disorders even if the disorders are chronic. Therefore, if the pH is less than 7.40, the primary process is acidosis (either respiratory or metabolic). If the pH is higher than 7.40, the primary process is either respiratory or metabolic alkalosis. The presence of one disorder with its appropriate compensatory change is a simple disorder.

Mixed Acid-Base Disorders

The presence of more than one simple disorder (not compensatory) is a mixed disorder. Double or triple disorders can coexist but not quadruple ones, since simultaneous respiratory acidosis and alkalosis are not possible.

Clinicians frequently find it difficult to decide if a mixed disorder is present. One useful scheme is to determine if the degree of compensation for the primary disorder is appropriate ([Table 21-13](#)). In respiratory disorders, if the magnitude of compensation in HCO_3^- level differs from that which is predicted, the patient has a mixed disorder. Therefore, superimposed metabolic acidosis will decrease HCO_3^- to lower than the predicted level, and a metabolic alkalosis will increase HCO_3^- over the predicted value. For example, a patient with chronic respiratory acidosis and PCO_2 of 60 mm Hg should have a HCO_3^- of 31 meq/L (assuming that normal HCO_3^- is 24 meq/L). If the HCO_3^- is 25 meq/L, a superimposed metabolic acidosis exists, and if the HCO_3^- is 45 meq/L, there is a superimposed metabolic alkalosis. Using data from [Table 21-13](#), similar calculations can be made for primary metabolic disorders.

Furthermore, corrected bicarbonate (cHCO_3^-), calculated from measured HCO_3^- plus the increase in anion gap (see below), is useful to assess the superimposed metabolic alkalosis or normal anion gap metabolic acidosis. In increased anion gap acidosis, there must be a mole for mole decrease in HCO_3^- as anion gap decreases. Therefore, an HCO_3^- value higher or lower than normal (24 meq/L) indicates the concomitant presence of metabolic alkalosis or normal anion gap acidosis, respectively.

STEP-BY-STEP ANALYSIS OF ACID-BASE STATUS

Step 1: Determine the primary (or main) disorder--whether it is metabolic or respiratory--from blood pH, HCO_3^- , and Pco_2 values.

Step 2: Determine the presence of mixed acid-base disorders by calculating the range of compensatory responses (Table 21-13).

Step 3: Calculate the anion gap (Table 21-15).

Step 4: Calculate the HCO_3^- concentration if the anion gap is increased (see above).

Step 5: Examine the patient to determine whether the clinical signs are compatible with the acid-base analysis thus obtained.

RESPIRATORY ACIDOSIS

Respiratory acidosis results from decreased alveolar ventilation and subsequent hypercapnia. Pulmonary as well as nonpulmonary disorders can cause hypoventilation. The clinician must be mindful of readily reversible causes of respiratory acidosis, especially opioid-induced central nervous system depression.

Acute respiratory failure is associated with severe acidosis and only a small increase in the plasma bicarbonate. After 6-12 hours, the primary increase in PCO_2 evokes a renal compensatory response to generate more HCO_3^- , which tends to ameliorate the respiratory acidosis. This usually takes several days to complete.

Chronic respiratory acidosis is generally seen in patients with underlying lung disease, such as chronic obstructive disease. Urinary excretion of acid in the form of NH_4^+ and Cl^- ions results in the characteristic hypochloremia of chronic respiratory acidosis. When chronic respiratory acidosis is corrected suddenly, especially in patients who receive mechanical ventilation, there is a 2- to 3-day lag in renal bicarbonate excretion, resulting in posthypercapnic metabolic alkalosis.

Clinical Findings

A. Symptoms and Signs

With acute onset, there is somnolence and confusion, and myoclonus with asterixis may be seen. Coma from CO_2 narcosis ensues. Severe hypercapnia increases cerebral blood flow and cerebrospinal fluid pressure. Signs of increased intracranial pressure (papilledema, pseudotumor cerebri) may be seen.

B. Laboratory Findings

Arterial pH is low, and PCO_2 is increased. Serum HCO_3^- is elevated, but not enough to completely compensate for the hypercapnia. If the disorder is chronic, hypochloremia is seen.

Treatment

Since drug overdose is an important reversible cause of acute respiratory acidosis, administration of naloxone, 0.04-2 mg intravenously (see [Chapter 39](#)) is given to all such patients if no obvious cause for respiratory depression is present. In all forms of respiratory acidosis, treatment is directed at the underlying disorder to improve ventilation.

RESPIRATORY ALKALOSIS

Respiratory alkalosis, or hypocapnia, occurs when hyperventilation reduces the PCO_2 , which increases the pH. The most common cause of respiratory alkalosis is hyperventilation syndrome ([Table 21-14](#)), but bacterial septicemia and cirrhosis are other common causes. Symptoms in acute respiratory alkalosis are related to decreased cerebral blood flow induced by the disorder. Pregnancy is another cause of chronic respiratory alkalosis, probably from progesterone stimulation of the respiratory center, with an average PCO_2 of 30 mm Hg.

Determination of appropriate compensatory changes in the HCO_3^- is useful to sort out the presence of an associated metabolic disorder (see above under Mixed Acid-Base Disorders). As in respiratory acidosis, the changes in HCO_3^- values are greater if the respiratory alkalosis is chronic ([Table 21-13](#)). While serum HCO_3^- is frequently below 15 meq/L in metabolic acidosis, it is unusual to see such a low level in respiratory alkalosis, and its presence would imply a superimposed (noncompensatory) metabolic acidosis.

Clinical Findings

A. Symptoms and Signs

In acute cases (hyperventilation), there is light-headedness, anxiety, paresthesias, numbness about the mouth, and a tingling sensation in the hands and feet. Tetany occurs in more severe alkalosis from a fall in ionized calcium. In chronic cases, findings are those of the responsible condition.

B. Laboratory Findings

Arterial blood pH is elevated, and PCO_2 is low. Serum bicarbonate is decreased in chronic respiratory alkalosis.

Treatment

Treatment is directed toward the underlying cause. In acute hyperventilation syndrome from anxiety, rebreathing into a paper bag will increase the PCO_2 . The processes are usually self-limited since muscle weakness caused by hyperventilation-induced alkalemia will suppress ventilation. Sedation may be necessary if the process persists. Rapid correction of chronic respiratory alkalosis may result in metabolic acidosis as PCO_2 is increased in the setting of previous compensatory decrease in HCO_3^- .

METABOLIC ACIDOSIS

Essentials of Diagnosis

- Decreased HCO_3^- with acidemia.
- Classified into high anion gap acidosis and normal anion gap acidosis.
- The highest anion gap acidoses are seen in lactic acidosis, ketoacidosis, or toxins.
- Normal anion gap acidosis is mainly caused by gastrointestinal HCO_3^- loss or renal tubular acidosis. Urinary anion gap may help distinguish between these causes.

General Considerations

The hallmark of metabolic acidosis is decreased HCO_3^- , seen also in respiratory alkalosis (see above), but the pH distinguishes between the two disorders. Calculation of the anion gap is useful in determining the cause of the metabolic acidosis ([Table 21-15](#)). The anion gap represents the difference between readily measured anions and cations.

In plasma,

$$\text{Na}^+ + \text{Unmeasured cations} = \text{HCO}_3^- + \text{Cl}^- + \text{Unmeasured anions}$$

$$\text{Anion gap} = \text{Na}^+ - (\text{HCO}_3^- + \text{Cl}^-)$$

The major unmeasured cations are calcium (1 meq/L), magnesium (2 meq/L), gamma globulins, and potassium (4 meq/L). The major unmeasured anions are negatively charged albumin (2 meq/L per g/dL), phosphate (2 meq/L), sulfate (1 meq/L), lactate (1-2 meq/L), and other organic anions (3-4 meq/L). Traditionally, the normal anion gap has been 12 ± 4 meq/L. With the current generation of autoanalyzers, the reference range may be lower (6 ± 1 meq/L), primarily from an increase in Cl^- values. Despite its usefulness, the serum anion gap can be misleading. Non-acid-base disorders that may contribute to an error in anion gap interpretation include hypoalbuminemia (see below), antibiotic administration (eg, carbenicillin is an unmeasured anion; polymyxin is an unmeasured cation), hypernatremia, or hyponatremia.

Decreased Anion Gap

A decreased anion gap can occur because of a reduction in unmeasured anions or an increase in unmeasured cations.

A. Decreased Unmeasured Anions

If the sodium concentration remains normal but HCO_3^- and Cl^- increase, the anion gap will decrease. This is seen when there are decreased unmeasured anions, especially in hypoalbuminemia. For every 1-g/dL decline in serum albumin, a 2-meq/L decrease in anion gap will occur.

B. Increased Unmeasured Cations

If the sodium concentration falls because of addition of unmeasured cations but HCO_3^- and Cl^- remain unchanged, the anion gap will decrease. This is seen in (1) severe hypercalcemia, hypermagnesemia, or hyperkalemia; (2) IgG myeloma, where the immunoglobulin is cationic in 70% of cases; and (3) lithium toxicity.

Jurado RL et al: Low anion gap. South Med J 1998;91:624. [PMID: 9671832]

Increased Anion Gap Acidosis (Increased Unmeasured Anions)

The hallmark of this disorder is that metabolic acidosis (thus low HCO_3^-) is associated with normal serum Cl^- , so that the anion gap increases. Normochloremic metabolic acidosis generally results from addition to the blood of nonchloride acids such as lactate, acetoacetate, β -hydroxybutyrate, and exogenous toxins. An exception is uremia, with underexcretion of organic acids and anions.

A. Lactic Acidosis

Lactic acid is formed from pyruvate in anaerobic glycolysis. Therefore, most of the lactate is produced in tissues with high rates of glycolysis, such as gut (responsible for over 50% of lactate production), skeletal muscle, brain, skin, and erythrocytes. Normally, lactate levels remain low (1 meq/L) because of metabolism of lactate principally by the liver through gluconeogenesis or oxidation via the Krebs cycle. Furthermore, the kidneys metabolize about 30% of lactate.

In lactic acidosis, lactate levels are at least 4-5 meq/L but commonly 10-30 meq/L. The mortality rate exceeds 50%. There are two basic types of lactic acidosis, both associated with increased lactate production and decreased lactate utilization. Type A is characterized by hypoxia or decreased tissue perfusion, whereas in type B there is no clinical evidence of hypoxia.

Type A (hypoxic) lactic acidosis is the more common type, resulting from poor tissue perfusion; cardiogenic, septic, or hemorrhagic shock; and carbon monoxide or cyanide poisoning. These conditions not only cause lactic acid production to increase peripherally but, more importantly, hepatic metabolism of lactate to decrease as liver perfusion declines. In addition, severe acidosis impairs the ability of the liver to extract the perfused lactate.

Type B lactic acidosis may be due to metabolic causes, such as diabetes, ketoacidosis, liver disease, renal failure, infection, leukemia, or lymphoma, or it may occur as a result of toxicity from ethanol, methanol, salicylates, isoniazid, or metformin. Propylene glycol, used as a vehicle for intravenous agents such as nitroglycerin, etomidate, and high-dose diazepam, may cause lactic acidosis from liver metabolism. Nutritional problems are important causes of lactic acidosis. Parenteral nutrition without thiamine causes severe refractory lactic acidosis from the deranged metabolism of pyruvate. Patients with short bowel syndrome may develop D-lactic acidosis with encephalopathy due to carbohydrate malabsorption in the intestine and subsequent fermentation by colonic bacteria.

AIDS without AIDS-related lymphoma is associated with type B lactic acidosis. Treatment of HIV patients with nucleoside analog reverse transcriptase inhibitors may cause lactic acidosis due to mitochondrial toxicity.

Idiopathic lactic acidosis, usually in debilitated patients, has an extremely high mortality rate. (For treatment of lactic acidosis, see below and [Chapter 27](#).)

B. Diabetic Ketoacidosis

This metabolic abnormality is characterized by hyperglycemia and metabolic acidosis ($\text{pH} < 7.25$ or plasma bicarbonate < 16 meq/L). Anion gap metabolic acidosis is the acid-base disturbance generally ascribed to diabetic ketoacidosis:

where B^- is β -hydroxybutyrate or acetoacetate. The anion gap should be calculated from the serum electrolytes as measured, since correction of the serum sodium for the dilutional effect of hyperglycemia will incorrectly exaggerate the anion gap. The increased anion gap is due to hyperketonemia (acetoacetate and β -hydroxybutyrate) and at times to an increase in serum lactate secondary to reduced tissue perfusion and increased anaerobic metabolism. If a rise in anion gap from normal is equal to a fall in HCO_3^- , a diagnosis of simple metabolic acidosis can be made. However, the presence of concurrent metabolic alkalosis or normal anion gap metabolic acidosis is suggested if the value of the measured HCO_3^- plus the increase in anion gap (cHCO_3^-) is higher or lower than the normal value for HCO_3^- , respectively.

During the recovery phase of diabetic ketoacidosis, anion gap acidosis can be transformed into hyperchloremic non-anion gap acidosis. The mechanism for this is as follows: As GFR increases from NaCl therapy of diabetic ketoacidosis, the retention of Cl^- causes a mild decrease in the anion gap from dilution. More importantly, the increased GFR causes the urinary excretion of ketone salts (NaB), which are formed as bicarbonate is consumed:

The kidney reabsorbs ketone anions poorly but can compensate for the loss of anions (and therefore Na^+) by increasing the reabsorption of Cl^- . Conversely, even on presentation, patients with diabetic ketoacidosis and normal renal perfusion may have marked ketonuria, severe metabolic acidosis, and only a mildly increased anion gap. Again, the variable relationship between the rise in the anion gap and the fall in the HCO_3^- can occur with the urinary loss of Na^+ or K^+ salts of β -hydroxybutyrate, which will lower the anion gap without altering the H^+ excretion or the severity of the acidosis. Since Ketostix reacts to acetoacetate, less to acetone, and not at all to the predominant keto acid, β -hydroxybutyrate, the test may become more positive even as the patient improves owing to the metabolism of hydroxybutyrate. Thus, the patient's clinical status and the reduction of the anion gap are better markers of improvement than monitoring the serum acetone test. Conversely, in the presence of concomitant lactic acidosis, a shift in the redox state can increase β -hydroxybutyrate and decrease the readily detectable acetoacetate, thus lowering the nitroprusside reaction.

C. Alcoholic Ketoacidosis

This is a common disorder of chronically malnourished patients who consume large quantities of alcohol daily. Most of these patients have mixed acid-base disorders (10% have a triple acid-base disorder). While decreased HCO_3^- is usual, half the patients may have normal or alkalemic pH. The three types of metabolic acidosis seen in alcoholic ketoacidosis are the following: (1) Ketoacidosis due to β -hydroxybutyrate and acetoacetate excess. (2) Lactic acidosis: Alcohol metabolism increases the NADH:NAD ratio, causing increased production and decreased utilization of lactate. Accompanying thiamin deficiency, which inhibits pyruvate carboxylase, further enhances lactic acid production in many cases. Moderate to severe elevations of lactate (> 6 mmol/L) are seen with concomitant disorders such as sepsis, pancreatitis, or hypoglycemia. (3) Hyperchloremic acidosis from bicarbonate loss in the urine associated with ketonuria (see above). Metabolic alkalosis occurs from volume contraction and vomiting. Respiratory alkalosis results from alcohol withdrawal, pain, or associated disorders such as sepsis or liver disease. Half of the patients have either hypoglycemia or hyperglycemia. When serum glucose levels are greater than 250 mg/dL, the distinction from diabetic ketoacidosis is difficult. The diagnosis of alcoholic ketoacidosis is supported by absence of a diabetic history and by no evidence of glucose intolerance after initial therapy.

D. Toxins

(See also [Chapter 39](#).) Multiple toxins and drugs can increase the anion gap by increasing endogenous acid production. Examples include methanol (metabolized to formic acid), ethylene glycol (glycolic and oxalic acid), and salicylates (salicylic acid and lactic acid), which can cause a mixed disorder of metabolic acidosis with

respiratory alkalosis.

In toluene poisoning, a metabolite hippurate is rapidly excreted by the kidney and may present as a normal anion gap acidosis.

E. Uremic Acidosis

At glomerular filtration rates below 20 mL/min, the inability to excrete H^+ with retention of acid anions such as PO_4^{3-} and SO_4^{2-} results in an increased anion gap acidosis, which rarely is severe. The unmeasured anions "replace" HCO_3^- (which is consumed as a buffer). Hyperchloremic normal anion gap acidosis may be seen in milder cases of renal insufficiency.

Normal Anion Gap Acidosis (Table 21-16)

The hallmark of this disorder is that the low HCO_3^- of metabolic acidosis is associated with hyperchloremia, so that the anion gap remains normal. The most common causes are gastrointestinal HCO_3^- loss and defects in renal acidification (renal tubular acidoses). The urinary anion gap can differentiate between these two common causes (see below).

A. Gastrointestinal HCO_3^- Loss

Bicarbonate is secreted in multiple areas in the gastrointestinal tract. Small bowel and pancreatic secretions contain large amounts of HCO_3^- . Therefore, massive diarrhea or pancreatic drainage can result in HCO_3^- loss because of increased HCO_3^- secretion and decreased absorption. Hyperchloremia occurs because the ileum and colon secrete HCO_3^- in a one-to-one exchange for Cl^- by countertransport. The resultant volume contraction causes further increased Cl^- retention by the kidney in the setting of decreased anion, HCO_3^- . Patients with ureterosigmoidostomies can develop hyperchloremic metabolic acidosis because the colon secretes HCO_3^- in the urine in exchange for Cl^- .

B. Renal Tubular Acidosis

In renal tubular acidosis, the defect is either inability to excrete H^+ (inadequate generation of new HCO_3^-) or inappropriate reabsorption of HCO_3^- . Four discrete types can be differentiated by the clinical setting, urinary pH, urinary anion gap (see below), and serum K^+ level. Since mutations of $\text{Cl}^-/\text{HCO}_3^-$ exchanger and H^+ -ATPase genes have been recently demonstrated in hereditary distal renal tubular acidosis, further classification depending upon molecular mechanisms may soon become possible.

1. Classic distal renal tubular acidosis (type I)—This disorder is characterized by hypokalemic hyperchloremic metabolic acidosis and is due to selective deficiency in H^+ secretion in the distal nephron. Despite acidosis, urinary pH cannot be acidified and is above 5.5, which retards the binding of H^+ to phosphate ($\text{H}^+ + \text{HPO}_4^{2-} \rightarrow \text{H}_2\text{PO}_4$), and thus inhibits titratable acid excretion. Furthermore, urinary excretion of NH_4^+Cl^- is decreased, and the urinary anion gap is positive (see below). Enhanced K^+ excretion occurs probably because there is less competition from H^+ in the distal nephron transport system. Furthermore, as a response to renal salt wasting, hyperaldosteronism occurs. Nephrocalcinosis and nephrolithiasis frequently accompany this disorder since chronic acidosis decreases tubular calcium reabsorption. The hypercalciuria, alkaline urine, and lowered level of urinary citrate cause calcium phosphate stones and nephrocalcinosis.

2. Proximal renal tubular acidosis (type II)—Proximal renal tubular acidosis is a hypokalemic hyperchloremic metabolic acidosis due to a selective defect in the proximal tubule's ability to adequately reabsorb filtered HCO_3^- . Carbonic anhydrase inhibitors (acetazolamide) can cause proximal renal tubular acidosis. About 90% of filtered HCO_3^- is absorbed by the proximal tubule. The distal nephron has a limited ability to absorb HCO_3^- but becomes overwhelmed and does not function adequately when there is increased delivery. Eventually, distal delivery of filtered HCO_3^- declines because the plasma HCO_3^- level has dropped as a result of progressive urinary HCO_3^- wastage. When the plasma HCO_3^- level drops to 15-18 meq/L, delivery of HCO_3^- drops to the point where the distal nephron is no longer overwhelmed and can regain function. At that point, bicarbonaturia disappears, and urinary pH can be acidic. Thiazide-induced volume contraction can be used to enhance proximal HCO_3^- reabsorption, leading to the decrease in distal HCO_3^- delivery and improvement of bicarbonaturia and renal acidification. The increased delivery of HCO_3^- to the distal nephron also increases K^+ secretion, and hypokalemia results if a patient is loaded with excess HCO_3^- and K^+ is not adequately supplemented. Proximal renal tubular acidosis often exists with other defects of absorption in the proximal tubule, resulting in glucosuria, aminoaciduria, phosphaturia, and uricaciduria. Causes include multiple myeloma with Fanconi's syndrome and nephrotoxic drugs.

3. Renal tubular acidosis of glomerular insufficiency (type III)—When GFR decreases to 20-30 mL/min, ability to generate adequate NH_3 is impaired, with subsequent decreased NH_4^+Cl^- excretion. A normokalemic, hyperchloremic metabolic acidosis ensues. Further reduction in GFR results in increased anion gap acidosis of uremia (see above).

4. Hyporeninemic hypoaldosteronemic renal tubular acidosis (type IV)—Type IV is the only type characterized by hyperkalemic, hyperchloremic acidosis. The defect is aldosterone deficiency or antagonism, which impairs distal nephron Na^+ reabsorption and K^+ and H^+ excretion. Renal salt wasting is frequently present. Relative hypoaldosteronism from hyporeninemia is most commonly found in diabetic nephropathy, tubulointerstitial renal diseases, hypertensive nephrosclerosis, and AIDS. In patients with these disorders, caution must be taken when using drugs that can exacerbate the hyperkalemia, such as angiotensin-converting enzyme inhibitors (which will further reduce aldosterone levels), aldosterone receptor blockers such as spironolactone, and NSAIDs.

C. Dilutional Acidosis

Rapid dilution of plasma volume by 0.9% NaCl may cause a mild hyperchloremic acidosis.

D. Recovery From Diabetic Ketoacidosis

See above.

E. Posthypocapnia

In prolonged respiratory alkalosis, HCO_3^- decreases and Cl^- increases from decreased renal NH_4^+Cl^- excretion. If the respiratory alkalosis is corrected quickly, PCO_2 will increase acutely but HCO_3^- will remain low until the kidneys can generate new HCO_3^- , which generally takes several days. In the meantime, the increased PCO_2 with low HCO_3^- causes metabolic acidosis.

F. Hyperalimentation

Hyperalimentation fluids may contain amino acid solutions that acidify when metabolized, such as arginine hydrochloride and lysine hydrochloride.

Urinary Anion Gap to Assess Hyperchloremic Metabolic Acidosis

Increased renal NH_4^+Cl^- excretion to enhance H^+ removal is a normal physiologic response to metabolic acidosis. NH_3 reacts with H^+ to form NH_4^+ , which is accompanied by the anion Cl^- for excretion. The normal daily urinary excretion of NH_4Cl of about 30 meq can be increased up to 200 meq in response to acid load.

Urinary anion gap from a random urine sample ($[\text{Na}^+ + \text{K}^+] - \text{Cl}^-$) reflects the ability of the kidney to excrete NH_4Cl as in the following equation:

where 80 is the average value for the difference in the urinary anions and cations other than Na^+ , K^+ , NH_3^+ , and Cl^- . Therefore, urinary anion gap is equal to $(80 - \text{NH}_3^+)$, and thus aids in the distinction between gastrointestinal and renal causes of hyperchloremic acidosis. If the cause of the metabolic acidosis is gastrointestinal HCO_3^- loss (diarrhea), renal acidification ability remains normal and NH_4Cl excretion increases in response to the acidosis. The urinary anion gap is negative (eg, -30 meq/L). If the cause is distal renal tubular acidosis, the urinary anion gap is positive (eg, +25 meq/L), since the basic lesion in the disorder is inability of the kidney to excrete H^+ and thus inability to increase NH_4Cl excretion. Urinary pH may not as readily differentiate between the two causes. Despite acidosis, if volume depletion from diarrhea causes inadequate Na^+ delivery to the distal nephron and therefore decreased exchange with H^+ , urinary pH may not be lower than 5.3. In the presence

of this relatively high urine pH, however, H^+ excretion continues due to buffering of NH_3 to NH_4^+ , since the pK of this reaction is as high as 9.1. Potassium depletion, which can accompany diarrhea (and surreptitious laxative abuse), may also impair renal acidification. Thus, when volume depletion is present, the urinary anion gap is a better measurement of ability to acidify the urine than urinary pH.

Clinical Findings

A. Symptoms and Signs

Symptoms of metabolic acidosis are mainly those of the underlying disorder. Compensatory hyperventilation is an important clinical sign and may be misinterpreted as a primary respiratory disorder; when severe, Kussmaul respirations (deep, regular, sighing respirations) are seen.

B. Laboratory Findings

Blood pH, serum HCO_3^- , and PCO_2 are decreased. Anion gap may be normal (hyperchloremic) or increased (normochloremic). Hyperkalemia may be seen (see above).

Treatment

A. Increased Anion Gap Acidosis

Treatment is aimed at the underlying disorder, such as insulin and fluid therapy for diabetes and appropriate volume resuscitation to restore tissue perfusion. The metabolism of lactate will produce HCO_3^- and increase pH. The use of supplemental HCO_3^- is indicated for treatment of hyperkalemia ([Table 21-7](#)) and some forms of normal anion gap acidosis but has been controversial for treatment of increased anion gap metabolic acidosis.

Administration of large amounts of HCO_3^- may have deleterious effects, including hyponatremia and hyperosmolality. Furthermore, intracellular pH may decrease because administered HCO_3^- is converted to CO_2 , which easily diffuses into cells. There, it combines with water to create additional hydrogen ions and worsening of intracellular acidosis. Theoretically, this could impair cellular function, but the clinical significance of this phenomenon is uncertain.

In addition, alkali administration is known to stimulate phosphofructokinase activity, thus exacerbating lactic acidosis via enhanced lactate production. Ketogenesis is also augmented by alkali therapy.

In salicylate intoxication, however, alkali therapy must be started unless blood pH is already alkalinized by respiratory alkalosis, since the increment in pH converts salicylate to more impermeable salicylic acid and thus prevents central nervous system damage. In alcoholic ketoacidosis, thiamine should be given together with glucose to avoid the development of Wernicke's encephalopathy. The amount of HCO_3^- deficit can be calculated as follows:

$$\text{Amount of } \text{HCO}_3^- \text{ deficit} = 0.5 \times \text{Body weight} \times (24 - \text{HCO}_3^-)$$

Half of the calculated deficit should be administered within the first 3-4 hours to avoid overcorrection and volume overload. In methanol intoxication, ethanol has been used as a competitive substrate for alcohol dehydrogenase, which metabolizes methanol to formaldehyde. Recently, direct inhibition of alcohol dehydrogenase by fomepizole has been reported and may be used in near future.

B. Normal Anion Gap Acidosis

([Table 21-16](#).) In distal renal tubular acidosis, supplementation of bicarbonate is necessary since acid accumulates systemically in this disorder. However, in proximal renal tubular acidosis, correction of low serum bicarbonate is sometimes hazardous and unnecessary except in severe cases. If the blood bicarbonate concentration is elevated in response to its administration, and the concentration in the glomerular filtrate exceeds the capacity of the proximal tubule to reabsorb it, a large quantity of bicarbonate is excreted into the urine accompanied by potassium, exacerbating hypokalemia. Thus, potassium should also be given when bicarbonate therapy is indicated in proximal renal tubular acidosis.

METABOLIC ALKALOSIS

Essentials of Diagnosis

- High HCO_3^- with alkalemia.
- Evaluate effective circulating volume by physical examination and check urinary chloride concentration. This will help differentiate saline-responsive metabolic alkalosis from saline-unresponsive alkalosis.

Classification

Metabolic alkalosis is characterized by high HCO_3^- . The high HCO_3^- is seen also in chronic respiratory acidosis (see above), but pH differentiates the two disorders. Abnormalities that generate HCO_3^- within the body are called "initiation factors" of metabolic alkalosis, whereas abnormalities that promote renal conservation of HCO_3^- are called "maintenance factors." Metabolic alkalosis may remain even after the initiation factors have disappeared.

It is useful to classify the causes of metabolic alkalosis into two groups based on "saline responsiveness" or urinary Cl^- , which are markers for volume status ([Table 21-17](#)). Saline-responsive metabolic alkalosis is a sign of extracellular volume contraction, and saline-unresponsive alkalosis implies a volume-expanded state. It is rare for a compensatory increase in PCO_2 to exceed 55 mm Hg. A higher value implies a superimposed respiratory acidosis.

A. Saline-Responsive Metabolic Alkalosis

Saline-responsive metabolic alkalosis is by far the more common disorder. It is characterized by normotensive extracellular volume contraction and hypokalemia. Less frequently, hypotension or orthostatic hypotension may be seen. In vomiting or nasogastric suction, for example, loss of acid (HCl) initiates the alkalosis, but volume contraction from loss of Cl^- sustains the alkalosis because the decline in GFR causes avid renal Na^+ and HCO_3^- reabsorption. Since there is Cl^- depletion from loss of HCl, NaCl, and KCl from the stomach, the available anion is HCO_3^- , whose reabsorption is increased proximally, and urine pH may remain acidic despite alkalemia (paradoxical aciduria). Renal Cl^- reabsorption (as well as Na^+) reabsorption is high, and the urinary Cl^- is therefore low ($< 10\text{-}20$ meq/L). In alkalosis, bicarbonaturia may force Na^+ excretion as the accompanying cation even if volume depletion is present. Therefore, urinary Cl^- is preferred to urinary Na^+ as a measure of extracellular volume. An exception to the usefulness of urinary Cl^- is in patients who have recently received diuretics. Their urine may contain high Na^+ and Cl^- despite extracellular volume contraction. If diuretics are discontinued, the urinary Cl^- will decrease.

Metabolic alkalosis is generally associated with hypokalemia. This is due partly to the direct effect of alkalosis per se on renal potassium excretion and partly to secondary hyperaldosteronism from volume depletion. Hypokalemia induced in this fashion further worsens the metabolic alkalosis by increasing bicarbonate reabsorption in the proximal tubule and hydrogen ion secretion in the distal tubule. Administration of KCl will correct the disorder. Repletion of KCl is important to reverse the disorder.

1. Contraction alkalosis—Diuretics can acutely decrease extracellular volume from urinary loss of NaCl and water. There is no associated bicarbonaturia, so that body HCO_3^- content remains normal. However, plasma HCO_3^- increases because of extracellular fluid contraction—the reverse of what occurs in dilutional acidosis.

2. Posthypercapnia alkalosis—In chronic respiratory acidosis, compensatory increases in HCO_3^- occur ([Table 21-13](#)). Hypercapnia also directly affects the proximal tubule to decrease NaCl reabsorption, which can cause extracellular volume depletion. If PCO_2 is corrected rapidly, as with mechanical ventilation, metabolic alkalosis will ensue until adequate bicarbonaturia occurs. Hypovolemia will inhibit bicarbonaturia until Cl^- is repleted. Many patients with chronic respiratory acidosis receive diuretics, which further exacerbates the metabolic alkalosis.

B. Saline-Unresponsive Alkalosis

1. Hyperaldosteronism—Primary hyperaldosteronism causes expansion of extracellular volume with hypertension. Metabolic alkalosis with hypokalemia results from the renal mineralocorticoid effect. In an attempt to decrease extracellular volume, high levels of NaCl are excreted, and for that reason the urinary Cl^- is high (> 20 meq/L, often higher). Therapy with NaCl will only increase volume expansion and hypertension and will not treat the underlying problem of mineralocorticoid excess.

2. Alkali administration with decreased GFR—Despite large ingestions of HCO_3^- , enhanced bicarbonaturia almost always prevents a patient with normal renal function from developing metabolic alkalosis. However, with renal insufficiency, urinary excretion of bicarbonate is inadequate. If large amounts of HCO_3^- or metabolizable salts of organic acids such as sodium lactate, sodium citrate, or sodium gluconate are consumed, as with intensive antacid therapy, metabolic alkalosis will occur. In milk-alkali syndrome, large and sustained ingestion of absorbable antacids and milk causes renal insufficiency from hypercalcemia. Decreased GFR prevents appropriate bicarbonaturia from the ingested alkali, and metabolic alkalosis occurs. Volume contraction from renal hypercalcemic effects further exacerbates the alkalosis.

Clinical Findings

A. Symptoms and Signs

There are no characteristic symptoms or signs. Orthostatic hypotension may be encountered. Weakness and hyporeflexia occur if serum K^+ is markedly low. Tetany and neuromuscular irritability occur rarely.

B. Laboratory Findings

The arterial blood pH and bicarbonate are elevated. The arterial PCO_2 is increased. Serum potassium and chloride are decreased. There may be an increased anion gap.

Treatment

Mild alkalosis is generally well tolerated. Severe or symptomatic alkalosis ($\text{pH} > 7.60$) requires urgent treatment.

A. Saline-Responsive Metabolic Alkalosis

Therapy for saline-responsive metabolic alkalosis is aimed at correction of extracellular volume deficit. Depending on the degree of hypovolemia, adequate amounts of 0.9% NaCl and KCl should be administered. Discontinuation of diuretics and administration of H_2 -blockers in patients whose alkalosis is due to nasogastric suction can be useful. If impaired pulmonary or cardiovascular status prohibits adequate volume repletion, acetazolamide, 250-500 mg intravenously every 4-6 hours, can be used. One must be alert to the possible development of hypokalemia, since potassium depletion can be induced by forced kaliuresis via bicarbonaturia. Administration of acid can be used as emergency therapy. HCl, 0.1 mol/L, is infused via a central vein (the solution is sclerosing). Dosage is calculated to decrease the HCO_3^- level by one-half over 2-4 hours, assuming a HCO_3^- volume of distribution (L) of $0.5 \times \text{body weight (kg)}$. Patients with marked renal insufficiency may require dialysis.

B. Saline-Unresponsive Metabolic Alkalosis

Therapy for saline-unresponsive metabolic alkalosis includes surgical removal of a mineralocorticoid-producing tumor and blockage of aldosterone effect with an angiotensin-converting enzyme inhibitor or with spironolactone. Metabolic alkalosis in primary aldosteronism can be treated only with potassium repletion.

■ FLUID MANAGEMENT

Most of those who require water and electrolyte intravenously are relatively normal people who cannot take orally what they require for maintenance. The range of tolerance for water and electrolytes (homeostatic limits) permits reasonable latitude in therapy provided normal renal function exists to accomplish the final regulation of volume and concentration.

Normal saline distributes only in extracellular fluid, whereas 5% dextrose distributes both in extracellular and intracellular fluid.

An average adult whose entire intake is parenteral would require for maintenance 2500-3000 mL of 5% dextrose in 0.2% saline solution (34 meq Na^+ plus 34 meq Cl^- /L). To each liter, 30 meq of KCl could be added. In 3 L, the total chloride intake would be 192 meq, which is easily tolerated. Guidelines for gastrointestinal fluid losses are shown in [Table 21-18](#).

Weight loss or gain is the best indication of water balance. Insensible water loss should be further considered in febrile patients. Water loss increases by 100-150 mL/d for each degree of body temperature over 37 °C.

In situations requiring maintenance or maintenance plus replacement of fluid and electrolyte by parenteral infusion, the total daily ration should be administered continuously over the 24-hour period in order to ensure the best utilization by the patient.

If parenteral fluids are the only source of water, electrolytes, and calories for longer than a week, more complex fluids containing amino acids, lipid, trace metals, and vitamins may be indicated. (See Total Parenteral Nutrition, [Chapter 29](#).)

Central nervous system disorders

- Head trauma
- Stroke
- Subarachnoid hemorrhage
- Hydrocephalus
- Brain tumor
- Encephalitis
- Guillain-Barre syndrome
- Meningitis
- Acute psychosis
- Acute intermittent porphyria

Pulmonary lesions

- Tuberculosis
- Bacterial pneumonia
- Aspergillosis
- Bronchiectasis
- Neoplasms
- Positive pressure ventilation

Malignancies

- Bronchogenic carcinoma
- Pancreatic carcinoma
- Prostatic carcinoma
- Renal cell carcinoma
- Adenocarcinoma of colon
- Thymoma
- Osteosarcoma
- Malignant lymphoma
- Leukemia

Drugs

- Increased ADH production
- Antidepressants: tricyclics, monoamine oxidase inhibitors, SSRIs
- Antineoplastics: cyclophosphamide, vincristine
- Carbamazepine
- Methylenedioxymethamphetamine (MDMA; Ecstasy)
- Clofibrate
- Neuroleptics: thiothixene, thioridazine, fluphenazine, haloperidol, trifluoperazine
- Potentiated ADH action
- Carbamazepine
- Chlorpropamide, tolbutamide
- Cyclophosphamide
- NSAIDs
- Somatostatin and analogs

Others

- Postoperative
- Pain
- Stress
- AIDS
- Pregnancy (physiologic)
- Hypokalemia

-

Table 21-4. Causes of hypokalemia.

Decreased potassium intake

Potassium shift into the cell

- Increased postprandial secretion of insulin
- Alkalosis
- Trauma (via beta-adrenergic stimulation?)
- Periodic paralysis (hypokalemic)

Renal potassium loss

- Increased aldosterone (mineralocorticoid) effects
- Primary aldosteronism
- Secondary aldosteronism (dehydration, heart failure)
- Renovascular hypertension
- Malignant hypertension
- Ectopic ACTH-producing tumor
- Bartter's syndrome
- Cushing's syndrome
- Licorice (European)
- Renin-producing tumor
- Congenital abnormality of steroid metabolism (eg, adrenogenital syndrome, 17 α -hydroxylase defect, apparent mineralocorticoid excess)
- Increased flow of distal nephron
- Diuretics (furosemide, thiazides)
- Salt-losing nephropathy
- Hypomagnesemia
- Unreabsorbable anion
- Carbenicillin, penicillin
- Renal tubular acidosis (type I or II)
- Fanconi's syndrome
- Interstitial nephritis
- Metabolic alkalosis (bicarbonaturia)
- Congenital defect of distal nephron
- Liddle's syndrome

Extrarenal potassium loss

- Vomiting, diarrhea, laxative abuse
- Villous adenoma, Zollinger-Ellison syndrome

Table 21-5. Genetic disorders associated with electrolyte metabolism disturbances.

Disease	Site of Mutation
Potassium	
Hypokalemia	Dihydropyridine-sensitive skeletal muscle
Hypokalemic periodic paralysis	voltage-gated calcium channel
Bartter's syndrome	Na-K-2Cl cotransporter, K ⁺ channel (ROMK), or Cl ⁻ channel of thick ascending limb of Henle (hypofunction)
Liddle's syndrome	β or ? subunit of amiloride-sensitive Na ⁺ channel (hyperfunction)
Apparent mineral-ocorticoïd excess	11β-Hydroxysteroid dehydrogenase (failure to inactivate cortisol)
Glucocorticoïd-remediable aldosteronism	Regulatory sequence of 11β-hydroxylase controls aldosterone synthase inappropriately
Hyperkalemia	a subunit of calcium channel
Hyperkalemic periodic paralysis	
Pseudohypoaldo-steronism type I	β or ? subunit of amiloride-sensitive Na ⁺ channel (hypofunction)
Calcium	
Familial hypocalciuric hypercalcemia	Ca ²⁺ -sensing protein (hypofunction)
Familial hypocalcemia	Ca ²⁺ -sensing protein (hyperfunction)
Phosphate	
Hypophosphatemic rickets	PEX gene
Water	
X-linked (type I) nephrogenic diabetes insipidus	Vasopressin receptor

 - TABLES
 - Table 21-5. Genetic disorders associated with electrolyte metabolism disturbances.
-

Table 21-6. Causes of hyperkalemia.

Spurious

- Leakage from erythrocytes when separation of serum from clot is delayed (plasma K⁺ normal)
- Marked thrombocytosis or leukocytosis with release of K⁺ (plasma K⁺ normal)
- Repeated fist clenching during phlebotomy, with release of K⁺ from forearm muscles
- Specimen drawn from arm with K⁺ infusion

Decreased excretion

- Renal failure, acute and chronic
- Renal secretory defects (may or may not have frank renal failure): renal transplant, interstitial nephritis, systemic lupus erythematosus, sickle cell disease, amyloidosis, obstructive uropathy
- Hyporeninemic hypoaldosteronism (often in diabetic patients with mild to moderate nephropathy) or selective hypoaldosteronism (some patients with AIDS)
- Heparin (regardless of molecular size; suppresses aldosterone secretion)
- Drugs that inhibit potassium excretion (spironolactone, triamterene, ACE inhibitors, trimethoprim, NSAIDs, cyclosporine, tacrolimus [FK506])

Shift of K⁺ from within the cell

- Massive release of intracellular K⁺ in burns, rhabdomyolysis, hemolysis, severe infection, internal bleeding, vigorous exercise
- Metabolic acidosis (in the case of organic acid accumulationeg, lactic acidosis a shift of K⁺ does not occur since organic acid can easily move across the cell membrane)
- Hypertonicity (solvent drag)
- Insulin deficiency (metabolic acidosis may not be apparent)
- Hyperkalemic periodic paralysis
- Drugs: succinylcholine, arginine, digitalis toxicity, beta-adrenergic antagonists
- Alpha-adrenergic stimulation?

Excessive intake of K⁺

Table 21-7. Treatment of hyperkalemia.¹

EMERGENCY					
Modality	Mechanism of Action	Onset	Duration	Prescription	K ⁺ Removed From Body
Calcium	Antagonizes cardiac conduction abnormalities	0-5 minutes	1 hour	Calcium gluconate 10%, 5-30 mL IV; or calcium chloride 5%, 5-30 mL IV	0
Bicarbonate	Distributes K ⁺ into cells	15-30 minutes	1-2 hours	NaHCO ₃ , 44-88 meq (1-2 ampules) IV	0
Insulin glucose 50%, 25 g (1 ampule) IV	Distributes K ⁺ into cells	15-60 minutes	4-6 hours	Regular insulin, 5-10 units IV, plus	0
Albuterol	Distributes K ⁺ into cells	15-30 minutes	2-4 hours	Nebulized albuterol, 10-20 mg in 4 mL normal saline, inhaled over 10 minutes	0
NONEMERGENCY					
Modality	Mechanism of Action	Duration of Treatment		Prescription	K ⁺ Removed From Body
Loop diuretic	? Renal K ⁺ excretion	0.5-2 hours		Furosemide, 40-160 mg IV or orally with or without NaHCO ₃ , 0.5-3 meq/kg daily	Variable
Sodium polystyrene sulfonate (Kayexalate)	Ion exchange resin binds K ⁺	1-3 hours		Oral: 15-30 g in 20% sorbitol (50-100 mL) Rectal: 50 g in 20% sorbitol	0.5-1 meq/g
Hemodialysis	Extracorporeal K ⁺ removal	48 hours		Blood flow = 200-300 mL/min. Dialysate [K ⁺] ~ 0	200-300 meq
Peritoneal dialysis	Peritoneal K ⁺ removal	48 hours		Fast exchange, 3-4 L/h	200-300 meq

Absorption blocked by oral aluminum hydroxide or bicarbonate
Vitamin D-deficient and vitamin D-resistant osteomalacia

Increased loss

Phosphaturic drugs: theophylline, diuretics, bronchodilators, corticosteroids
Hyperparathyroidism (primary or secondary)
Hyperthyroidism
Renal tubular defects permitting excessive phosphaturia (congenital, induced by monoclonal gammopathy, heavy metal poisoning)
Hypokalemic nephropathy
Inadequately controlled diabetes mellitus
Alcoholism
Hypophosphatemic rickets
Oncogenic osteomalacia

Intracellular shift of phosphorus

Administration of glucose, fructose (transient)
Anabolic steroids, estrogen, oral contraceptives
Respiratory alkalosis
Salicylate poisoning

Electrolyte abnormalities

Hypercalcemia
Hypomagnesemia
Metabolic alkalosis

Abnormal losses followed by inadequate repletion

Diabetes mellitus with acidosis, particularly during aggressive therapy
Recovery from starvation or prolonged catabolic state
Chronic alcoholism, particularly during restoration of nutrition; associated with hypomagnesemia
Respiratory alkalosis
Recovery from severe burns

■ APPROACH TO RENAL DISEASE

A patient will present with renal disease in one of two ways: discovered incidentally during a routine medical evaluation or with evidence of renal dysfunction such as hypertension, edema, nausea, and hematuria. The initial approach in both situations should be to assess the cause and severity of renal abnormalities. In all cases this evaluation includes (1) an estimation of disease duration, (2) a careful urinalysis, and (3) an assessment of the glomerular filtration rate (GFR). The history and physical examination, though equally important, are variable among renal syndromes—thus, specific symptoms and signs are discussed under each disease entity. Further diagnostic categorization is according to anatomic distribution: prerenal disease, postrenal disease, and intrinsic renal disease. Intrinsic renal disease can further be divided into glomerular, tubular, interstitial, and vascular abnormalities.

DISEASE DURATION

Renal disease may be acute or chronic. Acute renal failure is worsening of renal function over hours to days, resulting in the retention of nitrogenous wastes (such as urea nitrogen) and creatinine in the blood. Retention of these substances is called azotemia. Chronic renal failure (chronic kidney disease) results from an abnormal loss of renal function over months to years. Differentiating between the two is important for diagnosis, treatment, and outcome. Oliguria is unusual in chronic renal insufficiency. Anemia (from low renal erythropoietin production) is rare in the initial period of acute renal failure. Small kidneys are most consistent with chronic renal failure, whereas normal to large sizes can be seen with both.

URINALYSIS

A urinalysis has been likened to "a poor man's renal biopsy." The urine is collected in midstream or, if that is not feasible, by bladder catheterization. The urine should be examined within 1 hour after collection. Urinalysis includes a dipstick examination followed by microscopic assessment if the dipstick has positive findings. The dipstick examination measures urinary specific gravity, pH, protein, hemoglobin, glucose, ketones, bilirubin, nitrites, and leukocyte esterase. Microscopy searches for all formed elements—crystals, cells, casts, and infecting organisms.

Various findings on the urinalysis are indicative of certain patterns of renal disease ([Table 22-1](#)). A bland urinary sediment is common, especially in chronic renal disease and prerenal and postrenal disorders. The presence of hematuria with dysmorphic red blood cells, red blood cell casts, and mild proteinuria is indicative of glomerulonephritis. Red blood cells are misshapen during passage from the capillary through the glomerular basement membrane into the urinary space of Bowman's capsule.

Casts are composed of Tamm-Horsfall urinary mucoprotein in the shape of the nephron segment where they were formed. Heavy proteinuria and lipiduria are consistent with the nephrotic syndrome. Pigmented granular casts and renal tubular epithelial cells alone or in casts suggest acute tubular necrosis. White blood cells, including neutrophils and eosinophils, white blood cell casts, red blood cells, and small amounts of protein can be found in interstitial nephritis and pyelonephritis; Wright's stain can detect eosinophiluria. Pyuria alone can indicate a urinary tract infection. Hematuria and proteinuria are discussed more thoroughly below.

Proteinuria

Proteinuria is defined as excessive protein excretion in the urine, generally > 150-160 mg/24 h in adults. Significant proteinuria is a sign of an underlying renal abnormality, usually glomerular in origin when greater than 1 g/d. It is typically accompanied by other clinical abnormalities—elevated BUN and serum creatinine levels, abnormal urinary sediment, or evidence of systemic illness (eg, fever, rash, vasculitis).

There are four primary reasons for development of proteinuria: (1) Functional proteinuria is a benign process stemming from stressors such as acute illness, exercise, and "orthostatic proteinuria." The latter condition, generally found in people under age 30, results in the excretion of abnormal amounts of urinary protein, typically less than 1 g/d. This can be diagnosed by measuring an 8-hour overnight supine urinary protein excretion, which should be less than 50 mg. (2) Overload proteinuria can result from overproduction of circulating, filterable plasma proteins, such as Bence Jones proteins associated with multiple myeloma. Urinary protein electrophoresis will exhibit a discrete protein peak. Other examples of overload proteinuria include myoglobinuria in rhabdomyolysis and lysozymuria in certain leukemias. (3) Glomerular proteinuria results from effacement of epithelial cell foot processes and altered glomerular permeability with an increased filtration fraction of normal plasma proteins. Glomerular diseases exhibit some degree of proteinuria. The urinary electrophoresis will have a pattern exhibiting a large albumin spike indicative of increased permeability of albumin across a damaged GBM. (4) Tubular proteinuria occurs as a result of faulty reabsorption of normally filtered proteins in the proximal tubule, such as β_2 -microglobulin and immunoglobulin light chains. Causes include acute tubular necrosis, toxic injury (lead, aminoglycosides), drug-induced interstitial nephritis, and hereditary metabolic disorders (Wilson's disease and Fanconi's syndrome).

Evaluation of proteinuria by urinary dipstick primarily detects albumin and intact globulins, while overlooking positively charged light chains of immunoglobulins. These proteins can be detected by the addition of sulfosalicylic acid to the urine specimen. The lack of precipitation indicates the absence of paraproteins.

The next step—and the most reliable way to quantify proteinuria—is a 24-hour urine collection. A finding of > 150 mg/24 h is abnormal, and > 3.5 g/24 h is consistent with nephrotic-range proteinuria. A simpler but less accurate method is to collect a random urine sample. The ratio of urinary protein concentration to urinary creatinine concentration ($U_{\text{protein}}/U_{\text{creatinine}}$) correlates with 24-hour urine protein collection (< 0.2 is normal and corresponds to excretion of less than 200 mg/d). If a patient has proteinuria with loss of renal function, renal biopsy may be indicated, particularly if the renal insufficiency is acute in onset. The clinical consequences of proteinuria are discussed in the section on the nephrotic syndrome.

In both diabetics and nondiabetics, therapy aimed at reducing proteinuria may also reduce progression of renal disease. ACE inhibitors are effective by lowering efferent arteriolar resistance out of proportion to afferent arteriolar resistance, thereby reducing glomerular capillary pressure and lowering urinary protein excretion. Other effects include alterations of glomerular mesangial proliferation. ACE inhibitors can be used in patients despite compromised GFR as long as significant hyperkalemia does not occur and serum creatinine rises less than 30%, stabilizing over 2 months. More recently, large randomized controlled trials (the RENAAL and IDNT studies) have also proved the benefit of angiotensin II receptor blockers in reducing proteinuria and preventing the progression of renal disease in diabetic nephropathy. The consequences of dietary restrictions in patients with proteinuria are discussed in the section on chronic renal failure.

Hematuria

Hematuria is significant if there are more than three to five red cells per high-power field. It is usually detected incidentally by the urine dipstick examination or by an episode of macroscopic hematuria. The diagnosis must be confirmed via microscopic examination, as false-positive dipstick tests can be caused by vitamin C, beets and rhubarb, bacteria, and myoglobin. Transient hematuria is common, but in patients under 40 it is less often of clinical significance.

Hematuria may be due to renal or extrarenal causes. Extrarenal causes are addressed in [Chapter 23](#); the most worrisome of these are urologic malignancies. Renal causes account for approximately 10% of cases and are best considered anatomically as glomerular or nonglomerular. The most common extraglomerular sources include cysts, calculi, interstitial nephritis, and renal neoplasia. Glomerular causes include IgA nephropathy, thin GBM disease, postinfectious glomerulonephritis, membranoproliferative glomerulonephritis, and the systemic nephritic syndromes.

Currently, the United States Health Preventive Services Task Force does not recommend screening for hematuria. See [Chapter 23](#) for evaluation of hematuria.

ESTIMATION OF GFR

The glomerular filtration rate (GFR) provides a useful index of overall renal function; however, patients with renal disease can actually have a normal or increased GFR. The GFR measures the amount of plasma ultrafiltered across the glomerular capillaries and correlates with the ability of the kidneys to filter fluids and various substances. Daily GFR in normal individuals is variable, with a range of 150-250 L/24 h or 100-120 mL/min/ 1.73 m² of body surface area. GFR can be measured indirectly by determining the renal clearance of plasma substances which are not bound to plasma proteins, are freely filterable across the glomerulus, and are neither secreted nor reabsorbed along the renal tubules.

The formula used to determine the renal clearance of a substance is

$$C = \frac{U \times V}{P}$$

where C is the clearance, U and P are the urine and plasma concentrations of the substance (mg/dL), and V is the urine flow rate (mL/min). Inulin and creatinine

clearance are used as markers of GFR. Inulin clearance following a continuous infusion is one of the most accurate methods for measurement of GFR. The cost and the complexity of the administration and analysis of inulin preclude its routine use. In clinical practice, the clearance rate of endogenous creatinine, the creatinine clearance (C_{cr}), is the usual means of estimating GFR. Creatinine is a product of muscle metabolism produced at a relatively constant rate and cleared by renal excretion. It is freely filterable by the glomerulus and not reabsorbed by the renal tubules. With stable renal function, creatinine production and excretion are equal; thus, plasma creatinine concentrations remain constant. However, it is not a perfect indicator of GFR for the following reasons: (1) A small amount is normally eliminated by tubular secretion, and the fraction secreted progressively increases as GFR declines (overestimating GFR); (2) with severe renal failure, gut microorganisms degrade creatinine; (3) an individual's meat intake and muscle mass affect baseline plasma creatinine levels; (4) commonly used drugs such as cimetidine, probenecid, and trimethoprim reduce tubular secretion of creatinine, increasing the plasma creatinine concentration and falsely indicating renal dysfunction; and (5) the accuracy of the measurement necessitates a stable plasma creatinine concentration over a 24-hour period, so that during the development of and recovery from acute renal failure, the C_{cr} is of questionable value (see [Table 22-2](#)).

To measure creatinine clearance, collect a 24-hour urine sample and determine the plasma creatinine level on the same day. An incomplete or prolonged urine collection is a common source of error. One way of estimating the completeness of the collection is to calculate a 24-hour creatinine excretion; the amount should be constant:

$$U_{cr} \times V = 15 - 20 \text{ mg/kg for healthy young women}$$

$$U_{cr} \times V = 20 - 25 \text{ mg/kg for healthy young men}$$

The creatinine clearance is approximately 100 mL/min/1.73 m² in healthy young women and 120 mL/min/1.73 m² in healthy young men. The C_{cr} declines by 1 mL/min/yr after age 40 as part of the aging process. Since urine collection may be difficult, creatinine clearance can be estimated from the formula of Cockcroft and Gault, which incorporates age, sex, and weight to estimate creatinine clearance from plasma creatinine levels without any urinary measurements:

$$C_{cr} = \frac{(140 - \text{Age}) \times \text{Weight (kg)}}{P_{cr} \times 72}$$

For women, the estimated GFR is multiplied by 0.85 because muscle mass is less. This formula overestimates GFR in patients who are obese or edematous.

Urea is another index helpful in assessing renal function. It is synthesized mainly in the liver and is the end product of protein catabolism. Urea is freely filtered by the glomerulus, and about 30-70% is reabsorbed in the nephron. Unlike creatinine clearance, which overestimates GFR, urea clearance underestimates GFR. Urea reabsorption may be decreased in well-hydrated patients, whereas dehydration causes increased reabsorption, increasing blood urea nitrogen (BUN). A normal BUN:creatinine ratio is 10:1. With dehydration, the ratio can increase to 20:1 or higher. Other causes of increased BUN include increased catabolism (gastrointestinal bleeding, cell lysis, and steroid usage), increased dietary protein, and decreased renal perfusion (congestive heart failure, renal artery stenosis ([Table 22-3](#)). Reduced BUN is seen in liver disease and in the syndrome of inappropriate antidiuretic hormone secretion (SIADH).

As patients approach end-stage renal disease, a more accurate measure of GFR than creatinine clearance is the average of the creatinine and urea clearances. The creatinine clearance overestimates GFR, as mentioned above, while the urea clearance underestimates GFR.

IMAGING STUDIES

Radionuclide Studies

Radionuclide studies can measure renal function. ¹²⁵I-iothalamate gives a surprisingly accurate measurement of GFR. It is injected intravenously, excreted renally, and sampled from the venous circulation over time. Technetium diethylenetriamine pentaacetic acid (^{99m}Tc-DTPA) is freely filtered by the glomerulus and not reabsorbed and is used to estimate GFR. Technetium dimercaptosuccinate (^{99m}Tc-DMSA) is bound to the tubules and provides an assessment of functional renal mass. Radioiodinated (¹³¹I) orthiodohippurate is secreted into the renal tubules and assesses renal plasma flow (RPF). The indications for nuclear renography are to measure function and flow; to determine the contribution of each kidney to overall renal function; to demonstrate the presence or absence of functioning renal tissue in mass lesions; to detect obstruction; and to evaluate renovascular disease.

Poor flow along with poor function is consistent with acute tubular necrosis or end-stage renal disease. Decreased flow to one kidney suggests arterial occlusion of that kidney. To further investigate renal artery stenosis, the test is done both with and without captopril (see [Chapter 11](#)).

Ultrasonography

Ultrasonography can identify the thickness and echogenicity of the renal cortex, medulla, pyramids, and a distended urinary collecting system. Kidney size can be determined; a kidney less than 9 cm in length in an adult indicates significant irreversible renal disease. A difference in size of more than 1.5 cm between the two kidneys is observed in unilateral renal disease. Renal ultrasound is also performed to search for hydronephrosis and obstruction, to characterize renal mass lesions, to screen for autosomal dominant polycystic kidney disease, to evaluate the perirenal space, to localize the kidney for a percutaneous invasive procedure, and to assess postvoiding bladder residual urine volume.

Intravenous Urography

The intravenous pyelogram (IVP) has been for many years the standard imaging procedure for evaluating the urinary tract since it provides an assessment of the kidneys, ureters, and bladder. The dye is filtered and secreted by the renal tubules in normal kidneys, resulting in a nephrogram formed by opacification of the renal parenchyma. The density of the nephrogram is dependent on the GFR. Filling of the pelvicaliceal system produces the pyelogram. The IVP can demonstrate differential function between the right and left kidneys by the rate of appearance of the nephrogram phase.

An IVP necessitates the injection of contrast and is relatively contraindicated in patients with an increased risk for developing acute renal failure (eg, diabetes mellitus with serum creatinine > 2 mg/dL, severe volume contraction, or prerenal azotemia), chronic renal failure with serum creatinine greater than 5 mg/dL, and multiple myeloma. IVP is performed to obtain a detailed view of the pelvicaliceal system, assess renal size and shape, detect and localize renal stones, and assess renal function. It is particularly useful in diagnosing certain disorders such as medullary sponge kidney and papillary necrosis. Helical computed tomography is replacing IVP for stone evaluation, and ultrasonography is replacing IVP to avoid dye administration.

Computed Tomography

Computed tomography (CT) is required for further investigation of abnormalities detected by ultrasound or IVP. Although the routine study requires radiographic contrast administration, no contrast is necessary if the reason for the study is to demonstrate hemorrhage or calcifications in the kidneys such as suspected stone disease. Since contrast is filtered by the glomeruli and concentrated in the tubules, there is enhancement of parenchymal tissue, making abnormalities such as cysts or neoplasms easily identified and allowing good visualization of renal vessels and ureters. CT is especially useful for evaluation of solid or cystic lesions in the kidney or the retroperitoneal space, particularly if the ultrasound results are suboptimal.

Magnetic Resonance Imaging (MRI)

MRI can easily distinguish renal cortex from medulla. Loss of corticomedullary function, which can be seen in a variety of disorders (glomerulonephritis, hydronephrosis, renal vascular occlusion, and renal failure) will be evident on MRI. Renal cysts seen on a CT scan can also be identified by MRI. For some solid lesions, MRI may be superior to CT scanning. MRI is indicated as an addition or alternative to CT for staging renal cell cancer and as a substitute for CT in the evaluation of a renal mass, especially for patients in whom contrast is contraindicated; in addition, the adrenals are well imaged. MRI is a particularly sensitive test for the diagnosis of renal artery stenosis.

Arteriography & Venography

Renal arteriography is useful in the evaluation of atherosclerotic or fibrodysplastic stenotic lesions, aneurysms, vasculitis, and renal mass lesions. Venography is the best test for diagnosis of renal vein thrombosis, though CT and MRI are less invasive for this purpose.

RENAL BIOPSY

Indications for percutaneous needle biopsy include (1) unexplained acute renal failure or chronic renal insufficiency; (2) acute nephritic syndromes; (3) unexplained proteinuria and hematuria; (4) previously identified and treated lesions to plan future therapy; (5) systemic diseases associated with kidney dysfunction, such as systemic lupus erythematosus, Goodpasture's syndrome, and Wegener's granulomatosis, to confirm the extent of renal involvement and to guide management; (6) suspected transplant rejection, to differentiate it from other causes of acute renal failure; and (7) to guide treatment. Relative contraindications include a solitary or ectopic kidney (exception: transplant allografts), horseshoe kidney, uncorrected bleeding disorder, severe uncontrolled hypertension, renal infection, renal neoplasm, hydronephrosis, end-stage renal disease, congenital anomalies, multiple cysts, or an uncooperative patient. Prior to biopsy, patients should have well-controlled blood pressure; blood work should include a hematocrit, platelet count, prothrombin time, partial thromboplastin time, and perhaps a bleeding time. After biopsy, hematuria occurs in nearly all patients. Fewer than 10% will have macroscopic hematuria. A patient with a postbiopsy hematocrit more than 3% lower than baseline should be closely monitored.

Percutaneous kidney biopsies are generally safe. One percent of patients will experience significant bleeding and 0.1% will require blood transfusions. The risks of nephrectomy and mortality are about 0.01-0.06%. When a percutaneous needle biopsy is technically not feasible and renal tissue is deemed clinically essential, a closed renal biopsy via interventional radiologic techniques or open renal biopsy under general anesthesia can be done.

■ ACUTE RENAL FAILURE

Essentials of Diagnosis

- Sudden increase in BUN or serum creatinine.
- Oliguria often associated.
- Symptoms and signs depend on cause.

General Considerations

Five percent of hospital admissions and 30% of ICU admissions carry a diagnosis of acute renal failure, and 25% of hospitalized patients will develop it. Acute renal failure is defined as a sudden decrease in renal function, resulting in an inability to maintain fluid and electrolyte balance and to excrete nitrogenous wastes. Serum creatinine is a convenient marker. In the absence of functioning kidneys, serum creatinine concentration will typically increase 1-1.5 mg/dL daily—although with certain conditions, such as rhabdomyolysis, serum creatinine can increase more rapidly.

Clinical Findings

A. Symptoms and Signs

The uremic milieu of acute renal failure can cause nonspecific symptoms. When present, they are often due to azotemia and the underlying cause of acute renal failure. Azotemia can cause nausea, vomiting, malaise, and altered sensorium. Hypertension is rare, but fluid homeostasis is often altered. Hypovolemia can cause prerenal failure, whereas hypervolemia can result from intrinsic renal failure or postrenal failure. Pericardial effusions can occur with azotemia, and a pericardial friction rub can be present. Effusions may result in cardiac tamponade. Arrhythmias occur especially with hyperkalemia. The pulmonary examination may show rales in the presence of hypervolemia. Acute renal failure can cause nonspecific diffuse abdominal pain and ileus as well as platelet dysfunction; thus, bleeding is more common in these patients. The neurologic examination reveals encephalopathic changes with asterixis and confusion; seizures may ensue.

B. Laboratory Findings

Elevated BUN and creatinine are present, though these elevations do not in themselves distinguish acute from chronic renal failure (Table 22-4). Hyperkalemia often occurs from impaired renal potassium excretion. The ECG can reveal peaked T waves, PR prolongation, and QRS widening. A long QT segment can occur with hypocalcemia. Anion gap metabolic acidosis (due to decreased organic acid clearance) is often noted. Hyperphosphatemia occurs when phosphorus cannot be secreted by damaged tubules either with or without increased cell catabolism. Hypocalcemia with metastatic calcium phosphate deposition may be observed when the product of calcium and phosphorus exceeds 70 mg/dL. Anemia can occur as a result of decreased erythropoietin production, and associated platelet dysfunction is typical.

Classification & Etiology

Acute renal failure can be divided into three categories: prerenal azotemia, intrinsic renal failure, and postrenal azotemia. Identifying the cause is the first step toward managing the patient. (See Table 22-4.)

A. Prerenal Azotemia

Prerenal azotemia is the most common cause of acute renal failure. It is due to renal hypoperfusion. This is an appropriate physiologic change. If it can be immediately reversed with restoration of renal blood flow, renal parenchymal damage does not occur. If hypoperfusion persists, ischemia can result, causing intrinsic renal failure.

Decreased renal perfusion can occur in one of three ways: a decrease in intravascular volume, a change in vascular resistance, or low cardiac output. Causes of volume depletion include hemorrhage, gastrointestinal losses, dehydration, excessive diuresis, extravascular space sequestration, pancreatitis, burns, trauma, and peritonitis.

Changes in vascular resistance can occur systemically with sepsis, anaphylaxis, anesthesia, and afterload-reducing drugs. ACE inhibitors prevent efferent renal arteriolar constriction out of proportion to the afferent arteriole; thus, GFR will decrease. NSAIDs prevent afferent arteriolar vasodilation by inhibiting prostaglandin-mediated signals. Thus, in cirrhosis and congestive heart failure, when prostaglandins are recruited to increase renal blood flow, NSAIDs will have particularly deleterious effects. Epinephrine, norepinephrine, high-dose dopamine, anesthetic agents, and cyclosporine also can cause renal vasoconstriction. Renal artery stenosis causes increased resistance and decreased perfusion.

Low cardiac output is a state of effective hypovolemia. This occurs in states of cardiogenic shock, congestive heart failure, pulmonary embolus, and pericardial tamponade. Arrhythmias and valvular disorders can also reduce cardiac output. In the ICU setting, positive-pressure ventilation will decrease venous return, also decreasing cardiac output.

When GFR falls acutely, it is important to determine whether acute renal failure is due to prerenal or intrinsic renal causes. The history and physical examination are important, and urinalysis can be helpful. The BUN:creatinine ratio will typically exceed 20:1 owing to increased urea reabsorption. Another useful index is the fractional excretion of sodium. With decreased GFR, the kidney will reabsorb salt and water avidly if there is no intrinsic tubular dysfunction. Thus, patients with prerenal failure should have a low fractional excretion percent of sodium (< 1%). The FE_{Na} is calculated as follows: Fractional excretion of Na^+ (FE_{Na}) = clearance of Na^+ /GFR = clearance of Na^+ /creatinine clearance (C_{Cr}):

$$FE_{Na} = \frac{\text{Urine}_{\text{sodium}} / \text{Plasma}_{\text{sodium}}}{\text{Urine}_{\text{creatinine}} \text{ Plasma}_{\text{creatinine}}} \times 100\%$$

The causes of oliguric states are more accurately assessed with this formula than the causes of nonoliguric states because the kidneys do not avidly reabsorb water and sodium in nonoliguric states. (Oliguria is defined as urine output < 500 mL/d.) Diuretics can cause increased sodium excretion. Thus, if the FE_{Na} is high within 12-24 hours after diuretic administration, the cause of acute renal failure may not be accurately predicted. Acute renal failure due to glomerulonephritis can have a low FE_{Na} because sodium reabsorption and tubular function may not be compromised.

Treatment of prerenal azotemia depends entirely on its cause, but maintenance of euolemia, attention to serum potassium, and avoidance of nephrotoxic drugs are

the benchmarks of therapy. This involves careful assessment of volume status, drug usage, and cardiac function.

B. Postrenal Azotemia

Postrenal azotemia is the least common cause of acute renal failure, accounting for approximately 5% of cases, but is perhaps the most important cause to detect because of its reversibility. It occurs when urinary flow from both kidneys is obstructed. Each nephron has an elevated intraluminal pressure, causing a decrease in GFR.

Causes include urethral obstruction, bladder dysfunction or obstruction, and obstruction of both ureters or renal pelvises. In men, benign prostatic hyperplasia is the most common cause. Patients taking anticholinergic drugs are particularly at risk. Bladder, prostate, and cervical cancers as well as retroperitoneal processes and neurogenic bladder can also cause obstruction. Less common causes are blood clots, bilateral ureteral stones, urethral stones or stricture, and bilateral papillary necrosis. In patients with a single functioning kidney, obstruction of a solitary ureter can cause postrenal azotemia.

Patients may be anuric or polyuric and may complain of lower abdominal pain. Obstruction can be constant or intermittent and partial or complete. On examination, the patient may have an enlarged prostate, distended bladder, or a mass detected on pelvic examination.

Laboratory examination may initially reveal high urine osmolality, low urine sodium, high BUN:creatinine ratio, and low FE_{Na} . These indices are similar to a prerenal picture because extensive intrinsic renal damage has not occurred. After several days, the urine sodium increases as the kidneys fail and are unable to concentrate the urine—thus, isosthenuria is present. The urine sediment is generally benign.

Patients with acute renal failure and suspected postrenal azotemia should undergo bladder ultrasonography and bladder catheterization if hydroureter and hydronephrosis are present along with an enlarged bladder. These patients often undergo a postobstructive diuresis, and care should be taken to avoid dehydration. Rarely, the presence of obstruction is not seen via ultrasonography. For example, patients with retroperitoneal fibrosis from tumor or radiation may not show dilation of the urinary tract. If suspicion does exist, a CT scan or MRI can establish the diagnosis. Promptly treated obstruction with catheters or stents can result in complete reversal of the acute process.

C. Intrinsic Renal Failure

Intrinsic renal disorders account for half of all cases of acute renal failure. Intrinsic (or parenchymal) dysfunction is considered after prerenal and postrenal causes have been excluded. The sites of injury are the tubules, the interstitium, the vasculature, and the glomeruli.

ACUTE TUBULAR NECROSIS

Essentials of Diagnosis

- Acute renal insufficiency.
- $FE_{Na} > 1\%$.
- Urine sediment with pigmented granular casts and renal tubular epithelial cells.

General Considerations

Acute renal failure due to tubular damage is termed acute tubular necrosis and accounts for 85% of intrinsic acute renal failure. The two major causes of acute tubular necrosis are ischemia and toxin exposure. Ischemia causes tubular damage from states of low perfusion and is often preceded by a state of prerenal azotemia. Ischemic acute renal failure is characterized not only by inadequate GFR but also by renal blood flow inadequate to maintain parenchymal cellular formation. This occurs in the setting of prolonged hypotension or hypoxemia such as dehydration, shock, and sepsis. Major surgical procedures can involve prolonged periods of hypoperfusion which are exacerbated by vasodilating anesthetic agents.

The other major cause of acute tubular necrosis is nephrotoxin exposure. Exogenous nephrotoxins more commonly cause damage than endogenous toxins.

A. Exogenous Nephrotoxins

Up to 25% of hospitalized patients receiving therapeutic levels of aminoglycosides sustain some degree of acute tubular necrosis. Nonoliguric renal failure typically occurs after 5-10 days of exposure. Predisposing factors include underlying renal damage, dehydration, and advanced age. Aminoglycosides can remain in renal tissues for up to a month, so renal function may not recover for some time after stopping the medication. Monitoring of peak and trough levels is important, but trough levels are more helpful in predicting renal toxicity. Gentamicin is the most and tobramycin the least nephrotoxic. Amphotericin B is typically nephrotoxic after a dose of 2-3 g. This causes severe vasoconstriction with distal tubular damage and can lead to distal renal tubular acidosis with hypokalemia and nephrogenic diabetes insipidus. Vancomycin, acyclovir, and several cephalosporins have been known to cause acute tubular necrosis.

Radiographic contrast media can be directly nephrotoxic. Contrast nephropathy is the third leading cause of new acute renal failure in hospitalized patients. It results from the synergistic combination of direct renal tubular epithelial cell toxicity and renal medullary ischemia. Predisposing factors include advanced age, preexisting renal disease (serum creatinine > 2 mg/dL), volume depletion, diabetic nephropathy, congestive heart failure, repeated doses of contrast, and recent exposure to other nephrotoxic agents, including NSAIDs and ACE inhibitors. The combination of diabetes mellitus and renal dysfunction poses the greatest risk for contrast nephropathy. Lower volumes of contrast are recommended in high-risk patients, though this has never been consistently demonstrated in trials. Toxicity usually occurs 24-48 hours after the radiocontrast study. Nonionic contrast media may be less toxic, but this has never been proved. Prevention should be the goal when using these agents. Patients should be hydrated with 1 L of 0.45% saline over 12 hours both before and after the contrast administration—cautiously in patients with preexisting cardiac dysfunction. Neither mannitol nor furosemide offers benefit over saline hydration. In fact, furosemide may lead to increased rates of renal dysfunction in this setting. In a recent study, acetylcysteine given before and after contrast decreased the incidence of dye-induced nephrotoxicity. Other nephrotoxic agents should be avoided during the day before and after administration.

Cyclosporine toxicity is usually dose-dependent. It causes distal tubular dysfunction from severe vasoconstriction. Regular blood level monitoring is important to prevent nephrotoxicity. With patients who are taking cyclosporine for renal transplant rejection, kidney biopsy is often necessary to distinguish transplant rejection from cyclosporine toxicity. Renal function usually improves after reducing the dose or stopping the drug.

Other exogenous nephrotoxins include antineoplastics, such as cisplatin and organic solvents, and heavy metals such as mercury, cadmium, and arsenic.

B. Endogenous Nephrotoxins

Endogenous nephrotoxins include heme-containing products, uric acid, and paraproteins. Myoglobinuria as a consequence of rhabdomyolysis leads to acute tubular necrosis. Necrotic muscle releases large amounts of myoglobin, which is freely filtered across the glomerulus. The myoglobin is reabsorbed by the renal tubules, and direct damage can occur. Distal tubular obstruction from pigmented casts and intrarenal vasoconstriction can also cause damage. This type of renal failure occurs in the setting of crush injury, muscle necrosis from prolonged unconsciousness, seizures, cocaine, and alcohol abuse. Dehydration and acidosis predisposes to the development of myoglobinuric acute renal failure. Patients may complain of muscular pain and often have signs of muscle injury. Rhabdomyolysis of clinical importance commonly occurs with a serum creatine kinase $> 20,000$ - $50,000$ IU/L. One study showed that 58% of patients with acute renal failure from rhabdomyolysis had CK levels $> 16,000$ IU/L. Only 11% of patients without renal failure had CK values $> 16,000$ IU/L. The globin moiety of myoglobin will cause the urine dipstick to read falsely positive for hemoglobin: the urine appears dark brown, but no red cells are present. With lysis of muscle cells, patients also become hyperkalemic, hyperphosphatemic, and hyperuricemic. The mainstay of treatment is hydration. Other adjunctive treatments include mannitol for free radical clearance and diuresis as well as alkalinization of the urine. These modalities have not been proved to change outcomes in human trials.

Hemoglobin can cause a similar form of acute renal tubular necrosis. Massive intravascular hemolysis is seen in transfusion reactions and in certain hemolytic anemias. Reversal of the underlying disorder and hydration are the mainstays of treatment.

Hyperuricemia can occur in the setting of rapid cell turnover and lysis. Chemotherapy for germ cell neoplasms and leukemia and lymphoma are the primary causes. Acute renal failure occurs with intratubular deposition of uric acid crystals; serum uric acid levels are often > 20 mg/dL and urine uric acid levels > 600 mg/24 h. A urine uric acid to urine creatinine ratio > 1.0 indicates risk for acute renal failure.

Bence Jones protein seen in conjunction with multiple myeloma can cause direct tubular toxicity and tubular obstruction. Other renal complications from multiple myeloma include hypercalcemia and proximal renal tubular acidosis.

Clinical Findings

A. Symptoms and Signs

See Acute Renal Failure, above.

B. Laboratory Findings

Urinalysis may show evidence of acute tubular damage. The urine may be brown. On microscopic examination, an active sediment may show pigmented granular casts or "muddy brown" casts. Renal tubular epithelial cells and epithelial cell casts are often present as well. Hyperkalemia and hyperphosphatemia are commonly encountered.

Treatment

Treatment is aimed at hastening recovery and avoiding complications. Preventive measures should be taken to avoid volume overload and hyperkalemia. Loop-blocking diuretics are often used in large doses (eg, furosemide in doses ranging from 20 mg to 160 mg orally or intravenously twice daily) to effect adequate diuresis, and may help convert oliguric to nonoliguric renal failure. Recent studies, however, have shown potentially worse outcomes in patients who receive doses of furosemide, including an increased risk of death and nonrecovery of renal function. Widespread use of diuretics in critically ill patients with acute renal failure should be discouraged. Side effects of supranormal dosing include deafness. This is mainly due to peak furosemide levels and can be avoided by the use of a furosemide drip. A starting dose of 0.4-0.6 mg/kg/h is appropriate, increasing to a maximum of 1 mg/kg/h. A bolus of the hourly dose should be administered at the beginning of treatment. Intravenous thiazide diuretics can be used to augment urine output; chlorothiazide, 500 mg intravenously every 8-12 hours, is a reasonable choice. Nutritional support should maintain adequate intake while preventing excessive catabolism. Dietary protein restriction of 0.6 g/kg/d helps to prevent metabolic acidosis. Hypocalcemia and hyperphosphatemia can be improved with diet and phosphate-binding agents such as aluminum hydroxide (500 mg orally with meals) over the short term, calcium carbonate (500-1500 mg orally three times daily), calcium acetate, or sevelamer. Hypocalcemia should not be treated in patients with rhabdomyolysis unless they are symptomatic. Hypermagnesemia can occur because of reduced magnesium excretion by the renal tubules, so magnesium-containing antacids and laxatives should be avoided in these patients. Dosages must be adjusted according to the estimated degree of renal impairment for drugs eliminated by the kidney.

Indications for dialysis in acute renal failure from acute tubular necrosis or other intrinsic disorders are as follows: life-threatening electrolyte disturbances (such as hyperkalemia), volume overload unresponsive to diuresis, worsening acidosis, and uremic complications (eg, encephalopathy, pericarditis, and seizures). In gravely ill patients, less severe but worsening abnormalities may also be indications for dialytic support.

Course & Prognosis

The clinical course of acute tubular necrosis is often divided into three phases: initial injury, maintenance, and recovery. The maintenance phase is expressed as either oliguric (urine output < 500 mL/d) or nonoliguric. Nonoliguric acute tubular necrosis has a better outcome. Conversion from oliguric to nonoliguric states may be attempted but has not been shown to change the prognosis. Drugs such as dopamine and diuretics are sometimes used for this purpose but have not been shown to improve outcomes. "Renal dose" dopamine (1-3 ug/kg/min) can increase renal blood flow but can also potentiate arrhythmias and myocardial ischemia. Rarely, dopamine can cause a significant diuresis. If dopamine does not improve urinary output within a few hours, it should be discontinued. Average duration of this period is 1-3 weeks but may be several months. Cellular repair and removal of tubular debris occur during the maintenance phase. The recovery phase is heralded by diuresis. GFR begins to rise; BUN and serum creatinine fall.

The mortality rate from acute renal failure is 20-50% in medical illness and up to 70% in a surgical setting. Increased mortality is associated with advanced age, severe underlying disease, and multisystem organ failure. Leading causes of death are infections, fluid and electrolyte disturbances, and worsening of underlying disease. Mortality rates have not changed significantly over 20 years, making prevention of acute renal failure a high priority.

INTERSTITIAL NEPHRITIS

Essentials of Diagnosis

- Fever.
- Transient maculopapular rash.
- Acute renal insufficiency.
- Pyuria (including eosinophiluria), white blood cell casts, and hematuria.

General Considerations

Acute interstitial nephritis accounts for 10-15% of cases of intrinsic renal failure. An interstitial inflammatory response with edema and possible tubular cell damage is the typical pathologic finding. Cell-mediated immune reactions prevail over humoral responses. T lymphocytes can cause direct cytotoxicity or release lymphokines that recruit monocytes and inflammatory cells.

Although drugs account for over 70% of cases, acute interstitial nephritis also occurs in infectious diseases or immunologic disorders or may be idiopathic. The most common drugs are penicillins and cephalosporins, sulfonamides and sulfonamide-containing diuretics, NSAIDs, rifampin, phenytoin, and allopurinol. Infectious causes include streptococcal infections, leptospirosis, CMV, histoplasmosis, and Rocky Mountain spotted fever. Immunologic entities are more commonly associated with glomerulonephritis, but systemic lupus erythematosus, Sjogren's syndrome, sarcoidosis, and cryoglobulinemia can cause interstitial nephritis.

Clinical Findings

Clinical features can include fever (> 80%), rash (25- 50%), arthralgias, and peripheral blood eosinophilia (80%). The urine often contains red cells (95%), white cells, and white cell casts. Proteinuria can be a feature, particularly in NSAID-induced interstitial nephritis but is usually modest. Eosinophiluria can be detected by Wright's stain.

Treatment & Prognosis

Acute interstitial nephritis often carries a good prognosis. Recovery occurs over weeks to months, but acute dialytic therapy may be necessary in up to one-third of all patients before resolution. (See indications for dialysis, above.) Patients rarely progress to end-stage renal disease. Those with prolonged courses of oliguric failure and advanced age have a worse prognosis. Treatment consists of supportive measures and removal of the inciting agent. If renal failure persists after removal of the inciting agent, a short course of steroids can be given. Short-term, high dose methylprednisolone (0.5-1 g/d for 1-4 days) or prednisone (60 mg/d for 1-2 weeks) followed by a prednisone taper can be used in these more severe cases of drug-induced interstitial nephritis.

GLOMERULONEPHRITIS

Essentials of Diagnosis

- Hematuria, dysmorphic red cells, red cell casts, and mild proteinuria.
- Dependent edema and hypertension.
- Acute renal insufficiency.

General Considerations

Acute glomerulonephritis is a relatively uncommon cause of acute renal failure, accounting for about 5% of cases of intrinsic renal failure. Pathologically, inflammatory glomerular lesions are seen. These include mesangioproliferative, focal and diffuse proliferative, and crescentic lesions. The larger the percentage of glomeruli involved and the more severe the lesion, the more likely it is that the patient will have a poor clinical outcome.

Categorization of acute glomerulonephritis can be done by serologic analysis. Markers include antineutrophil cytoplasmic antibodies (ANCA), anti-glomerular basement membrane (GBM) antibodies, and other immune markers of disease.

Immune complex deposition usually occurs when moderate antigen excess over antibody production occurs. Complexes formed with marked antigen excess tend to remain in the circulation. Antibody excess with large antigen-antibody aggregates usually results in phagocytosis and clearance of the precipitates by the mononuclear phagocytic system in the liver and spleen. Causes include IgA nephropathy (Berger's disease), peri- or postinfectious glomerulonephritis, lupus nephritis, cryoglobulinemic glomerulonephritis (often associated with hepatitis C virus), and membranoproliferative glomerulonephritis.

Anti-GBM-associated acute glomerulonephritis is either confined to the kidney or associated with pulmonary hemorrhage. The latter is termed Goodpasture's syndrome. Injury is related to autoantibodies aimed against type IV collagen in the glomerular basement membrane rather than to immune complex deposition.

Pauci-immune acute glomerulonephritis is a form of small-vessel vasculitis associated with ANCA, causing primary and secondary renal diseases that do not have direct immune complex deposition or antibody binding. Tissue injury is believed to be due to cell-mediated immune processes. An example is Wegener's granulomatosis, a systemic necrotizing vasculitis of small arteries and veins associated with intravascular and extravascular granuloma formation. In addition to glomerulonephritis, these patients can have upper airway, pulmonary, and skin manifestations of disease. Cytoplasmic ANCA (c-ANCA) is both specific (88%) and sensitive (95%) for this entity. Microscopic polyangiitis is another pauci-immune vasculitis causing acute glomerulonephritis. Perinuclear staining (p-ANCA) is the common pattern. ANCA-associated and anti-GBM-associated acute glomerulonephritis can evolve to crescentic glomerulonephritis and often have poor outcomes unless treatment is started early. Both are described more fully below.

Other vascular causes of acute glomerulonephritis include malignant hypertension and the thrombotic microangiopathies such as hemolytic-uremic syndrome ([Chapter 11](#)) and thrombotic thrombocytopenic purpura ([Chapter 13](#)).

Clinical Findings

A. Symptoms and Signs

Patients with acute glomerulonephritis are often hypertensive, edematous, and have an abnormal urinary sediment. The edema is found first in body parts with low tissue tension such as the periorbital and scrotal regions.

B. Laboratory Findings

Dipstick and microscopic evaluation will reveal evidence of hematuria, moderate proteinuria (usually < 2 g/d), and cellular elements such as red cells, red cell casts, and white cells. Red cell casts are specific for glomerulonephritis, and a detailed search is warranted. Twenty-four hour urine for protein excretion and creatinine clearance quantifies the amount of proteinuria and documents the degree of renal dysfunction. However, in cases of rapidly changing serum creatinine values, the urinary creatinine clearance is an unreliable marker of GFR. FE_{Na} is usually low unless renal dysfunction is marked.

Further tests include complement levels (C3, C4, CH50), ASO titer, anti-GBM antibody levels, ANCAs, ANA titers, cryoglobulin and hepatitis panels, C3 nephritic factor, renal ultrasound, and renal biopsy.

Treatment

Depending on the nature and severity of disease, treatment can consist of high-dose steroids and cytotoxic agents such as cyclophosphamide. Plasma exchange can be used in Goodpasture's disease. Treatment and prognosis for specific diseases are more fully discussed below.

■ CHRONIC KIDNEY DISEASE

- Progressive azotemia over months to years.
- Symptoms and signs of uremia when nearing end-stage disease.
- Hypertension in the majority.
- Isosthenuria and broad casts in urinary sediment are common.
- Bilateral small kidneys on ultrasound are diagnostic.

General Considerations

Chronic kidney disease affects up to 20 million Americans, or one in nine adults. Most are unaware of the condition because they remain asymptomatic until their disease has significantly progressed. The National Kidney Foundation has developed a new staging system that helps clinicians formulate practice plans. ([Table 22-5](#)). Over 50% of cases of late-stage chronic kidney disease are due to diabetes mellitus or hypertension. Glomerulonephritis, cystic diseases, and other urologic diseases account for another 20-25%, and nearly one-sixth of patients have unknown causes. The major causes of chronic renal failure are listed in [Table 22-6](#).

Chronic kidney disease is rarely reversible and leads to progressive decline in renal function. This occurs even after an inciting event has been removed. Reduction in renal mass leads to hypertrophy of the remaining nephrons with hyperfiltration, and the glomerular filtration rate in these nephrons is transiently at supranormal levels. These adaptations place a burden on the remaining nephrons and lead to progressive glomerular sclerosis and interstitial fibrosis, suggesting that hyperfiltration may worsen renal function. However, decreased renal mass in kidney donors is not associated with chronic renal failure.

Clinical Findings

A. Symptoms and Signs

The symptoms of chronic kidney disease often develop slowly and are nonspecific ([Table 22-7](#)). Individuals can remain asymptomatic until renal failure is far-advanced (GFR < 10-15 mL/min). Manifestations include fatigue, weakness, and malaise. Gastrointestinal complaints such as anorexia, nausea, vomiting, a metallic taste in the mouth, and hiccups are common. Neurologic problems include irritability, difficulty in concentrating, insomnia, restless legs, and twitching. Pruritus is common and difficult to treat. As uremia progresses, decreased libido, menstrual irregularities, chest pain from pericarditis, and paresthesias can develop. Symptoms of drug toxicity—especially for drugs eliminated by the kidney—increase as renal clearance worsens. (See [Table 22-8](#) for antimicrobial dosages.)

On physical examination, the patient appears chronically ill. Hypertension is common. The skin may be yellow, with signs of easy bruisability. Rarely seen in the dialysis era is uremic frost, a cutaneous reflection of end-stage renal disease. Uremic fetor is the characteristic fishy odor of the breath. Cardiopulmonary signs may include rales, cardiomegaly, edema, and a pericardial friction rub. Mental status can vary from decreased concentration to confusion, stupor, and coma. Myoclonus and asterixis are additional signs of uremic effects on the central nervous system.

The term "uremia" is used for this clinical syndrome, but the exact cause remains unknown. BUN and serum creatinine are believed to be markers for unknown toxins, with urea and parathyroid hormone believed to play a partial role in the syndrome.

In any patient with renal failure, it is important to identify and correct all possibly reversible causes. Urinary tract infections, obstruction, extracellular volume depletion,

nephrotoxins, hypertension, and congestive heart failure should be excluded ([Table 22-9](#)). Any of the above can worsen underlying chronic renal failure.

B. Laboratory Findings

The diagnosis of renal failure is made by documenting elevations of the BUN and serum creatinine concentrations. Further evaluation is needed to differentiate between acute and chronic renal failure. Evidence of previously elevated BUN and creatinine, abnormal prior urinalyses, and stable but abnormal serum creatinine on successive days is most consistent with a chronic process. It is helpful to plot the inverse of serum creatinine ($1/S_{Cr}$) versus time if three or more prior measurements are available; this estimates time to end-stage renal disease ([Figure 22-1](#)). If the slope of the line acutely declines, new causes of renal failure should be excluded as outlined above. Anemia, metabolic acidosis, hyperphosphatemia, hypocalcemia, and hyperkalemia can occur with both acute and chronic renal failure. The urinalysis shows isosthenuria if tubular concentrating and diluting ability are impaired. The urinary sediment can show broad waxy casts as a result of dilated, hypertrophic nephrons.

C. Imaging

The findings of small echogenic kidneys bilaterally (< 10 cm) by ultrasonography supports a diagnosis of chronic renal failure, though normal or even large kidneys can be seen with chronic renal failure caused by adult polycystic kidney disease, diabetic nephropathy, HIV-associated nephropathy, multiple myeloma, amyloidosis, and obstructive uropathy. Radiologic evidence of renal osteodystrophy is another helpful finding, since x-ray changes of secondary hyperparathyroidism do not appear unless parathyroid levels have been elevated for at least 1 year. Evidence of subperiosteal reabsorption along the radial sides of the digital bones of the hand confirms hyperparathyroidism.

Complications

A. Hyperkalemia

Potassium balance generally remains intact in chronic renal failure until the GFR is less than 10-20 mL/min. However, certain states pose an increased risk of hyperkalemia at higher GFRs. Endogenous causes include any type of cellular destruction such as hemolysis and trauma, the hyporeninemic hypoaldosteronism (type IV renal tubular acidosis, seen particularly in diabetes mellitus), and acidemic states (0.6 meq/L elevation in K^+ for each 0.1 unit decrease in pH). Exogenous causes include diet (eg, citrus fruits and salt substitutes containing potassium) and drugs that decrease K^+ secretion (amiloride, triamterene, spironolactone, NSAIDs, ACE inhibitors) or block cellular uptake (beta-blockers).

Treatment of acute hyperkalemia involves cardiac monitoring, intravenous calcium chloride or gluconate, insulin administration with glucose, bicarbonate, and an orally or rectally administered ion exchange resin (sodium polystyrene sulfonate). The resin exchanges sodium for potassium and can administer a significant sodium load to a patient. Chronic hyperkalemia is best treated with dietary potassium restriction and sodium polystyrene sulfonate when necessary. The usual dose is 15-30 g once a day in juice or sorbitol.

B. Acid-Base Disorders

Damaged kidneys are unable to excrete the 1 meq/ kg/d of acid generated by metabolism of dietary proteins. The resultant metabolic acidosis is primarily due to loss of renal mass. This limits production of ammonia (NH_3) and limits buffering of H^+ in the urine. (Other causes include decreased filtration of titratable acids such as sulfates and phosphates, decreased proximal tubular bicarbonate resorption, and decreased renal tubular hydrogen ion secretion.) Although patients with chronic renal failure are in positive hydrogen ion balance, the arterial blood pH is maintained at 7.33-7.37 and serum bicarbonate concentration rarely falls below 15 meq/L. The excess hydrogen ions are buffered by the large calcium carbonate and calcium phosphate stores in bone. This contributes to the renal osteodystrophy of chronic renal failure described below.

The serum bicarbonate level should be maintained at > 20 meq/L. Base supplements include sodium bicarbonate, calcium bicarbonate, and sodium citrate. Administration should begin with 20-30 mmol/d of alkali divided into two doses per day and titrated as needed.

C. Cardiovascular Complications

1. Hypertension—As renal failure progresses, hypertension due to salt and water retention usually develops. Hyperreninemic states and exogenous erythropoietin administration can also exacerbate hypertension. Hypertension is the most common complication of end-stage renal disease and must be meticulously controlled. Failure to do so can accelerate the progression of renal damage.

Control of hypertension can be achieved with salt and water restriction, weight loss if indicated, and pharmacologic therapy. The ability of the kidney to adjust to variations in sodium and water intake becomes limited as renal failure progresses. An elevated sodium chloride intake leads to congestive heart failure, edema, and hypertension, whereas low salt intake leads to volume contraction and hypotension. A mildly decreased salt diet (4-6 g/d) can be started, and salt intake should be reduced to 2 g/d if hypertension persists. Initial drug therapy can include ACE inhibitors or angiotensin II receptor blockers (if serum potassium and GFR permit), calcium channel-blocking agents, diuretics, and beta-blocking agents. The adjunctive drugs that are often needed (clonidine, hydralazine, minoxidil, etc) reflect the difficulty of achieving and maintaining hypertensive control in these patients.

2. Pericarditis—With uremia, pericarditis may develop. The cause is believed to be retention of metabolic toxins. Symptoms include chest pain and fever. Pulsus paradoxus can be present. A friction rub may be auscultated, but the lack of a rub does not rule out a significant pericardial effusion. Chest radiography will show an enlarged cardiac silhouette, and electrocardiography will show characteristic findings as explained in [Chapter 10](#). Cardiac tamponade can occur; these patients have signs of poor cardiac output, with jugular venous distention and lungs clear to auscultation. Pericarditis is an absolute indication for initiation of hemodialysis.

3. Congestive heart failure—Patients with end-stage renal disease tend toward a high cardiac output. They often have extracellular fluid overload, shunting of blood through an arteriovenous fistula for dialysis, and anemia. In addition to hypertension, these abnormalities cause increased myocardial work and oxygen demand. Patients with chronic renal failure may also have accelerated rates of atherosclerosis. All of these factors contribute to left ventricular hypertrophy and dilation. Parathyroid hormone may also play a role in the pathogenesis of the cardiomyopathy of renal failure.

Water and salt intake should be controlled in patients who are oliguric or anuric. Diuretics are of value, though thiazides are ineffective when the GFR is less than 10-15 mL/min. Loop diuretics are commonly used, and higher doses are required as renal function declines. Digoxin should be used with caution since it is excreted by the kidney. The proved efficacy of ACE inhibitors in congestive heart failure holds true for patients with chronic renal failure. However, they are typically not used with a serum creatinine greater than 3 mg/dL without close supervision because of the risks of hyperkalemia and worsening renal function. Nonetheless, ACE inhibitors are being increasingly used with higher levels of stable serum creatinines. Along with angiotensin II receptor-blocking drugs, they have been shown to slow the progression to end-stage renal disease. (See above section regarding treatment of proteinuria.) Once a patient is on dialysis, these risks become less relevant. When an ACE inhibitor is initiated, patients should have serum creatinine and potassium checked within 2-7 days.

D. Hematologic Complications

1. Anemia—The anemia of chronic renal failure is characteristically normochromic and normocytic. It is due primarily to decreased erythropoietin production, which becomes clinically significant when GFR falls below 20-25 mL/min. Many patients are iron-deficient as well. Low-grade hemolysis and blood loss from platelet dysfunction or hemodialysis play an additional role.

Recombinant erythropoietin (epoetin alfa) is used in patients whose hematocrits are less than 30-35%. The effective dose can vary, and patients are started on 50 units/kg (3000-4000 units/dose) once or twice a week. It can be given intravenously (eg, in the hemodialysis patient) or subcutaneously (eg, in the peritoneal dialysis patient or one who has not yet started dialysis). Iron stores must be adequate to ensure response. Subcutaneous administration is preferable to intravenous administration because it requires a lower overall dose for the same effect. Iron supplementation is given at the minimum if the serum ferritin is less than 100 ng/mL or if iron saturation is < 20 -25%. Depending on the clinical situation, iron therapy should be withheld if the serum ferritin is > 800 ng/mL. Oral therapy with ferrous sulfate, 325 mg once daily to three times daily, is adequate but not always well tolerated, and gut absorption of iron is impaired in uremic patients. Ferrous fumarate is the best-accepted formulation, and intravenous iron may be used in dialysis patients. The importance of observing trends in iron stores and hemoglobin levels cannot be overemphasized.

Hypertension is a complication of epoetin alfa therapy in about 20% of patients. It develops more abruptly in the patients with the lowest hematocrit values at initiation of therapy. Patients may require dosage adjustment or may have to be started on antihypertensive drugs. Hemoglobin levels should rise no more than 1 g/dL every 3-4 weeks.

2. Coagulopathy—The coagulopathy of chronic renal failure is mainly caused by platelet dysfunction. Platelet counts are only mildly decreased, but the bleeding time is prolonged. Platelets show abnormal adhesiveness and aggregation. Clinically, patients can have petechiae, purpura, and an increased tendency for bleeding during surgery.

Treatment is required only in patients who are symptomatic. Raising the hematocrit to 30% can reduce bleeding time in many patients. Desmopressin (25 ug intravenously every 8-12 hours for 2 doses) is effective and often used in preparation for surgery. It causes release of factor VIII bound to von Willebrand's factor from endothelial cells. Conjugated estrogens, 0.6 mg/kg diluted in 50 mL of 0.9% sodium chloride infused over 30-40 minutes daily, or 2.5-5 mg orally for 5-7 days, have an effect for several weeks. Dialysis improves the bleeding time but does not normalize it. Peritoneal dialysis is preferable to hemodialysis because the latter requires

heparin use to prevent clotting in the dialyzer. Cryoprecipitate (10-15 bags) is rarely used and lasts less than 24 hours.

E. Neurologic Complications

Uremic encephalopathy does not occur until GFR falls below 10-15 mL/min. Parathyroid hormone is believed to be one of the uremic toxins. Patients can develop markedly elevated intact PTH levels from tertiary hyperparathyroidism. When calcium levels exceed 12-15 mg/dL, mental status changes often follow. Symptoms begin with difficulty in concentrating and can progress to lethargy, confusion, and coma. Physical findings include nystagmus, weakness, asterixis, and hyperreflexia. These symptoms and signs may improve after initiation of dialysis.

Neuropathy is found in 65% of patients on or nearing dialysis but not until GFR is 10% of normal. Peripheral neuropathies manifest themselves as sensorimotor polyneuropathies (stocking and glove distribution) and isolated or multiple isolated mononeuropathies. Patients can have restless legs, loss of deep tendon reflexes, and distal pain. The earlier initiation of dialysis may prevent peripheral neuropathies, and the response to dialysis is variable. Other neuropathies result in impotence and autonomic dysfunction.

F. Disorders of Mineral Metabolism

The disorders of calcium, phosphorus, and bone are referred to as renal osteodystrophy. The most common disorder is osteitis fibrosa cystica—the bony changes of secondary hyperparathyroidism. As GFR decreases below 25% of normal, phosphorus excretion is impaired. Hyperphosphatemia leads to hypocalcemia, stimulating secretion of parathyroid hormone, which has a phosphaturic effect and normalizes serum phosphorus. This continuous process leads to markedly elevated parathyroid hormone levels and high bone turnover with osteoclastic bone resorption and subperiosteal lesions. Clinically, patients experience bony pain and proximal muscle weakness. Metastatic calcifications can occur. Radiographically, lesions are most prominent in the phalanges and lateral ends of the clavicles.

Osteomalacia is a form of renal osteodystrophy with low bone turnover. With worsening renal function, there is decreased renal conversion of 25-hydroxycholecalciferol to the 1,25-dihydroxy form. Gut absorption of calcium is diminished, leading to hypocalcemia and abnormal bone mineralization. Deposition of aluminum in bone can also lead to osteomalacia. Elevated aluminum levels are seen in patients after years of chronic aluminum hydroxide administration for phosphorus binding. This entity is seen with decreasing frequency because aluminum-based binders are used less in the chronic setting and water used for hemodialysis is now cleared of aluminum.

Both of the above entities can cause bony pain and proximal muscle weakness. Spontaneous bone fractures can occur which are slow to heal. When the calcium-phosphorus product (serum calcium [mg/dL] × serum phosphate [mg/dL]) is above 60-70, metastatic calcifications are commonly seen in blood vessels, soft tissues, lungs, and myocardium. Treatment should begin with dietary phosphorus restriction. Oral phosphorus binding agents such as calcium carbonate or calcium acetate act in the gut and are given in divided doses three or four times daily with meals. These should be titrated to a serum calcium of 10 mg/dL (preventing hypercalcemia) and serum phosphorus of 4.5 mg/dL. Sevelamer is another phosphorus-binding agent that does not contain calcium; it is particularly useful in patients with hypercalcemia. Aluminum hydroxide is an effective phosphorus binder but can cause osteomalacia and neurologic complications. It can be used in the acute setting, but chronic use should be avoided. If aluminum levels are high, chelation with deferoxamine can be effective. Vitamin D or vitamin D analogs should be given with hyperparathyroidism (iPTH more than two to three times normal) if phosphorus levels are < 7 mg/dL and calcium < 11 mg/dL. Vitamin D suppresses PTH and increases serum calcium and phosphorus levels; both need to be followed closely to prevent hypercalcemia and hyperphosphatemia. If calcitriol is used, the dosage should be 0.25-0.5 ug daily or every other day initially.

G. Endocrine Disorders

Circulating insulin levels are higher because of decreased renal insulin clearance. Glucose intolerance can occur in chronic renal failure when GFR is less than 10-20 mL/min. Primarily, this is due to peripheral insulin resistance. Fasting glucose levels are usually normal or only slightly elevated. Therefore, patients can be either hyperglycemic or hypoglycemic depending on the predominant disturbance. Most commonly, diabetic patients require decreased doses of hypoglycemic agents.

Decreased libido and impotence are common in chronic renal failure. Men have decreased testosterone levels; women are often anovulatory. Despite a high degree of infertility, pregnancy can occur—particularly in women who are well dialyzed and well nourished. Therefore, contraception is advisable for women who do not wish to become pregnant.

Thyroid, pituitary, and adrenal function are often normal despite abnormalities in thyroxine, growth hormone, aldosterone, and cortisol levels.

Treatment

A. Dietary Management

Every patient with chronic renal failure should be evaluated by a renal nutritionist. Specific recommendations should be made concerning protein, salt, water, potassium, and phosphorus intake.

1. Protein restriction—Experimental models have shown that protein restriction slows the progression to end-stage renal disease; however, clinical trials have not consistently proved this. The Modification of Diet in Renal Disease (MDRD) Study was meant to clarify the issue, but the results were inconclusive. A subsequent meta-analysis of five clinical trials did show a significant benefit but did not control for certain effects such as ACE inhibitor therapy. Protein intake should not exceed 1 g/kg/d, and if protein restriction proves to be beneficial, the level of restriction may approach 0.6-0.8 g/kg/d.

2. Salt and water restriction—In advanced renal failure, the kidney is unable to adapt to large changes in sodium intake. Intake greater than 3-4 g/d can lead to edema, hypertension, and congestive heart failure, whereas intake of less than 1 g/d can lead to volume depletion and hypotension. For the nondialysis patient approaching end-stage renal disease, 2 g/d of sodium is an initial recommendation. A daily intake of 1-2 L of fluid maintains water balance.

3. Potassium restriction—Restriction is needed once the GFR has fallen below 10-20 mL/min. Patients should receive detailed lists concerning potassium content of foods and should limit their intake to less than 60-70 meq/d. Normal intake is about 100 meq/d.

4. Phosphorus restriction—Phosphorus levels should be kept below 4.5 mg/dL, although levels < 5.5 mg/dL are acceptable. Foods rich in phosphorus such as cola beverages, eggs, dairy products, and meat should be limited. Renal failure patients with a GFR > 10-20 mL/min should restrict phosphorus intake to 5-10 mg/kg/d. Below this GFR, phosphorus binders are usually required. The treatment of hyperphosphatemia is discussed in the section on disorders of mineral metabolism.

5. Magnesium restriction—Magnesium is excreted primarily by the kidneys. Dangerous hypermagnesemia is rare unless the patient ingests medications high in magnesium or receives it parenterally. All magnesium-containing laxatives and antacids are relatively contraindicated in renal failure.

B. Dialysis

When conservative management of end-stage renal disease is inadequate, hemodialysis, peritoneal dialysis, and kidney transplantation are alternatives (see below). Indications for dialysis include the following: (1) uremic symptoms such as pericarditis, encephalopathy, or coagulopathy; (2) fluid overload unresponsive to diuresis; (3) refractory hyperkalemia; (4) severe metabolic acidosis (pH < 7.20); and (5) neurologic symptoms such as seizures or neuropathy. According to the Dialysis Outcomes Quality Initiative (DOQI) guidelines, dialysis should be started when a patient has a GFR of 10 mL/min or serum creatinine of 8 mg/dL. Diabetics should start when the GFR reaches 15 mL/min or serum creatinine is 6 mg/dL. Preparation for dialysis requires a team approach. Dietitians, social workers, psychiatrists, and transplant surgeons should be involved as well as primary care physicians and nephrologists. The patient and family need early counseling regarding the risks and benefits of therapy. The option of not starting therapy or withdrawing therapy should be discussed openly.

1. Hemodialysis—Hemodialysis requires a constant flow of blood along one side of a semipermeable membrane with a cleansing solution, or dialysate, along the other. Diffusion and convection allow the dialysate to remove unwanted substances from the blood while adding back needed components. Vascular access for hemodialysis can be accomplished by an arteriovenous fistula or prosthetic shunt. Indwelling catheters should be considered temporary measures. Native fistulas typically last longer than prosthetic shunts but require longer (6-8 weeks or more after surgical construction) before they can be used. Infection, thrombosis, and aneurysm formation are complications seen more often in shunts than fistulas. *Staphylococcus aureus* is the most common infecting agent.

Patients typically require hemodialysis three times a week. Sessions last 3-5 hours depending on patient size, type of dialyzer used, and other factors. Periodic measurement of dialysis adequacy should determine the duration of treatment. Home hemodialysis is an option that is becoming less popular because of the need for a trained helper, large equipment, and costs.

2. Peritoneal dialysis—With peritoneal dialysis, the peritoneal membrane is the "dialyzer." Fluids and solutes move across the capillary bed that lies between the visceral and parietal layers of the membrane into the dialysate. Dialysate enters the peritoneal cavity through a catheter. The most common kind of peritoneal dialysis is continuous ambulatory peritoneal dialysis (CAPD). Patients exchange the dialysate four to six times a day. Continuous cyclic peritoneal dialysis (CCPD) utilizes a cyclor machine to automatically perform exchanges at night. The dialysate remains in the peritoneal cavity between exchanges. As with hemodialysis, actual peritoneal dialysis prescriptions are guided by adequacy measurements.

The percentage of dialysis patients using peritoneal dialysis has been decreasing over the past several years. Peritoneal dialysis permits greater patient autonomy; its continuous nature minimizes the symptomatic swings observed in hemodialysis patients; and poorly dialyzable compounds such as phosphates are better cleared, which permits less dietary restriction. The dialysate removes large amounts of albumin, and nutritional status must be closely watched.

The most common complication of peritoneal dialysis is peritonitis. Rates are as high as 0.8 episodes per patient year. The patient can experience nausea and vomiting, abdominal pain, diarrhea or constipation, and fever. The dialysate will be cloudy and contain > 100 white cells per microliter of which over 50% should be polymorphonuclear neutrophils. *S aureus* is the most common infecting organism.

The total costs of peritoneal dialysis and hemodialysis are approximately the same. Equipment expenses are less for peritoneal dialysis, but the costs of peritonitis are high. Patients treated with both modalities more often prefer peritoneal to hemodialysis.

Survival rates on dialysis depend on the underlying disease process. Five-year Kaplan-Meier survival rates vary from 21% for diabetics to 47% for patients with glomerulonephritis. Overall 5-year survival is currently estimated at 36%. Patients undergoing dialysis have an average life expectancy of 3-4 years, but survival for as long as 25 years is seen depending on the disease entity. Most studies have shown no survival advantage associated with either peritoneal dialysis or hemodialysis.

C. Kidney Transplantation

Up to one-half of all patients with end-stage renal disease are suitable for transplantation. Age is becoming less of a barrier. Two-thirds of kidney transplants come from deceased donors, the remainder from living related or unrelated donors. Immunosuppressive drugs include corticosteroids, azathioprine, mycophenolate mofetil, tacrolimus, cyclosporine, and rapamycin. A patient with a deceased-donor renal transplant typically requires stronger immunosuppression than patients with living related kidney transplants. However, this depends to a great extent on the degree of HLA-type matching. The 1- and 5-year kidney graft survival rates are approximately 94% and 72%, respectively, for living related and living unrelated donor transplants and 89% and 58%, respectively, for deceased donor transplants. The average wait for a cadaveric transplant is 2-4 years; this is becoming progressively longer as more people are going onto waiting lists while the deceased donor pool is not expanding. Aside from medication use, the life of a transplanted patient can return to nearly normal.

D. Prognosis

Mortality is higher for patients on dialysis than for age-matched controls. Yearly mortality is 22.4 deaths per 100 patient years. The expected remaining lifetime for the age group 55-64 is 22 years, whereas that of the end-stage renal disease population is 5 years. The most common cause of death is cardiac dysfunction (48%). Other causes include infection (15%), cerebrovascular disease (6%), and malignancy (4%). Diabetes, age, a low serum albumin, lower socioeconomic status, and inadequate dialysis are all significant predictors of mortality.

For those who require dialysis to sustain life but elect not to undergo dialysis, death ensues within days to weeks. In general, patients develop uremia and lose consciousness prior to death. Arrhythmias can occur as a result of electrolyte imbalance. Volume overload and dyspnea can be managed by volume restriction and opioids as described in [Chapter 5](#). Meticulous efforts at palliative care are essential.

RENAL ARTERY STENOSIS

The two most common forms of renal artery stenosis are atherosclerotic ischemic renal disease and fibromuscular dysplasia. The prevalence of this condition has only been estimated by autopsy and angiographic studies. Approximately 5% of Americans with hypertension suffer from renal artery stenosis.

Atherosclerotic ischemic renal disease accounts for 67-95% of all cases of renal artery stenosis. It occurs most commonly in those over 45 years of age with a history of atherosclerotic disease. Other risk factors include renal insufficiency, diabetes mellitus, tobacco use, and hypertension.

Clues to diagnosis include refractory hypertension, new-onset hypertension in an older patient, pulmonary edema with poorly controlled blood pressure, and acute renal failure upon starting an angiotensin-converting enzyme inhibitor. In addition to hypertension, physical examination may reveal an audible abdominal bruit on the affected side. Laboratory values can show elevated BUN and serum creatinine levels in the setting of significant renal ischemia, and abdominal ultrasound discloses asymmetric kidney size when one renal artery is affected out of proportion to the other.

Three prevailing methods used for screening are Doppler ultrasonography, captopril renography, and magnetic resonance angiography (MRA). Doppler ultrasonography is highly sensitive and specific (> 90% with an experienced ultrasonographer) and relatively inexpensive. However, this method is extremely operator- and patient-dependent. Measurements of blood flow must be made at the aorta and along each third of the renal artery in order to assess the disease. This test is a poor choice for patients who are obese, unable to lie supine, or have interfering bowel gas patterns.

Captopril renography capitalizes on the difference in renal perfusion with and without ACE inhibitors. A kidney distal to a significant stenosis requires high angiotensin II levels to maintain adequate perfusion. With an ACE inhibitor, perfusion is markedly diminished. The affected kidney enhances less, whereas the unaffected one enhances more in the setting of a captopril challenge. Sensitivity ranges from 75% to 100% and specificity from 60% to 90%. This procedure is not accurate in moderate to severe renal insufficiency.

MRA is an excellent but expensive way to screen for renal artery stenosis. Sensitivity is 99-100%. Specificity ranges from 71% to 96%. Turbulent blood flow can cause falsely positive results.

Renal angiography is the best procedure for diagnosis. CO₂ subtraction angiography can be used in place of dye when the risk of dye nephropathy exists—eg, in diabetic patients with renal insufficiency. Lesions are most commonly found in the proximal third or ostial region of the renal artery. The risk of atheroembolic phenomena after angiography is not trivial in this population, ranging from 5% to 10%.

Treatment is controversial. Options include medical management, angioplasty with or without stenting, and surgical bypass. Angioplasty might reduce the number of antihypertensive medications but does not significantly change outcome in comparison to patients medically managed. Stenting produces significantly better angioplastic results. However, blood pressure is equally improved, and serum creatinines are similar at 6 months of observation. Angioplasty is equally as effective as and safer than surgical revision.

Fibromuscular dysplasia primarily affects young women. Unexplained hypertension in a young woman is reason to screen for this disorder. The noninvasive tests mentioned above should be used for detection. This disorder has a characteristic "beads-on-a-string" appearance on angiography. Treatment with percutaneous transluminal angioplasty is often curative.

■ GLOMERULONEPHROPATHIES

Abnormalities of glomerular function can be caused by damage to the major components of the glomerulus: the epithelium (podocytes), the basement membrane, the capillary endothelium, or the mesangium. The damage is often manifested as an inflammatory process. A specific histologic pattern of glomerular injury can be seen on renal biopsy, one of the most helpful techniques available for defining the cause of glomerular disease. Clinically, hematuria, proteinuria, hypertension, and a reduced GFR are typical findings of glomerular diseases presenting as *nephritic* syndromes; heavy proteinuria (> 3.5 g/24 h), hypoalbuminemia, hyperlipidemia, and edema are typical findings of glomerular diseases presenting as *nephrotic* syndromes.

Classification

Glomerular diseases generally can be classified into one of three major syndromes: nephritic syndrome, nephrotic syndrome, and asymptomatic renal disease. Specific glomerular diseases usually exhibit characteristics of one of the above syndromes, though some can have varying components of all three.

Glomerular diseases can also be classified according to whether they cause only renal abnormalities (primary renal disease) or whether the renal abnormalities result from a systemic disease (secondary renal disease).

NEPHRITIC SYNDROME

Essentials of Diagnosis

- Edema.
- Hypertension.
- Hematuria (with or without dysmorphic red cells, red blood cell casts).

General Considerations

Acute glomerulonephritis usually signifies an inflammatory process causing renal dysfunction over days to weeks that may or may not resolve. If the inflammatory process is severe, the glomerulonephritis may lead to a greater than 50% loss of nephron function over the course of just weeks to months. Such a process, called rapidly progressive acute glomerulonephritis, can cause permanent damage to glomeruli if not identified and treated rapidly. Prolonged inflammatory changes can result in chronic glomerulonephritis with persistent renal abnormalities that progress to end-stage renal disease.

Clinical Findings

A. Symptoms and Signs

Edema is first seen in regions of low tissue pressure such as the periorbital and scrotal areas. Hypertension, if present, is due to volume overload rather than vasoactive substances such as angiotensin II, whose levels are low.

B. Laboratory Findings

1. Serum chemistries—There are no serum chemistries characteristic of nephritic syndrome, but certain special tests are often performed depending on the history and the results of the preliminary evaluation. These include complement levels, antinuclear antibodies (ANA), cryoglobulins, hepatitis panels, ANCA, anti-GBM antibodies, ASO titers, and C3 nephritic factor. (See [Figure 22-2](#).)

2. Urinalysis—The urinalysis shows red blood cells. These may be misshapen from traversing a damaged capillary membrane—so-called dysmorphic red blood cells. Red blood cell casts and moderate degrees of proteinuria are also characteristic of the urinary sediment. Placing the patient in a lordotic position for an hour increases sensitivity for finding red cell casts in the next urine specimen.

3. Biopsy—Renal biopsy should be considered if there are no other contraindications to biopsy (eg, bleeding disorders, thrombocytopenia, uncontrolled hypertension). Rapidly progressive glomerulonephritis is likely when over 50% of glomeruli contain crescents. The type of disease can be categorized according to the immunofluorescent pattern and appearance on electron microscopy (see [Table 22-10](#)).

Treatment

Treatment includes aggressive reduction of hypertension and fluid overload and specific therapeutic maneuvers aimed at the underlying cause. Salt and water restriction, diuretic therapy, and possibly dialysis are needed. The inflammatory glomerular injury may require corticosteroids and cytotoxic agents. (See specific diseases discussed below.)

POSTINFECTIOUS GLOMERULONEPHRITIS

Postinfectious glomerulonephritis is most often associated with poststreptococcal infection due to nephritogenic group A beta-hemolytic streptococci, especially type 12. It can occur sporadically or in clusters and during epidemics can account for up to 10% of known streptococcal infections. It commonly appears after pharyngitis or impetigo. Onset occurs within 1-3 weeks after infection (average, 7-10 days).

Other causes of postinfectious glomerulonephritis include bacteremic states such as systemic *Staphylococcus aureus* infection. Infective endocarditis and shunt infections cause similar lesions. These are referred to as peri-infectious glomerulonephritides. Viral, fungal, and parasitic causes include hepatitis B, cytomegalovirus infection, infectious mononucleosis, coccidioidomycosis, malaria, and toxoplasmosis.

Clinical Findings

A. Symptoms and Signs

The patient is oliguric, edematous, and variably hypertensive.

B. Laboratory Findings

Serum complement levels are low; antistreptolysin O (ASO) titers can be high unless the immune response had been blunted with previous antibiotic treatment. Classically, the urine is described as cola-colored. Urinary red blood cells, red cell casts, and proteinuria under 3.5 g/d are present. On microscopy, this entity appears as a diffuse proliferative glomerulonephritis. Immunofluorescence shows IgG and C3 in a granular pattern in the mesangium and along the capillary basement membrane. Electron microscopy shows large, dense subepithelial deposits or "humps."

Treatment

Treatment for this entity is supportive. Appropriate antibiotics should be used. Antihypertensives, salt restriction, and diuretics should be employed if needed. Corticosteroids have not been shown to improve outcome. Prognosis in children is very favorable, but adults are more prone to crescentic formation and chronic renal insufficiency. Less than 5% of adults will develop a rapidly progressive glomerulonephritis, and a smaller percentage will progress to end-stage renal disease.

IGA NEPHROPATHY & HENOCHE -SCHONLEIN PURPURA

IgA Nephropathy

IgA nephropathy (Berger's disease) is a primary renal disease of IgA deposition in the glomerular mesangium. The inciting cause is unknown, but the same lesion is seen in Henoch-Schonlein purpura. IgA nephropathy is also associated with hepatic cirrhosis, celiac disease, and infections such as with HIV and CMV.

IgA nephropathy is the most common form of acute glomerulonephritis in the United States and is even more prevalent worldwide, particularly in Asia. It is most commonly seen in children and young adults, with males affected two to three times more commonly than females.

An episode of gross hematuria is the commonest presenting complaint. Frequently this is associated with an upper respiratory infection (50%), gastrointestinal symptoms (10%), or a flu-like illness (15%). The urine becomes red or cola-colored 1-2 days after onset. In contrast to postinfectious glomerulonephritis, this feature has been called "synpharyngitic hematuria" since there is no significant latent period. Other findings include asymptomatic microscopic hematuria as an incidental finding and the nephrotic syndrome (see below). Approximately one-third of patients will experience a clinical remission. Forty to 50 percent of patients will have progressive renal insufficiency. The remainder will show chronic microscopic hematuria and a stable serum creatinine. The most unfavorable prognostic indicator is proteinuria > 1 g/d. Others include hypertension, persistent microscopic hematuria and proteinuria, glomerulosclerosis, and abnormal renal function.

The serum IgA level is increased in up to 50% of patients, and for that reason a normal serum IgA does not rule out the disease. Serum complement levels are usually normal, and renal biopsy is the standard for diagnosis. Glomeruli show a focal glomerulonephritis with diffuse mesangial IgA deposits and proliferation of mesangial cells. IgG and C3 can also be seen in the mesangium of all glomeruli. Skin biopsy often reveals granular deposits of IgA in dermal capillaries of affected patients.

In patients with significant proteinuria (> 1 g/d), ACE inhibitors or angiotensin II receptor-blocking drugs should be used to reduce proteinuria. The target blood pressure is < 130/80 mm Hg. In nephrotic patients, prior regimens suggested short courses of steroids, but this practice rarely prevented progression of disease. A recent regimen showed a 2% doubling of creatinine after 6 years in the treatment group versus a 21% doubling of creatinine in the control group. The regimen consisted of giving methylprednisolone, 1 g/d intravenously, for 3 days during months 1, 3, and 5, plus prednisone in a dosage of 0.5 mg/kg every other day for 6 months. This was aimed at patients with creatinine clearances > 70 mL/min. ACE inhibitors or angiotensin II receptor antagonists should also be considered as first-line therapy for the treatment of hypertension in this population.

Other treatments have included fish oil, with variable results in clinical trials. Recent studies that have shown a benefit also show that low doses (2-5g/d) are just as efficacious as high doses (9-12 g/d). There are very few side effects of long-term fish oil administration. Thus, many clinicians will use this as adjunctive therapy. Renal transplantation is an excellent option for patients with end-stage renal disease, but recurrent disease has been documented in 30% of patients 5-10 years posttransplant. Fortunately, recurrent disease rarely leads to failure of the allograft.

Henoch-Schonlein Purpura (Anaphylactoid Purpura)

This disease is a leukocytoclastic vasculitis of unknown cause. It is most common in children and has a male predominance. It classically presents with palpable purpura, arthralgias, and abdominal symptoms such as nausea, colic, and melena. Purpuric skin lesions are most often found on the lower extremities. Renal insufficiency is common with a nephritic presentation. The renal lesions are identical to those found in IgA nephropathy. Most patients will recover fully over several weeks.

Further details about Henoch-Schonlein purpura are provided in [Chapter 20](#).

PAUCI-IMMUNE GLOMERULONEPHRITIS (ANCA-ASSOCIATED)

Pauci-immune glomerular lesions are seen with Wegener's granulomatosis, Churg-Strauss disease, and microscopic polyangiitis. All are small-vessel vasculitides. Wegener's granulomatosis also involves granulomatous inflammation of the respiratory tract with a necrotizing vasculitis of small and medium-sized vessels. Microscopic polyangiitis (polyarteritis) is similar to Wegener's granulomatosis without granulomatous inflammation, but both commonly exhibit a necrotizing glomerulonephritis. ANCA-associated glomerulonephritis can also present as a primary renal lesion. The pathogenesis of these entities is unknown, but more than 80% of pauci-immune glomerulonephritis is associated with antineutrophil cytoplasmic antibodies.

Clinical Findings

A. Symptoms and Signs

Patients can present with symptoms of a systemic inflammatory disease, including fever, malaise, and weight loss. In addition to hematuria and proteinuria from glomerular inflammation, some patients exhibit purpura from dermal capillary involvement and mononeuritis multiplex from nerve arteriolar involvement. Ninety percent of patients with Wegener's will have upper or lower respiratory tract symptoms with nodular lesions that can cavitate and bleed.

B. Laboratory Findings

Serologically, ANCA subtype analysis can be done. A cytoplasmic pattern (c-ANCA) is specific for antiproteinase 3 antibodies, while a perinuclear pattern (p-ANCA) is specific for antimyeloperoxidase antibodies. Over 90% of patients with Wegener's syndrome will have c-ANCA; the remainder can have a p-ANCA pattern. Microscopic angiitis will have either a p-ANCA or c-ANCA pattern about 80% of the time. Pathologically, the small vessels and glomeruli will lack immune deposits (pauci-immune); however, a cell-mediated immune response is often seen. Necrotizing lesions and crescents signify a rapidly progressive glomerulonephritis.

Treatment

Treatment should be instituted early if aggressive disease is suspected. High doses of corticosteroids (methylprednisolone, 1-2 g/d for 3 days, followed by prednisone, 1 mg/kg for 1 month, with a slow taper over the next 6 months) and cytotoxic agents (cyclophosphamide, 1.5-2 mg/kg orally for 3 months, tapered over 1 year) are recommended for controlling end-organ damage. Without treatment, prognosis is extremely poor, but with the above regimen complete remission can be achieved in about 75% of patients. The addition of plasmapheresis does not seem to improve outcomes. Prognosis depends mainly on the extent of glomerular involvement before treatment is started. ANCA levels can be followed to help determine the efficacy of treatment.

ANTI-GBM GLOMERULONEPHRITIS & GOODPASTURE'S SYNDROME

Goodpasture's syndrome is defined by the clinical constellation of glomerulonephritis and pulmonary hemorrhage; injury to both is mediated by anti-glomerular basement membrane (anti-GBM) antibodies. Up to one-third of patients with anti-GBM glomerulonephritis have no evidence of lung injury. Anti-GBM-associated glomerulonephritis accounts for about 5% of patients with rapidly progressive acute glomerulonephritis. The incidence in males is approximately six times that in females, and the disease occurs most commonly in the second and third decades but has a wide range. It has been associated with influenza A infection, hydrocarbon solvent exposure, and HLA-DR2 and -B7 antigens.

Clinical Findings

A. Symptoms and Signs

The onset of disease is preceded by an upper respiratory tract infection in 20-60% of cases. Patients experience hemoptysis, dyspnea, and possible respiratory failure. Hypertension and edema are seen as components of the nephritic syndrome.

B. Laboratory Findings

Laboratory evaluation can show iron deficiency anemia, and complement levels are normal. Sputum contains hemosiderin-laden macrophages. Chest x-rays can show shifting pulmonary infiltrates due to pulmonary hemorrhage. The diffusion capacity of carbon monoxide is markedly increased. Diagnosis is confirmed by finding circulating anti-GBM antibodies, which are positive in over 90% of patients.

Treatment

The treatment of choice is a combination of plasma exchange therapy to remove circulating antibodies and administration of immunosuppressive drugs to prevent

formation of new antibodies and control the inflammatory response. Steroids are given initially in pulse doses of prednisone or methylprednisolone, 1-2 g/d for 3 days, then 1 mg/kg/d. Cyclophosphamide is administered at a dosage of 2-3 mg/kg/d. Daily plasmapheresis is performed for up to 2 weeks. A poorer prognosis exists in patients with oliguria and a serum creatinine greater than 6-7 mg/dL. Anti-GBM antibody levels should decrease as the clinical course improves. A recently published retrospective review emphasized the importance of aggressive treatment.

CRYOGLOBULIN-ASSOCIATED GLOMERULONEPHRITIS

Essential (mixed) cryoglobulinemia is a disorder associated with cold-precipitable immunoglobulins (cryoglobulins). Glomerular disease results from the precipitation of cryoglobulins in glomerular capillaries. The cause is typically an underlying infection such as hepatitis B and C or other occult viral, bacterial, and fungal infections.

Patients exhibit necrotizing skin lesions in dependent areas, arthralgias, fever, and hepatosplenomegaly. Serum complement levels are depressed. Rapidly progressive glomerulonephritis is seen on pathologic examination with the presence of crescents.

Treatment consists of aggressively treating the underlying infection. Pulse steroids, plasma exchange, and cytotoxic agents can be used. Alfa-interferon has been shown to benefit patients with hepatitis C-related cryoglobulinemia.

Other important examples of glomerulonephritis include systemic lupus erythematosus and membranoproliferative glomerulonephritis. These are described below under the heading of diseases exhibiting manifestations of nephritic and nephrotic syndrome.

NEPHROTIC SYNDROME

Essentials of Diagnosis

- Urine protein excretion > 3.5 g/1.73 m² per 24 hours.
- Hypoalbuminemia (albumin < 3 g/dL).
- Peripheral edema.

General Considerations

In adults, about one-third of patients with nephrotic syndrome have a systemic renal disease such as diabetes mellitus, amyloidosis, or systemic lupus erythematosus. With the current epidemic of type 2 diabetes mellitus, this proportion is slowly increasing. The remainder have idiopathic nephrotic syndrome. The four most common are minimal change disease, focal glomerular sclerosis, membranous nephropathy, and membranoproliferative glomerulonephritis.

Clinical Findings

A. Symptoms and Signs

Peripheral edema is a hallmark of the nephrotic syndrome, occurring when the serum albumin concentration is less than 3 g/dL. Edema is most likely due to sodium retention (from renal disease) rather than arterial underfilling from low plasma oncotic pressure. Initially this presents in the dependent areas of the body such as the lower extremities; however, such edema can become generalized. Patients can experience dyspnea due to pulmonary edema, pleural effusions, and diaphragmatic compromise with ascites. Complaints of abdominal fullness may also be present in patients with ascites.

Patients may show symptoms and signs of infection more frequently than the general population owing to loss of immunoglobulins and certain complement moieties in the urine.

B. Laboratory Findings

1. Urinalysis—Proteinuria occurs as a result of an alteration of the negative charge in the GBM. The screening test for proteinuria is the urinary dipstick analysis; however, one must bear in mind that this test indicates albumin only. The addition of sulfosalicylic acid to the urine sediment can detect the presence of abnormal paraproteins. Urine dipstick testing can detect as little as 15 mg/dL of protein, but the results must be interpreted along with the urine specific gravity. Trace protein seen on highly concentrated specimens may be insignificant, while trace protein on dilute specimens may indicate true renal disease.

Microscopically, the urinary sediment has relatively few cellular elements or casts. However, if marked hyperlipidemia is present, patients can have oval fat bodies in the urine. These represent lipid deposits in sloughed renal tubular epithelial cells. They appear as "grape clusters" under light microscopy and "Maltese crosses" under polarized light.

2. Blood chemistries—Characteristic blood chemistries include a decreased serum albumin (< 3 g/dL) and total serum protein < 6 g/dL. Hyperlipidemia occurs in over one-half of those with early nephrotic syndrome. As patients excrete larger amounts of protein per day, the frequency of hyperlipidemia increases. There is increased hepatic production of lipids (cholesterol and apolipoprotein B), owing to a fall in oncotic pressure. There is also decreased clearance of VLDLs, causing hypertriglyceridemia. Patients can also have an elevated erythrocyte sedimentation rate as a result of alterations in some plasma components such as increased levels of fibrinogen.

Other less common tests may be necessary depending on the patient's clinical presentation, including complement levels, serum and urine protein electrophoresis, ANA, and serologic tests for hepatitis. Patients may become deficient in vitamin D, zinc, and copper from loss of binding proteins in the urine.

3. Renal biopsy—Specific classification and findings are set forth in [Table 22-11](#). Specimens are examined by light microscopy, with immunofluorescent stains, and by electron microscopy. Renal biopsy is often performed in adults with new-onset idiopathic nephrotic syndrome if one suspects a primary renal disease that may require drug therapy (eg, corticosteroids, cytotoxic agents). Significantly elevated creatinine levels may indicate irreversible renal disease mitigating the need for renal biopsy. Disease due to amyloid or diabetes mellitus often does not need to be biopsied, since nephrotic range proteinuria in these diseases represents irreversible damage, although bone marrow transplant with high-dose chemotherapy can be considered in some patients with amyloid. The role of biopsy for other systemic renal diseases is debated. However, it can be useful for prognosis and treatment. An occasional unexpected diagnosis is made, such as membranous nephropathy due to lupus erythematosus without serologic evidence of that illness.

Management of Nephrotic Syndrome

A. Protein Loss

The daily total dietary protein intake should replace the daily urinary protein losses so as to avoid negative nitrogen balance. Protein malnutrition often occurs with urinary protein losses greater than 10 g/d. In the past, protein restriction was suggested for patients with renal insufficiency because experimental animal models had

demonstrated a decrease in glomerulosclerosis among those animals fed low-protein diets. The largest human trial to date (the Modification of Diet in Renal Disease Study) did not show a significant benefit, but two recent meta-analyses have shown a mild renal benefit. For this reason, the Kidney Disease Outcomes Quality Initiative (KDOQI) recommends protein restriction to 0.6 g/kg/d in patients with a GFR < 25 mL/min prior to starting dialysis.

B. Edema

Dietary salt restriction is essential for managing edema; however, most patients also require diuretic therapy. Commonly used diuretics include thiazide and loop diuretics. Both are highly protein-bound. With hypoalbuminemia, diuretic delivery to the kidney is reduced, and patients often require large doses. The combination of loop and thiazide diuretics can potentiate the diuretic effect. This may be needed for patients with refractory fluid retention associated with pleural effusions and ascites.

C. Hyperlipidemia

Hypercholesterolemia and hypertriglyceridemia occur as outlined above. Dietary management in patients with nephrotic syndrome is of little value; however, dietary modification and exercise should be advocated. Aggressive pharmacologic treatment should be pursued. This is discussed in [Chapter 27](#).

D. Hypercoagulable State

Patients with serum albumin less than 2 g/dL can become hypercoagulable. Nephrotic patients have urinary losses of antithrombin III, protein C, and protein S and increased platelet activation. Patients are prone to renal vein thrombosis and other venous thromboemboli, especially with membranous glomerulopathy. Anticoagulation therapy is warranted for at least 3-6 months in patients with evidence of thrombosis. Patients with renal vein thrombosis and recurrent thromboemboli require indefinite anticoagulation.

■ NEPHROTIC DISEASE IN PRIMARY RENAL DISORDERS

MINIMAL CHANGE DISEASE

Minimal change disease is most commonly seen in children but is occasionally present in adults. In patients over 40 with primary nephrotic syndrome, the incidence of minimal change disease is 20-25%, with equal distribution between men and women. In younger patients, there is a male predominance. Minimal change disease can be idiopathic but also occurs following viral upper respiratory infections, in association with tumors such as Hodgkin's disease, with drugs (gold and lithium), and with hypersensitivity reactions (especially to NSAIDs and bee stings).

Clinical Findings

A. Symptoms and Signs

Patients can exhibit the manifestations of nephrotic syndrome. They are more susceptible to infection, especially with gram-positive organisms, have a tendency toward thromboembolic events, develop severe hyperlipidemia, and experience protein malnutrition. Minimal change disease can rarely cause acute renal failure due to tubular changes and interstitial edema.

B. Histologic Findings

Glomeruli show no changes on light microscopy or immunofluorescence. On electron microscopy, there is a characteristic fusion of epithelial foot processes. A subgroup of patients also show mesangial cell proliferation. These people have more hematuria and hypertension and respond poorly to steroid treatment.

Treatment

Treatment is with prednisone, 1 mg/kg/d. In children the response is excellent, but about 10% of patients become steroid-resistant after 4-6 weeks. Adults often require longer therapy. It can take up to 16 weeks to achieve a response to steroids. Treatment should be continued for several weeks after complete remission of proteinuria. A significant number of patients will relapse and require further steroid treatment. Patients with frequent relapses and steroid resistance may need cyclophosphamide or chlorambucil to induce subsequent remissions. Progression to end-stage renal disease is rare. Complications most often arise from prolonged steroid use.

MEMBRANOUS NEPHROPATHY

Membranous nephropathy is the most common cause of primary nephrotic syndrome in adults. It is an immune-mediated disease characterized by immune complex deposition in the subepithelial portion of glomerular capillary walls. The antigens in primary disease are not known. Secondary disease is associated with infections such as hepatitis B, endocarditis, and syphilis; autoimmune disease such as systemic lupus erythematosus, mixed connective tissue disease, and thyroiditis; carcinoma; and certain drugs such as gold, penicillamine, and captopril. Membranous nephropathy occurs most commonly in adults in their fifth and sixth decades and almost always after age 30.

Clinical Findings

A. Symptoms and Signs

Patients exhibit the signs of nephrotic syndrome and have a higher incidence of renal vein thrombosis than most nephrotic patients. A higher incidence of occult neoplasms of lung, stomach, and colon are found in people over 50. The course of disease is variable, with about 50% of patients progressing to end-stage renal disease over 3-10 years. Poorer outcome is associated with concomitant tubulointerstitial fibrosis, male gender, elevated serum creatinine, hypertension, and heavy proteinuria (> 10 g/d).

B. Laboratory Findings

By light microscopy, capillary wall thickness is increased without inflammatory changes or cellular proliferation. When stained with silver methenamine, a "spike and dome" pattern may be observed owing to projections of excess basement membrane between the subepithelial deposits. Immunofluorescence shows IgG and C3 uniformly along capillary loops. Electron microscopy shows a discontinuous pattern of dense deposits along the subepithelial surface of the basement membrane.

Treatment

Treatment is controversial. After underlying causes are excluded, treatment should depend on the risk of renal disease progression. One algorithm is based on the degree of proteinuria. In patients with proteinuria < 4 g/d, the risk of progression is low. These individuals should be closely monitored with a low-salt diet, strict blood pressure control, and an ACE inhibitor for reduction of proteinuria. Patients with proteinuria of 4-8 g/d but normal renal function are at medium risk. They should follow the above suggestions and can elect immunosuppressive regimens with steroids and chlorambucil or cyclophosphamide for 6 months. Cyclosporine is a second choice. The highest-risk patients—those with > 8 g/d of proteinuria and possible renal dysfunction—might receive cyclosporine as a first-line immunosuppressant, though the choice of steroids with a cytotoxic agent is also reasonable. These treatments should be carefully chosen in consultation with a nephrologist. Patients with membranous nephropathy are excellent candidates for transplant.

FOCAL SEGMENTAL GLOMERULAR SCLEROSIS

This lesion can present as idiopathic disease or secondary to conditions such as heroin use, morbid obesity, and HIV infection. Clinically, patients show evidence of nephrotic syndrome, but they also have more nephritic features than membranous nephropathy or minimal change disease. Eighty percent of patients have microscopic hematuria at presentation, and many are hypertensive. Decreased renal function is present in 25-50% at time of diagnosis. Patients with focal segmental glomerular sclerosis and nephrotic syndrome typically progress to end-stage renal disease in 6-8 years.

Diagnosis requires renal biopsy. Light microscopy shows the lesions of focal segmental glomerular sclerosis. It is thought that these lesions occur first in the juxtamedullary glomeruli and are then seen in the superficial renal cortex. IgM and C3 are seen in the sclerotic lesions on immunofluorescence. Electron microscopy shows fusion of epithelial foot processes as seen in minimal change disease ([Table 22-11](#)).

Treatment is controversial, though supportive care for nephrotic patients is indicated. Longer courses of steroids are now being used because a higher percentage of patients are entering remissions. High-dose oral prednisone (1-1.5 mg/kg/d) for 2-3 months followed by a slow steroid taper can induce remission in over half of patients. Most patients achieve remission within 5-9 months. Other cytotoxic drug therapy can be considered but is disappointing (< 20% remission in most series).

■ NEPHROTIC DISEASE FROM SYSTEMIC DISORDERS

AMYLOIDOSIS

Amyloidosis consists of extracellular deposition of the fibrous protein amyloid in one or more sites in the body. Primary amyloidosis may occur in the absence of systemic disease or associated with multiple myeloma; indeed, both are plasma cell dyscrasias. Secondary amyloidosis is due to a chronic inflammatory disease such as rheumatoid arthritis, inflammatory bowel disease, or chronic infection. The acute phase reactant serum amyloid A is synthesized in the liver and deposited in the tissues. Primary amyloidosis usually occurs in older age groups and displays a benign urinary sediment; the amyloid is derived from immunoglobulin light chain. The degree of proteinuria is not associated with the extent of renal lesions. Kidneys can be enlarged as a result of amyloid deposition. Pathologically, glomeruli are filled with amorphous deposits that stain positive with Congo red and show green birefringence.

Treatment options are few. Remissions can occur in secondary amyloidosis if the inciting agent is removed. Primary amyloidosis of the kidney progresses to end-stage renal disease in an average of 2-3 years. Five-year overall survival is less than 20%, with death occurring from end-stage renal disease and heart disease. The use of alkylating agents and corticosteroids—eg, melphalan and prednisone—can reduce proteinuria and improve renal function in a small percentage of patients. Melphalan and stem cell transplantation is associated with high toxicity (45% deaths) but induces remission in 80% of the remaining patients. Renal transplant is an option in patients with secondary amyloid.

DIABETIC NEPHROPATHY

Diabetic nephropathy is the most common cause of end-stage renal disease in the United States (about 4000 cases a year). Type 1 diabetes mellitus carries a 30-40% chance of nephropathy after 20 years, whereas type 2 has a 15-20% chance after 20 years. With the current epidemic of type 2 diabetes mellitus, rates of diabetic nephropathy are projected to continue to increase over at least the next 2 decades. Patients at higher risk include males, African-Americans, and Native Americans.

Patients at risk for nephropathy progress to develop the nephrotic syndrome. Diabetic retinopathy is invariably present in these patients. Initial screening of diabetics should always include urine examination for microalbuminuria. Dipstick examination may not be sensitive enough; a 24-hour urine collection is the accepted standard measure. (An albumin excretion of > 30 mg/d is abnormal.) However, an early morning spot urine albumin or albumin-creatinine ratio is adequate. (More than 20-30 ug/L of albumin or 30 mg of albumin per gram of creatinine is considered abnormal.) In patients prone to nephropathy, microalbuminuria will develop within 10-15 years after onset of diabetes and progress over the next 3-7 years to overt proteinuria. During the onset of subclinical proteinuria, aggressive treatment is called for. Strict glycemic control and treatment of hypertension have been proved to slow progression of disease. In particular, ACE inhibitors and angiotensin II receptor antagonists lower the rate of progression to clinical proteinuria; angiotensin II receptor antagonists have been shown to slow progression to end-stage renal disease. They may reduce intraglomerular pressure as well as treat hypertension. Even in the subset of patients with markedly diminished renal function, angiotensin II receptor blockers seem to provide renal benefit if patients can tolerate the medication from the perspective of hyperkalemia and the acute decrease in GFR.

The most common lesion is diffuse glomerulosclerosis, but nodular glomerulosclerosis (Kimmelstiel-Wilson nodules) is pathognomonic for this entity. The kidneys in these patients are usually enlarged as a result of cellular hypertrophy and proliferation. At the onset of diabetic nephropathy, glomerular disease will cause an increase in GFR. As the nephropathy progresses, with the development of macroalbuminuria, the GFR returns to normal and continues to decrease.

Patients with diabetes are prone to other renal disease. These include papillary necrosis, chronic interstitial nephritis, and type IV renal tubular acidosis (hyporeninemic hypoaldosteronemic type). Patients are more susceptible to acute renal failure from contrast material and have a poor prognosis once dialysis is begun.

HIV-ASSOCIATED NEPHROPATHY

HIV-associated nephropathy can present as the nephrotic syndrome in patients with HIV infection. Most patients are young black men. In these patients, the more common mode of acquisition of HIV is through intravenous drug use.

Patients can have a nephrotic picture with normal complement levels. Light microscopy shows focal segmental glomerulosclerosis as described above. Lesions can be of the collapsing variety and often exhibit severe tubulointerstitial damage.

There is no effective treatment for HIV-associated nephropathy. Highly active antiretroviral therapy (HAART) for a prolonged course may be beneficial. Occasionally, corticosteroid treatment has been used with variable success at a dosage of 1 mg/kg/d along with cyclosporine and ACE inhibitors.

■ DISEASES DEMONSTRATING NEPHRITIC & NEPHROTIC COMPONENTS

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus is a systemic autoimmune disease in which renal involvement is common. In various series, clinical renal involvement ranges from 35% to 90%.

Patients present with nephritic or nephrotic syndromes. All patients with systemic lupus erythematosus should have routine urinalyses to monitor for the appearance of hematuria or proteinuria. If urinary abnormalities are detected, renal biopsy is often performed. The type of glomerular injury depends on the site of immune complex deposition. Five patterns of renal histology are seen on biopsy: type I, normal; type II, mesangial proliferative; type III, focal and segmental proliferative; type IV, diffuse proliferative; and type V, membranous nephropathy.

Individuals with type I and type II patterns require no treatment. Transformation of these types to a more active lesion is usually accompanied by an increase in lupus serologic activity and evidence of deteriorating renal function (eg, rising serum creatinine, increasing proteinuria). Repeat biopsy to confirm the transformation in these patients is standard. Patients with extensive type III lesions and all type IV lesions should receive aggressive immunosuppressive therapy. Poorest prognostic features in patients with type IV lesions are an elevated serum creatinine, hematocrit < 26%, and black race. Indications for treatment of type V disease are unclear; however, if superimposed proliferative lesions exist, aggressive therapy should be instituted.

Corticosteroids are the mainstay of treatment (methylprednisolone 1 g intravenously daily for 3 days followed by prednisone, 60 mg orally daily for 4-6 weeks) but are associated with many side effects and may not prevent progression of chronic lesions. Cytotoxic agents such as cyclophosphamide are almost always added because they improve long-term renal survival in patients with aggressive type III and type IV nephritis. They are typically used for 18-24 months (eg, cyclophosphamide intravenously every month for six doses and then every 3 months for six doses). Ongoing trials of newer therapies include cyclosporine and mycophenolate mofetil. In a recent randomized study, patients receiving mycophenolate mofetil and prednisolone versus cyclophosphamide and prednisolone had the same rates of remission and relapse but had fewer side effects. The return of serologic measurements to normal can be useful in monitoring treatment. Markers include dsDNA antibodies, C3, C4, CH50, and serum creatinine. Urinary protein and sediment are also helpful markers. Systemic lupus erythematosus patients on dialysis have a favorable prospect for long-term survival. Patients with kidney transplants have recurrent renal disease in 8% of cases.

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS

Membranoproliferative glomerulonephritis in its primary form is an idiopathic syndrome that can present with nephritic or nephrotic features. (The secondary form can be seen in the immune complex, paraprotein deposition, and thrombotic microangiopathic glomerulonephritides discussed above.) Most patients are under 30 years of age. At least two major subgroups are recognized: type I and type II.

Patients with type I membranoproliferative glomerulonephritis present with a history of recent upper respiratory tract infection about a third of the time. Patients typically have a nephrotic picture, and complement levels are low. Histologically, the GBM is thickened because of immune complex deposition and abnormal mesangial cell proliferation between the GBM and the endothelial cells. This gives a characteristic "splitting" appearance to the capillary wall. Immunofluorescence shows IgG, IgM, and granular deposits of C3, C1q, and C4 ([Table 22-11](#)).

Type II membranoproliferative glomerulonephritis often presents with a nephritic picture and is less common than type I. Light microscopy is similar to type I. Serologically, type II is associated with C3 nephritic factor, which is a circulating IgG antibody. EM shows a characteristic dense deposit of homogeneous material that replaces part of the glomerular basement membrane.

Treatment is controversial in this disorder. After ruling out secondary causes, it consists of steroid therapy (there is no standard dosage for adults) and antiplatelet drugs (aspirin, 500-975 mg/d, plus dipyridamole 225 mg/d). The rationale for antiplatelet therapy is that platelet consumption is increased in membranoproliferative glomerulonephritis and may play a role in glomerular injury. Fifty percent of patients used to progress to end-stage renal disease in 10 years; these rates may now be slightly lower with the introduction of more aggressive therapy. Less favorable prognostic findings include type II disease, early renal insufficiency, hypertension, and persistent nephrotic syndrome. Both types of membranoproliferative glomerulonephritis will recur after renal transplantation; however, type II recurs more commonly.

■ TUBULOINTERSTITIAL DISEASES

Tubulointerstitial disease may be acute or chronic. Acute disease is most commonly associated with toxins and ischemia. Interstitial edema, infiltration with polymorphonuclear neutrophils, and tubular cell necrosis can be seen. (See Acute Renal Failure, above, and [Table 22-12](#).) Chronic disease is associated with insult from an acute factor or progressive insult without any obvious acute cause. Interstitial fibrosis and tubular atrophy are present, with a mononuclear cell predominance. The chronic disorders are described below.

CHRONIC TUBULOINTERSTITIAL DISEASES

Essentials of Diagnosis

- Kidney size: small and contracted.
- Decreased urinary concentrating ability.
- Hyperchloremic metabolic acidosis.
- Hyperkalemia.
- Reduced GFR.

General Considerations

There are four main causes of chronic tubulointerstitial disease. These are discussed below. Other causes include multiple myeloma and gout, which are discussed in the section on multisystem disease with variable kidney involvement.

A. Obstructive Uropathy

The most common cause of chronic tubulointerstitial disease is prolonged obstruction of the urinary tract. In partial obstruction, urine output alternates between polyuria (due to vasopressin insensitivity) and oliguria (due to decreased GFR). Azotemia and hypertension (due to increased renin-angiotensin production) are usually present. The major causes are prostatic disease in men; bilateral ureteral calculi; carcinoma of the cervix, colon, and bladder; and involvement of the retroperitoneum with other tumors or fibrosis.

Abdominal, rectal, and genitourinary examinations are helpful. Urinalysis can show hematuria, pyuria, and bacteriuria but is often benign. Abdominal ultrasound may detect mass lesions, hydroureter, and hydronephrosis. CT scanning and MRI provide more detailed information.

B. Vesicoureteral Reflux

Reflux nephropathy is primarily a disorder of childhood and occurs when urine passes retrograde from the bladder to the kidneys during voiding. It is the second most common cause of chronic tubulointerstitial disease. It occurs as a result of an incompetent vesicoureteral sphincter. Urine can extravasate into the interstitium; an inflammatory response develops, and fibrosis occurs. The inflammatory response is due to either bacteria or the normal urinary components.

Patients present as adolescents or young adults with hypertension, renal insufficiency, and a history of urinary tract infections as a child. Focal glomerulosclerosis is often seen. This is a cause of substantial proteinuria, unusual in most tubular diseases. Renal ultrasound or IVP can show renal scarring and hydronephrosis. Although most damage occurs before age 5, progressive renal deterioration to end-stage renal disease continues as a result of the early insults.

C. Analgesics

Analgesic nephropathy is most commonly seen in patients who ingest large quantities of analgesic combinations. The drugs of concern are phenacetin, paracetamol, aspirin, and NSAIDs. Chronic ingestion of 1 g/d for 3 years is the typical amount needed for renal dysfunction. This disorder occurs most frequently in individuals who are using analgesics for chronic headaches, muscular pains, and arthritis. Most patients grossly underestimate their analgesic use.

Tubulointerstitial inflammation and papillary necrosis are seen on pathologic examination. Papillary tip and inner medullary concentrations of some analgesics are tenfold higher than in the renal cortex. Phenacetin—once a common cause of this disorder and now rarely available—is metabolized in the papillae by the prostaglandin hydroperoxidase pathway to reactive intermediates that bind covalently to interstitial cell macromolecules, causing necrosis. Aspirin and other NSAIDs may worsen the damage by decreasing medullary blood flow (via inhibition of prostaglandin synthesis) and decreasing glutathione levels (which are necessary for detoxification).

Patients can exhibit hematuria, mild proteinuria, polyuria (from tubular damage), anemia (from gastrointestinal bleeding) and sterile pyuria. As a result of papillary necrosis, sloughed papillae can be found in the urine. An IVP may be helpful for detecting these—contrast will fill the area of the sloughed papillae, leaving a "ring shadow" sign at the papillary tip.

D. Heavy Metals

Environmental exposure to heavy metals—such as lead and cadmium—is seen less frequently now in the United States. Chronic lead exposure can lead to tubulointerstitial disease. Individuals at risk are those with occupational exposure (eg, among welders who work with lead-based paint) and drinkers of alcohol distilled in automobile radiators (moonshine users). Lead is filtered by the glomerulus and is transported across the proximal convoluted tubules, where it accumulates and causes cell damage. Fibrosed arterioles and cortical scarring also lead to damaged kidneys. Proximal tubular damage leads to decreased secretion of uric acid, resulting in hyperuricemia and saturnine gout. Patients commonly are hypertensive. Diagnosis is most reliably performed with a calcium disodium edetate (EDTA) chelation test. Urinary excretion of more than 600 mg of lead in 24 hours following 1 g of EDTA indicates excessive lead exposure.

Occupational exposure to cadmium also causes proximal tubular dysfunction. Hypercalciuria and nephrolithiasis can be seen. Other heavy metals that can cause tubulointerstitial disease include mercury and bismuth.

Clinical Findings

A. Symptoms and Signs

Polyuria is common because tubular damage leads to inability to concentrate the urine. Dehydration can also occur as a result of a salt-wasting defect in some individuals.

B. Laboratory Findings

Patients are hyperkalemic because the distal tubules become aldosterone-resistant. A hyperchloremic renal tubular acidosis is characteristic. The cause of the renal

tubular acidosis is threefold: (1) reduced ammonia production, (2) inability to acidify the distal tubules, and (3) proximal tubular bicarbonate wasting. The urinalysis is nonspecific, as opposed to that seen in acute interstitial nephritis. Proteinuria is typically less than 2 g/d (owing to inability of the proximal tubule to reabsorb freely filterable proteins); a few cells may be seen; and broad waxy casts are often present.

Treatment

Treatment depends first upon identifying the disorder responsible for renal dysfunction. The degree of interstitial fibrosis that has developed can help to predict recovery of renal function. Once there is evidence for loss of parenchyma (small shrunken kidneys or interstitial fibrosis on biopsy), nothing can prevent the progression toward end-stage renal disease. Treatment is then directed at medical management. Tubular dysfunction may require potassium and phosphorus restriction and sodium, calcium, or bicarbonate supplements.

If hydronephrosis is present, relief of obstruction should be accomplished promptly. Prolonged obstruction leads to further tubular damage—particularly in the distal nephron—which may be irreversible despite relief of obstruction. Neither surgical correction of reflux nor medical therapy with antibiotics can prevent deterioration toward end-stage renal disease once renal scarring has occurred.

Those suspected of having lead nephropathy should continue chelation therapy with EDTA if there is no evidence of irreversible renal damage (eg, renal scarring or small kidneys). Continued exposure should be avoided.

Treatment of analgesic nephropathy requires withdrawal of all analgesics. Stabilization or improvement of renal function may occur if significant interstitial fibrosis is not present. Hydration during exposure to analgesics may also have some beneficial effects.

■ CYSTIC DISEASES OF THE KIDNEY

Renal cysts are epithelium-lined cavities filled with fluid or semisolid material. They develop primarily from renal tubular elements. One or more simple cysts are found in 50% of individuals over the age of 50. They are rarely symptomatic and have little clinical significance. In contrast, generalized cystic diseases are associated with cysts scattered throughout the cortex and medulla of both kidneys and can progress to end-stage renal disease ([Table 22-13](#)).

SIMPLE OR SOLITARY CYSTS

Simple cysts account for 65-70% of all renal masses. They are generally found at the outer cortex and contain fluid that is consistent with an ultrafiltrate of plasma. Most are found incidentally on ultrasonographic examination. Simple cysts are typically asymptomatic but can become infected.

The main concern with simple cysts is to differentiate them from malignancy, abscess, or polycystic kidney disease. Renal cystic disease can develop in dialysis patients. These cysts have a potential for progression to malignancy. Ultrasound and CT scanning are the recommended procedures for evaluating these masses. Simple cysts must meet three sonographic criteria to be considered benign: (1) echo-free, (2) sharply demarcated mass with smooth walls, and (3) an enhanced back wall (indicating good transmission through the cyst). Complex cysts can have thick walls, calcifications, solid components, and mixed echogenicity. On CT scan, the simple cyst should have a smooth thin wall which is sharply demarcated. It should not enhance with contrast media. A renal cell carcinoma will enhance but typically is of lower density than the rest of the parenchyma. Arteriography can also be used to evaluate a mass preoperatively. A renal cell carcinoma is hypervascular in 80%, hypovascular in 15%, and avascular in 5% of cases.

If a cyst meets the criteria for being benign, periodic reevaluation is the standard of care. If the lesion is not consistent with a simple cyst, surgical exploration is recommended.

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

This disorder is among the most common hereditary disease in the United States, affecting 1:1000 to 1:400 individuals. Fifty percent of patients will have end-stage renal disease by age 60. The disease has variable penetrance but accounts for 10% of dialysis patients in the USA. At least two genes account for this disorder: *ADPKD1* on the short arm of chromosome 16 (86% of patients) and *ADPKD2* on chromosome 4.

Clinical Findings

Most patients present with abdominal or flank pain and microscopic or gross hematuria. A history of urinary tract infections and nephrolithiasis is common. A family history is positive in 75% of cases, and more than 50% of patients have hypertension (see below) that may antedate the clinical manifestations of the disease. Patients have large kidneys that may be palpable on abdominal examination. The combination of hypertension and an abdominal mass should suggest the disease. Forty to 50 percent have concurrent hepatic cysts, and pancreatic and splenic cysts occur also. Hemoglobin and hematocrit tend to be maintained as a result of erythropoietin production by the cysts. The urinalysis may show hematuria and mild proteinuria. Ultrasonography confirms the diagnosis—two or more cysts in patients under age 30, two or more cysts in each kidney in patients age 30-59, and four or more cysts in each kidney in patients age 60 or over are diagnostic for autosomal dominant polycystic kidney disease. If sonographic results are unclear, CT scan is recommended and highly sensitive.

Complications & Treatment

A. Pain

Abdominal or flank pain is caused by infection, bleeding into cysts, and nephrolithiasis. Bed rest and analgesics are recommended. Cyst decompression can help with chronic pain.

B. Hematuria

Gross hematuria is most commonly due to rupture of a cyst into the renal pelvis, but it can also be caused by a renal stone or urinary tract infection. Hematuria typically resolves within 7 days with bed rest and hydration. Recurrent bleeding should suggest the possibility of underlying renal cell carcinoma, particularly in men over age 50.

C. Renal Infection

Patients presenting with flank pain, fever, and leukocytosis should be suspected of having an infected renal cyst. Blood cultures may be positive, and urinalysis may be normal because the cyst does not communicate directly with the urinary tract. CT scans can be helpful because an infected cyst may have an increased wall thickness. Bacterial cyst infections are difficult to treat. Antibiotics with cystic penetration should be used, eg, fluoroquinolones, trimethoprim-sulfamethoxazole, and chloramphenicol. Treatment may require 2 weeks of parenteral therapy followed by long-term oral therapy.

D. Nephrolithiasis

Up to 20% of patients have kidney stones, primarily calcium oxalate. Hydration (2-3 L/d) is recommended.

E. Hypertension

Fifty percent of patients have hypertension at time of presentation, and most will develop it during the course of the disease. Cyst-induced ischemia appears to cause activation of the renin-angiotensin system, and cyst decompression can lower blood pressure temporarily. Hypertension should be treated aggressively, as this may prolong the time to end-stage renal disease. (Diuretics should be used cautiously since the effect on renal cyst formation is unknown.)

F. Cerebral Aneurysms

About 10-15% of these patients have arterial aneurysms in the circle of Willis. Screening arteriography is not recommended unless the patient has a family history of aneurysms or is undergoing elective surgery with a high risk of developing hypertension.

G. Other Complications

Vascular problems include mitral valve prolapse in up to 25% of patients, aortic aneurysms, and aortic valve abnormalities. Colonic diverticula are more common in this population.

Prognosis

No medical therapy has been shown to prevent the development of renal failure, though treatment of hypertension and a low-protein diet may slow the progression of disease.

MEDULLARY SPONGE KIDNEY

This disease is a relatively common and benign disorder that is present at birth and not usually diagnosed until the fourth or fifth decade. Kidneys have a marked irregular enlargement of the medullary and interpapillary collecting ducts. This is associated with medullary cysts that are diffuse, giving a "Swiss cheese" appearance in these regions.

Clinical Findings

Medullary sponge kidney presents with gross or microscopic hematuria, recurrent urinary tract infections, or nephrolithiasis. Common abnormalities are a decreased urinary concentrating ability and nephrocalcinosis; less common is incomplete type I distal renal tubular acidosis. The diagnosis is confirmed with intravenous pyelography, which shows striations in the papillary portions of the kidney produced by the accumulation of contrast in dilated collecting ducts.

Treatment

There is no known therapy. Adequate fluid intake (2 L/d) helps to prevent stone formation. If hypercalciuria is present, thiazide diuretics are recommended because they decrease calcium excretion. Alkali therapy is recommended if renal tubular acidosis is present.

Prognosis

Renal function is well maintained unless there are complications from recurrent urinary tract infections and nephrolithiasis.

JUVENILE NEPHRONOPHTHISIS-MEDULLARY CYSTIC DISEASE

This is a rare disorder associated with almost universal progression to end-stage renal disease. The childhood type—juvenile nephronophthisis—is an autosomal recessive disorder; the type appearing in adulthood—medullary cystic disease—is autosomal dominant. Both types are manifested by multiple small renal cysts at the corticomedullary junction and medulla. The cortex becomes fibrotic, and as the disease progresses, interstitial inflammation and glomerular sclerosis appear.

Clinical Findings

Patients with both forms exhibit polyuria, pallor, and lethargy. Hypertension occurs at the later stages of disease. The juvenile form causes growth retardation and end-stage renal disease before age 20. Patients require large amounts of salt and water as a result of renal salt wasting. Ultrasound and CT scan show small, scarred kidneys, and an open renal biopsy may be necessary to recover tissue from the corticomedullary junction.

Treatment & Prognosis

There is no medical therapy that will prevent progression to renal failure. Adequate salt and water intake are essential to replenish renal losses.

■ MULTISYSTEM DISEASES WITH VARIABLE KIDNEY INVOLVEMENT*

*Other diseases with variable renal involvement described elsewhere in this chapter include systemic lupus erythematosus, diabetes mellitus, and the vasculitides such as Wegener's granulomatosis and Goodpasture's disease.

MULTIPLE MYELOMA

Multiple myeloma is a malignancy of plasma cells (see [Chapter 13](#)). Renal involvement occurs in about one-fourth of all patients. "Myeloma kidney" is the presence of light chain immunoglobulins (Bence Jones protein) in the urine causing renal toxicity. Bence Jones protein causes direct renal tubular toxicity and results in tubular obstruction by precipitating in the tubules. The earliest tubular damage results in Fanconi's syndrome (a type II proximal renal tubular acidosis). The proteinuria seen with multiple myeloma is primarily due to light chains which are not detected on urine dipstick, which mainly detects albumin. Patients with multiple myeloma can also develop glomerular amyloidosis; in these patients, dipstick protein determinations are positive. Hypercalcemia and hyperuricemia are frequently seen. Other conditions resulting in renal dysfunction include plasma cell infiltration of the renal parenchyma and a hyperviscosity syndrome compromising renal blood flow.

SICKLE CELL DISEASE

Renal dysfunction associated with sickle cell disease is most commonly due to sickling of red blood cells in the renal medulla because of low oxygen tension and hypertonicity. Congestion and stasis lead to hemorrhage, interstitial inflammation, and papillary infarcts. Clinically, hematuria is common. Damage to renal capillaries also leads to diminished concentrating ability. Isosthenuria (urine osmolality equal to that of serum) is routine, and patients can easily become dehydrated. Papillary necrosis occurs as well. These abnormalities are commonly encountered in sickle cell trait. Sickle cell glomerulopathy is less common but will inexorably progress to end-stage renal disease. Its primary clinical manifestation is proteinuria. Optimal treatment requires adequate hydration and control of the sickle cell disease.

TUBERCULOSIS

The classic renal manifestation of tuberculosis is the presence of microscopic pyuria with a sterile urine culture—or "sterile pyuria." More often, other bacteria are present in addition. Microscopic hematuria is often present with pyuria. Urine cultures may demonstrate tubercle bacilli, and cavitation of the renal parenchyma occurs. Adequate drug therapy can result in resolution of renal involvement.

GOUT & THE KIDNEY

The kidney is the primary organ for excretion of uric acid. Depending on the pH and uric acid concentration, deposition can occur in the tubules, the interstitium, or the urinary tract. The more alkaline pH of the interstitium causes urate salt deposition, whereas the acidic environment of the tubules and urinary tract causes uric acid crystal deposition at high concentrations.

Three disorders are commonly seen: (1) uric acid nephrolithiasis, (2) acute uric acid nephropathy, and (3) chronic urate nephropathy. Renal dysfunction with uric acid nephrolithiasis stems from obstructive nephropathy. Acute uric acid nephropathy presents similarly to acute tubulointerstitial nephritis with direct toxicity from uric acid crystals. Chronic nephropathy is caused by deposition of urate crystals in the alkaline medium of the interstitium; this can lead to fibrosis and atrophy.

Treatment between gouty attacks involves avoidance of food and drugs causing hyperuricemia, aggressive hydration, and pharmacotherapy aimed at reducing serum uric acid levels. These disorders are seen in both "overproducers" and "underexcretors" of uric acid. The latter situation may seem counterintuitive; however, these patients have hyperacidic urine, which explains the deposition of relatively insoluble uric acid crystals.

■ THE KIDNEY & AGING

Renal mass declines progressively after the fourth decade. The renal medulla is spared in comparison to the cortex. Renal blood flow decreases with a resultant increase in arteriolar resistance. This allows for an increased filtration fraction and a relative sparing of the glomerular filtration rate (GFR). After the age of 40, GFR declines at a rate of approximately 0.8 mL/min/1.73 m²/yr (though some older patients show little or no change). Serum creatinine values remain relatively constant because of decreased muscle mass along with the decrease in GFR. GFR impairment is partially due to thickening of the glomerular basement membrane, leading to glomerulosclerosis.

Renal tubular changes include impaired sodium handling, decreased concentration and dilutational ability, and impaired acidification. Thus, older patients are more prone

to volume overload, hypo- and hypernatremia, and acidosis. Decreased renin synthesis and 1a-hydroxylase activity are also observed. These abnormalities can result in hyperkalemia, hypocalcemia, and elevated parathyroid hormone activity.

More adverse drug reactions occur in older patients. Three main pharmacokinetic changes occur: (1) altered volume of distribution, (2) altered drug half-life, and (3) altered elimination. The latter two are directly related to impaired renal clearance of drug.

The average age of patients starting dialysis is 61; the average age of patients receiving dialysis is 65. Both are increasing steadily. Hemodialysis is the modality of choice for those with functional impairment. Peritoneal dialysis is tolerated much better in those with cardiovascular disease. Sudden fluid and electrolyte shifts can cause hypotension, ischemia, and arrhythmias.

Renal transplantation is being offered to older individuals more often as it seems to benefit even those over 65. The main complications in this population are infection and cardiovascular disease. A reduced steroid requirement with the introduction of steroid-sparing agents such as cyclosporine has diminished infection rates.

Table 22-1. Significance of specific urinary casts.

Type	Significance
Hyaline casts	Concentrated urine, febrile disease, after strenuous exercise, in the course of diuretic therapy (not indicative of renal disease)
Red cell casts	Glomerulonephritis
White cell casts	Pyelonephritis, interstitial nephritis (indicative of infection or inflammation)
Renal tubular cell casts	Acute tubular necrosis, interstitial nephritis
Coarse, granular casts	Nonspecific; can represent acute tubular necrosis
Broad, waxy casts	Chronic renal failure (indicative of stasis in collecting tubule)

■ UROLOGIC EVALUATION

HISTORY

Pain

Pain in the genitourinary tract is usually associated with distention of a hollow viscus (ureteral obstruction, urinary retention) or the capsule of an organ (acute prostatitis, acute pyelonephritis). Pain may be local or referred. Pain associated with malignancy is usually a late manifestation and indicative of advanced disease.

A. Renal Pain

Pain of renal origin is usually located in the ipsilateral costovertebral angle. It may radiate to the umbilicus and may be referred to the ipsilateral testicle in men or the labium in women. In infection, the pain is typically constant, whereas in obstruction it may come and go. Nausea and vomiting may result from reflex stimulation of the celiac ganglion. Patients with intraperitoneal pathology will typically lie motionless to avoid pain, while patients with renal disease will move about to try to find a more comfortable position.

B. Ureteral Pain

Ureteral pain is usually acute and a result of obstruction. Distention of the ureter along with hyperperistalsis and spasm of the smooth muscle of the ureter may result in two different pain patterns. Distention may cause a constant dull ache, while the spasms result in colic. The site of obstruction is often predicted by the site of pain. Upper ureteral obstruction may result in pain referred to the scrotum in males or to the labium in females. Midureteral obstruction may cause pain in the lower quadrant and thus may be confused with appendicitis in right-sided ureteral obstruction or diverticulitis in left-sided ureteral obstruction. Lower ureteral obstruction may cause inflammation of the ureteral orifice and thus be associated with symptoms of vesical irritability.

C. Vesical Pain

Acute urinary retention results in severe suprapubic discomfort. Chronic urinary retention is usually painless despite tremendous vesical distention. Suprapubic pain not related to the act of micturition is rarely vesical in origin. Acute cystitis pain is usually referred to the distal urethra and is associated with micturition.

D. Prostatic Pain

Prostatic pain is associated with inflammation and is located in the perineum. Pain radiates to the lumbosacral spine, inguinal canals, or lower extremities. Because of its location near the bladder neck, inflammatory processes of the prostate result in irritative voiding complaints.

E. Penile Pain

Pain in the flaccid penis is secondary to inflammatory processes caused by sexually transmitted diseases or paraphimosis, a condition of the uncircumcised male in which the retracted foreskin is trapped behind the glans penis, resulting in vascular congestion and painful swelling of the glans. Pain in the erect penis may be due to Peyronie's disease (fibrous plaque of the tunica albuginea, resulting in painful curvature of the erect penis) or to priapism (prolonged painful erection).

F. Testicular Pain

Acute conditions such as trauma, torsion of the testis or one of its appendices, or epididymo-orchitis cause acute pain within the scrotum with radiation to the ipsilateral groin. Chronic pain may persist for months following successful treatment of acute epididymitis. Chronic pain produced by a varicocele or hydrocele results in "heaviness" without radiation. Disorders of the kidney, retroperitoneal structures, or inguinal canal may result in pain referred to the testis.

Hematuria

Gross hematuria in adults is considered a sign of malignancy until proved otherwise.

The character of the hematuria may give a clue to the site of origin. **Initial hematuria**, the presence of blood at the beginning of the urinary stream that clears during the stream, implies an anterior (penile) urethral source. **Terminal hematuria**, the presence of blood at the end of the urinary stream, implies a bladder neck or prostatic urethral source. **Total hematuria**, the presence of blood throughout the urinary stream, implies a bladder or upper tract source.

Associated symptoms give clues to the cause. Hematuria associated with renal colic suggests ureteral stone, but the passage of blood clots from a bleeding tumor mimics this scenario. Irritative voiding symptoms in a young woman may suggest acute bacterial infection and associated hemorrhagic cystitis, yet the same picture in an older woman or in any male raises concerns about neoplasm. In any situation, if cultures are negative or symptoms persist after therapy, further evaluation is warranted. Absent other symptoms, gross hematuria may be more indicative of tumor, but staghorn calculi, glomerulonephropathies, and polycystic kidney disease are in the differential.

Irritative Voiding Symptoms

Urgency is the sudden desire to void. It is observed in inflammatory conditions such as cystitis or in hyperreflexic neuropathic conditions such as neurogenic bladders resulting from upper motor neuron lesions. **Dysuria** (painful urination) is usually associated with inflammation. The pain is typically referred to the tip of the penis in men or to the urethra in women. **Frequency** is the increased number of voids during the daytime, and **nocturia** is nocturnal frequency. Adults normally void five or six times a day and once at most during the nighttime hours. Increased numbers of voidings may result from increased urinary output or decreased functional bladder capacity. Diabetes mellitus, diabetes insipidus, excess fluid ingestion, and diuretics (including caffeine and alcohol) are a few of the causes of increased urinary output. Decreased functional bladder capacities may result from bladder outlet obstruction (increased residual urine volume results in a lower functional capacity), neurogenic bladder disorders (spasticity and reduced compliance), extrinsic bladder compression (uterine fibroids, radiation-induced fibrosis, pelvic neoplasms), or psychologic factors (anxiety).

Obstructive Voiding Symptoms

Hesitancy is a delay in the initiation of micturition. It results from the increased time required for the bladder to attain the high pressure necessary to exceed that of the urethra in the obstructed setting. **Decreased force of stream** results from the high resistance the bladder faces and is often associated with a decrease in caliber of the stream. **Intermittency** and **postvoid dribbling** are interruption of the urinary stream and the uncontrolled release of the terminal few drops of urine, respectively. Obstructive symptoms are most commonly due to benign prostatic hyperplasia, urethral stricture, or neurogenic bladder disorders. Prostatic or urethral carcinoma and foreign body are other causes.

Incontinence

Urinary incontinence is the involuntary loss of urine. The history permits subclassification into one of four categories of incontinence. Such a distinction is necessary, as the workup and treatment vary with each of the categories. With **total incontinence**, patients lose urine at all times and in all positions. **Stress incontinence** is the loss of urine associated with activities that result in an increase in intra-abdominal pressure (coughing, sneezing, lifting, exercising). Uncontrolled loss of urine preceded by a strong urge to void is known as **urge incontinence**. Chronic urinary retention may result in **overflow incontinence**.

Systemic Manifestations

Fever when associated with other symptoms of a urinary tract infection (see below) helps to localize the site of infection. In women, high fevers occur in acute pyelonephritis. Fevers are not typical of uncomplicated cystitis. In men, a febrile urinary tract infection implies acute pyelonephritis, acute prostatitis, or acute epididymitis. Fever may also be seen associated with malignancy of the kidney, bladder, or testis.

Weight loss and malaise also may be associated with tumor or disease states associated with chronic renal failure.

Other Symptoms

Hematospermia, the presence of blood in the ejaculate, results from inflammation of the prostate or seminal vesicles. Blood in the initial portion of the ejaculate implicates the prostate, whereas terminal hematospermia implies a seminal vesicle origin. Workup should include urinalysis, digital rectal examination with prostate massage, and microscopic evaluation of the expressed prostatic secretions. More invasive procedures such as cystoscopy or transrectal ultrasound with prostate biopsy are reserved for patients with hematuria or abnormal rectal examinations, respectively. Persistent hematospermia warrants similar testing. The risk of

malignancy with isolated hematospermia, normal urinalysis, and normal digital rectal examination is low.

Pneumaturia, the presence of gas in the urine, is usually secondary to a fistula between the bladder and the gastrointestinal tract. Diverticulitis is the most common cause, followed by colonic carcinoma, Crohn's disease, and radiation enteritis. The patient reports bubbles or particulate matter in the urine. On occasion, pneumaturia may be due to infection by gas-producing organisms.

Urethral discharge is the most common symptom of sexually transmitted diseases. Dysuria and urethral itching are seen in association with the discharge. A bloody urethral discharge, especially in an elderly patient, suggests urethral carcinoma.

Cloudy urine may be secondary to a urinary tract infection, yet in the absence of infection it can be a result of an alkaline urinary pH. Such conditions result in phosphate crystal precipitation. Chyluria, the presence of lymph in the urine, results from a fistula between the urinary tract and the lymphatic system. Filariasis, tuberculosis, and retroperitoneal tumors are some of the possible causes of this rare symptom.

PHYSICAL EXAMINATION

General Examination

The pallor of anemia and cachexia may be seen in malignancy. Gynecomastia occurs in testicular carcinomas or as a complication of hormonal therapy in prostatic cancer. Hypertension can be a result of renovascular disease or adrenal cancer.

Detailed Examination

A. Kidney

Because of the liver, the right kidney is lower than the left. The lower pole of the right kidney may be palpable in thin patients, yet the left kidney is usually not palpable unless abnormally enlarged. To palpate the kidney, one hand is placed posteriorly in the costovertebral angle to push the kidney anteriorly, while the second hand is placed anteriorly under the costal margin. With inspiration, the kidney may be palpated between the two hands.

Auscultation of the upper abdominal quadrants in hypertensive patients may reveal a systolic bruit associated with renal artery stenosis or an arteriovenous malformation; however, aortic bruits or transmitted heart murmurs may give similar findings.

Patients with flank pain should be tested for hyperesthesia of the overlying skin by pin testing, as this may be secondary to nerve root irritation and radiculitis rather than being of renal origin.

B. Bladder

The normal adult bladder is not palpable unless filled with at least 150 mL of urine. Percussion is better than palpation in diagnosing the distended bladder. Dullness is appreciated over the full bladder and changes to tympany if the air-filled bowel is anterior to the bladder.

Bimanual examination under anesthesia is helpful in the evaluation of patients with suspected bladder neoplasms. In the male, the bladder is palpated between the abdominal wall and the rectum while in the female it is palpated between the abdominal wall and the vagina. This is the best means of assessing vesical mobility and thus resectability.

C. Penis

The foreskin must be retracted in the uncircumcised male to permit inspection of the urethral meatus and glans. The position of the urethral meatus and the presence of urethral discharge, inflammation, penile tumor, and skin lesions must be noted. In **phimosis**, the foreskin cannot be retracted over the glans. In **paraphimosis**, the foreskin has been left retracted behind the glans, resulting in painful engorgement and edema of the glans. If not attended to, this may result in glandular ischemia. Congenital anomalies of position of the urethral meatus are called **hypospadias** when the meatus is located on the ventral aspect of the penis, scrotum, or perineum and **epispadias** when it is located on the dorsal aspect of the penis. A thick yellow urethral discharge is seen in gonococcal urethritis, whereas a thin clear or white discharge is noted in nongonococcal urethritis. Palpation of the dorsal penile shaft for plaques of Peyronie's disease and of the ventral surface for urethral tumors should be performed.

D. Scrotum and Its Contents

The most common referral to the urologist concerning the scrotum is for evaluation of a mass. It is important to determine whether the lesion resides within the testicle or is related to the epididymis or cord structures. The testes are palpated between the fingertips of both hands. Normal testes measure 4.5 × 2.5 cm and are rubbery in consistency. The epididymis rests posterolateral to the testis and varies in its degree of testicular attachment. Masses arising from within the testes are usually malignant; those from the epididymis and spermatic cord structures are usually benign. Transillumination will distinguish solid and cystic lesions.

The history and physical examination can make the diagnosis in the majority of cases. Tumors of the testis are usually painless, firm, solid lesions within the substance of the testis. These lesions do not transilluminate.

Acute epididymitis is an acute infectious process and is associated with painful enlargement of the epididymis. Fever and irritative voiding symptoms are common. In advanced states, the infection can spread to the testis, making the distinction between the epididymis and the testicle difficult on physical examination. The entire scrotal contents may be painful on palpation, yet relief may be offered to the supine patient by elevation of the scrotum above the pubic symphysis (Prehn's sign).

A **hydrocele** is a collection of fluid between the two layers of the tunica vaginalis. The diagnosis is readily made by transillumination. Evaluation of the testis is necessary, as approximately 10% of testicular tumors may have an associated hydrocele.

A **varicocele** is engorgement of the internal spermatic veins above the testis. These almost always occur on the left side as the left spermatic vein empties into the left renal vein while the right empties into the inferior vena cava. Varicoceles should diminish in size or disappear with the patient in the supine position. The sudden onset of a right varicocele should raise the question of a retroperitoneal malignancy resulting in obstruction of the right spermatic vein; a left varicocele suggests obstruction of the left renal vein, as in renal cell carcinoma.

Torsion of the testis typically occurs in the 10- to 20-year age group and presents with acute onset of pain and swelling within the testis. Examination reveals a painful testis that may have a "high lie" in relation to the other testis. The acute onset, lack of voiding symptoms, and the different age distribution may help distinguish it from epididymitis.

Torsion of the appendices of the testis or epididymis may be indistinguishable from torsion of the testis and affects a similar age group as torsion of the testis. On occasion a small palpable lump on the superior pole of the testis or epididymis is discernible that may appear blue when the skin is pulled tautly over it ("blue dot sign").

E. Rectal Examination in the Male

Inspection for anal pathology (fissures, warts, carcinoma, hemorrhoids) should be performed first. Upon insertion of the finger, anal tone can be estimated and a bulbocavernosus reflex can be elicited. As the anal and urinary sphincter derive from a common innervation, clues to neurogenic disorders may be obtained. The entire prostate is then examined, with attention being directed toward size and consistency. The normal prostate is approximately 4 × 4 cm and weighs 25 g. Normal consistency is that of the contracted thenar eminence with the thumb opposed to the little finger. Rubbery enlargement of the prostate is noted in benign prostatic hyperplasia. Induration may be perceived with carcinoma but also with chronic inflammation. The remainder of the rectum is then examined to exclude primary rectal disease.

F. Pelvic Examination in the Female

Examination of the introitus should include inspection for atrophic changes, ulcers, discharge, and warts. The urethral meatus can be inspected for caruncles and palpated for tumors or diverticula. Bimanual examination of the bladder, uterus, and adnexa should be performed with two fingers in the vagina and one hand on the abdomen, and attention is directed toward abnormal masses.

URINALYSIS

Collection of Specimens

In the male, a clean-catch urine is obtained in separate aliquots. Such a scheme may permit localization of disease. The first 5-10 mL is collected and represents the urethral specimen; a midstream specimen reflects conditions in the bladder and upper urinary tracts. If necessary, the prostate is then massaged and the expressed secretions collected. If no fluid is obtained, the next 2-3 mL of urine are collected, which reflects prostatic pathology. (See also Hematuria.)

Dipstick Urinalysis

A. pH

There is no role for dipstick urinalysis screening for urinary tract disorders in asymptomatic adults except for pregnant women. Urinary pH (range 5.0-9.0) may be helpful in the diagnosis and treatment of some urologic conditions. Alkaline urine in a patient with a urinary tract infection suggests the presence of a urea-splitting organism, most commonly *Proteus mirabilis*, though some strains of *Klebsiella*, *Pseudomonas*, *Providencia*, and *Staphylococcus* may also produce urease. Acidic urine in a patient with urolithiasis suggests uric acid or cystine stones. Failure to acidify the urine below a pH of 5.5 despite a metabolic acidosis suggests a distal renal tubular acidosis.

B. Protein

Dipsticks using bromphenol blue can detect protein in concentrations exceeding 10 mg/dL. It measures albumin and is not sensitive for the light chain of immunoglobulins (Bence Jones proteins). False-positive results are seen in urine containing numerous leukocytes or epithelial cells. (See Proteinuria in [Chapter 22](#).)

C. Urobilinogen and Bilirubin

Urobilinogen is formed from the catabolism of conjugated bilirubin in the gut by bacteria, and the majority is cleared by the liver. Normally, only 1-4 mg of urobilinogen is excreted in the urine per day. Hemolytic processes or hepatocellular disease can lead to increased urinary levels, while complete biliary obstruction or broad-spectrum antibiotics that alter the gut bacterial flora may result in absent urinary urobilinogen. Unconjugated bilirubin is not filtered by the glomerulus, while only 1% of conjugated bilirubin is filtered. Normally no bilirubin is detected by urinary dipstick, since only concentrations greater than 0.4 mg/dL are detectable. Conditions manifesting elevated conjugated bilirubin in the serum will result in higher urinary levels. Ascorbic acid may cause false-negative results, while phenazopyridine may cause false-positive results.

D. Glucose and Ketones

Only small amounts of glucose are normally excreted in the urine, and these levels are below the sensitivity of the dipstick. Any positive finding requires evaluation for diabetes. The test is specific for glucose and does not cross-react with any other sugars. Ascorbic acid or elevated ketones may result in false-negative results.

Ketones are not normally found in the urine, but fasting, postexercise states, and pregnancy may result in elevated urinary ketones. Diabetics often demonstrate elevated urinary ketone levels prior to an elevation in serum levels. False-positive results occur in dehydration or in the presence of levodopa metabolites, mesna (sodium mercaptoethanesulfonate), and other sulphydryl-containing compounds.

E. Nitrites

Normally, the urine does not contain nitrites. Many gram-negative bacteria can reduce nitrate to nitrite, which is thus an indicator of bacteriuria. However, the low sensitivity of the test requires clarification. Adequate numbers of bacteria must be present (10^5 organisms/mL), nitrates must be available in the urine, and the bacteria must be in contact with the urine for a sufficient time (usually 4 hours). Therefore, the first morning voided sample is preferable. False-negative results may be due to non-nitrate-reducing organisms, frequent urination, dilute or acidic urine (pH < 6.0), and the presence of urobilinogen. False-positive results are usually secondary to contaminated specimens, so that bacteria are indeed present in the sample yet not present in the urinary tract.

F. Leukocyte Esterase

Leukocyte esterase is an enzyme produced by white cells. The dipstick detects leukocytes in the urine, which is thus suggestive but not diagnostic for bacteria. False-positive tests result from specimen contamination. False-negative tests result from high specific gravity, glycosuria, the presence of urobilinogen, and medications, including rifampin, phenazopyridine, and ascorbic acid.

G. Blood

The urinary dipstick for blood measures intact erythrocytes, free hemoglobin, and myoglobin. False-positive results in women may occur as a result of contamination at collection with menstrual blood. Concentrated urine may also cause a false-positive result, as patients normally excrete 1000 erythrocytes per milliliter of urine. Vigorous exercise and vitamins or foods associated with high oxidant levels may also give a false-positive result. High ascorbic acid levels may give a false-negative result.

Microscopic Urinalysis

A. Leukocytes

The presence of more than five leukocytes per high-power field is considered significant pyuria. Leukocytes in the urine are indicative of injury to the urinary tract, which may or may not be due to infection. Other causes of pyuria include calculous disease, strictures, neoplasm, glomerulonephropathy, or interstitial cystitis. Leukocyte counts will vary by the state of hydration, method of collection, and degree of injury to the urinary tract.

B. Erythrocytes

The presence of more than five erythrocytes per high-power field is considered significant and warrants further investigation. (See Evaluation of Hematuria, below.) The appearance of the red cells sometimes gives a clue to their origin within the urinary tract. Dysmorphic (irregularly shaped) cells have an uneven distribution of hemoglobin and cytoplasm, and usually indicate glomerular disease. Red cells that are round, with evenly distributed hemoglobin, suggest disease along the epithelial lining of the urinary tract. All patients with hematuria require further diagnostic workup (see below); morphology, though of interest, is not of sufficient accuracy to allow firm diagnostic conclusions.

C. Epithelial Cells

The presence of squamous epithelial cells in the urinary sediment is indicative of contamination and thus requires a repeat collection. Transitional epithelial cells are occasionally noted in normal urinary sediment, but if present in large numbers or clumps they cause concern about possible neoplasm. Cytologic examination may be necessary to confirm the finding.

D. Bacteria and Yeasts

The identification of organisms in an uncontaminated specimen implies infection, which must be confirmed by culture. The presence of several organisms per high-power field usually correlates with a culture count of 10^5 organisms per milliliter. Gram staining may further aid in characterizing the organism. *Candida albicans* is the most common yeast seen in the urine, and characteristic budding and clumps are typically observed.

E. Casts

Casts are formed in the distal tubules and collecting ducts as a result of Tamm-Horsfall mucoprotein precipitation. They congregate near the edges of the coverslip and are detected best in a fresh specimen viewed under low power. If the urine is devoid of cells, hyaline casts are formed. Casts with entrapped red cells are indicative of glomerulonephritis or vasculitis. Leukocyte casts are suggestive of pyelonephritis. Epithelial casts in small numbers are normal, but in large numbers they suggest intrinsic renal disease. Granular casts result from degeneration of other cellular casts and also suggest intrinsic renal disease.

F. Crystals

Uric acid, oxalate, and cystine crystals are more often precipitated in acid urine, while phosphate crystals are more commonly seen in alkaline urine. The presence of uric acid, phosphate, and oxalate crystals can be seen in normal patients as well as in stone-formers. Cystine crystals, with a characteristic hexagonal benzene ring shape, are seen only in patients with cystinuria and are thus pathologic.

Bove P et al: Reexamining the value of hematuria testing in patients with acute flank pain. J Urol 1999;162(3 Part 1):685. [\[PMID: 10458342\]](#)

■ EVALUATION OF HEMATURIA

If gross hematuria occurs, a description of the timing (initial, terminal, total) may give a clue to the localization of disease. Associated symptoms (ie, renal colic, irritative voiding symptoms, constitutional symptoms) should be investigated. Drug ingestion and associated medical problems may also provide diagnostic clues. Anticoagulants, analgesic abuse (papillary necrosis), cyclophosphamide (chemical cystitis), antibiotics (interstitial nephritis), diabetes mellitus, sickle cell trait or disease (papillary necrosis), a history of stone disease, or malignancy should all be investigated. The presence of hematuria in patients on anticoagulation therapy warrants a complete evaluation consisting of upper tract imaging, cystoscopy, and urine cytology.

Physical examination should emphasize signs of systemic disease (fever, rash, lymphadenopathy, abdominal or pelvic masses) as well as signs of medical renal disease (hypertension, volume overload). Urologic evaluation may demonstrate an enlarged prostate, flank mass, or urethral disease.

Initial laboratory investigations include a urinalysis and urine culture. Proteinuria and casts suggest renal origin. Irritative voiding symptoms, bacteriuria, and a positive urine culture in the female suggest urinary tract infection, but follow-up urinalysis is important after treatment to ensure resolution of the hematuria.

Further evaluation includes urinary cytology, upper tract imaging, and cystoscopy. Cytology especially assists in the diagnosis of bladder neoplasm, and three voided

samples are recommended to maximize sensitivity. Upper tract imaging (usually abdominal and pelvic CT with and without contrast) may identify neoplasms of the kidney or ureter as well as identifying benign conditions such as urolithiasis, obstructive uropathy, papillary necrosis, medullary sponge kidney, or polycystic kidney disease. The role of ultrasonographic evaluation of the urinary tract for hematuria is unclear. While it may provide adequate information for the kidney, its sensitivity in detecting ureteral disease may be lower. In addition, its higher degree of operator dependence may further confound the issue. Cystoscopy can assess for bladder or urethral neoplasm, benign prostatic enlargement, and radiation or chemical cystitis. For gross hematuria, cystoscopy is ideally performed while the patient is actively bleeding to allow better localization (ie, lateralize to one side of the upper tracts, bladder, or urethra).

In patients with gross or microscopic hematuria, an upper tract source (kidneys and ureters) can be identified in 10% of cases. For upper tract sources, stone disease accounts for 40%, medical renal disease (medullary sponge kidney, glomerulonephritis, papillary necrosis) for 20%, renal cell carcinoma for 10%, and transitional cell carcinoma of the ureter or renal pelvis for 5%. In the absence of infection, gross hematuria from a lower tract source is most commonly from transitional cell carcinoma of the bladder. Microscopic hematuria in the male is most commonly from benign prostatic hyperplasia. In patients with negative evaluations, repeat evaluations are warranted to avoid a missed malignancy; however, the ideal frequency of such evaluations is not defined. Urinary cytology can be repeated in 3-6 months, and cystoscopy and upper tract imaging after a year.

■ GENITOURINARY TRACT INFECTIONS

Urinary tract infections are among the most common entities encountered in medical practice. In acute infections, a single pathogen is usually found, whereas two or more pathogens are often seen in chronic infections. Coliform bacteria are responsible for most nonnosocomial, uncomplicated urinary tract infections, with *E coli* being the most common. Such infections typically are sensitive to a wide variety of orally administered antibiotics and respond quickly. Nosocomial infections often are due to more resistant pathogens and may require parenteral antibiotics. Renal infections are of particular concern because if they are inadequately treated, loss of renal function may result. Previously, a colony count $> 10^5$ /mL was considered the criterion for urinary tract infection. However, it is now recognized that up to 50% of women with symptomatic infections have lower counts. In addition, the presence of pyuria correlates poorly with the diagnosis of urinary tract infection, and thus urinalysis alone is not adequate for diagnosis. With respect to treatment, soft tissue infections (pyelonephritis, prostatitis) require intensive therapy for 1-2 weeks, while mucosal infections (cystitis) may require 1-3 days of therapy.

Classification & Pathogenesis

First infections—ie, first documented infections—in young women tend to be uncomplicated. **Unresolved bacteriuria** occurs when the urinary tract is never sterilized during therapy. This may result from bacterial resistance to therapy, noncompliance, mixed infections with organisms having different susceptibilities, renal insufficiency, or the rapid emergence of resistance from an initially sensitive organism. **Persistent bacteriuria** occurs when the urinary tract is initially sterilized during therapy but a persistent source of infection in contact with the urinary tract remains. This may result from infected stones, chronic pyelonephritis or prostatitis, vesicoenteric or vesicovaginal fistulas, obstructive uropathy, foreign bodies, or urethral diverticula. **Reinfections** occur when new infections with new pathogens occur following successful treatment.

Ascending infection from the urethra is the most common route. Women are particularly at risk for urinary tract infections because the female urethra is short and the vagina becomes colonized with bacteria. Sexual intercourse is a major precipitating factor in young women, and the use of diaphragms and spermicidal creams (alters normal vaginal bacterial flora) further increases the risk for cystitis. Pyelonephritis most commonly results from ascent of infection up the ureter. **Hematogenous spread** to the urinary tract is uncommon, the exceptions being tuberculosis and cortical renal abscesses. **Lymphogenous spread** is rare. **Direct extension** from other organs may occur, especially from intraperitoneal abscesses in inflammatory bowel disease or pelvic inflammatory disease.

Susceptibility Factors

A. Bacterial Virulence Factors

Over 90% of first infections are caused by *E coli*. While there are over 150 strains of *E coli*, most infections are caused by only five serogroups (O1, O4, O6, O18, and O75). It appears that strains implicated in infection have a higher degree of bacterial adherence, which is mediated by the bacterial fimbriae or pili. A relationship between the type of fimbriae and the type of infection exists. P-fimbriated strains of *E coli* are associated with pyelonephritis in normal urinary tracts, whereas strains without P fimbriae are associated with pyelonephritis only when vesicoureteral reflux is present.

B. Host Susceptibility Factors

1. Bladder and upper tract factors—Intrinsic defense mechanisms in the bladder include efficient emptying of the bladder with voiding, which decreases colony counts; a protective glycosaminoglycan layer, which interferes with bacterial adherence; and the antimicrobial properties of urine (high osmolality and extremes of pH). The presence of vesicoureteral reflux, diminished renal blood flow, or intrinsic renal disease may increase the likelihood of upper tract involvement.

2. Female-specific factors—The anatomically short female urethra facilitates the ascent of organisms from the introitus into the bladder. Women with recurrent urinary tract infections have more adhesive receptors on their genitourinary mucosa and therefore have more binding sites for pathogens. Women whose mucosal secretions lack fucosyltransferase activity ("nonsecretors") are more prone to urinary tract infections. The lack of this enzyme results in lack of expression of the A, B, and H blood group antigens that normally may mask some of the bacterial adhesin receptors, making these receptors more available for pathogen binding.

3. Male-specific factors—A higher incidence of urinary tract infections in the uncircumcised male in comparison to the circumcised male has been observed. The mucosal surface of the foreskin has a propensity for colonization with P-fimbriated bacteria in a fashion analogous to that of the female introitus. The prostate in normal males secretes zinc, which is a potent antibacterial agent and thus prevents ascending infection. Lower zinc levels are seen in prostatic secretions of men with bacterial prostatitis.

Prevention of Reinfections

Prophylactic antibiotic therapy is given to prevent recurrence after treatment of urinary tract infection. Women who have more than three episodes of cystitis per year are considered candidates for prophylaxis. Prior to institution of therapy, a thorough urologic evaluation is warranted to exclude any anatomic abnormality (stones, reflux, fistula, etc). Only selected antimicrobial agents are effective in prophylaxis. To be successful, the agent must eliminate pathogenic bacteria from the fecal or introital reservoirs and not cause bacterial resistance. Single dosing at bedtime or at the time of intercourse is the recommended schedule. The three most commonly used agents for prophylaxis are trimethoprim-sulfamethoxazole (40 mg/200 mg), nitrofurantoin (100 mg), and cephalexin (250 mg).

ACUTE CYSTITIS

Essentials of Diagnosis

- Irritative voiding symptoms.
- Patient usually afebrile.
- Positive urine culture; blood cultures may also be positive.

General Considerations

Acute cystitis is an infection of the bladder most commonly due to the coliform bacteria (especially *E coli*) and occasionally gram-positive bacteria (enterococci). The

route of infection is typically ascending from the urethra. Viral cystitis due to adenovirus is sometimes seen in children but is rare in adults.

Clinical Findings

A. Symptoms and Signs

Irritative voiding symptoms (frequency, urgency, dysuria) and suprapubic discomfort are common. Women may experience gross hematuria, and symptoms in women may often appear following sexual intercourse. Physical examination may elicit suprapubic tenderness, but examination is often unremarkable. Systemic toxicity is absent.

B. Laboratory Findings

Urinalysis shows pyuria and bacteriuria and varying degrees of hematuria. The degree of pyuria and bacteriuria does not necessarily correlate with the severity of symptoms. Urine culture is positive for the offending organism, but colony counts exceeding 10^5 /mL are not essential for the diagnosis.

C. Imaging

Follow-up imaging is warranted only if pyelonephritis, recurrent infections, or anatomic abnormalities are suspected.

Differential Diagnosis

In women, infectious processes such as vulvovaginitis and pelvic inflammatory disease can usually be distinguished by pelvic examination and urinalysis. In men, urethritis and prostatitis may be distinguished by physical examination (urethral discharge or prostatic tenderness). Cystitis in men is rare and implies a pathologic process such as infected stones, prostatitis, or chronic urinary retention requiring further investigation.

Noninfectious causes of cystitis-like symptoms include pelvic irradiation, chemotherapy (cyclophosphamide), bladder carcinoma, interstitial cystitis, voiding dysfunction disorders, and psychosomatic disorders.

Treatment

Uncomplicated cystitis in women can be treated with short-term antimicrobial therapy, which consists of single-dose therapy or 1-3 days of therapy. Trimethoprim-sulfamethoxazole can be ineffective in significant numbers of patients because of the emergence of resistant organisms. Fluoroquinolones and nitrofurantoin are now the drugs of choice for uncomplicated cystitis ([Table 23-1](#)). Because uncomplicated cystitis is rare in men, elucidation of the underlying problem with appropriate investigations is warranted. Hot sitz baths or urinary analgesics (phenazopyridine, 200 mg orally three times daily) may provide symptomatic relief.

Prognosis

Infections typically respond rapidly to therapy, and failure to respond suggests resistance to the selected drug or anatomic abnormalities requiring further investigation.

ACUTE PYELONEPHRITIS

Essentials of Diagnosis

- Fever.
- Flank pain.
- Irritative voiding symptoms.
- Positive urine culture.

General Considerations

Acute pyelonephritis is an infectious inflammatory disease involving the kidney parenchyma and renal pelvis. Gram-negative bacteria are the most common causative agents including *E coli*, proteus, klebsiella, enterobacter, and pseudomonas. Gram-positive bacteria are less commonly seen but include *Enterococcus faecalis* and *Staphylococcus aureus*. The infection usually ascends from the lower urinary tract—with the exception of *S aureus*, which usually is spread by a hematogenous route.

Clinical Findings

A. Symptoms and Signs

Symptoms include fever, flank pain, shaking chills, and irritative voiding symptoms (urgency, frequency, dysuria). Nausea and vomiting and diarrhea are not uncommon. Signs include fever and tachycardia. Costovertebral angle tenderness is usually pronounced.

B. Laboratory Findings

Complete blood count shows leukocytosis and a left shift. Urinalysis shows pyuria, bacteriuria, and varying degrees of hematuria. White cell casts may be seen. Urine culture demonstrates heavy growth of the offending agent, and blood culture may also be positive.

C. Imaging

In complicated pyelonephritis, renal ultrasound may show hydronephrosis from a stone or other source of obstruction.

Differential Diagnosis

Acute intra-abdominal disease such as appendicitis, cholecystitis, pancreatitis, or diverticulitis must be distinguished from pyelonephritis. A normal urinalysis is usually seen in gastrointestinal disorders; however, on occasion, inflammation from adjacent bowel (appendicitis or diverticulitis) may result in hematuria or pyuria. Abnormal liver function tests or elevated amylase levels may assist in the differentiation. Lower lobe pneumonia is distinguishable by the abnormal chest radiograph.

In males, the main differential diagnosis for acute pyelonephritis includes acute epididymitis, acute prostatitis, and acute cystitis. Physical examination and the location of the pain should permit this distinction.

Complications

Sepsis with shock can occur with acute pyelonephritis. In diabetics, emphysematous pyelonephritis resulting from gas-producing organisms may be life-threatening if not adequately treated. Healthy adults usually recover complete renal function, yet if coexistent renal disease is present, scarring or chronic pyelonephritis may result. Inadequate therapy could result in abscess formation.

Treatment

Severe infections or complicating factors require hospital admission. Urine and blood cultures are obtained to identify the causative agent and to determine antimicrobial sensitivity. Intravenous ampicillin and an aminoglycoside are initiated prior to obtaining sensitivity results ([Table 23-1](#)). In the outpatient setting, quinolones or nitrofurantoin may be initiated ([Table 23-1](#)). Antibiotics are adjusted according to sensitivities. Fevers may persist for up to 72 hours; failure to respond warrants radiographic imaging (ultrasound) to exclude complicating factors that may require intervention. Catheter drainage may be necessary in the face of urinary retention and nephrostomy drainage if there is ureteral obstruction. In inpatients, intravenous antibiotics are maintained for 24 hours after the fever resolves, and oral antibiotics are then given to complete a 7-day course of therapy. Follow-up urine cultures are mandatory several weeks following the completion of treatment.

Prognosis

With prompt diagnosis and appropriate treatment, acute pyelonephritis carries a good prognosis. Complicating factors, underlying renal disease, and increasing patient age may lead to a less favorable outcome.

Weidner W et al: Rational diagnostic steps in acute pyelonephritis with special reference to ultrasonography and computed tomography scan. Int J Antimicrob Agents 1999;11:257. [PMID: 10394980]

ACUTE BACTERIAL PROSTATITIS

Essentials of Diagnosis

- Fever.
- Irritative voiding symptoms.
- Perineal or suprapubic pain; exquisite tenderness common on rectal examination.
- Positive urine culture.

General Considerations

Acute bacterial prostatitis is usually caused by gram-negative rods, especially *E coli* and *Pseudomonas* species and less commonly by gram-positive organisms (eg, enterococci). The most likely routes of infection include ascent up the urethra and reflux of infected urine into the prostatic ducts. Lymphatic and hematogenous routes are probably rare.

Clinical Findings

A. Symptoms and Signs

Perineal, sacral, or suprapubic pain, fever, and irritative voiding complaints are common. Varying degrees of obstructive symptoms may occur as the acutely inflamed prostate swells, which may lead to urinary retention. High fevers and a warm and often exquisitely tender prostate are detected on examination. Care should be taken in performing a gentle rectal examination, as vigorous manipulations may result in septicemia. Prostatic massage is contraindicated.

B. Laboratory Findings

Complete blood count shows leukocytosis and a left shift. Urinalysis shows pyuria, bacteriuria, and varying degrees of hematuria. Urine cultures will demonstrate the offending pathogen.

Differential Diagnosis

Acute pyelonephritis or acute epididymitis should be distinguishable by the location of pain as well as by physical examination. Acute diverticulitis is occasionally confused with acute prostatitis; however, the history and urinalysis should permit clear distinction. Urinary retention from benign or malignant prostatic enlargement is distinguishable by initial or follow-up rectal examination.

Treatment

Hospitalization may be required, and parenteral antibiotics (ampicillin and aminoglycoside) should be initiated until organism sensitivities are available ([Table 23-1](#)). After the patient is afebrile for 24-48 hours, oral antibiotics (eg, quinolones) are used to complete 4-6 weeks of therapy. If urinary retention develops, urethral catheterization or instrumentation is contraindicated, and a percutaneous suprapubic tube is required. Follow-up urine culture and examination of prostatic secretions should be performed after the completion of therapy to ensure eradication.

Prognosis

With effective treatment, chronic bacterial prostatitis is rare.

CHRONIC BACTERIAL PROSTATITIS

Essentials of Diagnosis

- Irritative voiding symptoms.
- Perineal or suprapubic discomfort, often dull and poorly localized.
- Positive expressed prostatic secretions and culture.

General Considerations

Although chronic bacterial prostatitis may evolve from acute bacterial prostatitis, many men have no history of acute infection. Gram-negative rods are the most common etiologic agents, but only one gram-positive organism (enterococcus) is associated with chronic infection. Routes of infection are the same as discussed for acute infection.

Clinical Findings

A. Symptoms and Signs

Clinical manifestations are variable. Some patients are asymptomatic, but most have varying degrees of irritative voiding symptoms. Low back and perineal pain are not uncommon. Many patients report a history of urinary tract infections. Physical examination is often unremarkable, though the prostate may feel normal, boggy, or indurated.

B. Laboratory Findings

Urinalysis is normal unless a secondary cystitis is present. Expressed prostatic secretions demonstrate increased numbers of leukocytes (> 10/hpf), especially lipid-laden macrophages. However, this finding is consistent with inflammation and is not diagnostic of bacterial prostatitis. Culture of the secretions or the post-prostatic massage urine specimen is necessary to make the diagnosis.

C. Imaging

Imaging tests are not necessary, though pelvic radiographs or transrectal ultrasound may demonstrate prostatic calculi.

Differential Diagnosis

Chronic urethritis may mimic chronic prostatitis, though cultures of the fractionated urine may localize the source of infection. Cystitis may be secondary to prostatitis, but fractionated urine samples should localize the infection. Anal disease may share some of the symptoms of prostatitis, but physical examination should permit a distinction between the two.

Treatment

Few antimicrobial agents attain therapeutic intraprostatic levels in the absence of acute inflammation. Trimethoprim does diffuse into the prostate, and trimethoprim-sulfamethoxazole is associated with the best cure rates ([Table 23-1](#)). Other effective agents include carbenicillin, erythromycin, cephalexin, and the quinolones. The optimal duration of therapy remains controversial, ranging from 6 to 12 weeks. Symptomatic relief may be provided by anti-inflammatory agents (indomethacin, ibuprofen) and hot sitz baths.

Prognosis

Chronic bacterial prostatitis is difficult to cure, but its symptoms and tendency to cause recurrent urinary tract infections can be controlled by suppressive antibiotic

therapy.

NONBACTERIAL PROSTATITIS

Essentials of Diagnosis

- Irritative voiding symptoms.
- Perineal or suprapubic discomfort, similar to that of chronic bacterial prostatitis.
- Positive expressed prostatic secretions, but culture is negative.

General Considerations

Nonbacterial prostatitis is the most common of the prostatitis syndromes, and its cause is unknown. Speculation implicates chlamydiae, mycoplasmas, ureaplasmas, and viruses, but no substantial proof exists. In some cases, nonbacterial prostatitis may represent a noninfectious inflammatory disorder. Some investigators have postulated an autoimmune origin. Because the cause of nonbacterial prostatitis remains unknown, the diagnosis is usually one of exclusion.

Clinical Findings

A. Symptoms and Signs

The clinical presentation is identical to that of chronic bacterial prostatitis; however, no history of urinary tract infections is present.

B. Laboratory Findings

Increased numbers of leukocytes are seen on expressed prostatic secretions, but all cultures are negative.

Differential Diagnosis

The major distinction is from chronic bacterial prostatitis. The absence of a history of urinary tract infection and of positive cultures makes the distinction ([Table 23-2](#)). In older men with irritative voiding symptoms and negative cultures, the possibility of bladder cancer must be excluded. Urinary cytologic examination and cystoscopy are warranted.

Treatment

Because of the uncertainty regarding the etiology of nonbacterial prostatitis, a trial of antimicrobial therapy directed against ureaplasma, mycoplasma, or chlamydia is warranted. Erythromycin (250 mg orally four times daily) can be initiated for 14 days yet should only be continued (for 3-6 weeks) if a favorable clinical response ensues. Some symptomatic relief may be obtained with anti-inflammatory agents or sitz baths. Dietary restrictions are not necessary unless the patient relates a history of symptom exacerbation by certain substances such as alcohol, caffeine, and perhaps certain foods.

Prognosis

Annoying, recurrent symptoms are common, but serious sequelae have not been identified.

Litwin MS et al: The National Institutes of Health chronic prostatitis symptom index: development and validation of a new outcome measure. Chronic Prostatitis Collaborative Research Network. J Urol 1999;162:369. [\[PMID: 10411041\]](#)

Nickel JC et al: Research guidelines for chronic prostatitis: consensus report from the first National Institutes of Health International Prostatitis Collaborative Network. Urology 1999;54:229. [\[PMID: 10443716\]](#)

PROSTATODYNIA

Prostatodynia is a noninflammatory disorder that affects young and middle-aged men and has variable causes, including voiding dysfunction and pelvic floor musculature dysfunction. The term "prostatodynia" is a misnomer, as the prostate is actually normal.

Clinical Findings

A. Symptoms and Signs

Symptoms are the same as those seen with chronic prostatitis, yet there is no history of urinary tract infection. Additional symptoms may include hesitancy and interruption of flow. Patients may relate a lifelong history of voiding difficulty. Physical examination is unremarkable, but increased anal sphincter tone and periprostatic tenderness may be observed.

B. Laboratory Findings

Urinalysis is normal. Expressed prostatic secretions show normal numbers of leukocytes. Urodynamic testing may show signs of dysfunctional voiding (detrusor contraction without urethral relaxation, high urethral pressures, spasms of the urinary sphincter) and is indicated in patients failing empiric trials of alpha-blockers or anticholinergics.

Differential Diagnosis

Normal urinalysis will distinguish it from acute infectious processes. Examination of expressed prostatic secretions will distinguish this entity from prostatitis syndromes ([Table 23-2](#)).

Treatment

Bladder neck and urethral spasms can be treated by α -blocking agents (terazosin, 1-10 mg orally once a day, or doxazosin, 1-8 mg orally once a day). Pelvic floor muscle dysfunction may respond to diazepam and biofeedback techniques. Sitz baths may contribute to symptomatic relief.

Prognosis

Prognosis is variable depending upon the specific cause.

ACUTE EPIDIDYMITIS

Essentials of Diagnosis

- Fever.
- Irritative voiding symptoms.
- Painful enlargement of epididymis.

General Considerations

Most cases of acute epididymitis are infectious and can be divided into one of two categories that have different age distributions and etiologic agents. Sexually transmitted forms typically occur in men under age 40, are associated with urethritis, and result from *C trachomatis* or *N gonorrhoeae*. Non-sexually transmitted forms

typically occur in older men, are associated with urinary tract infections and prostatitis, and are caused by gram-negative rods. The route of infection is probably via the urethra to the ejaculatory duct and then down the vas deferens to the epididymis. Amiodarone has been associated with self-limited epididymitis.

Clinical Findings

A. Symptoms and Signs

Symptoms may follow acute physical strain (heavy lifting), trauma, or sexual activity. Associated symptoms of urethritis (pain at the tip of the penis and urethral discharge) or cystitis (irritative voiding symptoms) may occur. Pain develops in the scrotum and may radiate along the spermatic cord or to the flank. Fever and scrotal swelling are usually apparent. Early in the course, the epididymis may be distinguishable from the testis; however, later the two may appear as one enlarged, tender mass. The prostate may be tender on rectal examination.

B. Laboratory Findings

Complete blood count shows leukocytosis and a left shift. In the sexually transmitted variety, Gram staining of a smear of urethral discharge may be diagnostic of gram-negative intracellular diplococci (*N gonorrhoeae*). White cells without visible organisms on urethral smear represent nongonococcal urethritis, and *C trachomatis* is the most likely pathogen. In the non-sexually transmitted variety, urinalysis shows pyuria, bacteriuria, and varying degrees of hematuria. Urine cultures will demonstrate the offending pathogen.

C. Imaging

Scrotal ultrasound may aid in the diagnosis if examination is difficult because of the presence of a large hydrocele or because questions exist regarding the diagnosis.

Differential Diagnosis

Tumors generally cause painless enlargement of the testis. Urinalysis is negative, and examination reveals a normal epididymis. Scrotal ultrasound is helpful to define the pathology. Testicular torsion usually occurs in prepubertal males but is occasionally seen in young adults. Acute onset of symptoms and a negative urinalysis favor testicular torsion or torsion of one of the testicular or epididymal appendages. Prehn's sign (elevation of the scrotum above the pubic symphysis improves pain from epididymitis) may be helpful but is not reliable.

Treatment

Bed rest with scrotal elevation is important in the acute phase. Treatment is directed toward the identified pathogen ([Table 23-1](#)). The sexually transmitted variety is treated with 10-21 days of antibiotics, and the sexual partner must be treated as well. Non-sexually transmitted forms are treated for 21-28 days with appropriate antibiotics, at which time evaluation of the urinary tract is warranted to identify underlying disease.

Prognosis

Prompt treatment usually results in a favorable outcome. Delayed or inadequate treatment may result in epididymo-orchitis, decreased fertility, or abscess formation.

■ URINARY STONE DISEASE

Urinary stone disease is exceeded in frequency as a urinary tract disorder only by infections and prostatic disease and is estimated to afflict 240,000-720,000 Americans per year. Men are more frequently affected by urolithiasis than women, with a ratio of 3:1. Initial presentation predominates in the third and fourth decades. The ratio of men to women approaches parity in the sixth and seventh decades.

Urinary calculi are polycrystalline aggregates composed of varying amounts of crystalloid and a small amount of organic matrix. Stone formation requires saturated urine that is dependent upon pH, ionic strength, solute concentration, and complexation. There are five major types of urinary stones: calcium oxalate, calcium phosphate, struvite, uric acid, and cystine. The most common types are composed of calcium, and for that reason most urinary stones (85%) are radiopaque. Uric acid stones can be radiolucent yet frequently are composed of a combination of uric acid and calcium oxalate and thus are radiopaque. Cystine stones frequently have a smooth-edged ground-glass appearance.

Geographic factors contribute to the development of stones. Areas of high humidity and elevated temperatures appear to be contributing factors, and the incidence of symptomatic ureteral stones is greatest during hot summer months.

Diet and fluid intake may be important factors in the development of urinary stones. Those afflicted with recurrent urinary stone disease are encouraged to maintain a diet restricted in sodium and protein intake. Sodium should be restricted to 100 meq/d. Increased sodium intake will increase sodium and calcium excretion and increase monosodium urate saturation (that can act as a nidus for stone growth), and increase the relative saturation of calcium phosphate, and a decrease in urinary citrate excretion. All of these factors encourage stone growth. Protein intake should be limited to 1 g/kg/d. An increased protein load can also increase calcium, oxalate, and uric acid excretion and can also decrease urinary citrate excretion. Carbohydrates and fats have not been proved to have any impact on urinary stone disease. Bran can significantly decrease urinary calcium by increasing bowel transit time and mechanically binding to calcium. Excess intake of oxalate and purines can increase the incidence of stones in predisposed individuals. Although a reduction in dietary calcium results in reduced urinary calcium, the concurrent increase in urinary oxalate may promote stone formation. Only type II absorptive hypercalciuric patients (see below) benefit from a low-calcium diet. Persons in sedentary occupations have a higher incidence of stones than manual laborers.

Genetic factors may contribute to urinary stone formation. Cystinuria is an autosomal recessive disorder. Homozygous individuals have markedly increased excretion of cystine and frequently have numerous recurrent episodes of urinary stones despite attempts to optimize medical treatment. Distal renal tubular acidosis may be transmitted as a hereditary trait, and urolithiasis occurs in up to 75% of patients affected with this disorder.

Clinical Findings

A. Symptoms and Signs

Obstructing urinary stones usually present with colic. Pain usually occurs suddenly and may awaken patients from sleep. It is localized to the flank, is usually severe, and may be associated with nausea and vomiting. Patients are constantly moving—in sharp contrast to those with an acute abdomen. The pain may occur episodically and may radiate anteriorly over the abdomen. As the stone progresses down the ureter, the pain may be referred into the ipsilateral testis or labium. If the stone becomes lodged at the ureterovesical junction, patients will complain of marked urinary urgency and frequency. Stone size does not correlate with the severity of the symptoms.

B. Metabolic Evaluation

Stone analysis should be performed on recovered stones. Controversy exists in deciding which patients need a thorough metabolic evaluation for stone disease. Uncomplicated first-time stone-formers should probably undergo blood screening for abnormalities of serum calcium, phosphate, electrolytes, and uric acid as a baseline.

More extensive evaluation is required in recurrent stone-formers or patients with a family history of stone disease. A 24-hour urine collection on a random diet should ascertain volume, urinary pH, and calcium, uric acid, oxalate, phosphate, and citrate excretion. A second collection on a restricted calcium (400 mg/d) and sodium (100 meq/d) diet is undertaken to subcategorize patients, if necessary. Serum PTH and calcium load tests can be performed at a third visit. A calcium load test is performed as follows: After a patient has been on a restricted calcium diet for at least 1 week, the patient is told to fast from 9 PM. The patient discards his early morning voided specimen (7 AM). While still fasting, the patient voids at 9 AM, which is the fasting sample. The patient then ingests 1 g of calcium gluconate, and all urine is collected from 9 AM to 1 PM, the calcium load sample. [Table 23-3](#) demonstrates the diagnostic criteria for the hypercalciuric states. (See discussion below.)

C. Laboratory Findings

Urinalysis usually reveals microscopic or gross (~ 10%) hematuria. However, the absence of microhematuria does not exclude urinary stones. Infection must be excluded, because the combination of infection and urinary tract obstruction requires prompt intervention as described below. Urinary pH is a valuable clue to the cause of the possible stone. Normal urine pH is 5.85. There is a normal postprandial urinary alkaline tide. Numerous dipstick measurements are valuable in the complete workup of a stone patient. Persistent urinary pH below 5.5 is suggestive of uric acid or cystine stones, both relatively radiolucent as seen on plain films of the abdomen. In contrast, a persistent pH above 7.2 is suggestive of a struvite infection stone, radiopaque on plain films.

D. Imaging

A plain film of the abdomen and renal ultrasound examination will diagnose most stones. Spiral CT has emerged as a first-line tool in evaluating flank pain. Stones suspected of being located at the ureterovesical junction can be imaged with abdominal ultrasonography with the aid of the acoustic window of a full bladder. Alternatively, transvaginal or transrectal ultrasonography will help identify calculi near the ureterovesical junction. When the diagnosis remains uncertain, intravenous urography is indicated.

Medical Treatment & Prevention

To reduce the recurrence rate of urinary stones, one must attempt to achieve a stone-free status. Small stone fragments may serve as a nidus for future stone development. Selected patients must be thoroughly evaluated to reduce stone recurrence rates. Uric acid stone-formers may have recurrences within months if appropriate therapy is not initiated. If no medical treatment is provided after surgical stone removal, stones will generally recur in 50% of patients within 5 years. Of greatest importance in reducing stone recurrence is an increased fluid intake. Absolute volumes are not established, but doubling previous fluid intake is recommended. Patients are encouraged to ingest fluids during meals, 2 hours after each meal (when the body is most dehydrated), and prior to going to sleep in the evening—enough to awaken the patient to void and to ingest additional fluids during the night. Increasing fluids only during daylight hours may not dilute a supersaturated urine overnight and thus initiate a new stone. Sleep posture may be implicated in selected recurrent stone-formers when calculi recur on the same side; typically, such patients sleep "stone side down."

A. Calcium Nephrolithiasis

1. Hypercalciuric—Hypercalciuric calcium nephrolithiasis (> 200 mg/24 h) can be caused by absorptive, resorptive, and renal disorders.

Absorptive hypercalciuria is secondary to increased absorption of calcium at the level of the small bowel, predominantly in the jejunum, and can be further subdivided into types I, II, and III. Type I absorptive hypercalciuria is independent of calcium intake. There is increased urinary calcium on a regular or even a calcium-restricted diet. Treatment is centered upon decreasing bowel absorption of calcium. Cellulose phosphate, a chelating agent, is an effective form of therapy. An average dose is 10-15 g in three divided doses. It binds to the calcium and impedes small bowel absorption due to its increased bulk. Cellulose phosphate does not change the intestinal transport mechanism. It should be given with meals so it will be available to bind to the calcium. Taking this chelating agent prior to bedtime is ineffective. Postmenopausal women should be treated with caution. It is interesting, however, that there is no enhanced decline in bone density after long-term use. Inappropriate use without an initial metabolic evaluation (see above) may result in a negative calcium balance and a secondary parathyroid stimulation. Long-term use without follow-up metabolic surveillance may result in hypomagnesuria and secondary hyperoxaluria and recurrent calculi. Routine follow-up every 6-8 months will help encourage medical compliance and permit adjustments in medical therapy based upon repeat metabolic studies.

Thiazide therapy is an alternative to cellulose phosphate in the treatment of type I absorptive hypercalciuria. Thiazides decrease renal calcium excretion but have no impact on intestinal absorption. This therapy results in increased bone density of approximately 1% per year. Thiazides have limited long-term utility (< 5 years) as they lose their hypocalciuric effect with continued therapy.

Type II absorptive hypercalciuria is diet-dependent. Decreasing calcium intake by 50% (approximately 400 mg/d) will decrease the hypercalciuria to normal values (150-200 mg/24 h). There is no specific medical therapy.

Type III absorptive hypercalciuria is secondary to a renal phosphate leak. This results in increased vitamin D synthesis and secondarily increased small bowel absorption of calcium. This can be readily reversed by orthophosphates (250 mg three times per day). Orthophosphates do not change intestinal absorption but rather inhibit vitamin D synthesis.

Resorptive hypercalciuria is secondary to hyperparathyroidism. Hypercalcemia, hypophosphatemia, hypercalciuria, and an elevated parathyroid hormone value are found. Appropriate surgical resection of the adenoma cures the disease and the urinary stones. Medical management is invariably a failure.

Renal hypercalciuria occurs when the renal tubules are unable to efficiently reabsorb filtered calcium, and hypercalciuria results. Spilling calcium in the urine results in secondary hyperparathyroidism. Serum calcium is normal. Thiazides are effective long-term therapy in patients with this disorder.

2. Hyperuricosuric—Hyperuricosuric calcium nephrolithiasis is secondary to dietary excesses or uric acid metabolic defects. Both disorders can be treated with purine dietary restrictions or allopurinol therapy (or both). In contrast to uric acid nephrolithiasis, patients with hyperuricosuric calcium stones will maintain a urinary pH greater than 5.5. Monosodium urates absorb inhibitors and promote heterogeneous nucleation. Hyperuricosuric calcium nephrolithiasis is probably secondary to epitaxy, or heterogeneous nucleation. In such situations, similar crystal structures (ie, uric acid and calcium oxalate) can grow together with the aid of a protein matrix infrastructure.

3. Hyperoxaluric—Hyperoxaluric calcium nephrolithiasis is usually due to primary intestinal disorders. Patients usually present with a history of chronic diarrhea frequently associated with inflammatory bowel disease or steatorrhea. Increased bowel fat combines with intraluminal calcium to form a soap-like product. Calcium is therefore unavailable to bind to oxalate, which is then freely and rapidly absorbed. A small increase in oxalate absorption will significantly increase stone formation. If the diarrhea or steatorrhea cannot be effectively curtailed, oral calcium supplements should be given with meals. More than 2g/d of ascorbic acid will increase urinary oxalate levels. Emphasis on encouraging increased fluid intake is required for these patients as for all stone-formers.

4. Hypocitraturic—Hypocitraturic calcium nephrolithiasis may be secondary to chronic diarrhea, type I (distal) renal tubular acidosis, chronic hydrochlorothiazide treatment, and, in rare cases, is idiopathic. Any condition that results in metabolic acidosis (including prolonged fasting, hypomagnesemia, and hypokalemia) will decrease urinary citrate excretion, since it will be consumed by the citric acid cycle within the mitochondria of renal cells. Hypocitraturia is frequently associated with other forms of calcium stone formation. Citrate appears to bind to calcium in solution, thereby decreasing available calcium for stone formation. Potassium citrate supplements are usually effective. Urinary citrate is decreased in acidosis and is increased during alkalosis. The potassium will supplement the frequently associated hypokalemic states, and citrate will help to correct the acidosis. A typical dose is 20 meq three times a day (available in solution or in 5- and 10-meq tablets or in crystal formulations).

B. Uric Acid Calculi

The average urinary pH is 5.85. Uric acid stone-formers frequently have urinary pH values less than 5.5. The pK of uric acid is 5.75, at which point half of the uric acid is ionized as a urate salt and is soluble, while the other half is insoluble. Increasing the pH above 6.5 dramatically increases solubility and can effectively dissolve large calculi. Potassium citrate is the most frequently used medication to increase urinary pH. It can be given in liquid preparation, as crystals that need to be taken with fluids, or as tablets (10 meq), two by mouth three or four times daily. Compliant urinary alkalinization may dissolve uric acid calculi at a rate of 1 cm of stone per month. Patients with uric acid calculi should be given Nitrazine pH paper with which to monitor the effectiveness of their urinary alkalinization. Other contributing factors include hyperuricemia, myeloproliferative disorders, malignancy with increased uric acid production, abrupt and dramatic weight loss, and uricosuric medications. If hyperuricemia is present, allopurinol (300 mg/d) may be given. Although pure uric acid stones are relatively radiolucent, most have some calcium components and can be visualized on plain abdominal radiographs. Renal ultrasonography is a helpful adjunct for appropriate diagnosis and long-term management.

C. Struvite Calculi

Struvite stones are synonymous with magnesium-ammonium-phosphate stones. They are commonly seen in women with recurrent urinary tract infections recalcitrant to appropriate antibiotics. They rarely form as ureteral stones without prior upper tract endourologic intervention. Frequently they are discovered as a large staghorn calculus forming a cast of the renal collecting system. These stones are radiodense. Urinary pH is high, usually above 7.2. These stones are formed secondary to urease-producing organisms, including proteus, pseudomonas, providencia, and, less commonly, klebsiella, staphylococci, and mycoplasma. An *E coli* urinary tract infection is not consistent with an infectious reservoir originating from a struvite calculus. These frequently large stones are relatively soft and amenable to percutaneous nephrolithotomy. Appropriate perioperative antibiotics are required. They can recur rapidly, and efforts should be taken to render the patient stone-free. Postoperative irrigation through nephrostomy tubes can eliminate small fragments. Acetohydroxamic acid is an effective urease inhibitor, but it is poorly tolerated by most patients because of its gastrointestinal toxicity.

D. Cystine Calculi

Cystine stones are a result of abnormal excretion of cystine, ornithine, lysine, and arginine. Cystine is the only amino acid that becomes insoluble in urine. These stones are particularly difficult to manage medically. Prevention is centered around increased fluid intake, alkalinization of the urine above pH 7.5 (monitored with Nitrazine pH paper), and a variety of medications including penicillamine and tiopronin (alpha-mercaptopropionylglycine).

Surgical Treatment

Forced intravenous fluids will not push stones down the ureter. Effective peristalsis directing a bolus of urine down the ureter requires opposing ureteral walls to approach each other and touch, which large dilated systems cannot do. In fact, diuresis is counterproductive and will exacerbate the pain. Associated fever may represent infection, a medical emergency requiring prompt drainage by a ureteral catheter or a percutaneous nephrostomy tube. Antibiotics alone are inadequate unless obstruction is released.

A. Ureteral Stones

Impediment to urine flow by ureteral stones usually occurs at three sites: (1) at the ureteropelvic junction, (2) at the crossing of the ureter over the iliac vessels, and

finally (3) as the ureter enters the bladder at the ureterovesical junction. Prediction of spontaneous stone passage is difficult. Stones less than 6 mm in diameter as seen on a plain abdominal radiograph will usually pass spontaneously. Conservative observation with appropriate pain medications is appropriate for the first 6 weeks. If spontaneous stone passage has failed, therapeutic intervention is required. Distal ureteral stones are best managed either with ureteroscopic stone extraction or in situ extracorporeal shock wave lithotripsy (SWL). Ureteroscopic stone extraction involves placement of a small endoscope through the urethra and into the ureter. Under direct vision, basket extraction or fragmentation followed by extraction is performed. Complications during endoscopic retrieval increase as the duration of conservative observation increases beyond 6 weeks. Indications for earlier intervention include severe pain unresponsive to medications, fever, persistent nausea and vomiting requiring intravenous hydration, social requirements requiring return to work, or anticipated travel. Most upper tract stones that enter the bladder can exit the urethra with minimal discomfort.

In situ SWL, an alternative, utilizes an external energy source that is focused upon the stone. This focused energy is additive, resulting in minimal tissue insult except at the focus where the stone is positioned with the aid of fluoroscopy or ultrasonography. This can be performed under anesthesia as an outpatient procedure and usually results in stone fragmentation. Most stone fragments will pass uneventfully within 2 weeks, but those that have not passed within 3 months are unlikely to pass without intervention. Women of childbearing age are best not treated with SWL for a stone in the lower ureter, as the impact upon the ovary is unknown.

Proximal and midureteral stones—those above the inferior margin of the sacroiliac joint—can be treated with SWL or ureteroscopy. SWL is delivered directly to the stone (in situ), or the stones can be pushed back into the renal pelvis (via a retrograde ureteral catheter) to allow for a more capacious surrounding space and possibly more efficient fragmentation. To help ensure adequate drainage after SWL, a double J ureteral stent is frequently placed. Double J stents do not ensure passage of stone fragments after SWL. Occasionally, stone fragments will obstruct the ureter after SWL. Conservative management will usually result in spontaneous resolution with eventual passage of the stone fragments. If this is unsuccessful, adequate proximal drainage through a percutaneous nephrostomy tube will facilitate passage. In rare instances, ureteroscopic extraction will be required.

B. Renal Stones

Patients with renal calculi presenting without pain, urinary tract infections, or obstruction need not be treated. They should be followed with serial abdominal radiographs or renal ultrasonographic examinations. If calculi are growing or become symptomatic, intervention should be undertaken. Renal stones less than 3 cm in diameter are best treated with SWL. Stones located in the inferior calix frequently result in suboptimal stone-free rates as measured at 3 months by x-ray. Such stones and others of larger diameter are best treated via percutaneous nephrolithotomy. Perioperative antibiotic coverage should be given on the basis of preoperative urine cultures.

■ URINARY INCONTINENCE

Urinary incontinence is most common in older patients. Its prevalence varies from 5% to 15% in the community to perhaps more than 50% in long-term care facilities. The normal urinary bladder can store relatively large volumes of urine at low pressures. Continence is dependent upon a compliant reservoir and sphincteric efficiency that has two components: the involuntary smooth muscle of the bladder neck and the voluntary skeletal muscle of the external sphincter. (See also discussion in [Chapter 3](#).)

Classification

Urinary incontinence occurs when urine leaks involuntarily and can be classified into one of four categories.

A. Total Incontinence

With total incontinence, patients lose urine at all times and in all positions. This results when sphincteric efficiency is lost (previous surgery, nerve damage, cancerous infiltration) or when an abnormal connection between the urinary tract and the skin exists that bypasses the urinary sphincter (vesicovaginal or ureterovaginal fistulas).

B. Stress Incontinence

Stress incontinence is the loss of urine associated with activities that result in an increase in intra-abdominal pressure (coughing, sneezing, lifting, exercising). Patients do not leak in the supine position. Laxity of the pelvic floor musculature—most commonly seen in the multiparous woman or in patients who have undergone pelvic surgery—results in urethral sphincteric insufficiency.

C. Urge Incontinence

The uncontrolled loss of urine that is preceded by a strong, unexpected urge to void is known as urge incontinence. It is unrelated to position or activity and is indicative of detrusor hyperreflexia or sphincter dysfunction. Inflammatory conditions or neurogenic disorders of the bladder are commonly associated with urge incontinence.

D. Overflow Incontinence

Chronic urinary retention may result in overflow incontinence. Incontinence results from the chronically distended bladder receiving an additional increment of urine, so that intravesical pressure just exceeds the outlet resistance, allowing a small amount of urine to dribble out.

Clinical Findings

A. Symptoms and Signs

The history is the most important step in the evaluation of urinary incontinence. It may be supplemented with a voiding diary prepared by the patient. Physical examination is important to exclude fistula for cases of total incontinence, neurologic abnormalities in cases of urge incontinence (spasticity, flaccidity, rectal sphincter tone), or the distended bladder in cases of overflow incontinence. Rectal examination will reveal the general function of the pelvic floor. Normal anal tone suggests an intact external sphincter. A tender levator ani suggests an overfacilitated pelvic floor. A lax sphincter suggests a lower motor neuron lesion. The bulbocavernosus reflex further confirms the integrity of the lower motor neurons. This reflex is confirmed by feeling an anal contraction in response to pressure on the glans penis or the clitoris.

B. Laboratory Findings

Urinalysis and urine culture are important to exclude urinary tract infection in cases of urge incontinence. Abnormal renal function may be detected in cases of overflow incontinence. Cystograms may demonstrate fistula sites. Lateral stress cystograms may show descensus of the bladder neck (descent of bladder neck more than 1.5 cm on straining view) in cases of stress incontinence. Those suspected of overflow incontinence can have postvoid residual urine volume assessed by urethral catheterization or ultrasonography.

C. Special Tests

Urinary continence depends upon both bladder and sphincteric mechanisms; dysfunction of either component may result in incontinence. Urodynamic evaluation can assess both bladder and sphincteric function. Such testing is indicated in patients with moderate to severe incontinence, those suspected of having neurologic disease, and those with urge incontinence when infection and neoplasm have been excluded.

Bladder capacity, accommodation, sensation, voluntary control, contractility, and response to pharmacologic intervention can be assessed by cystometry. Cystometry is performed by filling the bladder with water or CO₂ and simultaneously recording intravesical pressure.

During filling, the normal bladder has the ability to maintain a low pressure. As volume increases, compliance increases. Normal sensation is first appreciated with volumes less than 150 mL. There is a strong sensation prior to micturition. Normal capacity in an adult bladder is 350-500 mL. Micturition is consciously initiated starting with pelvic floor relaxation followed by a sustained bladder contraction. Normal bladder function will empty the bladder completely. Uninhibited contractions during the normal filling phase are abnormal and are usually associated with a strong urge to void. Causes of decreased urinary capacity include incontinence, infections, interstitial cystitis, radiation damage, upper motor neuron lesions, and postoperative changes. Increased bladder capacity is seen with chronic urinary tract obstruction, lower motor neuron lesions, and sensory neuropathies.

Responses to routine medications during cystometry will help confirm a diagnosis and facilitate appropriate therapy. Lack of an appropriate detrusor contraction may be

secondary to poor bladder muscle function or inadequate filling. Myogenic function can be assessed with bethanechol chloride, a parasympathomimetic drug. Lack of response to intravenous bethanechol suggests intrinsic muscle damage. In contrast, an exaggerated response is suggestive of a lower motor neuron lesion.

Sphincteric function assessment is necessary in the evaluation of urinary incontinence. More formal evaluation of the urinary sphincter may be performed using urethral profilometry, electromyography, or combined video studies.

Treatment

A. Total Incontinence

True incontinence is due to anatomic abnormalities, either congenital or acquired. Congenital defects, including bladder exstrophy, ectopic ureteral orifices, and urethral diverticula, and acquired lesions such as vesicovaginal fistulas require surgical correction. Sphincter injuries following prostatectomy may be managed by surgical reconstruction (bladder neck reconstruction), periurethral bulking agents, or placement of an artificial urinary sphincter.

B. Stress Incontinence

In patients with stress urinary incontinence, the bladder neck will descend below the midportion of the pubic symphysis when viewed on a lateral stress cystogram. Urodynamic investigations usually reveal a shortened functional urethral length, decreased urethral closure pressure, minimal augmentation of closure pressure with stress activities, decreased urethral pressure and length when assuming an upright position, and decreased closure pressure with bladder filling.

If hypoestrogenism of the vagina or urethra is discovered, topical estrogen creams applied locally are indicated. Surgical treatment is centered upon placing the bladder neck into an appropriate anatomic location, allowing increased intra-abdominal pressure to be transmitted to both the bladder and the bladder neck. These procedures also lengthen the urethra. Transvaginal sling suspension or suprapubic (culpocystourethropexy) approaches can pull the bladder neck into proper position. Surgery is usually corrective.

C. Urge Incontinence

The etiology of urge urinary incontinence includes urethral or detrusor instability or a combination of these mechanisms. Treatment is medical rather than surgical. Effective agents include anticholinergic medications (oxybutinin, 5-15 mg/d, or tolterodine, 2-4 mg/d) or tricyclic antidepressants (imipramine, 25-75 mg orally at bedtime). Sacral nerve stimulation can be effective in treating refractory urinary urge incontinence.

D. Overflow Incontinence

Placement of a urethral catheter is both diagnostic and therapeutic in the acute setting. Further treatment must address the underlying disease. Men with benign prostatic hyperplasia can be treated with medical therapy, prostatectomy, or newer less invasive procedures (see below). Patients with urethral strictures can be treated with a direct internal urethrotomy or open urethroplasty. Neurogenic causes (external sphincteric spasticity) may be managed with intermittent catheterization regimens with or without pharmacotherapy.

INTERSTITIAL CYSTITIS

Essentials of Diagnosis

- Pain with a full bladder or urinary urgency.
- Submucosal petechiae on cystoscopic examination.
- Diagnosis of exclusion.

General Considerations

Interstitial cystitis is characterized by pain with bladder filling that is relieved by emptying and is often associated with urgency and frequency. This is a diagnosis of exclusion, and patients must have a negative urine culture and cytology and no other obvious cause such as radiation cystitis, chemical cystitis (cyclophosphamide), vaginitis, urethral diverticulum, or genital herpes.

Population-based studies have demonstrated a prevalence of between 18 and 40 per 100,000 people. Both sexes are involved, but the majority of patients are women, with a mean age of 40 years at onset. Patients with interstitial cystitis are more likely to report bladder problems in childhood, and there appears to be a higher prevalence in Jewish women. Up to 50% of patients may experience spontaneous remission of symptoms, with a mean duration of 8 months without treatment.

The etiology of interstitial cystitis is unknown, and it is most likely not a single disease but rather several diseases with similar symptomatology. Associated diseases include severe allergies, irritable bowel syndrome, or inflammatory bowel disease. Theories regarding the cause of interstitial cystitis include increased epithelial permeability, neurogenic causes (sensory nervous system abnormalities), and autoimmunity.

Clinical Findings

A. Symptoms and Signs

Pain with bladder filling that is relieved with urination or urgency, frequency, and nocturia are the most common symptoms. Exposures such as pelvic radiation or prior cyclophosphamide should be inquired about. Examination should exclude genital herpes, vaginitis, or a urethral diverticulum.

B. Laboratory Findings

Urinalysis and urine culture are obtained to exclude infectious causes. Urinary cytology is obtained to exclude bladder malignancy. Urodynamic testing assesses bladder sensation and compliance and excludes detrusor instability.

C. Cystoscopy

The bladder is distended with fluid (hydrodistention) to detect glomerulations (submucosal hemorrhage), which must be present in at least three quadrants of the bladder. Biopsy should be performed to exclude other causes such as carcinoma, eosinophilic cystitis, and tuberculous cystitis. The presence of submucosal mast cells is not needed to make the diagnosis of interstitial cystitis.

Differential Diagnosis

Exposures to radiation or cyclophosphamide are obtained by the history. Bacterial cystitis, genital herpes, or vaginitis can be excluded by urinalysis, culture, and physical examination. A urethral diverticulum may be suspected if palpation of the urethra demonstrates an indurated mass that results in the expression of pus from the urethral meatus. Urethral carcinoma presents as a firm mass on palpation.

Treatment

There is no cure for interstitial cystitis, but most patients achieve symptomatic relief from one of several approaches, including hydrodistention, which is usually done as part of the diagnostic evaluation. Approximately 20-30% of patients will notice symptomatic improvement following this maneuver. Also of importance is the measurement of bladder capacity during hydrodistention, since patients with very small bladder capacities (< 200 mL) are unlikely to respond to medical therapy.

Amitriptyline is often used as first-line medical therapy in patients with interstitial cystitis. Both central and peripheral mechanisms may contribute to its activity. Nifedipine and other calcium channel blockers have also demonstrated some activity in patients with interstitial cystitis. Pentosan polysulfate sodium (Elmiron) is an oral synthetic sulfated polysaccharide that helps restore integrity to the epithelium of the bladder in a subset of patients. Other options include intravesical instillation of dimethyl sulfoxide (DMSO), heparin, or BCG, the latter achieving up to 60% response rates.

Other treatment modalities include transcutaneous electric nerve stimulation (TENS) and acupuncture. Surgical therapy for interstitial cystitis should only be considered as a last resort and may require cystourethrectomy with urinary diversion.

■ MALE ERECTILE DYSFUNCTION & SEXUAL DYSFUNCTION

Erectile dysfunction is defined as the consistent inability to maintain an erect penis with sufficient rigidity to allow sexual intercourse. This condition is thought to affect 10 million American men, and its incidence is age-related. Approximately 25% of all men older than age 65 suffer from this disorder. Most cases of male erectile disorders have an organic rather than a psychogenic cause. Normal male erection is a neurovascular phenomenon relying on an intact autonomic and somatic nerve supply to the penis, smooth and striated musculature of the corpora cavernosa and pelvic floor, and arterial inflow supplied by the paired pudendal arteries. Erection is precipitated and maintained by an increase in arterial flow, active relaxation of the smooth muscle elements of the sinusoids within the corporal bodies of the penis, and an increase in venous resistance. Contraction of the bulbocavernosus and ischiocavernosus muscles results in further rigidity of the penis. The neurotransmitters that initiate the process have not been identified with certainty, though nitric oxide, vasoactive intestinal peptide, acetylcholine, and prostaglandins have all been postulated to initiate or contribute to male erection.

Male sexual dysfunction may be manifested in a variety of ways, and the history is critical to the proper classification and subsequent treatment. Androgens have a strong influence on the sexual desire of men. A **loss of libido** may indicate androgen deficiency on the basis of either hypothalamic, pituitary, or testicular disease. Serum testosterone and gonadotropin levels may help localize the site of disease. **Loss of erections** may result from arterial, venous, neurogenic, or psychogenic causes. Concurrent medical problems may damage one or more of the mechanisms. In addition, many medications, especially antihypertensives, are associated with erectile dysfunction. Centrally acting sympatholytics (methyldopa, clonidine, reserpine) can result in loss of erection, while vasodilators, alpha-blockers, and diuretics rarely alter erections. Beta-blockers and spironolactone may result in loss of libido. It is important to determine whether the patient ever has any normal erections, such as early morning or during sleep. If normal erections do occur, an organic cause is unlikely. The gradual loss of erections over a period of time is more suggestive of an organic cause. The **loss of emission** (lack of antegrade seminal fluid during ejaculation) may result from several underlying disorders. **Retrograde ejaculation** may occur as a result of mechanical disruption of the bladder neck, especially following transurethral resection of the prostate or sympathetic denervation as a result of medications (alpha-blockers), diabetes mellitus, or radical pelvic or retroperitoneal surgery. Androgen deficiency may also result in lack of emission by decreasing the amount of prostatic and seminal vesicle secretions. If libido and erection are intact, the **loss of orgasm** is usually of psychologic origin. **Premature ejaculation** is usually an anxiety-related disorder and rarely has an organic cause. The history may elucidate the presence of a new partner, unreasonable expectations about performance, or emotional disorders.

Clinical Findings

A. Symptoms and Signs

Erectile dysfunction should be clearly distinguished from problems of ejaculation, libido, and orgasm. The degree of the dysfunction (whether chronic, occasional, or situational) as well as its timing should be noted. The history should include inquiries about hyperlipidemia, hypertension, depression, neurologic disease, diabetes mellitus, renal failure, and adrenal and thyroid disorders. Trauma to the pelvis or pelvic or peripheral vascular surgery also identifies patients at increased risk of impotence. A complete recording of drug use should be made, since about 25% of all cases of sexual dysfunction may be drug-related. The use of alcohol, tobacco, and recreational drugs should be recorded as well, since each is associated with an increased risk of sexual dysfunction.

During the physical examination, secondary sexual characteristics should be assessed. Neurologic and peripheral vascular examination should be performed. Motor and sensory examination should be performed as well as palpation and quantification of lower extremity vascular pulsations. The genitalia should be examined, noting the presence of penile scarring or plaque formation (Peyronie's disease) and any abnormalities in size or consistency of either testicle. Examination of the prostate is essential.

B. Laboratory Findings

Laboratory evaluation is limited and should consist of a complete blood count, urinalysis, lipid profile, determination of serum testosterone, glucose, and prolactin. Patients with abnormalities of testosterone or prolactin require further evaluation with measurement of serum FSH and LH, and endocrinologic consultation is advised.

C. Special Tests

Further testing is based on the patient's goals. Patients who will accept only noninvasive forms of therapy may be offered medical therapy or a vacuum constriction device, as described below. Most patients undergo further evaluation with direct injection of vasoactive substances into the penis. Such substances (prostaglandin E₁, papaverine, or a combination of drugs) will induce erections in men with intact vascular systems. Patients who respond with a rigid erection require no further vascular evaluation. However, organic and psychogenic impotence can be differentiated by use of nocturnal penile tumescence testing, where the frequency as well as the rigidity of erections are recorded by a simple device attached to the penis before sleep. Patients with psychogenic impotence will have nocturnal erections of adequate frequency and rigidity.

Additional vascular testing is indicated in patients who fail to achieve an erection with injection of vasoactive substances on serial attempts using increasing doses or combination of drugs and who would consider vascular reconstructive surgery. The diameter and flow in the cavernous arteries can be assessed using duplex ultrasound. Patients with poor arterial inflow in the absence of known peripheral vascular disease (as in patients who have sustained pelvic trauma) are candidates for pelvic arteriography before planned arterial reconstruction. Patients with normal arterial inflow should be suspected of suffering from venous leak. Further testing in this group would include cavernosometry (measurement of flow required to maintain erection) and cavernosography (contrast study of the penis to determine site and extent of venous leak).

Treatment

The vast majority of men suffering from erectile dysfunction can be managed successfully with one of the approaches outlined below. Men who do not suffer from organic dysfunction will probably benefit from behaviorally oriented sex therapy.

A. Hormonal Replacement

Testosterone injections (200 mg intramuscularly every 3 weeks) or topical patches (2.5-6 mg/d) are offered to men with documented androgen deficiency who have undergone endocrinologic evaluation as described and in whom prostatic cancer has been excluded by PSA screening and digital rectal examination.

B. Vacuum Constriction Device

The vacuum constriction device is a cylindric device that draws the penis into an erect state by inducing a vacuum within the cylinder. Once adequate tumescence has been achieved, a rubber constriction device or band is placed around the proximal penis to prevent loss of erection, and the cylinder is removed. Such devices are suitable for patients with venous disorders of the penis and those who fail to achieve an adequate erection with injection of vasoactive substances. Complications are rare.

C. Vasoactive Therapy

Direct injection of vasoactive prostaglandins into the penis is an acceptable form of treatment for most men with impotence. These injections are performed using a tuberculin syringe. The base and lateral aspect of the penis is used as the injection site to avoid injury to the superficial blood supply located anteriorly. Complications are rare and include dizziness, local pain, fibrosis, and infection. A prolonged erection requiring aspiration of blood and injection of epinephrine and phenylephrine to

achieve detumescence occurs very rarely. A mechanism of delivering vasoactive prostaglandins (alprostadil) via a urethral suppository has been developed, and results are good. Pellet sizes are 125, 250, 500, and 1000 ug.

Sildenafil (Viagra) inhibits phosphodiesterase 5—itself an inhibitor of erection—and allows cGMP to function unopposed. Ordinarily, nitric oxide-mediated release from parasympathetic nerves and endothelium generates this compound, and prolongation of its half-life results in sustained inflow of blood into the erect penis. Fifty milligrams taken 1 hour prior to anticipated sexual activity is recommended, with peak action at 2 hours. There is no effect on libido, nor is priapism a problem, but the additive effect on nitrates may lead to exaggerated cardiac preload reduction and hypotension. Thus, the drug is contraindicated in patients receiving nitroglycerin. All patients being evaluated for acute chest pain should be asked if they are taking sildenafil before administering nitroglycerin. Fixed atherosclerotic disease in the aortoiliac system is associated with diminished efficacy.

D. Penile Prostheses

Prosthetic devices may be implanted directly into the paired corporal bodies. Such prostheses may be rigid, malleable, hinged, or inflatable. Each is manufactured in a variety of sizes and diameters. Inflatable models may result in a more cosmetic appearance but may be associated with a greater likelihood of mechanical failure.

E. Vascular Reconstruction

Patients with disorders of the arterial system are candidates for various forms of arterial reconstruction, including endarterectomy and balloon dilation for proximal arterial occlusion and arterial bypass procedures utilizing arterial (epigastric) or venous (deep dorsal vein) segments for distal occlusion. Patients with venous disorders may be managed with ligation of certain veins (deep dorsal or emissary veins) or the crura of the corpora cavernosa. Experience with vascular reconstructive procedures is still limited, and many patients so treated still fail to achieve a rigid erection.

MALE INFERTILITY

Primary infertility affects 15-20% of married couples. Approximately one-third of cases result from male factors, one-third from female factors, and one-third from combined factors. It is thus critical to have simultaneous evaluation of both partners. Clinical evaluation is warranted following 6 months of unprotected intercourse. Endocrinologic profiles and detailed semen analyses are the cornerstones of laboratory investigations after the history and physical examination. **Oligospermia** is the presence of less than 20 million sperm/mL in the ejaculate; **azoospermia** is the absence of sperm. As spermatogenesis takes approximately 74 days, it is thus important to review events from the past 3 months.

Clinical Findings

A. Symptoms and Signs

The history should include prior testicular insults (torsion, cryptorchism, trauma), infections (mumps orchitis, epididymitis), environmental factors (excessive heat, radiation, chemotherapy), medications (anabolic steroids, cimetidine, and spironolactone may affect spermatogenesis; phenytoin may lower FSH; sulfasalazine and nitrofurantoin affect sperm motility), and drugs (alcohol, marijuana). Sexual habits, frequency and timing of intercourse, use of lubricants, and each partner's previous fertility experiences are important. Loss of libido and headaches or visual disturbances may indicate a pituitary tumor. The past medical or surgical history may reveal thyroid or liver disease (abnormalities of spermatogenesis), diabetic neuropathy (retrograde ejaculation), radical pelvic or retroperitoneal surgery (absent seminal emission secondary to sympathetic nerve injury), or hernia repair (damage to the vas deferens or testicular blood supply).

Physical examination should pay particular attention to features of hypogonadism: underdeveloped secondary sexual characteristics, diminished male pattern hair distribution (axillary, body, facial, pubic), eunuchoid skeletal proportions (arm span 2 inches > height; upper to lower body ratio < 1.0), and gynecomastia. The scrotal contents should be carefully evaluated. Testicular size should be noted (normal size approximately 4.5 × 2.5 cm, volume 18 mL). Varicoceles should be looked for in the standing position and on occasion may only be appreciated with the Valsalva maneuver. The vas deferens, epididymis, and prostate should be palpated.

B. Laboratory Findings

Semen analysis should be performed after 72 hours of abstinence. The specimen should be analyzed within 1 hour after collection. Abnormal sperm concentrations are less than 20 million/mL. Normal semen volumes range between 1.5 and 5 mL (volumes < 1.5 mL may result in inadequate buffering of the vaginal acidity and may be due to retrograde ejaculation or androgen insufficiency). Normal sperm motility and morphology demonstrate 50-60% motile cells and more than 60% normal morphology. Abnormal motility may result from antisperm antibodies or infection. Abnormal morphology may result from a varicocele, infection, or exposure history.

Endocrinologic evaluation is warranted if sperm counts are low or if there is a clinical basis (from the history and physical examination) for suspecting an endocrinologic origin. Testing should include serum FSH, LH, and testosterone. Elevated FSH and LH and low testosterone (hypergonadotropic hypogonadism) are associated with primary testicular failure, which is usually irreversible. Low FSH and LH associated with low testosterone occur in secondary testicular failure (hypogonadotropic hypogonadism) and may be of hypothalamic or pituitary origin. Such defects may be correctable. In such cases, serum prolactin should be checked to exclude pituitary prolactinoma.

C. Imaging

Scrotal ultrasound may detect a subclinical varicocele. Vasography may be required in patients with suspected ductal obstruction.

D. Special Tests

Azoospermic patients should have postmasturbation urine samples centrifuged and analyzed for sperm to exclude retrograde ejaculation. Azoospermic patients and patients with ejaculate volumes less than 1 mL should have fructose levels determined on the ejaculate. Fructose is produced in the seminal vesicles and if absent in the ejaculate implies obstruction of the ejaculatory ducts.

Treatment

A. General Measures

Education with respect to the proper timing for intercourse in relation to the female's ovulatory cycle as well as the avoidance of spermicidal lubricants should be discussed. In cases of toxic exposure or medication-related factors, the offending agent should be removed. Patients with active genitourinary tract infections should be treated with appropriate antibiotics.

B. Endocrine Therapy

Hypogonadotropic hypogonadism may be treated with chorionic gonadotropin once primary pituitary disease has been excluded or treated. Dosage is usually 2000 IU intramuscularly three times a week. If sperm counts fail to rise after 12 months, FSH therapy should be initiated. Menotropins (Pergonal) is available as a premixed vial of 75 IU of FSH and 75 IU of LH. The usual dosage ranges from one-half to one vial intramuscularly three times per week.

C. Retrograde Ejaculation Therapy

Oligospermic patients with retrograde ejaculation may benefit from alpha-adrenergic agonists (pseudoephedrine, 60 mg orally three times a day) or imipramine (25 mg orally three times a day). Medical failures may require the collection of postmasturbation urine for intrauterine insemination or electroejaculation in the case of absent emission.

D. Varicocele

Surgical approaches to varicoceles may be accomplished via a scrotal, inguinal, or laparoscopic approach. More recently, percutaneous venographic approaches have been developed, obviating the need for an anesthetic.

E. Ductal Obstruction

The level of obstruction must be delineated via a vasogram prior to operative treatment. Mechanical obstruction of the ejaculatory duct may be corrected by transurethral resection and unroofing of the ducts in the prostatic urethra. Obstruction of the vas deferens is best managed by a microsurgical approach, and a vasovasostomy or vasoepididymostomy may be required.

F. Assisted Reproductive Techniques

Advances in reproductive technology may provide alternatives to patients who have failed other means of treating reduced sperm counts and motility. Such measures include intrauterine insemination, in vitro fertilization, and gamete intrafallopian transfer.

■ BENIGN PROSTATIC HYPERPLASIA

Essentials of Diagnosis

- Obstructive or irritative voiding symptoms.
- May have enlarged prostate on rectal examination.
- Absence of urinary tract infection, neurologic disorder, stricture disease, prostatic or bladder malignancy.

General Considerations

Benign prostatic hyperplasia is the most common benign tumor in men, and its incidence is age-related. The prevalence of histologic benign prostatic hyperplasia in autopsy studies rises from approximately 20% in men aged 41-50 years, to 50% in men aged 51-60, and to over 90% in men over 80 years of age. Although clinical evidence of disease occurs less commonly, symptoms of prostatic obstruction are also age-related. At age 55, approximately 25% of men report obstructive voiding symptoms. At age 75 years, 50% of men report a decrease in the force and caliber of the urinary stream.

Risk factors for the development of benign prostatic hyperplasia are poorly understood. Some studies have suggested a genetic predisposition and some have noted racial differences. Approximately 50% of men under age 60 who undergo surgery for benign prostatic hyperplasia may have a heritable form of the disease. This form is most likely an autosomal dominant trait, and first-degree male relatives of such patients carry an increased relative risk of approximately fourfold.

Etiology

The etiology is not completely understood, but the disorder seems to be multifactorial and under endocrine control. The prostate is composed of both stromal and epithelial elements, and each, either alone or in combination, can give rise to hyperplastic nodules and the symptoms associated with benign prostatic hyperplasia. Each element may be targeted in medical management schemes.

Laboratory and clinical studies have identified two factors necessary for the development of benign prostatic hyperplasia: dihydrotestosterone (DHT) and aging. Animal studies have demonstrated that the aging prostate becomes more sensitive to androgens. Prostatic growth in aging dogs appears to be related more to a decrease in cell death than to an increase in cell proliferation. Laboratory studies have suggested several theories in this area, including the following: (1) stromal-epithelial interactions (stroma cell may regulate growth of epithelial cell or other stromal cells via a paracrine or autocrine mechanism by secreting growth factors such as basic fibroblast growth factor or transforming growth factor- β), and (2) aging may result in stem cells undergoing a block in the maturation process, preventing them from entering into programmed cell death (apoptosis). The impact of aging in animal studies appears to be mediated via estrogen synergism. In canines, estrogens induce the androgen receptor; alter steroid metabolism, resulting in higher levels of intraprostatic DHT; inhibit cell death when given in the presence of androgens; and stimulate stroma collagen production.

Studies have demonstrated that benign prostatic hyperplasia is under endocrine control. Castration results in the regression of established disease and improvement in urinary symptoms. Administration of a luteinizing hormone-releasing hormone (LHRH) analog in men reversibly shrinks established benign prostatic hyperplasia, resulting in objective improvement in flow rate and subjective improvement in symptoms. Further investigations have demonstrated a positive correlation between levels of free testosterone and estrogen and the volume of the gland. The latter may suggest that the association between aging and benign prostatic hyperplasia might reflect increasing estrogen levels of aging, resulting in induction of the androgen receptor and thus sensitizing the prostate to free testosterone. However, no studies to date have been able to demonstrate elevated estrogen receptor levels in humans with the disease.

Pathology

Benign prostatic hyperplasia is truly a hyperplastic process, resulting from an increase in cell numbers. Microscopic evaluation reveals a nodular growth pattern consisting of varying amounts of stroma or epithelium. Stroma is composed of varying amounts of collagen and smooth muscle. The differential representation of various histologic components of benign prostatic hyperplasia in part explains the potential responsiveness to medical therapy. Thus, alpha-blocker therapy may result in excellent responses in patients with benign prostatic hyperplasia when there is a significant component of smooth muscle, while hyperplasia composed predominantly of epithelium might respond better to 5 α -reductase inhibitors. Patients with significant components of collagen in the stroma may not respond to either form of medical therapy. One cannot reliably predict responsiveness to specific therapy (see below).

As benign prostatic hyperplasia nodules in the transition zone enlarge, they compress the outer zones of the prostate, resulting in the formation of a "surgical capsule." This boundary separates the transition zone from the peripheral zone of the gland and serves as a cleavage plane for open enucleation of the prostate during simple prostatectomies.

Pathophysiology

One can relate the symptoms of benign prostatic hyperplasia either to the obstructive component of the prostate or to the secondary response of the bladder to the outlet resistance. The obstructive component can be subdivided into mechanical obstruction and dynamic obstruction.

As prostatic enlargement occurs, mechanical obstruction may result from intrusion into the urethral lumen or bladder neck, resulting in a higher bladder outlet resistance. Prostatic size on digital rectal examination (DRE) correlates poorly with symptoms.

The dynamic component of prostatic obstruction explains the variable nature of the symptoms. The prostatic stroma is composed of smooth muscle and collagen and is rich in adrenergic nerve supply. The level of autonomic stimulation thus sets a "tone" to the prostatic urethra. Alpha-blocker therapy decreases this tone, resulting in a decrease in outlet resistance.

The irritative voiding complaints (see below) of benign prostatic hyperplasia result from the secondary response of the bladder to the increased outlet resistance. Bladder outlet obstruction results in detrusor muscle hypertrophy and hyperplasia as well as collagen deposition. The latter is most likely responsible for a decrease in bladder compliance, but detrusor instability also occurs. On gross inspection, thickened detrusor muscle bundles are seen as trabeculations on cystoscopic examination. If left unchecked, mucosal herniation between detrusor muscle bundles ensues, resulting in diverticulum formation ("false" diverticula composed of mucosa and serosa only).

Clinical Findings

A. Symptoms

The symptoms of benign prostatic hyperplasia can be divided into obstructive and irritative complaints. Obstructive symptoms include hesitancy, decreased force and caliber of the stream, sensation of incomplete bladder emptying, double voiding (urinating a second time within 2 hours), straining to urinate, and postvoid dribbling. Irritative symptoms include urgency, frequency, and nocturia.

The American Urological Association (AUA) has developed a self-administered questionnaire that is reliable in identifying patients who need therapy and in monitoring the response to therapy. The AUA symptom index ([Table 23-4](#)) is perhaps the single most important tool used in the evaluation of patients with this disorder and should be calculated for all patients before starting therapy. The answers to seven questions quantitate the severity of obstructive or irritative complaints on a scale of 0-5. Thus, the score can range from 0 to 35, in increasing severity of symptoms.

A detailed history focusing on the urinary tract should be obtained to exclude other possible causes of symptoms such as prostate cancer or disorders unrelated to the prostate such as urinary tract infection, neurogenic bladder, or urethral stricture.

B. Signs

A physical examination, DRE, and a focused neurologic examination should be performed on all patients. The size and consistency of the prostate should be noted, but prostate size does not correlate with the severity of symptoms or the degree of obstruction. Benign prostatic hyperplasia usually results in a smooth, firm, elastic

enlargement of the prostate. Induration, if detected, must alert the physician to the possibility of cancer, and further evaluation is needed (ie, PSA, transrectal ultrasound, and biopsy). Examination of the lower abdomen should be performed to assess for a distended bladder.

C. Laboratory Findings

Urinalysis should be performed to exclude infection or hematuria, and serum creatinine should be measured to assess renal function. Renal insufficiency may be observed in 10% of patients with prostatism and if observed warrants upper tract imaging. Patients with renal insufficiency are at an increased risk of developing complications following operative treatment for benign prostatic hyperplasia. A serum PSA is considered optional, yet most physicians will include it in the initial evaluation. PSA certainly increases the ability to detect prostate cancer over DRE alone, yet because there is much overlap between levels seen in benign prostatic hyperplasia and prostate cancer, its use remains controversial (see below in the section on screening for prostate cancer).

D. Imaging

Upper tract imaging (intravenous pyelogram, CT, or renal ultrasound) is only recommended in the presence of concomitant urinary tract disease or complications from benign prostatic hyperplasia (ie, hematuria, urinary tract infection, renal insufficiency, history of stone disease).

E. Cystoscopy

Cystoscopy is not recommended to determine the need for treatment but may assist in determining the surgical approach in patients opting for invasive therapy.

F. Additional Tests

Cystometrograms and urodynamic profiles should be reserved for patients with suspected neurologic disease or those who have failed prostate surgery. Flow rates, postvoid residual urine determination, and pressure-flow studies are considered optional.

Differential Diagnosis

Other obstructive conditions of the lower urinary tract such as urethral stricture, bladder neck contracture, bladder stone, or carcinoma of the prostate must be considered when evaluating men with presumptive benign prostatic hyperplasia. A history of prior urethral instrumentation, urethritis, or trauma should be elucidated to exclude urethral stricture or bladder neck contracture. Hematuria and pain are commonly associated with bladder stones. Carcinoma of the prostate may be detected by abnormalities on the DRE or an elevated PSA (see below). A urinary tract infection can mimic the irritative symptoms of benign prostatic hyperplasia and can be readily identified by urinalysis and culture; however, a urinary tract infection can also be a complication of benign prostatic hyperplasia. Carcinoma of the bladder, especially carcinoma in situ, may also present with irritative voiding complaints; however, urinalysis usually shows evidence of hematuria. Patients with neurogenic bladder may also have many of the same symptoms and signs as those with benign prostatic hyperplasia; however, a history of neurologic disease, stroke, diabetes mellitus, or back injury may be obtained, and diminished perineal or lower extremity sensation or alterations in rectal sphincter tone or the bulbocavernosus reflex might be observed on examination. Simultaneous alterations in bowel function (constipation) might also alert one to the possibility of a neurologic disorder.

Treatment

Clinical practice guidelines exist for the evaluation and treatment of patients with benign prostatic hyperplasia ([Figure 23-1](#)). Following evaluation as outlined above, patients should be offered various forms of therapy for benign prostatic hyperplasia. Patients are advised to consult with their primary care physicians and make an educated decision on the basis of the relative efficacy and side effects of the treatment options ([Table 23-5](#)).

Patients with mild symptoms (AUA scores 0-7) should be managed by watchful waiting only. Absolute surgical indications are refractory urinary retention (failing at least one attempt at catheter removal), large bladder diverticula, or any of the following sequelae of benign prostatic hyperplasia: recurrent urinary tract infection, recurrent gross hematuria, bladder stones, or renal insufficiency.

A. Watchful Waiting

The risk of progression or complications is uncertain. However, in men with symptomatic disease, it is clear that progression is not inevitable and that some men undergo spontaneous improvement or resolution of their symptoms.

Retrospective studies on the natural history of benign prostatic hyperplasia are inherently subject to bias, relating in part to patient selection and also to the type and extent of follow-up. Very few prospective studies addressing the natural history have been reported. One small series demonstrated that approximately 10% of symptomatic men may progress to urinary retention while half of patients demonstrate marked improvement or resolution of symptoms. Recently, a large randomized study was reported comparing finasteride with placebo in men with moderate to severely symptomatic disease and enlarged prostates on DRE. Patients in the placebo arm demonstrated a 7% risk of developing urinary retention over 4 years.

Men with moderate or severe symptoms can be managed also in this fashion if they so choose. The optimal interval for follow-up is not defined, nor are the specific end points for intervention.

B. Medical Therapy

1. Alpha-blockers—The human prostate and bladder base contains α_1 adrenoceptors, and the prostate will show a contractile response to such agonists. The contractile properties of the prostate and bladder neck seem to be mediated primarily by α_{1a} receptors. Alpha blockade has been shown to result in both objective and subjective degrees of improvement in the symptoms and signs of benign prostatic hyperplasia in some patients. Alpha-blockers can be classified according to their receptor selectivity as well as their half-life ([Table 23-6](#)).

The efficacies of phenoxybenzamine and prazosin are comparable with respect to symptomatic relief; however, the higher side-effect profile of phenoxybenzamine, resulting from its lack of alpha-receptor specificity, precludes its use in benign prostatic hyperplasia patients. Dose titration is necessary with prazosin, with typical therapy starting at 1 mg orally at bedtime for 3 nights, then increasing to 1 mg orally twice daily and then titrating up to 2 mg orally twice daily if necessary. Little additional symptomatic improvement is observed at higher doses, and side effects increase. Typical side effects include orthostatic hypotension, dizziness, tiredness, retrograde ejaculation, rhinitis, and headache.

Long-acting alpha-blockers allow for once-a-day dosing, but dose titration is still necessary. Terazosin is started at a dosage of 1 mg orally daily for 3 days, increased to 2 mg orally daily for 11 days, then 5 mg orally daily. Additional dose escalation to 10 mg orally daily can be performed if necessary. Doxazosin is started at a dosage of 1 mg orally daily for 7 days, increased to 2 mg orally daily for 7 days, then 4 mg orally daily. Additional dose escalation to 8 mg orally daily can be performed if necessary. Side effects are similar to those described above for prazosin.

The most recent advance in alpha-blocker therapy has been the identification of subtypes of α_1 receptors. The α_{1a} receptors are those localized to the prostate and bladder neck, and selective blockade results in fewer systemic side effects (orthostatic hypotension, dizziness, tiredness, rhinitis, and headache), thus obviating the need for dose titration. Tamsulosin is started at a dosage of 0.4 mg orally daily and can be increased to 0.8 mg orally daily if necessary.

Several randomized, double-blind, placebo-controlled trials have been performed comparing terazosin, doxazosin, or tamsulosin with placebo. All agents have demonstrated safety and efficacy.

2. 5 α -Reductase inhibitors—Finasteride is a 5 α -reductase inhibitor that blocks the conversion of testosterone to dihydrotestosterone. This drug impacts upon the epithelial component of the prostate, resulting in reduction in size of the gland and improvement in symptoms. Six months of therapy are required for maximum effects on prostate size (20% reduction) and symptomatic improvement.

Several randomized, double-blind, placebo-controlled trials have been performed comparing finasteride with placebo. Efficacy, safety, and durability are well established. However, symptomatic improvement is seen only in men with enlarged prostates (> 40 mL). Side effects include decreased libido, decrease in volume of ejaculate, and impotence. Serum PSA is reduced by approximately 50% in patients receiving finasteride therapy. However, individual values may vary, thus complicating cancer detection.

A recent report suggests that finasteride therapy may decrease the incidence of urinary retention and the need for operative treatment in men with enlarged prostates and moderate to severe symptoms. However, optimal identification of appropriate patients for prophylactic therapy remains to be determined.

3. Combination therapy—The first randomized, double-blind, placebo-controlled study investigating combination therapy of an alpha-blocker and a 5 α -reductase inhibitor was recently reported. This was a four-arm Veterans Administration Cooperative Trial comparing placebo, finasteride alone, terazosin alone, and combination of finasteride and terazosin. Over 1200 patients participated, and significant decreases in symptom scores and increases in urinary flow rates were seen only in the arms containing terazosin. However, one must note that enlarged prostates were not an entry criterion, and in fact prostate size in this study was much smaller than in previous controlled trials using finasteride (32 versus 52 mL). Additional combination therapy trials are ongoing.

4. Phytotherapy—Phytotherapy is the use of plants or plant extracts for medicinal purposes. Its use in benign prostatic hyperplasia has been popular in Europe for

years, and its use in the United States is growing as a result of patient-driven enthusiasm. Several plant extracts have been popularized, including the saw palmetto berry, the bark of *Pygeum africanum*, the roots of *Echinacea purpurea* and *Hypoxis rooperi*, pollen extract, and the leaves of the trembling poplar. The mechanisms of action of these agents are unknown, and their efficacy and safety have not been tested in multicenter, randomized, double-blind, placebo-controlled studies.

C. Conventional Surgical Therapy

1. Transurethral resection of the prostate (TURP)—Ninety-five percent of simple prostatectomies can be performed endoscopically. Most of these procedures are performed under a spinal anesthetic and require a 1- to 2-day hospital stay. Symptom scores and flow rate improvement are superior following TURP relative to any minimally invasive therapy; however, the length of the hospital stay is greater. Much controversy revolves around possible higher rates of morbidity and mortality associated with TURP in comparison with open surgery, but the higher rates observed in one study probably related to more significant comorbidities in the TURP patients compared with the patients who received open surgical treatment. Several other studies could not confirm the difference in mortality when controlling for age and comorbidities. The risks of TURP include retrograde ejaculation (75%), impotence (5-10%), and urinary incontinence (< 1%). Complications include bleeding, urethral stricture or bladder neck contracture, perforation of the prostate capsule with extravasation, and, if severe, transurethral resection syndrome, a hypervolemic, hyponatremic state resulting from absorption of the hypotonic irrigating solution. Clinical manifestations of the syndrome include nausea, vomiting, confusion, hypertension, bradycardia, and visual disturbances. The risk of transurethral resection syndrome increases with resection times over 90 minutes. Treatment includes diuresis and, in severe cases, hypertonic saline administration.

2. Transurethral incision of the prostate (TUIP)—Men with moderate to severe symptoms and small prostates often have posterior commissure hyperplasia or an "elevated bladder neck." These patients will often benefit from incision of the prostate. The procedure is more rapid and less morbid than TURP. Outcomes in well-selected patients are comparable, though a lower rate of retrograde ejaculation has been reported (25%). The technique involves two incisions using the Collins knife at the 5 and 7 o'clock positions. The incisions are started just distal to the ureteral orifices and extended outward to the verumontanum.

3. Open simple prostatectomy—When the prostate is too large to remove endoscopically, open enucleation is necessary. What size is "too large" depends upon the surgeon's experience with TURP. Glands over 100 g are usually considered for open enucleation. In addition to size, other relative indications for open prostatectomy include concomitant bladder diverticulum or bladder stone and whether dorsal lithotomy positioning is or is not possible.

Open prostatectomies can be performed with either a suprapubic or retropubic approach. Simple suprapubic prostatectomy is performed transvesically and is the operation of choice if there is concomitant bladder pathology. After the bladder is opened, a semicircular incision is made in the bladder mucosa distal to the trigone. The dissection plane is initiated sharply, and blunt dissection with the finger is then performed to deliver the adenoma. The apical dissection should be performed sharply to avoid injury to the distal sphincteric mechanism. After the adenoma is removed, hemostasis is attained with suture ligatures and both a urethral and a suprapubic catheter are inserted prior to closure.

In simple retropubic prostatectomy, the bladder is not entered but rather a transverse incision is made in the surgical capsule of the prostate and the adenoma is enucleated as described above. Only a urethral catheter is needed at the end of the case.

D. Minimally Invasive Therapy

1. Laser therapy—Many techniques of laser surgery for the prostate have been described. Two main energy sources of lasers have been utilized—neodymium: yttrium-aluminum-garnet (Nd:YAG) and holmium-YAG.

Several different coagulation necrosis techniques have been described. TULIP (transurethral laser-induced prostatectomy) is performed under transrectal ultrasound guidance. The instrument is placed in the urethra and transrectal ultrasound is used to direct the device as it is slowly pulled from the bladder neck to the apex. The depth of treatment is monitored with ultrasound.

Most urologists prefer to use visually directed laser techniques. Visual coagulative necrosis is performed under cystoscopic control, and the laser fiber is pulled through the prostate at several designated areas depending upon the size and configuration of the gland. Four-quadrant and sextant approaches have been described for lateral lobes, with additional treatments directed at enlarged median lobes. Coagulative techniques do not create an immediate visual defect in the prostatic urethra—tissue is sloughed over the course of several weeks up to 3 months following the procedure.

Visual contact ablative techniques take longer in the operating room because the fiber is placed in direct contact with the prostate tissue, which is vaporized. An immediate defect is obtained in the prostatic urethra, similar to that seen during TURP.

Interstitial laser therapy places fibers directly into the prostate, usually under cystoscopic control. At each puncture, the laser is fired, resulting in submucosal coagulative necrosis. Irritative voiding symptoms may be less in these patients as the urethral mucosa is spared and prostate tissue is resorbed by the body rather than sloughed.

Advantages to laser surgery include minimal blood loss, rare occurrence of transurethral resection syndrome, the ability to treat patients while on anticoagulation therapy, and outpatient surgery. Disadvantages are the lack of tissue for pathologic examination, the longer postoperative catheterization time, the more frequent irritative voiding complaints, and the expense of laser fibers and generators.

Large multicenter, randomized studies with long-term follow-up are needed in comparing laser prostate surgery with TURP and other forms of minimally invasive surgery.

2. Transurethral needle ablation of the prostate (TUNA)—This procedure uses a specially designed urethral catheter that is passed into the urethra. Interstitial radiofrequency needles are then deployed from the tip of the catheter, piercing the mucosa of the prostatic urethra. Radiofrequencies are then used to heat the tissue, resulting in coagulative necrosis. Bladder neck and median lobe enlargement are not well treated by TUNA. Subjective and objective improvement in voiding occurs. In randomized trials comparing TUNA to transurethral resection of the prostate (TURP), similar improvement was seen when comparing life scores, peak urinary flow rates, and postvoid residual urine.

3. Transurethral electrovaporization of the prostate—This technique uses the standard resectoscope but replaces a conventional loop with a variation of a grooved rollerball. High current densities result in heat vaporization of tissue, creating a cavity in the prostatic urethra. Because the device requires slower sweeping speeds over the prostatic urethra and the depth of vaporization is approximately one-third of a standard loop, this procedure usually takes longer than a standard TURP. Long-term comparative data are needed.

4. Hyperthermia—Microwave hyperthermia is most commonly delivered with a transurethral catheter. Some devices cool the urethral mucosa to decrease the risk of injury. However, if temperatures do not go above 45 °C, cooling is unnecessary. Symptom score and flow rate improvement are obtained, but (as with laser surgery) large randomized studies with long-term follow-up are needed to assess durability and cost-effectiveness.

5. High-intensity focused ultrasound (HIFU)—HIFU is another means of performing thermal tissue ablation. A specially designed dual-function ultrasound probe is placed in the rectum. This probe allows transrectal imaging of the prostate and also delivers short bursts of high-intensity focused ultrasound energy, which heats the prostate tissue and causes coagulative necrosis. Bladder neck and median lobe enlargement are not well treated by HIFU. Ongoing clinical trials demonstrate some improvement in symptom score and flow rate, but the durability of the response is not known.

6. Intraurethral stents—Intraurethral stents are placed endoscopically in the prostatic fossa to keep the prostatic urethra patent. They are usually covered by urothelium within 4-6 months following insertion. These devices are typically used for patients with limited life expectancies who are not deemed good surgical or anesthetic candidates; however, with the advent of other minimally invasive techniques requiring minimal anesthesia (conscious sedation, or prostatic blocks), their application has become more limited.

7. Transurethral balloon dilation of the prostate—Balloon dilation of the prostate is performed with specially designed catheters that permit dilation of the prostatic fossa alone or dilation of the prostatic fossa and bladder neck. The technique is most effective in small prostates (< 40 mL), and while it may result in improvement in symptom score and flow rates, the effects are transient. This technique is rarely used today.

■ MALIGNANT GENITOURINARY TRACT DISORDERS

PROSTATE CANCER

Essentials of Diagnosis

- Prostatic induration on digital rectal examination or elevation of PSA.
- Most often asymptomatic.
- Rarely: systemic symptoms (weight loss, bone pain).

General Considerations

Prostatic cancer is the most common cancer detected in American men and the second leading cause of cancer-related death. In the United States in 2002, over 189,000 new cases of prostate cancer were diagnosed, and about 30,200 deaths resulted. However, the clinical incidence of the disease does not match the prevalence noted at autopsy, where more than 40% of men over 50 years of age are found to have prostatic carcinoma. Most such occult cancers are small and contained within the prostate gland. Few are associated with regional or distant disease. The incidence of prostatic cancer increases with age. Whereas 30% of men age 60-69 will have the disease, autopsy incidence increases to 67% in men aged 80-89 years. Although the prevalence of prostatic cancer in autopsy specimens around the world varies little, the clinical incidence is considerably different (high in North America and European countries, intermediate in South America, and low in the Far East), suggesting that environmental or dietary differences among populations may be important for prostatic cancer growth. A 50-year-old American man has a lifetime risk of 40% for latent cancer, 9.5% for developing clinically apparent cancer, and a 2.9% risk of death due to prostatic cancer. Blacks, men with a family history of prostatic cancer, and those with a history of high dietary fat intake are at increased risk of developing it.

Clinical Findings

A. Symptoms and Signs

Prostate cancer may be manifested as focal nodules or areas of induration within the prostate at the time of digital rectal examination. However, a large number of prostate cancers are associated with palpably normal prostates and are detected on the basis of elevations in serum prostate-specific antigen.

Rarely, patients present with signs of urinary retention (palpable bladder) or neurologic symptoms as a result of epidural metastases and cord compression. Obstructive voiding symptoms are most often due to benign prostatic hyperplasia, which occurs in the same age group. However, large or locally extensive prostatic cancers can cause obstructive voiding symptoms. Lymph node metastases can lead to lower extremity lymphedema. As the axial skeleton is the most common site of metastases, patients may present with back pain or pathologic fractures.

B. Laboratory Findings

1. Serum tumor markers—Prostate-specific antigen (PSA) is a glycoprotein produced only in the cytoplasm of benign and malignant prostate cells. The serum level correlates with the volume of both benign and malignant prostatic tissue. Measurement of PSA may be useful in detecting and staging prostatic cancer, monitoring response to treatment, and detecting recurrence before it becomes obvious clinically. As a first-line screening test, PSA will be elevated in approximately 10-15% of men self-referred for screening. Approximately 18-30% of men with intermediate degrees of elevation (4.1-10 ng/mL; normal < 4 ng/mL) will be found to have prostatic cancer. Between 50% and 70% of those with elevations greater than 10 ng/mL will have prostatic cancer. (See age-specific PSA reference ranges under Screening for Prostatic Cancer, below.) Patients with intermediate levels of PSA will usually have localized and therefore potentially curable cancers. However, it should be remembered that approximately 20% of patients who undergo radical prostatectomy for localized prostatic cancer will have normal levels of PSA.

In untreated patients with prostatic cancer, the level of PSA correlates with the volume and stage of the disease. Whereas most organ-confined cancers are associated with PSA levels less than 10 ng/mL, more advanced disease (seminal vesicle invasion, lymph node involvement, or occult distant metastases) is more common in patients with PSA levels in excess of 40 ng/mL. Approximately 98% of patients with metastatic prostatic cancer will have elevated PSA. However, there are occasional cancers which are localized despite substantial elevations in PSA. Therefore, treatment decisions in patients with untreated cancers cannot be made on the basis of PSA testing alone. A rising level of PSA after treatment is usually consistent with progressive disease whether it be locally recurrent or metastatic.

2. Miscellaneous laboratory testing—Patients in urinary retention or those with ureteral obstruction due to locally or regionally advanced prostatic cancers may present with elevations in serum urea nitrogen or creatinine. Patients with bony metastases may have elevations in alkaline phosphatase or hypercalcemia. Laboratory and clinical evidence of disseminated intravascular coagulation can occur in patients with advanced prostatic cancers.

3. Prostatic biopsy—Transrectal ultrasound-guided biopsy seems to be a better method for detection of prostatic cancer than finger-guided biopsy. The use of a spring-loaded, 18-gauge biopsy needle has allowed transrectal biopsy to be performed with little patient discomfort and low attendant morbidity. The specimen preserves glandular architecture and allows for accurate grading as described below. Transrectal ultrasound-guided biopsies are taken from the apex, mid portion, and base of the prostate in men who have an abnormal digital rectal examination or an elevated serum PSA. Systematic rather than only lesion-directed biopsies are usually performed. Patients with abnormalities of the seminal vesicles can have guided biopsies of these structures performed to allow for detection of local tumor invasion. Aspiration biopsies of the prostate, though accurate and associated with low morbidity, have been used rarely since the introduction of the spring-loaded biopsy device but should be considered in patients at an increased risk of bleeding.

C. Imaging

Modern transrectal ultrasound instrumentation provides high-definition images of the prostate. Transrectal ultrasonography has been used largely for the staging of prostatic carcinomas. In addition, transrectal ultrasound-guided—rather than digitally guided—biopsy of the prostate may be a more accurate way to investigate suspicious lesions. Most prostatic cancers are hypoechoic.

MRI of the prostate allows for evaluation of the prostatic lesion as well as regional lymph nodes. The positive predictive value for detection of both capsular penetration and seminal vesicle invasion is similar for both transrectal ultrasound and MRI. CT scanning plays little role in evaluation because of its inability to accurately identify or stage prostatic cancers.

Radionuclide bone scan is superior to conventional plain skeletal x-rays in detecting bony metastases. Most prostatic cancer metastases are multiple and are most commonly localized to the axial skeleton. Because of the high frequency of abnormal scans in patients in this age group resulting from degenerative joint disease, plain films are often useful in evaluating patients with indeterminate radionuclide findings. Intravenous urography and cystoscopy are not routinely used to evaluate patients with prostatic cancer.

Imaging can be tailored to the likelihood of advanced disease in newly diagnosed patients. Asymptomatic patients with well to moderately well differentiated cancers—thought to be localized to the prostate on digital rectal examination and transurethral ultrasound and associated with normal or only modest elevations of PSA (ie, < 10 ng/mL)—need no further evaluation.

Those with more advanced local lesions, symptoms of metastases (ie, bone pain), and elevations in PSA greater than 10 ng/mL should undergo radionuclide bone scan. Cross-sectional imaging of the prostate is usually indicated only in those patients in the latter group who have negative bone scans in an attempt to detect lymph node metastases. Patients found to have enlarged pelvic lymph nodes are candidates for fine-needle aspiration. Despite application of modern and sophisticated imaging, understaging of prostatic cancer occurs in at least 20% of patients.

Screening for Prostatic Cancer

The reported incidence of prostate cancer rose significantly in the United States when early detection techniques (PSA testing and transrectal ultrasound) became widely available. The goal of a screening effort should be to detect and effectively treat only those prostatic carcinomas most likely to cause morbidity or mortality if left untreated. Detection of latent, nonprogressive cancers would expose patients to unnecessary treatment and its attendant complications and costs. Whether screening for prostatic cancer will result in a decrease in yearly mortality rates due to the disease is the subject of much current debate.

The screening tests currently available include digital rectal examination, PSA testing, and transrectal ultrasound. Depending on the patient population being evaluated, detection rates using digital rectal examination alone will vary from 1.5% to 7%. Unfortunately, most cancers detected in this way are advanced (stages T3 or greater).

Transrectal ultrasound should not be used as a first-line screening tool because of its expense, its low specificity (and therefore high biopsy rate), and the fact that it increases the detection rate very little when compared with the combined use of digital rectal examination and PSA testing.

PSA testing will increase the detection rate of prostatic cancers compared with digital rectal examination. Approximately 2-2.5% of men older than age 50 will be found to have prostatic cancer using PSA testing compared with a rate of approximately 1.5% using digital rectal examination alone. PSA is not specific for cancer, and there is considerable overlap of values between men with benign prostatic hyperplasia and those with prostatic cancers. The sensitivity, specificity, and positive predictive value of PSA and digital rectal examination are listed in [Table 23-7](#). PSA-detected cancers are more likely to be localized compared with those detected with digital rectal examination alone.

In order to improve the performance of PSA as a screening test, several investigators have developed alternative methods for its use. The serial measurement of PSA (PSA velocity) may increase specificity for cancer detection with little loss in sensitivity. A rate of change in PSA greater than 0.75 ng/mL per year is associated with an increased likelihood of cancer detection. In a patient with a normal digital rectal examination, an elevated PSA, and a normal transrectal ultrasound, the indications for prostate biopsy may be refined by calculating PSA density (serum PSA/volume of the prostate as measured by ultrasound). Patients with high PSA density are more likely to have disease in spite of a normal digital rectal examination and normal transrectal ultrasound. Some have found measurement of PSA transition zone density (the zone of the prostate that undergoes enlargement during development of benign prostatic hyperplasia) to be more predictive of the presence or absence of cancer than PSA density calculated using the entire prostate volume. As PSA concentration is directly related to patient age, establishment of age-specific reference ranges would increase specificity (fewer older men with benign prostatic hyperplasia would undergo evaluation) and increase sensitivity (more younger men with cancer would undergo evaluation). Age-specific reference ranges have been established: men 40-49, < 2.5 ng/mL; men 50-59, < 3.5 ng/mL; men 60-69, < 4.5 ng/mL; and men 70-79, < 6.5 ng/mL (based on a previously normal serum PSA of < 4 ng/mL). Black men have lower age-specific reference ranges (age 40-49, < 2 ng/mL; age 50-59, < 4 ng/mL; age 60-69, < 4.5 ng/mL; age 70-79, < 5.5 ng/mL). The most recent attempt at refining PSA has been the measurement of free serum and protein-bound levels (cancer patients have a lower percentage of free serum PSA). Numerous centers are analyzing this assay to define an optimal cutoff level. Generally, men with free fractions exceeding 25% are unlikely to have prostate cancer, whereas those with free fractions less than 10% have an approximately 50% chance of having prostate cancer. Early reports using cutoffs of 18-20% of free PSA resulted in 5-10% lost sensitivity for 15-40% gains in specificity. The frequency of PSA testing remains a matter of some debate. In men with a normal DRE and a PSA > 2.5 ng/mL, PSA testing should be performed yearly because approximately 50% of these patients convert to having a PSA > 4 ng/mL. It can be performed biennially in those with a normal DRE and serum PSA < 2.5 ng/mL. Conversion in this group is much less likely.

Pathology & Staging

The majority of prostatic cancers are adenocarcinomas. Most arise in the periphery of the prostate (peripheral zone), though a small percentage arise in the central (5-10%) and transition zones (20%) of the gland. Most pathologists employ the Gleason grading system whereby a "primary" grade is applied to the architectural pattern of cancerous glands occupying the largest area of the specimen and a "secondary" pattern is assigned to the next largest area of cancerous growth. Grading is based on architectural (rather than histologic) criteria, and five possible "grades" are possible. Adding the score of the primary and secondary patterns gives a Gleason score. Grade correlates well with tumor volume, stage, and prognosis. The TNM classification of the American Joint Cancer Committee for prostatic cancer is shown in [Table 23-8](#).

The patterns of prostatic cancer progression have been well defined. The likelihood of both local invasion and metastases is greater in larger or less well differentiated cancers. Small and well-differentiated cancers (grades 1 and 2) are usually confined within the prostate, whereas large-volume (> 4 mL) or poorly differentiated (grades 4 and 5) cancers are more commonly locally extensive or metastatic to regional lymph nodes or bone. Penetration of the prostatic capsule by cancer is common and often occurs along perineural spaces. Seminal vesicle invasion is associated with a high likelihood of regional or distant disease. Lymphatic metastases are most often identified in the obturator lymph node chain. The axial skeleton, as mentioned previously, is the most common site of distant metastases.

Treatment

A. Localized Disease

What constitutes the optimal form of treatment for patients with clinically localized cancers remains controversial. Treatment decisions are at present made on the basis of tumor grade and stage and the age and health of the patient. Although selected patients may be candidates for surveillance based on age or health and the presence of small-volume or well-differentiated cancers, most patients with an anticipated survival in excess of 10 years should be considered for treatment. Both radiation therapy and radical prostatectomy allow for acceptable levels of local control. A randomized trial comparing watchful waiting and radical prostatectomy in men with clinically localized prostate cancer is currently under way in the United States (PIVOT: Prostate Cancer Intervention Versus Observation Trial). This trial will randomize 1000 patients and will run for 15 years. Patients need to be advised of all treatment options (including surveillance) along with their particular benefits, risks, and limitations.

B. Radical Prostatectomy

In radical prostatectomy, the seminal vesicles, prostate, and ampullae of the vas deferens are removed. Refinements in technique have allowed maintenance of urinary continence in most patients and erectile function in selected patients. Local recurrence is uncommon after radical prostatectomy, and its incidence is related to pathologic stage. Organ-confined cancers rarely recur. However, cancers found to be locally extensive (capsular penetration, seminal vesicle invasion) are associated with higher local (10-25%) and distant (20-50%) relapse rates.

Ideal candidates for the procedure include healthy patients with stages T1 and T2 prostatic cancers. Patients with advanced local tumors (T3 and T4) and those with lymph node metastases are rarely candidates for this procedure.

Patients with positive surgical margins are at an increased risk for local and distant tumor relapse. Such patients are often considered candidates for adjuvant therapy (radiation for positive margins or androgen deprivation for lymph node metastases). Although adjuvant radiation seems to be associated with fewer local recurrences (0-5% with radiation versus 15-30% without), it has little or no impact on distant failure rates (30-35% with radiation versus 30-45% without).

C. Radiation Therapy

Radiation can be delivered by a variety of techniques including use of external beam radiotherapy and transperineal implantation of radioisotopes. Morbidity is limited, and the survival of patients with localized cancers (T1, T2, and selected T3) approaches 65% at 10 years. As with surgery, the likelihood of local failure correlates with technique and tumor stage. The likelihood of a positive prostatic biopsy more than 18 months after radiation varies between 20% and 60% in selected series. Patients with local recurrence are at an increased risk of cancer progression and cancer death compared with those who have negative biopsies. Ambiguous target definitions, inadequate radiation doses, and understaging of patients may be responsible for the failure noted in some series. Newer techniques of radiation (implantation, conformal therapy using three-dimensional reconstruction of CT-based tumor volumes, heavy particle, charged particle, and heavy charged particle) may improve local control rates. Three-dimensional conformal radiation delivers a higher dose because of improved targeting and appears to be associated with improved efficacy and a lower likelihood of adverse side effects compared with previous radiation techniques. As a result of improvements in imaging—most notably transrectal ultrasound—there has been a resurgence of interest in brachytherapy, the implantation of permanent or temporary radioactive sources (palladium, iodine, or iridium) into the prostate. Brachytherapy can be combined with external beam radiation in patients with higher-grade or higher-volume disease or as monotherapy in those with low-grade or low-volume malignancies.

D. Surveillance

A positive impact of localized prostatic cancer treatment with regard to survival has not been conclusively demonstrated. Surveillance alone may be an appropriate form of management for selected patients with prostatic cancer. However, many patients in such series are older and have very small and well-differentiated cancers. Even in such a selected population, cancer death rates approach 10%. In addition, end points for intervention in patients on surveillance regimens have not been defined.

E. Cryosurgery

Cryosurgery is a technique whereby liquid nitrogen is circulated through small hollow-core needles inserted into the prostate under ultrasound guidance. The freezing process results in tissue destruction. There has been a resurgence of interest in less invasive forms of therapy for localized prostate cancer as well as several recent technical innovations, including improved percutaneous techniques, expertise in transrectal ultrasound, improved cryotechnology, and better understanding of cryobiology. The positive biopsy rate after cryoablation ranges between 7% and 23%.

F. Locally and Regionally Advanced Disease

Prostatic cancers associated with minimal degrees of capsular penetration are candidates for standard irradiation or surgery. Those with locally extensive cancers, including those with seminal vesicle and bladder neck invasion, are at increased risk of both local and distant relapse despite conventional therapy. Currently, a variety of investigational regimens are being tested in an effort to improve local and distant relapse rates in such patients. Combination therapy (androgen deprivation combined with surgery or irradiation), newer forms of irradiation, and hormonal therapy alone are being tested in such patients. Neoadjuvant androgen deprivation therapy combined with external beam radiation therapy has demonstrated improved survival over external beam radiation therapy alone. Similarly, patients with lymph node metastases may benefit little from aggressive local therapy and are best treated with androgen deprivation, occasionally combined with local therapy.

G. Metastatic Disease

Since death due to prostatic carcinoma is almost invariably a result of failure to control metastatic disease, research has emphasized efforts to improve control of distant disease. It is well known that most prostatic carcinomas are hormone-dependent, and approximately 70-80% of men with metastatic prostatic carcinoma will respond to various forms of androgen deprivation. Testosterone, the major circulating androgen, is produced by Leydig cells in the testes (95%), with a smaller amount being produced by peripheral conversion of other steroids. Although 98% of serum testosterone is protein-bound, free testosterone enters prostate cells and is converted to dihydrotestosterone, the major intracellular androgen. Dihydrotestosterone binds a cytoplasmic receptor protein, and the complex moves to the cell nucleus, where it modulates transcription. Androgen deprivation may be induced at several levels along the pituitary-gonadal axis using a variety of methods or agents ([Table 23-9](#)). Use of LHRH agonists (leuprolide, goserelin)—drugs delivered in monthly or 3-monthly depot—has allowed induction of androgen deprivation without orchiectomy or administration of diethylstilbestrol. Presently, administration of LHRH agonists and orchiectomy are the most common forms of primary androgen blockade used. Because of its rapid onset of action, ketoconazole should be considered in patients with advanced prostatic cancer who present with spinal cord compression, bilateral ureteral obstruction, or disseminated intravascular coagulation. Although testosterone is the major circulating androgen, the adrenal gland secretes the androgens dehydroepiandrosterone, dehydroepiandrosterone sulfate, and androstenedione. Some investigators believe that suppressing both testicular and adrenal androgens will allow for a better initial and longer response than methods which inhibit production of only testicular androgens. Complete androgen blockade can be achieved by combining an antiandrogen with use of an LHRH agonist or orchiectomy. Nonsteroidal antiandrogen agents appear to act by competitively binding the receptor for dihydrotestosterone, the intracellular androgen responsible for prostatic cell growth and development. A meta-analysis of trials comparing the use of either an LHRH agonist or orchiectomy alone with the use of either in combination with an antiandrogen agent shows marginal (if any) benefit to the use of combination therapy. However, patients at risk of disease-related symptoms (bone pain, obstructive voiding symptoms) due to the initial elevation of serum testosterone that accompanies the use of an LHRH agonist should receive antiandrogens initially.

BLADDER CANCER

Essentials of Diagnosis

- Irritative voiding symptoms.
- Gross or microscopic hematuria.
- Positive urinary cytology in most patients.
- Filling defect within bladder noted on imaging.

General Considerations

Bladder cancer is the second most common urologic cancer, occurs more commonly in men than women (2.7:1), and the mean age at diagnosis is 65 years. Cigarette smoking and exposure to industrial dyes or solvents are risk factors for the disease and account for approximately 60% and 15% of new cases, respectively.

Clinical Findings

A. Symptoms and Signs

Hematuria—gross or microscopic, chronic or intermittent—is the presenting symptom in 85-90% of patients with bladder cancer. Irritative voiding symptoms (urinary frequency and urgency) will occur in a small percentage of patients as a result of the location or size of the cancer. Most patients with bladder cancer will fail to have signs of the disease because of its superficial nature. Masses detected on bimanual examination may be present in patients with large-volume or deeply infiltrating cancers. Hepatomegaly or supraclavicular lymphadenopathy may be present in patients with metastatic disease, and lymphedema of the lower extremities may be present as a result of locally advanced cancers or metastases to pelvic lymph nodes.

B. Laboratory Findings

Urinalysis will reveal hematuria in the majority of cases. On occasion, it may be accompanied by pyuria. Azotemia may be present in a small number of cases associated with ureteral obstruction. Anemia may occasionally be due to chronic blood loss or to bone marrow metastases. Exfoliated cells from normal and abnormal urothelium can be readily detected in voided urine specimens. Cytology may be useful in detecting the disease at the time of initial presentation or to detect recurrence. Cytology is very sensitive in detecting cancers of higher grade and stage (80-90%) but less so in detecting superficial or well-differentiated lesions (50%). Sensitivity of detection using exfoliated cells may be enhanced by flow cytometry.

C. Imaging

Bladder cancers may be detected using intravenous urography, ultrasound, CT, or MRI where filling defects within the bladder are noted. However, the presence of cancer is confirmed by cystoscopy and biopsy, so imaging is useful primarily for evaluating the upper urinary tract and in staging the more advanced lesions.

D. Cystourethroscopy and Biopsy

The diagnosis and staging of bladder cancers is made by cystoscopy and transurethral resection. If cystoscopy—performed usually under local anesthesia—confirms the presence of bladder cancer, the patient is scheduled for transurethral resection under general or regional anesthesia. A careful bimanual examination is performed initially and at the end of the procedure, noting the size, position, and degree of fixation of a mass, if present. Any suspicious lesions are resected using electrocautery. Resection is carried down to the muscular elements of the bladder wall so as to allow complete staging. Random bladder and, on occasion, prostatic urethral biopsies are performed to detect occult disease elsewhere in the bladder and, therefore, identify patients at high risk of recurrence and progression.

Pathology & Selection of Treatment

Ninety-eight percent of primary bladder cancers are epithelial malignancies, with the majority being transitional cell carcinomas (90%). These latter cancers most often appear as papillary growths, but higher-grade lesions are often sessile and ulcerated. Grading is based on histologic appearance: size, pleomorphism, mitotic rate, and hyperchromatism. The frequency of recurrence and progression is strongly correlated with grade. Whereas progression may be noted in few grade I cancers (19-37%), it is common with poorly differentiated lesions (33-67%). Carcinoma in situ is recognizable as a flat, nonpapillary, anaplastic epithelium and may occur focally or diffusely, but it is most often found in association with papillary bladder cancers. Its presence identifies a patient at increased risk of recurrence and progression.

Adenocarcinomas and squamous cell cancers account for approximately 2% and 7% (respectively) of all bladder cancers detected in the United States. The latter is often associated with schistosomiasis, vesical calculi, or chronic catheter use.

Bladder cancer staging is based on the extent of bladder wall penetration and the presence of either regional or distant metastases. The TNM classification of the

American Joint Cancer Committee for bladder cancer is shown in [Table 23-10](#).

The natural history of bladder cancer is based on two separate but related processes: tumor recurrence and progression to higher-stage disease. Both are related to tumor grade and stage. At initial presentation, approximately 50-80% of bladder cancers will be superficial: Ta, Tis, or T1. Lymph node metastases and progression are uncommon in such patients when they are properly treated, and survival is excellent at 81%. Patients with superficial cancers (Ta, T1) are treated with complete transurethral resection and the selective use of intravesical chemotherapy. The latter is used to prevent or delay recurrence. Patients who present with large, high-grade, recurrent Ta lesions or T1 cancers and those with carcinoma in situ are good candidates for intravesical chemotherapy. Patients with more invasive (T2, T3) but still localized cancers are at risk of both nodal metastases and progression, and they require more aggressive surgery, irradiation, or the combination of chemotherapy and selective surgery or irradiation due to the much higher risk of progression compared to patients with lower-stage lesions. Patients with evidence of lymph node or distant metastases should undergo systemic chemotherapy initially.

Treatment

A. Intravesical Chemotherapy

Immuno- or chemotherapeutic agents can be delivered directly into the bladder by a urethral catheter. They can be used to eradicate existing disease or to reduce the likelihood of recurrence in those who have undergone complete transurethral resection. Such therapy is more effective in the latter situation. Most agents are administered weekly for 6-12 weeks. The use of maintenance therapy after the initial induction regimen may be beneficial. Efficacy may be increased by prolonging contact time to 2 hours. Common agents include thiotepa, mitomycin, doxorubicin, and BCG, the latter being the most effective agent when compared with the others. Side effects of intravesical chemotherapy include irritative voiding symptoms and hemorrhagic cystitis. Systemic effects are rare. Patients who develop symptoms from BCG may require antituberculous therapy.

B. Surgical Treatment

Although transurethral resection is the initial form of treatment for all bladder cancers as it is diagnostic, allows for proper staging, and will control superficial cancers, muscle infiltrating cancers will require more aggressive treatment. Partial cystectomy may be indicated in patients with solitary lesions and those with cancers in a bladder diverticulum. Radical cystectomy entails removal of the bladder, prostate, seminal vesicles, and surrounding fat and peritoneal attachments in men and in women also the uterus, cervix, urethra, anterior vaginal vault, and usually the ovaries. Bilateral pelvic lymph node dissection is performed simultaneously.

Urinary diversion can be performed using a conduit of small or large bowel. However, continent forms of diversion have been developed that avoid the necessity of an external appliance.

C. Radiotherapy

External beam radiotherapy delivered in fractions over a 6- to 8-week period is generally well tolerated, but approximately 10-15% of patients will develop bladder, bowel, or rectal complications. Unfortunately, local recurrence is common after radiotherapy (30-70%). Increasingly, radiotherapy is being combined with systemic chemotherapy in an effort to improve local and distant relapse rates.

D. Chemotherapy

Fifteen percent of patients with newly diagnosed bladder cancer will present with metastatic disease, and 40% of those thought to have localized disease at the time of cystectomy or definitive radiotherapy will develop metastases usually within 2 years after the start of treatment. Cisplatin-based combination chemotherapy will result in partial or complete responses in 15-35% and 15-45% of patients, respectively.

Combination chemotherapy has been integrated into trials of surgery and radiotherapy. It has been used to decrease recurrence rates with either modality and in an attempt to preserve the bladder in those treated with radiation. Chemotherapy should be considered before surgery in those with bulky lesions or those suspected of having regional disease. Chemoradiation may be best suited for those with T2 or limited T3 disease without hydronephrosis. Alternatively, chemotherapy has been employed postoperatively in patients who have undergone cystectomy and have been found to be at high risk of recurrence. In current practice, adjuvant chemotherapy when indicated—ie, when the primary tumor invades perivesical fat or adjacent organs or when lymph nodes are found to have metastatic disease—is being offered mainly to patients being treated with radical cystectomy.

CANCERS OF THE URETER & RENAL PELVIS

Cancers of the renal pelvis and ureter are rare and occur more commonly in smokers, in those with Balkan nephropathy, in those exposed to Thorotrast (a contrast agent with radioactive thorium in use until the 1960s), or in those with a long history of analgesic abuse. The majority are transitional cell carcinomas. Gross or microscopic hematuria occurs in most patients, and flank pain secondary to bleeding and obstruction occurs less commonly. Like primary bladder cancers, urinary cytology is often positive. The most common signs identified at the time of intravenous pyelography include an intraluminal filling defect, unilateral nonvisualization of the collecting system, and hydronephrosis. Ureteral and renal pelvic tumors must be differentiated from calculi, blood clots, papillary necrosis, or inflammatory or infectious lesions. On occasion, such lesions are accessible to direct biopsy, fulguration, or resection using a ureteroscope. Treatment is based on the site, size, depth of penetration, and number of tumors present. Most such cancers are excised with nephroureterectomy (renal pelvic and upper ureteral lesions) or segmental excision of the ureter (distal ureteral lesions). Endoscopic resection may be indicated in patients with limited renal function and in the management of focal, low-grade, upper tract cancers.

Transitional Cell Cancer of Renal Pelvis and Ureter <http://www.cancer.gov/cancerinfo/types/transitionalcell>

PRIMARY TUMORS OF THE KIDNEY

1. Renal Cell Carcinoma

Essentials of Diagnosis

- Gross or microscopic hematuria.
- Flank pain or mass in some patients.
- Systemic symptoms such as fever, weight loss may be prominent.
- Solid renal mass on imaging.

General Considerations

Renal cell carcinoma accounts for 2.3% of all adult cancers. In the United States in 2002, approximately 31,800 cases of renal cell carcinoma were diagnosed and 19,100 deaths resulted. Renal cell carcinoma has a peak incidence in the sixth decade of life and a male-to-female ratio of 2:1.

The cause is unknown. Cigarette smoking is the only significant environmental risk factor that has been identified. Familial settings for renal cell carcinoma have been identified (von Hippel-Lindau syndrome) as well as an association with dialysis-related acquired cystic disease, but sporadic tumors are far more common.

Renal cell carcinoma originates from the proximal tubule cells. Various cell types (clear, granular, spindle) and histologic patterns (acinar, papillary, solid) are observed. However, cell type and histologic pattern do not affect treatment. The TNM classification of the American Joint Cancer Committee for kidney cancer is shown in [Table 23-11](#).

Clinical Findings

A. Symptoms and Signs

Historically, 60% of patients presented with gross or microscopic hematuria. Flank pain or an abdominal mass was detected in approximately 30% of cases. The triad

of flank pain, hematuria, and mass was found in only 10-15% of patients and is often a sign of advanced disease. Symptoms of metastatic disease (cough, bone pain) occur in 20-30% of patients at presentation. Because of the more widespread use of ultrasound and CT scanning for diverse indications, renal tumors are being detected incidentally in patients with no urologic symptoms.

B. Laboratory Findings

Hematuria is present in 60% of patients. Paraneoplastic syndromes are not uncommon in renal cell carcinoma. Erythrocytosis from increased erythropoietin production occurs in 5%, though anemia is far more common; hypercalcemia may be present in up to 10% of patients. Stauffer's syndrome is a reversible syndrome of hepatic dysfunction in the absence of metastatic disease.

C. Imaging

Renal masses are often first detected by intravenous urography. Further evaluation requires ultrasound to determine whether it is solid or cystic. CT scanning is the most valuable imaging test for renal cell carcinoma. It confirms the character of the mass and further stages the lesion with respect to regional lymph nodes, renal vein, or hepatic involvement. It also gives valuable information on the contralateral kidney (function, bilaterality of neoplasm). Chest radiographs exclude pulmonary metastases, and bone scans should be performed for large tumors and in patients with bone pain or elevated alkaline phosphatase levels. MRI and duplex Doppler ultrasonography are excellent methods of assessing for the presence and extent of tumor thrombus within the renal vein or vena cava in selected patients.

Differential Diagnosis

Solid lesions of the kidney are renal cell carcinoma until proved otherwise. Other solid masses include angiomyolipomas (fat density usually visible by CT), transitional cell cancers of the renal pelvis (more centrally located, involvement of the collecting system, positive urinary cytology reports), adrenal tumors (supero-anterior to the kidney) and oncocytomas (indistinguishable from renal cell carcinoma preoperatively), and renal abscesses.

Treatment & Prognosis

Radical nephrectomy is the primary treatment for localized renal cell carcinoma. Patients with a single kidney, bilateral lesions, or significant medical renal disease should be considered for partial nephrectomy. Patients with a normal contralateral kidney and good renal function but a small cancer may be good candidates for partial nephrectomy as well. The use of radiofrequency or cryosurgical ablation is being studied. Tumors confined to the renal capsule (T1-T2) demonstrate 5-year disease-free survivals of 90-100%. Tumors extending beyond the renal capsule (T3 or T4) and node-positive tumors have 50-60% and 0-15% 5-year disease-free survivals, respectively.

No effective chemotherapy is available for metastatic renal cell carcinoma. Vinblastine is the single most effective agent, with short-term partial response rates of 15%. Biologic response modifiers have received much attention, including alpha interferon and interleukin-2. Partial response rates of 15-20% and 15-35%, respectively, have been reported. Responders tend to have lower tumor burdens, metastatic disease confined to the lung, and a high performance status. Because of these low response rates, new investigations are ongoing with tumor vaccines and gene therapy. Nephrectomy is rarely considered in those with metastatic disease; such patients usually should be considered for palliative therapy. However, two randomized trials have shown a benefit to surgery followed by the use of systemic therapy—specifically, biologic response modifiers—compared with the use of systemic therapy alone.

One subgroup of metastatic patients has demonstrated long-term survival, namely, those with solitary resectable metastases. In this setting, radical nephrectomy with resection of the metastasis has resulted in 5-year disease-free survival rates of 15-30%.

2. Other Primary Tumors of the Kidney

Oncocytomas account for 3-5% of renal tumors and are indistinguishable from renal cell carcinoma by all imaging modalities. The biologic potential of these lesions is not well defined. These tumors are seen in other organs, including the adrenals, the salivary glands, and the thyroid and parathyroid glands.

Angiomyolipomas are rare benign tumors composed of fat, smooth muscle, and blood vessels. They are most commonly seen in patients with tuberous sclerosis (often multiple and bilateral) or in young to middle-aged women. CT scanning may identify the fat component, which is diagnostic for angiomyolipoma. Asymptomatic lesions less than 5 cm in diameter usually do not require intervention.

Dechet CB et al: Renal oncocytoma: multifocality, bilateralism, metachronous tumor development and coexistent renal cell carcinoma. J Urol 1999;162:40. [\[PMID: 10379735\]](#)

SECONDARY TUMORS OF THE KIDNEY

The kidney is not an infrequent site for metastatic disease. Of the solid tumors, the lung is the most common (20%), followed by breast (10%), stomach (10%), and the contralateral kidney (10%). Lymphoma, both Hodgkin's and non-Hodgkin's, may also involve the kidney, though it tends to be a diffusely infiltrative process resulting in renal enlargement rather than a discrete mass.

PRIMARY TUMORS OF THE TESTIS

Essentials of Diagnosis

- Commonest neoplasm in men aged 20-35.
- Typical presentation as a patient-identified painless nodule.
- Orchiectomy necessary for diagnosis.

General Considerations

Malignant tumors of the testis are rare, with approximately two to three new cases per 100,000 males being reported in the United States each year. Ninety to 95 percent of all primary testicular tumors are germ cell tumors (seminoma and nonseminoma), while the remainder are nongerminal neoplasms (Leydig cell, Sertoli cell, gonadoblastoma). The lifetime probability of developing testicular cancer is 0.2% for an American white male. For the purposes of this review, we will only consider germ cell tumors. Survival in testicular cancer has improved dramatically in recent years as a result of the development and application of effective combination chemotherapy.

Testicular cancer is slightly more common on the right than on the left, which parallels the increased incidence of cryptorchism on the right side. One to 2 percent of primary testicular tumors are bilateral, and up to 50% of these men have a history of unilateral or bilateral cryptorchism. Primary bilateral testicular tumors may occur synchronously or asynchronously but tend to be of the same histology. Seminoma is the most common histologic finding in bilateral *primary* testicular tumors, while malignant lymphoma is the most common bilateral testicular tumor.

While the cause of testicular cancer is unknown, both congenital and acquired factors have been associated with tumor development. Approximately 5% of testicular tumors develop in a patient with a history of cryptorchism, with seminoma being the most common. However, 5-10% of these tumors occur in the contralateral, normally descended testis. The relative risk of development of malignancy is highest for the intra-abdominal testis (1:20) and lower for the inguinal testis (1:80). Placement of the cryptorchid testis into the scrotum (orchiopexy) does not alter the malignant potential of the cryptorchid testis; however, it does facilitate examination and tumor detection.

In animal models, exogenous estrogen administration during pregnancy has been associated with an increased relative risk for testicular tumors ranging from 2.8 to

5.3. Other acquired factors such as trauma and infection-related testicular atrophy have been associated with testicular tumors; however, a causal relationship has not been established.

Histopathology & Clinical Staging

From a treatment standpoint, testicular carcinoma can be divided into two major categories: (1) nonseminomas, which include embryonal cell carcinomas (20%), teratomas (5%), choriocarcinomas (< 1%), and mixed cell types (40%), and (2) seminomas (35%). In a commonly used staging system for nonseminoma germ cell tumors, a stage A lesion is confined to the testis; stage B demonstrates regional lymph node involvement in the retroperitoneum; and stage C indicates distant metastasis. For seminoma, the M.D. Anderson system is commonly used. In this system, a stage I lesion is confined to the testis, a stage II lesion has spread to the retroperitoneal lymph nodes, and a stage III lesion has supradiaphragmatic nodal or visceral involvement. The TNM classification of the American Joint Cancer Committee for testis cancer is shown in [Table 23-12](#).

Clinical Findings

A. Symptoms and Signs

The most common symptom of testicular cancer is painless enlargement of the testis. Sensations of heaviness are not unusual. Patients are usually the first to recognize an abnormality, yet the typical delay in seeking medical attention ranges from 3 to 6 months. Acute testicular pain resulting from intratesticular hemorrhage occurs in approximately 10% of cases. Ten percent of patients are asymptomatic at presentation, and 10% manifest symptoms relating to metastatic disease such as back pain (retroperitoneal metastases), cough (pulmonary metastases), or lower extremity edema (vena cava obstruction).

A testicular mass or diffuse enlargement of the testis is found in the majority of cases on physical examination. Secondary hydroceles may be present in 5-10% of cases. In advanced disease, supraclavicular adenopathy may be detected, and abdominal examination may palpate a retroperitoneal mass. Gynecomastia is seen in 5% of germ cell tumors.

B. Laboratory Findings

Several biochemical markers are important in the diagnosis and treatment of testicular carcinoma, including human chorionic gonadotropin (hCG), alpha-fetoprotein, and LDH. Alpha-fetoprotein is never elevated in seminomas, and while hCG is occasionally elevated in seminomas, levels tend to be lower than those seen in nonseminomas. LDH may be elevated in either type of tumor. Liver function tests may be elevated in the presence of hepatic metastases, and anemia may be present in advanced disease. In patients with advanced disease who will receive chemotherapy, renal function is assessed with a 24-hour urine creatinine clearance.

C. Imaging

Scrotal ultrasound can readily determine whether the mass is intra- or extratesticular in origin. Once the diagnosis of testicular cancer has been established by inguinal orchiectomy, clinical staging of the disease is accomplished by chest, abdominal, and pelvic CT scanning.

Differential Diagnosis

An incorrect diagnosis is made at the initial examination in up to 25% of patients with testicular tumors. The differential diagnosis of scrotal masses has been discussed previously in this chapter. Scrotal ultrasonography should be performed if any uncertainty exists with respect to the diagnosis. Although most intratesticular masses are malignant, one benign lesion, an epidermoid cyst, may rarely be seen. Epidermoid cysts are usually very small benign nodules located just underneath the tunica albuginea; on occasion, however, they can be large.

Treatment

Inguinal exploration with early vascular control of the spermatic cord structures is the initial intervention to exclude neoplasm. If cancer cannot be excluded by examination of the testis, radical orchiectomy is warranted. Scrotal approaches and open testicular biopsies should be avoided. Further therapy is dependent upon the histology of the tumor as well as the clinical stage.

The 5-year disease-free survival rates for stage I and IIa (retroperitoneal disease < 10 cm in diameter) seminomas treated by radical orchiectomy and retroperitoneal irradiation are 98% and 92-94%, respectively. High-stage seminomas of stage IIb (> 10 cm retroperitoneal involvement) and stage III receive primary chemotherapy (etoposide and cisplatin or cisplatin, etoposide, and bleomycin). Ninety-five percent of patients with stage III disease will attain a complete response following orchiectomy and chemotherapy. Surgical resection of residual retroperitoneal masses is warranted only if the mass is larger than 3 cm in diameter, under which circumstances 40% will harbor residual carcinoma.

Up to 75% of stage A nonseminomas are cured by orchiectomy alone. Currently, such patients may be treated by modified retroperitoneal lymph node dissections designed to preserve the sympathetic innervation for ejaculation. Selected patients who meet specific criteria may be offered surveillance. These criteria are as follows: (1) tumor is confined within the tunica albuginea; (2) tumor does not demonstrate vascular invasion; (3) tumor markers normalize after orchiectomy; (4) radiographic imaging shows no evidence of disease (chest x-ray and CT); and (5) the patient is reliable. Patients most likely to experience relapse on a surveillance regimen include those with predominantly embryonal cancer and those with vascular or lymphatic invasion identified in the orchiectomy specimen. Surveillance should be considered an active process both by the physician and by the patient. Patients are followed monthly for the first 2 years and bimonthly in the third year. Tumor markers are obtained at each visit, and chest x-ray and CT scans are obtained every 3-4 months. Follow-up continues beyond the initial 3 years; however, the majority of relapses will occur within the first 8-10 months. With rare exceptions, patients who relapse can be cured by chemotherapy or surgery. The 5-year disease-free survival rate for patients with stage A disease ranges from 96% to 100%. For low-volume stage B disease, 90% 5-year disease-free survival is attainable.

Patients with bulky retroperitoneal disease (> 3 cm nodes) or metastatic nonseminomas are treated with primary cisplatin-based combination chemotherapy following orchiectomy (etoposide and cisplatin or cisplatin, etoposide, and bleomycin). If tumor markers normalize and a residual mass greater than 3 cm is apparent on imaging studies, resection of that mass is mandatory because 20% of the time it will harbor residual cancer and 40% of the time it will be teratoma. Even if patients have a complete response to chemotherapy, retroperitoneal lymphadenectomy is advocated by some as 10% of patients may harbor residual carcinoma and 10% may have teratoma in the retroperitoneum. If tumor markers fail to normalize following primary chemotherapy, salvage chemotherapy is required (cisplatin, etoposide, bleomycin, ifosfamide).

Prognosis

Patients with bulky retroperitoneal or disseminated disease treated with primary chemotherapy followed by surgery have a 5-year disease-free survival rate of 55-80%.

Sweeney CJ et al: Results and outcome of retroperitoneal lymph node dissection for clinical stage I embryonal carcinoma- predominant testis cancer. J Clin Oncol 2000;18:358. [\[PMID: 10637250\]](#)

SECONDARY TUMORS OF THE TESTIS

Secondary tumors of the testis are rare. Lymphoma is the most common testis tumor in a patient over the age of 50 and is the most common secondary neoplasm of the testis, accounting for 5% of all testicular tumors. It may be seen in three clinical settings: (1) as a late manifestation of widespread lymphoma, (2) as the initial presentation of clinically occult disease, and (3) as primary extranodal disease. Radical orchiectomy is indicated to make the diagnosis. Prognosis is related to the stage of disease.

Metastasis to the testis is rare. The most common primary site is the prostate, followed by the lung, gastrointestinal tract, melanoma, and kidney

HEADACHE

Headache is such a common complaint and can occur for so many different reasons that its proper evaluation may be difficult. Chronic headaches are commonly due to migraine, tension, or depression, but they may be related to intracranial lesions, head injury, cervical spondylosis, dental or ocular disease, temporomandibular joint dysfunction, sinusitis, hypertension, and a wide variety of general medical disorders. Although underlying structural lesions are not present in most patients presenting with headache, it is nevertheless important to bear this possibility in mind. About one-third of patients with brain tumors, for example, present with a primary complaint of headache.

The intensity, quality, and site of pain—and especially the duration of the headache and the presence of associated neurologic symptoms—may provide clues to the underlying cause. Migraine or tension headaches are often described as pulsating or throbbing; a sense of tightness or pressure is also common with tension headache. Sharp lancinating pain suggests a neuritic cause; ocular or periorbital icepick-like pains occur with migraine or cluster headache; and a dull or steady headache is typical of an intracranial mass lesion. Ocular or periocular pain suggests an ophthalmologic disorder; band-like pain is common with tension headaches; and lateralized headache is common with migraine or cluster headache. In patients with sinusitis, there may be tenderness of overlying skin and bone. With intracranial mass lesions, headache may be focal or generalized; in patients with trigeminal or glossopharyngeal neuralgia, the pain is localized to one of the divisions of the trigeminal nerve or to the pharynx and external auditory meatus, respectively.

Inquiry should be made of precipitating factors. Recent sinusitis or hay fever, dental surgery, head injury, or symptoms suggestive of a systemic viral infection may suggest the underlying cause. Migraine may be exacerbated by emotional stress, fatigue, foods containing nitrite or tyramine, or the menstrual period. Alcohol may precipitate cluster headache. Temporomandibular joint dysfunction causes headache or facial pain that comes on with chewing; trigeminal or glossopharyngeal neuralgia may also be precipitated by chewing, and masticatory claudication sometimes occurs with giant cell arteritis. Cough-induced headache occurs with structural lesions of the posterior fossa, but in many instances no specific cause can be found.

The timing of symptoms is important. Headaches are typically worse on awakening in patients with sinusitis or an intracranial mass. Cluster headaches tend to occur at the same time each day or night. Tension headaches are worse with stress or at the end of the day.

The onset of severe headache in a previously well patient is more likely than chronic headache to relate to an intracranial disorder such as subarachnoid hemorrhage or meningitis. The need for further investigation is determined by the initial clinical impression.

A progressive headache disorder, new onset of headache in middle or later life, headaches that disturb sleep or are related to exertion, and headaches that are associated with neurologic symptoms or a focal neurologic deficit usually require cranial MRI or CT scan to exclude an intracranial mass lesion. Signs of meningeal irritation and impairment of consciousness also indicate the need for further investigation (cranial CT scan or MRI and examination of the cerebrospinal fluid) to exclude subarachnoid hemorrhage or meningeal infection. The diagnosis and treatment of primary neurologic disorders associated with headache are considered separately under these disorders.

Tension Headache

Patients frequently complain of poor concentration and other vague nonspecific symptoms, in addition to constant daily headaches that are often vise-like or tight in quality and may be exacerbated by emotional stress, fatigue, noise, or glare. The headaches are usually generalized, may be most intense about the neck or back of the head, and are not associated with focal neurologic symptoms.

When treatment with simple analgesics is not effective, a trial of antimigrainous agents (see Migraine, below) is worthwhile. Techniques to induce relaxation are also useful and include massage, hot baths, and biofeedback. Exploration of underlying causes of chronic anxiety is often rewarding. Anecdotal reports of beneficial responses to local injection of botulinum toxin type A have been published.

Depression Headache

Depression headaches are frequently worse on arising in the morning and may be accompanied by other symptoms of depression. Headaches are occasionally the focus of a somatic delusional system. Antidepressant drugs are often helpful, as may be psychiatric consultation.

Migraine

Classic migrainous headache is a lateralized throbbing headache that occurs episodically following its onset in adolescence or early adult life. In many cases, however, the headaches do not conform to this pattern, although their associated features and response to antimigrainous preparations nevertheless suggest that they have a similar basis. In this broader sense, migrainous headaches may be lateralized or generalized, may be dull or throbbing, and are sometimes associated with anorexia, nausea, vomiting, photophobia, phonophobia, and blurring of vision. They usually build up gradually and may last for several hours or longer. They have been related to dilation and excessive pulsation of branches of the external carotid artery. Focal disturbances of neurologic function may precede or accompany the headaches and have been attributed to constriction of branches of the internal carotid artery. Visual disturbances occur quite commonly and may consist of field defects; of luminous visual hallucinations such as stars, sparks, unformed light flashes (photopsia), geometric patterns, or zigzags of light; or of some combination of field defects and luminous hallucinations (scintillating scotomas). Other focal disturbances such as aphasia or numbness, tingling, clumsiness, or weakness in a circumscribed distribution may also occur.

Patients often give a family history of migraine. Attacks may be triggered by emotional or physical stress, lack or excess of sleep, missed meals, specific foods (eg, chocolate), alcoholic beverages, menstruation, or use of oral contraceptives.

An uncommon variant is **basilar artery migraine**, in which blindness or visual disturbances throughout both visual fields are initially accompanied or followed by dysarthria, disequilibrium, tinnitus, and perioral and distal paresthesias and are sometimes followed by transient loss or impairment of consciousness or by a confusional state. This, in turn, is followed by a throbbing (usually occipital) headache, often with nausea and vomiting.

In **ophthalmoplegic migraine**, lateralized pain—often about the eye—is accompanied by nausea, vomiting, and diplopia due to transient external ophthalmoplegia. The ophthalmoplegia is due to third nerve palsy, sometimes with accompanying sixth nerve involvement, and may outlast the orbital pain by several days or even weeks. The ophthalmic division of the fifth nerve has also been affected in some patients. Ophthalmoplegic migraine is rare; more common causes of a painful ophthalmoplegia are internal carotid artery aneurysms and diabetes.

In rare instances, the neurologic or somatic disturbance accompanying typical migrainous headaches becomes the sole manifestation of an attack ("migraine equivalent"). Very rarely, the patient may be left with a permanent neurologic deficit following a migrainous attack.

The pathophysiology of migraine probably relates to the neurotransmitter serotonin. Headache may result from release of neuropeptides acting as neurotransmitters at trigeminal nerve branches, leading to an inflammatory process; another possible mechanism involves activation of the dorsal raphe nucleus.

Management of migraine consists of avoidance of any precipitating factors, together with prophylactic or symptomatic pharmacologic treatment if necessary.

During acute attacks, many patients find it helpful to rest in a quiet, darkened room until symptoms subside. A simple analgesic (eg, aspirin) taken right away often provides relief, but treatment with extracranial vasoconstrictors or other drugs is sometimes necessary. Cafergot, a combination of ergotamine tartrate (1 mg) and caffeine (100 mg), is often particularly helpful; one or two tablets are taken at the onset of headache or warning symptoms, followed by one tablet every 30 minutes, if necessary, up to six tablets per attack and ten tablets per week. Because of impaired absorption or vomiting during acute attacks, oral medication sometimes fails to help. Cafergot given rectally as suppositories (one-half to one suppository containing 2 mg of ergotamine) ergotamine tartrate given by inhalation (0.36 mg per puff; up to six puffs per attack) or sublingually (2 mg tablets; not more than three tablets per 24 hours) or dihydroergotamine mesylate (0.5-1 mg intravenously or 1-2 mg subcutaneously or intramuscularly) may be useful in such cases. Alternatively, prochlorperazine administered rectally (25 mg suppository) or intravenously (10 mg) may be prescribed. Ergotamine-containing preparations may affect the gravid uterus and thus should be avoided during pregnancy. Sumatriptan is a rapidly effective agent for aborting attacks when given subcutaneously by an autoinjection device. It has a high affinity for serotonin₁ receptors. It should probably be avoided in pregnancy. Sumatriptan can also be taken in a nasal form, but absorption is limited and a bitter aftertaste may be disturbing; an oral preparation is available but is poorly absorbed. Zolmitriptan, another selective serotonin₁ receptor agonist, has high bioavailability after oral administration and is also effective for the acute treatment of migraine. The optimal initial dose is 2.5 mg, and relief usually occurs within 1 hour. Intravenous propofol in subanesthetic doses may help in intractable cases.

Prophylactic treatment may be necessary if migrainous headaches occur more frequently than two or three times a month. Some of the more common drugs used for this purpose are listed in [Table 24-1](#). Their mode of action is unclear and may involve both an effect on extracerebral vasculature and a cerebral effect, eg, by stabilizing serotonergic neurotransmission. Several drugs may have to be tried in turn before the headaches are brought under control. Once a drug has been found to help, it should be continued for several months. If the patient remains headache-free, the dose can then be tapered and the drug eventually withdrawn.

Calcium channel antagonist drugs may decrease the frequency of attacks after an interval of several weeks, but the severity and duration of attacks are not influenced. They should not be used with beta-blockers.

Cluster Headache (Migrainous Neuralgia)

Cluster headache affects predominantly middle-aged men. Its cause is unclear but may relate to a vascular headache disorder or a disturbance of serotonergic mechanisms. There is often no family history of headache or migraine. Episodes of severe unilateral periorbital pain occur daily for several weeks and are often accompanied by one or more of the following: ipsilateral nasal congestion, rhinorrhea, lacrimation, redness of the eye, and Horner's syndrome. Episodes usually occur at night, awaken the patient, and last for less than 2 hours. Spontaneous remission then occurs, and the patient remains well for weeks or months before another bout of closely spaced attacks occurs. During a bout, many patients report that alcohol triggers an attack; others report that stress, glare, or ingestion of specific foods occasionally precipitates attacks. In occasional patients, typical attacks of pain and associated symptoms recur at intervals without remission. This variant has been referred to as chronic cluster headache.

Examination reveals no abnormality apart from Horner's syndrome that either occurs transiently during an attack or, in long-standing cases, remains as a residual deficit between attacks.

Treatment of an individual attack with oral drugs is generally unsatisfactory, but subcutaneous sumatriptan (6 mg) or dihydroergotamine (1-2 mg) or use of ergotamine tartrate aerosol or inhalation of 100% oxygen (7 L/min for 15 minutes) may be effective. Butorphanol tartrate, a synthetic opioid agonist-antagonist, may also be helpful when administered by nasal spray. The dose is 1 mg (one spray in one nostril), repeated after 60-90 minutes if necessary. Ergotamine tartrate is an effective prophylactic and can be given as rectal suppositories (0.5-1 mg at night or twice daily), by mouth (2 mg daily), or by subcutaneous injection (0.25 mg three times daily for 5 days per week). Various prophylactic agents that have been found to be effective in individual patients are propranolol, amitriptyline, valproate, cyproheptadine, lithium carbonate (monitored by plasma lithium determination), prednisone (20-40 mg daily or on alternate days for 2 weeks, followed by gradual withdrawal), verapamil (240-480 mg daily), and methysergide (4-6 mg daily).

Giant Cell (Temporal or Cranial) Arteritis

The superficial temporal, vertebral, ophthalmic, and posterior ciliary arteries are often the most severely affected pathologically. Most patients are elderly. The major symptom is headache, often associated with or preceded by myalgia, malaise, anorexia, weight loss, and other nonspecific complaints. Loss of vision is the most feared manifestation and occurs quite commonly. Clinical examination often reveals tenderness of the scalp and over the temporal arteries. Further details, including approaches to treatment, are given in [Chapter 20](#).

Posttraumatic Headache

A variety of nonspecific symptoms may follow closed head injury, regardless of whether consciousness is lost. Headache is often a conspicuous feature. Some authorities believe that psychologic factors may be important because there is no correlation of severity of the injury with neurologic signs.

The headache itself usually appears within a day or so following injury, may worsen over the ensuing weeks, and then gradually subsides. It is usually a constant dull ache, with superimposed throbbing that may be localized, lateralized, or generalized. It is sometimes accompanied by nausea, vomiting, or scintillating scotomas.

Disequilibrium, sometimes with a rotatory component, may also occur and is often enhanced by postural change or head movement. Impaired memory, poor concentration, emotional instability, and increased irritability are other common complaints and occasionally are the sole manifestations of the syndrome. The duration of symptoms relates in part to the severity of the original injury, but even trivial injuries are sometimes followed by symptoms that persist for months.

Special investigations are usually not helpful. The electroencephalogram may show minor nonspecific changes, while the electronystagmogram sometimes suggests either peripheral or central vestibulopathy. CT scans or MRI of the head usually show no abnormal findings.

Treatment is difficult, but optimistic encouragement and graduated rehabilitation, depending upon the occupational circumstances, are advised. Headaches often respond to simple analgesics, but severe headaches may necessitate treatment with amitriptyline, propranolol, or ergot derivatives.

Cough Headache

Severe head pain may be produced by coughing (and by straining, sneezing, and laughing) but, fortunately, usually lasts for only a few minutes or less. The pathophysiologic basis of the complaint is not known, and often there is no underlying structural lesion. However, intracranial lesions, usually in the posterior fossa (eg, Arnold-Chiari malformation), are present in about 10% of cases, and brain tumors or other space-occupying lesions may certainly present in this way. Accordingly, CT scanning or MRI should be undertaken in all patients and repeated annually for several years, since a small structural lesion may not show up initially.

The disorder is usually self-limited, although it may persist for several years. For unknown reasons, symptoms sometimes clear completely after lumbar puncture. Indomethacin (75-150 mg daily) may provide relief.

Headache Due to Intracranial Mass Lesions

Intracranial mass lesions of all types may cause headache owing to displacement of vascular structures. Posterior fossa tumors often cause occipital pain, and supratentorial lesions lead to bifrontal headache, but such findings are too inconsistent to be of value in attempts at localizing a pathologic process. The headaches are nonspecific in character and may vary in severity from mild to severe. They may be worsened by exertion or postural change and may be associated with nausea and vomiting, but this is true of migraine also. Headaches are also a feature of pseudotumor cerebri (see below). Signs of focal or diffuse cerebral dysfunction or of increased intracranial pressure will indicate the need for further investigation. Similarly, a progressive headache disorder or the new onset of headaches in middle or later life merits investigation if no cause is apparent.

Headache Due to Other Neurologic Causes

Cerebrovascular disease may be associated with headache, but the mechanism is unclear. Headache may occur with internal carotid artery occlusion or carotid dissection and after carotid endarterectomy. Diagnosis is facilitated by the clinical accompaniments and the circumstances in which the headache developed.

Acute severe headache accompanies subarachnoid hemorrhage and meningeal infections; accompanying signs of meningeal irritation and impairment of consciousness indicate the need for further investigations.

Dull or throbbing headache is a frequent sequela of lumbar puncture and may last for several days. It is aggravated by the erect posture and alleviated by recumbency. The exact mechanism is unclear, but it is commonly attributed to leakage of cerebrospinal fluid through the dural puncture site. Its incidence may be reduced if a small-diameter needle is used for the spinal tap, and perhaps also if the patient lies prone or supine after the procedure.

FACIAL PAIN

Trigeminal Neuralgia

Trigeminal neuralgia ("tic douloureux") is most common in middle and later life. It affects women more frequently than men. The disorder is characterized by momentary episodes of sudden lancinating facial pain that commonly arises near one side of the mouth and then shoots toward the ear, eye, or nostril on that side. The pain may be triggered or precipitated by such factors as touch, movement, drafts, and eating. Indeed, in order to lessen the likelihood of triggering further attacks, many patients try to hold the face still while talking. Spontaneous remissions for several months or longer may occur. As the disorder progresses, however, the episodes of pain become more frequent, remissions become shorter and less common, and a dull ache may persist between the episodes of stabbing pain. Symptoms

remain confined to the distribution of the trigeminal nerve (usually the second or third division) on one side only.

The characteristic features of the pain in trigeminal neuralgia usually distinguish it from other causes of facial pain. Neurologic examination shows no abnormality except in a few patients in whom trigeminal neuralgia is symptomatic of some underlying lesion, such as multiple sclerosis or a brain stem neoplasm, in which case the finding will depend on the nature and site of the lesion. Similarly, CT scans and radiologic contrast studies are normal in patients with classic trigeminal neuralgia.

In a young patient presenting with trigeminal neuralgia, multiple sclerosis must be suspected even if there are no other neurologic signs. In such circumstances, findings on evoked potential testing and examination of cerebrospinal fluid may be corroborative. When the facial pain is due to a posterior fossa tumor, CT scanning and MRI generally reveal the lesion.

The drug most helpful for treatment of trigeminal neuralgia is carbamazepine, given in a dose of up to 1200 mg/d, with monitoring by serial blood counts and liver function tests. If carbamazepine is ineffective or cannot be tolerated, phenytoin should be tried. (Doses and side effects of these drugs are shown in [Table 24-2](#).) Baclofen (10-20 mg three or four times daily) may also be helpful, either alone or in combination with carbamazepine or phenytoin. Gabapentin, another anticonvulsant agent, may also relieve pain, especially in patients refractory to conventional medical therapy and those with multiple sclerosis. Depending on response and tolerance, up to 2400 mg/d is given in divided doses.

In the past, alcohol injection of the affected nerve, rhizotomy, or tractotomy was recommended if pharmacologic treatment was unsuccessful. More recently, however, posterior fossa exploration has frequently revealed some structural cause for the neuralgia (despite normal findings on CT scans, MRI, or arteriograms), such as an anomalous artery or vein impinging on the trigeminal nerve root. In such cases, simple decompression and separation of the anomalous vessel from the nerve root produce lasting relief of symptoms. In elderly patients with a limited life expectancy, radiofrequency rhizotomy is sometimes preferred because it is easy to perform, has few complications, and provides symptomatic relief for a period of time. Gamma radiosurgery to the trigeminal root is another noninvasive approach that appears to be successful in 80% of patients, with essentially no side effects other than facial paresthesias in a few instances. Surgical exploration generally reveals no abnormality and is inappropriate in patients with trigeminal neuralgia due to multiple sclerosis.

Sindrup SH et al: Pharmacotherapy of trigeminal neuralgia. Clin J Pain 2002;18;22. [\[PMID: 11803299\]](#)

Atypical Facial Pain

Facial pain without the typical features of trigeminal neuralgia is generally a constant, often burning pain that may have a restricted distribution at its onset but soon spreads to the rest of the face on the affected side and sometimes involves the other side, the neck, or the back of the head as well. The disorder is especially common in middle-aged women, many of them emotionally depressed, but it is not clear whether depression is the cause of or a reaction to the pain. Simple analgesics should be given a trial, as should tricyclic antidepressants, carbamazepine, and phenytoin; the response is often disappointing. Opioid analgesics pose a danger of addiction in patients with this disorder. Attempts at surgical treatment are not indicated.

Glossopharyngeal Neuralgia

Glossopharyngeal neuralgia is an uncommon disorder in which pain similar in quality to that in trigeminal neuralgia occurs in the throat, about the tonsillar fossa, and sometimes deep in the ear and at the back of the tongue. The pain may be precipitated by swallowing, chewing, talking, or yawning and is sometimes accompanied by syncope. In most instances, no underlying structural abnormality is present; multiple sclerosis is sometimes responsible. Carbamazepine is the treatment of choice and should be tried (in daily doses up to 1200 mg) before any surgical procedures are considered. Microvascular decompression is generally preferred over destructive surgical procedures such as partial rhizotomy in medically refractory cases and is often effective without causing severe complications.

Patel A et al: Microvascular decompression in the management of glossopharyngeal neuralgia: analysis of 217 cases. Neurosurgery 2002;50:705. [\[PMID: 11904019\]](#)

Postherpetic Neuralgia

Herpes zoster (shingles) is due to infection of the nervous system by varicella-zoster virus. About 15% of patients who develop shingles suffer from postherpetic neuralgia. This complication seems especially likely to occur in the elderly, when the rash is severe, and when the first division of the trigeminal nerve is affected. A history of shingles and the presence of cutaneous scarring resulting from shingles aid in the diagnosis. Severe pain with shingles correlates with the intensity of postherpetic symptoms.

The incidence of postherpetic neuralgia may be reduced by the treatment of shingles with oral acyclovir or famciclovir, but this is disputed; systemic corticosteroids do not help. Management of the established complication is essentially medical. If simple analgesics fail to help, a trial of a tricyclic drug (eg, amitriptyline, up to 100-150 mg/d) in conjunction with a phenothiazine (eg, perphenazine, 2-8 mg/d) is often effective. Other patients respond to carbamazepine (up to 1200 mg/d), phenytoin (300 mg/d), or gabapentin (up to 3600 mg/d). Topical application of capsaicin cream (eg, Zostrix, 0.025%) may also be helpful, perhaps because of depletion of pain-mediating peptides from peripheral sensory neurons.

Rice AS et al: Gabapentin in postherpetic neuralgia: a randomized, double blind, placebo controlled study. Pain 2001; 94;215. [\[PMID: 11690735\]](#)

Facial Pain Due to Other Causes

Facial pain may be caused by temporomandibular joint dysfunction in patients with malocclusion, abnormal bite, or faulty dentures. There may be tenderness of the masticatory muscles, and an association between pain onset and jaw movement is sometimes noted. Treatment consists of correction of the underlying problem.

A relationship of facial pain to chewing or temperature changes may suggest a dental disturbance. The cause is sometimes not obvious, and diagnosis requires careful dental examination and x-rays. Pain on mastication may also occur in giant cell arteritis. Sinusitis and ear infections causing facial pain are usually recognized by the history of respiratory tract infection, fever, and, in some instances, aural discharge. There may be localized tenderness. Radiologic evidence of sinus infection or mastoiditis is confirmatory.

Glaucoma is an important ocular cause of facial pain, usually localized to the periorbital region.

On occasion, pain in the jaw may be the principal manifestation of angina pectoris. Precipitation by exertion and radiation to more typical areas establish the cardiac origin.

EPILEPSY

Essentials of Diagnosis

- Recurrent seizures.
- Characteristic electroencephalographic changes accompany seizures.
- Mental status abnormalities or focal neurologic symptoms may persist for hours postictally.

General Considerations

The term epilepsy denotes any disorder characterized by recurrent seizures. A seizure is a transient disturbance of cerebral function due to an abnormal paroxysmal neuronal discharge in the brain. Epilepsy is common, affecting approximately 0.5% of the population in the United States.

Etiology

Epilepsy has several causes. Its most likely cause in individual patients relates to the age at onset.

A. Idiopathic or Constitutional Epilepsy

Seizures usually begin between 5 and 20 years of age but may start later in life. No specific cause can be identified, and there is no other neurologic abnormality.

B. Symptomatic Epilepsy

There are many causes for recurrent seizures.

1. Pediatric age groups—Congenital abnormalities and perinatal injuries may result in seizures presenting in infancy or childhood.

2. Metabolic disorders—Withdrawal from alcohol or drugs is a common cause of recurrent seizures, and other metabolic disorders such as uremia and hypoglycemia or hyperglycemia may also be responsible.

3. Trauma—Trauma is an important cause of seizures at any age, but especially in young adults. Posttraumatic epilepsy is more likely to develop if the dura mater was penetrated and generally becomes manifest within 2 years following the injury. However, seizures developing in the first week after head injury do not necessarily imply that future attacks will occur. There is no clear evidence that prophylactic anticonvulsant drug treatment reduces the incidence of posttraumatic epilepsy.

4. Tumors and other space-occupying lesions—Neoplasms may lead to seizures at any age, but they are an especially important cause of seizures in middle and later life, when the incidence of neoplastic disease increases. The seizures are commonly the initial symptoms of the tumor and often are partial (focal) in character. They are most likely to occur with structural lesions involving the frontal, parietal, or temporal regions. Tumors must be excluded by appropriate imaging studies in all patients with onset of seizures after 30 years of age, focal seizures or signs, or a progressive seizure disorder.

5. Vascular diseases—Vascular diseases become increasingly frequent causes of seizures with advancing age and are the most common cause of seizures with onset at age 60 years or older.

6. Degenerative disorders—Alzheimer's disease and other degenerative disorders are a cause of seizures in later life.

7. Infectious diseases—Infectious diseases must be considered in all age groups as potentially reversible causes of seizures. Seizures may occur with an acute infective or inflammatory illness, such as bacterial meningitis or herpes encephalitis, or in patients with more long-standing or chronic disorders such as neurosyphilis or cerebral cysticercosis. In patients with AIDS, they may result from central nervous system toxoplasmosis, cryptococcal meningitis, secondary viral encephalitis, or other infective complications. Seizures are a common sequela of supratentorial brain abscess, developing most frequently in the first year after treatment.

Classification of Seizures

Seizures can be categorized in various ways, but the descriptive classification proposed by the International League Against Epilepsy is clinically the most useful. Seizures are divided into those that are generalized and those affecting only part of the brain (partial seizures).

A. Partial Seizures

The initial clinical and electroencephalographic manifestations of partial seizures indicate that only a restricted part of one cerebral hemisphere has been activated. The ictal manifestations depend upon the area of the brain involved. Partial seizures are subdivided into simple seizures, in which consciousness is preserved, and complex seizures, in which it is impaired. Partial seizures of either type sometimes become secondarily generalized, leading to a tonic, clonic, or tonic-clonic attack.

1. Simple partial seizures—Simple seizures may be manifested by focal motor symptoms (convulsive jerking) or somatosensory symptoms (eg, paresthesias or tingling) that spread (or "march") to different parts of the limb or body depending upon their cortical representation. In other instances, special sensory symptoms (eg, light flashes or buzzing) indicate involvement of visual, auditory, olfactory, or gustatory regions of the brain, or there may be autonomic symptoms or signs (eg, abnormal epigastric sensations, sweating, flushing, pupillary dilation). The sole manifestations of some seizures are phenomena such as dysphasia, dysmnestic symptoms (eg, *deja vu*, *jamais vu*), affective disturbances, illusions, or structured hallucinations, but such symptoms are usually accompanied by impairment of consciousness.

2. Complex partial seizures—Impaired consciousness may be preceded, accompanied, or followed by the psychic symptoms mentioned above, and automatisms may occur. Such seizures may also begin with some of the other simple symptoms mentioned above.

B. Generalized Seizures

There are several different varieties of generalized seizures, as outlined below. In some circumstances, seizures cannot be classified because of incomplete information or because they do not fit into any category.

1. Absence (petit mal) seizures—These are characterized by impairment of consciousness, sometimes with mild clonic, tonic, or atonic components (ie, reduction or loss of postural tone), autonomic components (eg, enuresis), or accompanying automatisms. Onset and termination of attacks are abrupt. If attacks occur during conversation, the patient may miss a few words or may break off in mid sentence for a few seconds. The impairment of external awareness is so brief that the patient is unaware of it. Absence seizures almost always begin in childhood and frequently cease by the age of 20 years, although occasionally they are then replaced by other forms of generalized seizure. Electroencephalographically, such attacks are associated with bursts of bilaterally synchronous and symmetric 3-Hz spike-and-wave activity. A normal background in the electroencephalogram and normal or above-normal intelligence imply a good prognosis for the ultimate cessation of these seizures.

2. Atypical absences—There may be more marked changes in tone, or attacks may have a more gradual onset and termination than in typical absences.

3. Myoclonic seizures—Myoclonic seizures consist of single or multiple myoclonic jerks.

4. Tonic-clonic (grand mal) seizures—In these seizures, which are characterized by sudden loss of consciousness, the patient becomes rigid and falls to the ground, and respiration is arrested. This tonic phase, which usually lasts for less than a minute, is followed by a clonic phase in which there is jerking of the body musculature that may last for 2 or 3 minutes and is then followed by a stage of flaccid coma. During the seizure, the tongue or lips may be bitten, urinary or fecal incontinence may occur, and the patient may be injured. Immediately after the seizure, the patient may either recover consciousness, drift into sleep, have a further convulsion without recovery of consciousness between the attacks (**status epilepticus**), or after recovering consciousness have a further convulsion (**serial seizures**). In other cases, patients will behave in an abnormal fashion in the immediate postictal period, without subsequent awareness or memory of events (**postepileptic automatism**). Headache, disorientation, confusion, drowsiness, nausea, soreness of the muscles, or some combination of these symptoms commonly occurs postictally.

5. Tonic, clonic, or atonic seizures—Loss of consciousness may occur with either the tonic or clonic accompaniments described above, especially in children. Atonic seizures (**epileptic drop attacks**) have also been described.

Clinical Findings

A. Symptoms and Signs

Nonspecific changes such as headache, mood alterations, lethargy, and myoclonic jerking alert some patients to an impending seizure hours before it occurs. These prodromal symptoms are distinct from the aura which may precede a generalized seizure by a few seconds or minutes and which is itself a part of the attack, arising locally from a restricted region of the brain.

In most patients, seizures occur unpredictably at any time and without any relationship to posture or ongoing activities. Occasionally, however, they occur at a particular time (eg, during sleep) or in relation to external precipitants such as lack of sleep, missed meals, emotional stress, menstruation, alcohol ingestion (or alcohol withdrawal; see below), or use of certain drugs. Fever and nonspecific infections may also precipitate seizures in known epileptics. In a few patients, seizures are provoked by specific stimuli such as flashing lights or a flickering television set (**photosensitive epilepsy**), music, or reading.

Clinical examination between seizures shows no abnormality in patients with idiopathic epilepsy, but in the immediate postictal period, extensor plantar responses may be seen. The presence of lateralized or focal signs postictally suggests that seizures may have a focal origin. In patients with symptomatic epilepsy, the findings on examination will reflect the underlying cause.

B. Imaging

MRI is indicated for patients with focal neurologic symptoms or signs, focal seizures, or electroencephalographic findings of a focal disturbance; some clinicians routinely order imaging studies for all patients with new-onset seizure disorders. Such studies should certainly be performed in patients with clinical evidence of a progressive disorder and in those presenting with new onset of seizures after the age of 20 years, because of the possibility of an underlying neoplasm. A chest radiograph should also be obtained in such patients, since the lungs are a common site for primary or secondary neoplasms.

C. Laboratory and Other Studies

Initial investigations should always include a full blood count, blood glucose determination, liver and renal function tests, and serologic tests for syphilis. The hematologic and biochemical screening tests are important both in excluding various causes of seizures and in providing a baseline for subsequent monitoring of

long-term effects of treatment.

Electroencephalography may support the clinical diagnosis of epilepsy (by demonstrating paroxysmal abnormalities containing spikes or sharp waves), may provide a guide to prognosis, and may help classify the seizure disorder. Classification of the disorder is important for determining the most appropriate anticonvulsant drug with which to start treatment. For example, absence (petit mal) and complex partial seizures may be difficult to distinguish clinically, but the electroencephalographic findings and treatment of choice differ in these two conditions. Finally, by localizing the epileptogenic source, the electroencephalographic findings are important in evaluating candidates for surgical treatment.

Differential Diagnosis

The distinction between the various disorders likely to be confused with generalized seizures is usually made on the basis of the history. The importance of obtaining an eyewitness account of the attacks cannot be overemphasized.

A. Differential Diagnosis of Partial Seizures

1. Transient ischemic attacks—These attacks are distinguished from seizures by their longer duration, lack of spread, and symptomatology. Level of consciousness, which is unaltered, does not distinguish them. There is a loss of motor or sensory function (eg, weakness or numbness) with transient ischemic attacks, whereas positive symptomatology (eg, convulsive jerking or paresthesias) characterizes seizures.

2. Rage attacks—Rage attacks are usually situational and lead to goal-directed aggressive behavior.

3. Panic attacks—These may be hard to distinguish from simple or complex partial seizures unless there is evidence of psychopathologic disturbances between attacks and the attacks have a clear relationship to external circumstances.

B. Differential Diagnosis of Generalized Seizures

1. Syncope—Syncope episodes usually occur in relation to postural change, emotional stress, instrumentation, pain, or straining. They are typically preceded by pallor, sweating, nausea, and malaise and lead to loss of consciousness accompanied by flaccidity; recovery occurs rapidly with recumbency, and there is no postictal headache or confusion. In some instances, however, motor accompaniments may simulate a seizure. Serum creatine kinase measured about 3 hours after the event is generally normal after syncopal episodes but markedly elevated after tonic-clonic seizures.

2. Cardiac dysrhythmias—Cerebral hypoperfusion due to a disturbance of cardiac rhythm should be suspected in patients with known cardiac or vascular disease or in elderly patients who present with episodic loss of consciousness. Prodromal symptoms are typically absent. A relationship of attacks to physical activity and the finding of a systolic murmur is suggestive of aortic stenosis. Repeated Holter monitoring may be necessary to establish the diagnosis; monitoring initiated by the patient ("event monitor") may be valuable if the disturbances of consciousness are rare.

3. Brain stem ischemia—Loss of consciousness is preceded or accompanied by other brain stem signs. Basilar artery migraine and vertebrobasilar vascular disease are discussed elsewhere in this chapter.

4. Pseudoseizures—The term pseudoseizures is used to denote both hysterical conversion reactions and attacks due to malingering when these simulate epileptic seizures. Many patients with pseudoseizures also have true seizures or a family history of epilepsy. Although pseudoseizures tend to occur at times of emotional stress, this may also be the case with true seizures.

Clinically, the attacks superficially resemble tonic-clonic seizures, but there may be obvious preparation before pseudoseizures occur. Moreover, there is usually no tonic phase; instead, there is an asynchronous thrashing of the limbs, which increases if restraints are imposed and which rarely leads to injury. Consciousness may be normal or "lost," but in the latter context the occurrence of goal-directed behavior or of shouting, swearing, etc, indicates that it is feigned. Postictally, there are no changes in behavior or neurologic findings.

Laboratory studies may aid in recognition of pseudoseizures. There are no electrocerebral changes, whereas the electroencephalogram changes during organic seizures accompanied by loss of consciousness. The serum level of prolactin has been found to increase dramatically between 15 and 30 minutes after a tonic-clonic convulsion in most patients, whereas it is unchanged after a pseudoseizure.

Treatment

A. General Measures

For patients with recurrent seizures, drug treatment is prescribed with the goal of preventing further attacks and is usually continued until there have been no seizures for at least 3 years. Epileptic patients should be advised to avoid situations that could be dangerous or life-threatening if further seizures should occur. State legislation may require clinicians to report to the state department of public health any patients with seizures or other episodic disturbances of consciousness.

1. Choice of medication—The drug with which treatment is best initiated depends upon the type of seizures to be treated ([Table 24-2](#)). The dose of the selected drug is gradually increased until seizures are controlled or side effects prevent further increases. If seizures continue despite treatment at the maximal tolerated dose, a second drug is added and the dose increased depending on tolerance; the first drug is then gradually withdrawn. In treatment of partial and secondarily generalized tonic-clonic seizures, the success rate is higher with carbamazepine, phenytoin, or valproic acid than with phenobarbital or primidone. Gabapentin, topiramate, lamotrigine, oxcarbazepine, levetiracetam, and zonisamide are newer antiepileptic drugs that are effective for partial or secondarily generalized seizures. Felbamate is also effective for such seizures but, because it may cause aplastic anemia or fulminant hepatic failure, it should be used only in selected patients unresponsive to other measures. Tiagabine is another adjunctive agent for partial seizures. In most patients with seizures of a single type, satisfactory control can be achieved with a single anticonvulsant drug. Treatment with two drugs may further reduce seizure frequency or severity, but usually only at the cost of greater toxicity. Treatment with more than two drugs is almost always unhelpful unless the patient is having seizures of different types.

2. Monitoring—Monitoring serum drug levels has led to major advances in the management of seizure disorders. The same daily dose of a particular drug leads to markedly different blood concentrations in different patients, and this will affect the therapeutic response. In general, the dose of an antiepileptic agent is increased depending on the clinical response regardless of the serum drug level. The trough drug level is then measured to provide a reference point for the maximum tolerated dose. Dosing should not be based simply on serum levels because many patients require levels that exceed the therapeutic range ("toxic levels") but tolerate these without ill effect. Steady-state drug levels in the blood should be measured after treatment is initiated, dosage is changed, or another drug is added to the therapeutic regimen and when seizures are poorly controlled. Dose adjustments are then guided by the laboratory findings. The most common cause of a lower concentration of drug than expected for the prescribed dose is poor patient compliance. Compliance can be improved by limiting to a minimum the number of daily doses. Recurrent seizures or status epilepticus may result if drugs are taken erratically, and in some circumstances noncompliant patients may be better off without any medication.

All anticonvulsant drugs have side effects, and some of these are shown in [Table 24-2](#). In most patients, a complete blood count should be performed at least annually because of the risk of anemia or blood dyscrasia. Treatment with certain drugs may require more frequent monitoring or use of additional screening tests. For example, periodic tests of hepatic function are necessary if valproic acid, carbamazepine, or felbamate is used, and serial blood counts are important with carbamazepine, ethosuximide, or felbamate.

3. Discontinuance of medication—Only when patients have been seizure-free for several (at least 3) years should withdrawal of medication be considered.

Unfortunately, there is no way of predicting which patients can be managed successfully without treatment, although seizure recurrence is more likely in patients who initially failed to respond to therapy, those with seizures having focal features or of multiple types, and those with continuing electroencephalographic abnormalities. Dose reduction should be gradual over a period of weeks or months, and drugs should be withdrawn one at a time. If seizures recur, treatment is reinstituted with the same drugs used previously. Seizures are no more difficult to control after a recurrence than before.

4. Surgical treatment—Patients with surgically remediable epilepsy or seizures refractory to pharmacologic management may be candidates for operative treatment, which is best undertaken in specialized centers.

5. Vagal nerve stimulation—Treatment by chronic vagal nerve stimulation for adults and adolescents with medically refractory partial-onset seizures is approved in the United States and provides an alternative approach for patients who are not optimal candidates for surgical treatment. The mechanism of therapeutic action is unknown. Adverse effects consist mainly of transient hoarseness during stimulus delivery.

B. Special Circumstances

1. Solitary seizures—In patients who have had only one seizure, investigation as outlined above should exclude an underlying cause requiring specific treatment. An EEG should also be performed, preferably within 24 hours after the seizure, because the findings may influence management—especially when focal abnormalities are present. Prophylactic anticonvulsant drug treatment is generally not required unless further attacks occur or investigations reveal some underlying pathology that itself is untreatable. The risk of seizure recurrence varies in different series between about 30% and 70%. Epilepsy should not be diagnosed on the basis of a solitary

seizure. If seizures occur in the context of transient, nonrecurrent systemic disorders such as acute cerebral anoxia, the diagnosis of epilepsy is inaccurate, and long-term prophylactic anticonvulsant drug treatment is unnecessary.

2. Alcohol withdrawal seizures—One or more generalized tonic-clonic seizures may occur within 48 hours or so of withdrawal from alcohol after a period of high or chronic intake. If the seizures have consistently focal features, the possibility of an associated structural abnormality, often traumatic in origin, must be considered. Head CT scan should be performed in patients with new onset of generalized seizures and whenever there are focal features associated with any seizures. Treatment with anticonvulsant drugs is generally not required for alcohol withdrawal seizures, since they are self-limited. Status epilepticus may rarely follow alcohol withdrawal and is managed along conventional lines (see below). Further attacks will not occur if the patient abstains from alcohol.

3. Tonic-clonic status epilepticus—Poor compliance with the anticonvulsant drug regimen is the most common cause; others include alcohol withdrawal, intracranial infection or neoplasms, metabolic disorders, and drug overdose. The mortality rate may be as high as 20%, and among survivors the incidence of neurologic and mental sequelae may be high. The prognosis relates to the length of time between onset of status epilepticus and the start of effective treatment.

Status epilepticus is a medical emergency. Initial management includes maintenance of the airway and 50% dextrose (25-50 mL) intravenously in case hypoglycemia is responsible. If seizures continue, 10 mg of diazepam is given intravenously over the course of 2 minutes, and the dose is repeated after 10 minutes if necessary. Alternatively, a 4-mg intravenous bolus of lorazepam, repeated once after 10 minutes if necessary, is given in place of diazepam. This is usually effective in halting seizures for a brief period but occasionally causes respiratory depression.

Regardless of the response to diazepam or lorazepam, phenytoin (18-20 mg/kg) is given intravenously at a rate of 50 mg/min; this provides initiation of long-term seizure control. The drug is best injected directly but can also be given in saline; it precipitates, however, if injected into glucose-containing solutions. Because arrhythmias may develop during rapid administration of phenytoin, electrocardiographic monitoring is prudent. Hypotension may complicate phenytoin administration, especially if diazepam has also been given. In the United States, injectable phenytoin has been replaced by fosphenytoin, which is rapidly and completely converted to phenytoin following intravenous administration. No dosing adjustments are necessary because fosphenytoin is expressed in terms of phenytoin equivalents (PE); fosphenytoin is less likely to cause reactions at the infusion site, can be given with all common intravenous solutions, and may be administered at a faster rate (150 mg PE/min). It is also more expensive.

If seizures continue, phenobarbital is then given in a loading dose of 10-20 mg/kg intravenously by slow or intermittent injection (50 mg/min). Respiratory depression and hypotension are common complications and should be anticipated; they may occur also with diazepam alone, though less commonly. If these measures fail, general anesthesia with ventilatory assistance and neuromuscular junction blockade may be required. Alternatively, intravenous midazolam may provide control of refractory status epilepticus; the suggested loading dose is 0.2 mg/kg, followed by 0.05-0.2 mg/kg/h.

After status epilepticus is controlled, an oral drug program for the long-term management of seizures is started, and investigations into the cause of the disorder are pursued.

4. Nonconvulsive status epilepticus—Absence (petit mal) and complex partial status epilepticus are characterized by fluctuating abnormal mental status, confusion, impaired responsiveness, and automatism. Electroencephalography is helpful both in establishing the diagnosis and in distinguishing the two varieties. Initial treatment with intravenous diazepam is usually helpful regardless of the type of status epilepticus, but phenytoin, phenobarbital, carbamazepine, and other drugs may also be needed to obtain and maintain control in complex partial status epilepticus.

SYNCOPE & DYSAUTONOMIA

Dysautonomia may occur as a result of central or peripheral pathologic processes. It is manifested by a variety of symptoms that may occur in isolation or in various combinations and relate to abnormalities of blood pressure regulation, thermoregulatory sweating, gastrointestinal function, sphincter control, sexual function, respiration, and ocular function. Such symptoms include syncope, postural hypotension, paroxysmal hypertension, persistent tachycardia without other cause, facial flushing, hypo- or hyperhidrosis, vomiting, constipation, diarrhea, dysphagia, abdominal distention, disturbances of micturition or defecation, apneic episodes, and declining night vision.

Syncope is characterized by a transient loss of consciousness, usually accompanied by hypotension and bradycardia. It may occur in response to emotional stress, postural hypotension, vigorous exercise in a hot environment, obstructed venous return to the heart, acute pain or its anticipation, fluid loss, and a variety of other circumstances. A prodrome of malaise, nausea, headache, diaphoresis, pallor, visual disturbance, loss of postural tone, and a sense of weakness and impending loss of consciousness is followed by actual loss of consciousness. Although the patient is usually flaccid, some motor activity is not uncommon, and urinary (and, rarely, fecal) incontinence may also occur, thereby simulating a seizure. Recovery is rapid once the patient becomes recumbent, but headache, nausea, and fatigue are common postictally.

Evaluation of the Patient

Clinical evaluation is important to exclude reversible, nonneurologic causes of symptoms. Postural hypotension and syncope, for example, may relate to a reduced cardiac output (eg, from aortic stenosis or cardiomyopathy), paroxysmal cardiac dysrhythmias, volume depletion, various medications, and endocrine and metabolic disorders such as Addison's disease, hypo- or hyperthyroidism, pheochromocytoma, and carcinoid syndrome. Testing of autonomic function helps to establish the diagnosis of dysautonomia, to exclude other causes of symptoms, to assess the severity of involvement, and to guide prognostication. Such testing includes evaluating the cardiovascular response to the Valsalva maneuver, startle, mental stress, postural change, and deep respiration, and the sudomotor (sweating) responses to warming or a deep inspiratory gasp. Tilt-table testing may reproduce syncopal or presyncopal symptoms. Pharmacologic studies to evaluate the pupillary responses, radiologic studies of the bladder or gastrointestinal tract, uroflowmetry and urethral pressure profiles, and recording of nocturnal penile tumescence may also be necessary in selected cases. Further investigation depends on the presence of other associated neurologic abnormalities. In patients with a peripheral cause, work-up for peripheral neuropathy may be required as discussed below. For those with evidence of a central lesion, imaging studies will exclude a treatable structural cause.

Neurologic Causes

A. Central Causes

Disease at certain sites in the central nervous system, regardless of its nature, may lead to dysautonomic symptoms. Postural hypotension, which is usually the most troublesome and disabling symptom, may result from spinal cord transection and other myelopathies (eg, due to tumor or syringomyelia) above the T6 level or from brain stem lesions such as syringobulbia and posterior fossa tumors. Sphincter or sexual disturbances may result from cord lesions below T6. Certain primary degenerative disorders are responsible for dysautonomia occurring in isolation (**pure autonomic failure**) or in association with more widespread abnormalities (**multisystem atrophy** or **Shy-Drager syndrome**) that may include parkinsonian, pyramidal symptoms, and cerebellar deficits.

B. Peripheral Causes

A pure autonomic neuropathy may occur acutely or subacutely after a viral infection or as a paraneoplastic disorder related usually to small cell lung cancer. Patients typically present with postural hypotension, impaired thermoregulatory sweating, xerostomia or xerophthalmia, abnormal gastrointestinal motility, dilated pupils, or acute urinary retention. Dysautonomia is often conspicuous in patients with Guillain-Barre syndrome, manifesting with marked hypotension or hypertension or cardiac arrhythmias that may have a fatal outcome. It may also occur with diabetic, uremic, amyloidotic, and various other metabolic or toxic neuropathies; in association with leprosy or Chagas' disease; and as a feature of certain hereditary neuropathies. Autonomic symptoms are prominent in the crises of hepatic porphyria. Patients with botulism or the Lambert-Eaton myasthenic syndrome may have constipation, urinary retention, and a sicca syndrome as a result of impaired cholinergic function.

Treatment

The most disabling symptom of dysautonomia is usually postural hypotension and syncope. Abrupt postural change, prolonged recumbency, and other precipitants should be avoided. Medications associated with postural hypotension should be discontinued or reduced in dose. Treatment may include wearing waist-high elastic

hosiery, salt supplementation, sleeping in a semierect position (which minimizes the natriuresis and diuresis that occur during recumbency), and fludrocortisone (0.1-0.2 mg daily). Vasoconstrictor agents may be helpful and include midodrine (2.5-10 mg three times daily) and ephedrine (15-30 mg three times daily). Other agents that have been used occasionally or experimentally are dihydroergotamine, yohimbine, and clonidine; refractory cases may respond to erythropoietin (epoetin alfa) or desmopressin. Patients must be monitored for recumbent hypertension. Postprandial hypotension is helped by caffeine. There is no satisfactory treatment for disturbances of sweating, but an air-conditioned environment is helpful in avoiding extreme swings in body temperature.

SENSORY DISTURBANCES

Patients may complain of either lost or abnormal sensations. The term "numbness" is often used by patients to denote loss of feeling, but the word also has other meanings and the patient's intention must be clarified. Abnormal spontaneous sensations are generally called paresthesias, and unpleasant or painful sensations produced by a stimulus that is usually painless are called dysesthesias.

Sensory symptoms may be due to disease located anywhere along the peripheral or central sensory pathways. The character, site, mode of onset, spread, and temporal profile of sensory symptoms must be established and any precipitating or relieving factors identified. These features—and the presence of any associated symptoms—help identify the origin of sensory disturbances, as do the physical signs as well. Sensory symptoms or signs may conform to the territory of individual peripheral nerves or nerve roots. Involvement of one side of the body—or of one limb in its entirety—suggests a central lesion. Distal involvement of all four extremities suggests polyneuropathy, a cervical cord or brain stem lesion, or—when symptoms are transient—a metabolic disturbance such as hyperventilation syndrome. Short-lived sensory complaints may be indicative of sensory seizures or cerebral ischemic phenomena as well as metabolic disturbances. In patients with cord lesions, there may be a transverse sensory level. "Dissociated sensory loss" is characterized by loss of some sensory modalities with preservation of others. Such findings may be encountered in patients with either peripheral or central disease and must therefore be interpreted in the clinical context in which they are found.

The absence of sensory signs in patients with sensory symptoms does not mean that symptoms have a nonorganic basis. Symptoms are often troublesome before signs of sensory dysfunction have had time to develop.

WEAKNESS & PARALYSIS

Loss of muscle power may result from central disease involving the upper or lower motor neurons; from peripheral disease involving the roots, plexus, or peripheral nerves; from disorders of neuromuscular transmission; or from primary disorders of muscle. The clinical findings help to localize the lesion and thus reduce the number of diagnostic possibilities.

Weakness due to upper motor neuron lesions is characterized by selective involvement of certain muscle groups and is associated with spasticity, increased tendon reflexes, and extensor plantar responses. The site of upper motor neuron (pyramidal) involvement may be indicated by the presence of other clinical signs or by the distribution of the motor deficit. Lower motor neuron lesions lead to muscle wasting as well as weakness, with flaccidity and loss of tendon reflexes, but no change in the plantar responses unless the neurons subserving them are directly involved. Fasciculations may be evident over affected muscles. In distinguishing between a root, plexus, or peripheral nerve lesion, the distribution of the motor deficit and of any sensory changes is of particular importance. In patients with disturbances of neuromuscular transmission, weakness is patchy in distribution, often fluctuates over short periods of time, and is not associated with sensory changes. In myopathic disorders, weakness is usually most marked proximally in the limbs, is not associated with sensory loss or sphincter disturbance, and is not accompanied by muscle wasting or loss of tendon reflexes—at least not until an advanced stage.

TRANSIENT ISCHEMIC ATTACKS

Essentials of Diagnosis

- Focal neurologic deficit of acute onset.
- Clinical deficit resolves completely within 24 hours.
- Risk factors for vascular disease often present.

General Considerations

Transient ischemic attacks are characterized by focal ischemic cerebral neurologic deficits that last for less than 24 hours (usually less than 1-2 hours). About 30% of patients with stroke have a history of transient ischemic attacks, and proper treatment of the attacks is an important means of prevention. The incidence of stroke does not relate to either the number or the duration of individual attacks but is increased in patients with hypertension or diabetes. The risk of stroke is highest in the month after a transient ischemic attack and progressively declines thereafter.

Etiology

An important cause of transient cerebral ischemia is embolization. In many patients with these attacks, a source is readily apparent in the heart or a major extracranial artery to the head, and emboli sometimes are visible in the retinal arteries. Moreover, an embolic phenomenon explains why separate attacks may affect different parts of the territory supplied by the same major vessel. Cardiac causes of embolic ischemic attacks include rheumatic heart disease, mitral valve disease, cardiac arrhythmia, infective endocarditis, atrial myxoma, and mural thrombi complicating myocardial infarction. Atrial septal defects and patent foramen ovale may permit emboli from the veins to reach the brain ("paradoxical emboli"). An ulcerated plaque on a major artery to the brain may serve as a source of emboli. In the anterior circulation, atherosclerotic changes occur most commonly in the region of the carotid bifurcation extracranially, and these changes may cause a bruit. In some patients with transient ischemic attacks or strokes, an acute or recent hemorrhage is found to have occurred into this atherosclerotic plaque, and this finding may have pathologic significance. Patients with AIDS have an increased risk of developing transient ischemic deficits or strokes.

Other (less common) abnormalities of blood vessels that may cause transient ischemic attacks include fibromuscular dysplasia, which affects particularly the cervical internal carotid artery; atherosclerosis of the aortic arch; inflammatory arterial disorders such as giant cell arteritis, systemic lupus erythematosus, polyarteritis, and granulomatous angiitis; and meningovascular syphilis. Hypotension may cause a reduction of cerebral blood flow if a major extracranial artery to the brain is markedly stenosed, but this is a rare cause of transient ischemic attack.

BR>Hematologic causes of ischemic attacks include polycythemia, sickle cell disease, and hyperviscosity syndromes. Severe anemia may also lead to transient focal neurologic deficits in patients with preexisting cerebral arterial disease.

The **subclavian steal syndrome** may lead to transient vertebrobasilar ischemia. Symptoms develop when there is localized stenosis or occlusion of one subclavian artery proximal to the source of the vertebral artery, so that blood is "stolen" from this artery. A bruit in the supraclavicular fossa, unequal radial pulses, and a difference of 20 mm Hg or more between the systolic blood pressures in the arms should suggest the diagnosis in patients with vertebrobasilar transient ischemic attacks.

Clinical Findings

A. Symptoms and Signs

The symptoms of transient ischemic attacks vary markedly among patients; however, the symptoms in a given individual tend to be constant in type. Onset is abrupt and without warning, and recovery usually occurs rapidly, often within a few minutes.

If the ischemia is in the carotid territory, common symptoms are weakness and heaviness of the contralateral arm, leg, or face, singly or in any combination. Numbness or paresthesias may also occur either as the sole manifestation of the attack or in combination with the motor deficit. There may be slowness of movement, dysphasia, or monocular visual loss in the eye contralateral to affected limbs. During an attack, examination may reveal flaccid weakness with pyramidal distribution, sensory changes, hyperreflexia or an extensor plantar response on the affected side, dysphasia, or any combination of these findings. Subsequently, examination reveals no neurologic abnormality, but the presence of a carotid bruit or cardiac abnormality may provide a clue to the cause of symptoms.

Vertebrobasilar ischemic attacks may be characterized by vertigo, ataxia, diplopia, dysarthria, dimness or blurring of vision, perioral numbness and paresthesias, and weakness or sensory complaints on one, both, or alternating sides of the body. These symptoms may occur singly or in any combination. Drop attacks due to bilateral leg weakness, without headache or loss of consciousness, may occur, sometimes in relation to head movements.

The natural history of attacks is variable. Some patients will have a major stroke after only a few attacks, whereas others may have frequent attacks for weeks or months without having a stroke. Attacks may occur intermittently over a long period of time, or they may stop spontaneously. In general, carotid ischemic attacks are

more liable than vertebrobasilar ischemic attacks to be followed by stroke. The stroke risk is greater in patients older than 60 years, in diabetics, or after TIAs that last longer than 10 minutes and with symptoms or signs of weakness, speech impairment, or gait disturbance. When stroke does occur, it is often during the first 48 hours after a TIA.

B. Imaging

CT scan of the head will exclude the possibility of a small cerebral hemorrhage or a cerebral tumor masquerading as a transient ischemic attack. A number of noninvasive techniques, such as ultrasonography, have been developed for studying the cerebral circulation and imaging the major vessels to the head. Carotid duplex ultrasonography is useful for detecting significant stenosis of the internal carotid artery, but arteriography remains important for demonstrating the status of the cerebrovascular system. MR angiography may reveal stenotic lesions of large vessels but is less sensitive than conventional arteriography. Accordingly, if findings on CT scan are normal, if there is no cardiac source of embolization, and if age and general condition indicate that the patient is a good operative risk, bilateral carotid arteriography should be considered in the further evaluation of carotid ischemic attacks, although the ultrasound findings may help in selecting patients for study.

C. Laboratory and Other Studies

Clinical and laboratory evaluation must include assessment for hypertension, heart disease, hematologic disorders, diabetes mellitus, hyperlipidemia, and peripheral vascular disease. It should include complete blood count, fasting blood glucose and serum cholesterol and homocysteine determinations, serologic tests for syphilis, and an ECG and chest x-ray. Echocardiography with bubble contrast is performed if a cardiac source is likely, and blood cultures are obtained if endocarditis is suspected. Holter monitoring is indicated if a transient, paroxysmal disturbance of cardiac rhythm is suspected.

Differential Diagnosis

Focal seizures usually cause abnormal motor or sensory phenomena such as clonic limb movements, paresthesias, or tingling, rather than weakness or loss of feeling. Symptoms generally spread ("march") up the limb and may lead to a generalized tonic-clonic seizure.

Classic migraine is easily recognized by the visual premonitory symptoms, followed by nausea, headache, and photophobia, but less typical cases may be hard to distinguish. The patient's age and medical history (including family history) may be helpful in this regard. Patients with migraine commonly have a history of episodes since adolescence and report that other family members have a similar disorder.

Focal neurologic deficits may occur during periods of hypoglycemia in diabetic patients receiving insulin or oral hypoglycemic agent therapy.

Treatment

When arteriography reveals a surgically accessible high-grade stenosis (70-99% in luminal diameter) on the side appropriate to carotid ischemic attacks and there is relatively little atherosclerosis elsewhere in the cerebrovascular system, operative treatment (carotid thromboendarterectomy) reduces the risk of ipsilateral carotid stroke, especially when transient ischemic attacks are of recent onset (< 2 months). Surgery is not indicated for mild stenosis (< 30%); its benefits are unclear with severe stenosis plus diffuse intracranial atherosclerotic disease. See [Chapter 12](#) for additional discussion.

In patients with carotid ischemic attacks who are poor operative candidates (and thus have not undergone arteriography) or who are found to have extensive vascular disease, medical treatment should be instituted. Similarly, patients with vertebrobasilar ischemic attacks are treated medically and are not subjected to arteriography unless there is clinical evidence of stenosis or occlusion in the carotid or subclavian arteries.

Medical treatment is aimed at preventing further attacks and stroke. Cigarette smoking should be stopped, and cardiac sources of embolization, hypertension, diabetes, hyperlipidemia, arteritis, or hematologic disorders should be treated appropriately.

A. Embolization from the Heart

If anticoagulants are indicated for the treatment of embolism from the heart, they should be started immediately, provided there is no contraindication to their use. There is no advantage in delay, and the common fear of causing hemorrhage into a previously infarcted area is misplaced, since there is a far greater risk of further embolism to the cerebral circulation if treatment is withheld. Treatment is initiated with intravenous heparin (in a loading dose of 5000-10,000 units of standard-molecular-weight heparin, and maintenance infusion of 1000-2000 units per hour depending on the partial thromboplastin time) while warfarin sodium is introduced in a daily dose of 5-15 mg orally, depending on the INR. Warfarin is more effective than aspirin in reducing the incidence of cardioembolic events, but when its use is contraindicated, aspirin (325 mg daily) may be used in patients with nonrheumatic atrial fibrillation to reduce the risk of stroke.

B. Embolization from the Cardiovascular System

In patients with presumed or angiographically verified atherosclerotic changes in the extracranial or intracranial cerebrovascular circulation, antithrombotic medication is prescribed. The evidence supporting a therapeutic role for aspirin to suppress platelet aggregation is convincing. Platelets adhere to and aggregate around an atherosclerotic plaque and release various substances including thromboxane A₂. Treatment with aspirin significantly reduces the frequency of transient ischemic attacks and the incidence of stroke or myocardial infarcts in high-risk patients. A daily dose of 325 mg is adequate; higher doses may provide added benefit but are associated with a higher incidence of gastrointestinal side effects. Dipyridamole is not as effective, and when added to aspirin does not offer any advantage over aspirin alone for stroke prevention. In patients intolerant of aspirin, ticlopidine (another platelet aggregation inhibitor) may be used in a dose of 250 mg twice daily, but patients must be monitored closely for the development of neutropenia or agranulocytosis. Some physicians use anticoagulant drugs (eg, warfarin, with temporary heparinization until the dose of warfarin is adequate) unless they are medically contraindicated, continuing them for 3-6 months before they are tapered and ultimately replaced with aspirin, which is continued for another year. However, there is no convincing evidence that anticoagulant drugs are of value.

Surgical extracranial-intracranial arterial anastomosis is generally not helpful in patients with transient ischemic attacks associated with stenotic lesions of the distal internal carotid or the proximal middle cerebral arteries.

STROKE

Essentials of Diagnosis

- Sudden onset of characteristic neurologic deficit.
- Patient often has history of hypertension, diabetes mellitus, valvular heart disease, or atherosclerosis.
- Distinctive neurologic signs reflect the region of the brain involved.

General Considerations

In the United States, stroke remains the third leading cause of death, despite a general decline in the incidence of stroke in the last 30 years. The precise reasons for this decline are uncertain, but increased awareness of risk factors (hypertension, diabetes, hyperlipidemia, cigarette smoking, cardiac disease, AIDS, recreational drug abuse, heavy alcohol consumption, family history of stroke) and improved prophylactic measures and surveillance of those at increased risk have been contributory. Elevation of the blood homocysteine level is also a risk factor for stroke, but it is unclear whether this risk is reduced by treatment to lower the level. A previous stroke makes individual patients more susceptible to further strokes.

For years, strokes have been subdivided pathologically into infarcts (thrombotic or embolic) and hemorrhages, and clinical criteria for distinguishing between these possibilities have been emphasized. However, it is often difficult to determine on clinical grounds the pathologic basis for stroke.

1. Lacunar Infarction

Lacunar infarcts are small lesions (usually < 5 mm in diameter) that occur in the distribution of short penetrating arterioles in the basal ganglia, pons, cerebellum, anterior limb of the internal capsule, and, less commonly, the deep cerebral white matter. Lacunar infarcts are associated with poorly controlled hypertension or diabetes and have been found in several clinical syndromes, including contralateral pure motor or pure sensory deficit, ipsilateral ataxia with crural paresis, and dysarthria with clumsiness of the hand. The neurologic deficit may progress over 24-36 hours before stabilizing.

Lacunar infarcts are sometimes visible on CT scans as small, punched-out, hypodense areas, but in other patients no abnormality is seen. In some instances, patients with a clinical syndrome suggestive of lacunar infarction are found on CT scanning to have a severe hemispheric infarct.

The prognosis for recovery from the deficit produced by a lacunar infarct is usually good, with partial or complete resolution occurring over the following 4-6 weeks in many instances.

2. Cerebral Infarction

Thrombotic or embolic occlusion of a major vessel leads to cerebral infarction. Causes include the disorders predisposing to transient ischemic attacks (see above) and atherosclerosis of cerebral arteries. The resulting deficit depends upon the particular vessel involved and the extent of any collateral circulation. Cerebral ischemia leads to release of excitatory and other neuropeptides that may augment calcium flux into neurons, thereby leading to cell death and increasing the neurologic deficit.

Clinical Findings

A. Symptoms and Signs

Onset is usually abrupt, and there may then be very little progression except that due to brain swelling. Clinical evaluation always includes examination of the heart and auscultation over the subclavian and carotid vessels to determine whether there are any bruits.

1. Obstruction of carotid circulation—Occlusion of the ophthalmic artery is probably symptomless in most cases because of the rich orbital collaterals, but its transient embolic obstruction leads to amaurosis fugax—sudden and brief loss of vision in one eye.

Occlusion of the anterior cerebral artery distal to its junction with the anterior communicating artery causes weakness and cortical sensory loss in the contralateral leg and sometimes mild weakness of the arm, especially proximally. There may be a contralateral grasp reflex, paratonic rigidity, and abulia (lack of initiative) or frank confusion. Urinary incontinence is not uncommon, particularly if behavioral disturbances are conspicuous. Bilateral anterior cerebral infarction is especially likely to cause marked behavioral changes and memory disturbances. Unilateral anterior cerebral artery occlusion proximal to the junction with the anterior communicating artery is generally well tolerated because of the collateral supply from the other side.

Middle cerebral artery occlusion leads to contralateral hemiplegia, hemisensory loss, and homonymous hemianopia (ie, bilaterally symmetric loss of vision in half of the visual fields), with the eyes deviated to the side of the lesion. If the dominant hemisphere is involved, global aphasia is also present. It may be impossible to distinguish this clinically from occlusion of the internal carotid artery. With occlusion of either of these arteries, there may also be considerable swelling of the hemisphere, leading to drowsiness, stupor, and coma in extreme cases. Occlusions of different branches of the middle cerebral artery cause more limited findings. For example, involvement of the anterior main division leads to a predominantly expressive dysphasia and to contralateral paralysis and loss of sensations in the arm, the face, and, to a lesser extent, the leg. Posterior branch occlusion produces a receptive (Wernicke's) aphasia and a homonymous visual field defect. With involvement of the nondominant hemisphere, speech and comprehension are preserved, but there may be a confusional state, dressing apraxia, and constructional and spatial deficits.

2. Obstruction of vertebrobasilar circulation—Occlusion of the posterior cerebral artery may lead to a thalamic syndrome in which contralateral hemisensory disturbance occurs, followed by the development of spontaneous pain and hyperpathia. There is often a macular-sparing homonymous hemianopia and sometimes a mild, usually temporary, hemiparesis. Depending on the site of the lesion and the collateral circulation, the severity of these deficits varies and other deficits may also occur, including involuntary movements and alexia. Occlusion of the main artery beyond the origin of its penetrating branches may lead solely to a macular-sparing hemianopia.

Vertebral artery occlusion distally, below the origin of the anterior spinal and posterior inferior cerebellar arteries, may be clinically silent because the circulation is maintained by the other vertebral artery. If the remaining vertebral artery is congenitally small or severely atherosclerotic, however, a deficit similar to that of basilar artery occlusion is seen unless there is good collateral circulation from the anterior circulation through the circle of Willis. When the small paramedian arteries arising from the vertebral artery are occluded, contralateral hemiplegia and sensory deficit occur in association with an ipsilateral cranial nerve palsy at the level of the lesion. An obstruction of the posterior inferior cerebellar artery or an obstruction of the vertebral artery just before it branches to this vessel leads ipsilaterally to spinothalamic sensory loss involving the face, ninth and tenth cranial nerve lesions, limb ataxia and numbness, and Horner's syndrome, combined with contralateral spinothalamic sensory loss involving the limbs.

Occlusion of both vertebral arteries or the basilar artery leads to coma with pinpoint pupils, flaccid quadriplegia and sensory loss, and variable cranial nerve abnormalities. With partial basilar artery occlusion, there may be diplopia, visual loss, vertigo, dysarthria, ataxia, weakness or sensory disturbances in some or all of the limbs, and discrete cranial nerve palsies. In patients with hemiplegia of pontine origin, the eyes are often deviated to the paralyzed side, whereas in patients with a hemispheric lesion, the eyes commonly deviate from the hemiplegic side.

Occlusion of any of the major cerebellar arteries produces vertigo, nausea, vomiting, nystagmus, ipsilateral limb ataxia, and contralateral spinothalamic sensory loss in the limbs. If the superior cerebellar artery is involved, the contralateral spinothalamic loss also involves the face; with occlusion of the anterior inferior cerebellar artery, there is ipsilateral spinothalamic sensory loss involving the face, usually in conjunction with ipsilateral facial weakness and deafness. Massive cerebellar infarction may lead to coma, tonsillar herniation, and death.

3. Coma—Infarction in either the carotid or vertebrobasilar territory may lead to loss of consciousness. For example, an infarct involving one cerebral hemisphere may lead to such swelling that the function of the other hemisphere or the rostral brain stem is disturbed and coma results. Similarly, coma occurs with bilateral brain stem infarction when this involves the reticular formation, and it occurs with brain stem compression after cerebellar infarction.

B. Imaging

Radiography of the chest may reveal cardiomegaly or valvular calcification; the presence of a neoplasm would suggest that the neurologic deficit is due to metastasis rather than stroke, or rarely to nonbacterial thrombotic endocarditis. A CT scan of the head (without contrast) is important in excluding cerebral hemorrhage, but it may not permit distinction between a cerebral infarct and tumor. CT scanning is preferable to MRI in the acute stage because it is quicker and because intracranial hemorrhage is not easily detected by MRI within the first 48 hours after a bleeding episode. In selected patients, carotid duplex studies, MRI and MR angiography, and conventional angiography may also be necessary. Diffusion-weighted MRI is more sensitive than standard MRI in detecting cerebral ischemia.

C. Laboratory and Other Studies

Investigations should include a complete blood count, sedimentation rate, blood glucose determination, and serologic tests for syphilis. Antiphospholipid antibodies (lupus anticoagulants and anticardiolipin antibodies) promote thrombosis and are associated with an increased incidence of stroke. Similarly, elevated serum cholesterol and lipids and serum homocysteine may indicate an increased risk of thrombotic stroke. Electrocardiography will help exclude a cardiac arrhythmia or recent myocardial infarction that might be serving as a source of embolization. Blood cultures should be performed if endocarditis is suspected, echocardiography if heart disease is suspected, and Holter monitoring if paroxysmal cardiac arrhythmia requires exclusion. Examination of the cerebrospinal fluid is not always necessary but may be helpful if there is diagnostic uncertainty; it should be delayed until after CT scanning.

Treatment

If the neurologic deficit progresses over the following minutes or hours, heparinization may be of value in limiting or arresting further deterioration. Since the signs of progressing stroke may be simulated by an intracerebral hematoma, the latter must be excluded by immediate CT scanning or angiography before the patient is heparinized.

Intravenous thrombolytic therapy with recombinant tissue plasminogen activator (0.9 mg/kg to a maximum of 90 mg, with 10% given as a bolus over 1 minute and the remainder over 1 hour) is effective in reducing the neurologic deficit in selected patients without CT evidence of intracranial hemorrhage when administered within 3 hours after onset of ischemic stroke, but later administration has not been proved effective or safe. Recent hemorrhage, increased risk of hemorrhage (eg, treatment with anticoagulants), arterial puncture at a noncompressible site, and systolic pressure above 185 mm Hg or diastolic pressure above 110 mm Hg are among the contraindications to this treatment. Early management of a completed stroke otherwise consists of attention to general supportive measures. During the acute stage, there may be marked brain swelling and edema, with symptoms and signs of increasing intracranial pressure, an increasing neurologic deficit, or herniation syndrome. Corticosteroids have been prescribed in an attempt to reduce vasogenic cerebral edema. Prednisone (up to 100 mg/d) or dexamethasone (16 mg/d) has been used, but the evidence that corticosteroids are of any benefit is conflicting. Dehydrating hyperosmolar agents have also been prescribed in efforts to reduce brain swelling, but there is little evidence of any lasting benefit. Likewise, clinical benefit from treatment with vasodilators such as papaverine is minimal. Neither hypercapnia nor hypocapnia has been shown to have any benefit. Barbiturates are known to decrease neuronal metabolism and energy requirements and have been reported to improve functional recovery in experimental stroke models; their use in humans, however, is experimental. Attempts to lower the blood pressure of hypertensive patients during the acute phase (ie, within 2 weeks) of a stroke should generally be avoided, as there is loss of cerebral autoregulation and lowering the blood pressure may further compromise ischemic areas. However, if the systolic pressure exceeds 200 mm Hg, it can be lowered with continuous monitoring to 170-200 mm Hg and then, after 2 weeks, the blood pressure reduced further to less than 140/90 mm Hg.

Anticoagulant drugs should be started when there is a cardiac source of embolization. Treatment is with intravenous heparin while warfarin is introduced. The target is an INR of 2.0-3.0 for the prothrombin time. If the CT scan shows no evidence of hemorrhage and the cerebrospinal fluid is clear, anticoagulant treatment may be started without delay. Some physicians prefer to wait for 2 or 3 days before initiating anticoagulant treatment; the CT scan is then repeated and anticoagulant therapy is initiated if it again shows no evidence of hemorrhagic transformation.

Physical therapy has an important role in the management of patients with impaired motor function. Passive movements at an early stage will help prevent contractures. As cooperation increases and some recovery begins, active movements will improve strength and coordination. In all cases, early mobilization and active rehabilitation are important. Occupational therapy may improve morale and motor skills, while speech therapy may be beneficial in patients with expressive dysphasia or dysarthria. When there is a severe and persisting motor deficit, a device such as a leg brace, toe spring, frame, or cane may help the patient move about, and the provision of other aids to daily living may improve the quality of life.

Prognosis

The prognosis for survival after cerebral infarction is better than after cerebral or subarachnoid hemorrhage. The only proved effective therapy for acute stroke requires initiation within 3 hours after stroke onset, and the prognosis therefore depends on the time that elapses before arrival at the hospital. Patients receiving such treatment with tissue plasminogen activator are at least 30% more likely to have minimal or no disability at 3 months than those not treated by this means. Loss of consciousness after a cerebral infarct implies a poorer prognosis than otherwise. The extent of the infarct governs the potential for rehabilitation. Patients who have had a cerebral infarct are at risk for further strokes and for myocardial infarcts. Statin therapy to lower serum lipid levels may reduce this risk. Antiplatelet therapy reduces the recurrence rate by 30% among patients without a cardiac cause for the stroke who are not candidates for carotid endarterectomy. Nevertheless, the cumulative risk of recurrence of noncardioembolic stroke is still 3-7% annually. A 2-year comparison did not show benefit of warfarin (INR 1.4-2.8) over aspirin (325 mg daily), and higher doses of warfarin should be avoided as they lead to an increased incidence of major bleeding. Patients with massive strokes from which meaningful recovery is unlikely should receive palliative care ([Chapter 5](#)).

3. Intracerebral Hemorrhage

Spontaneous intracerebral hemorrhage in patients with no angiographic evidence of an associated vascular anomaly (eg, aneurysm or angioma) is usually due to hypertension. The pathologic basis for hemorrhage is probably the presence of microaneurysms that develop on perforating vessels of 100-300 um in diameter in hypertensive patients. Hypertensive intracerebral hemorrhage occurs most frequently in the basal ganglia and less commonly in the pons, thalamus, cerebellum, and cerebral white matter. Hemorrhage may extend into the ventricular system or subarachnoid space, and signs of meningeal irritation are then found. Hemorrhages usually occur suddenly and without warning, often during activity.

In addition to its association with hypertension, nontraumatic intracerebral hemorrhage may occur with hematologic and bleeding disorders (eg, leukemia, thrombocytopenia, hemophilia, or disseminated intravascular coagulation), anticoagulant therapy, liver disease, cerebral amyloid angiopathy, and primary or secondary brain tumors. Bleeding is primarily into the subarachnoid space when it occurs from an intracranial aneurysm or arteriovenous malformation (see below), but it may be partly intraparenchymal as well. In some cases, no specific cause for cerebral hemorrhage can be identified.

Clinical Findings

A. Symptoms and Signs

With hemorrhage into the cerebral hemisphere, consciousness is initially lost or impaired in about one-half of patients. Vomiting occurs very frequently at the onset of bleeding, and headache is sometimes present. Focal symptoms and signs then develop, depending on the site of the hemorrhage. With hypertensive hemorrhage, there is generally a rapidly evolving neurologic deficit with hemiplegia or hemiparesis. A hemisensory disturbance is also present with more deeply placed lesions. With lesions of the putamen, loss of conjugate lateral gaze may be conspicuous. With thalamic hemorrhage, there may be a loss of upward gaze, downward or skew deviation of the eyes, lateral gaze palsies, and pupillary inequalities.

Cerebellar hemorrhage may present with sudden onset of nausea and vomiting, disequilibrium, headache, and loss of consciousness that may terminate fatally within 48 hours. Less commonly, the onset is gradual and the course episodic or slowly progressive—clinical features suggesting an expanding cerebellar lesion. In yet other cases, however, the onset and course are intermediate, and examination shows lateral conjugate gaze palsies to the side of the lesion; small reactive pupils; contralateral hemiplegia; peripheral facial weakness; ataxia of gait, limbs, or trunk; periodic respiration; or some combination of these findings.

B. Imaging

CT scanning (without contrast) is important not only in confirming that hemorrhage has occurred but also in determining the size and site of the hematoma. It is superior to MRI for detecting intracranial hemorrhage of less than 48 hours duration. If the patient's condition permits further intervention, cerebral angiography may be undertaken thereafter to determine if an aneurysm or arteriovenous malformation is present (see below).

C. Laboratory and Other Studies

A complete blood count, platelet count, bleeding time, prothrombin and partial thromboplastin times, and liver and renal function tests may reveal a predisposing cause for the hemorrhage. Lumbar puncture is contraindicated because it may precipitate a herniation syndrome in patients with a large hematoma, and CT scanning is superior in detecting intracerebral hemorrhage.

Treatment

Neurologic management is generally conservative and supportive, regardless of whether the patient has a profound deficit with associated brain stem compression, in which case the prognosis is grim, or a more localized deficit not causing increased intracranial pressure or brain stem involvement. Decompression is helpful, however, when a superficial hematoma in cerebral white matter is exerting a mass effect and causing incipient herniation. In patients with cerebellar hemorrhage, prompt surgical evacuation of the hematoma is appropriate, because spontaneous unpredictable deterioration may otherwise lead to a fatal outcome and because operative treatment may lead to complete resolution of the clinical deficit. The treatment of underlying structural lesions or bleeding disorders depends upon their nature.

Hill MD et al: Rate of stroke recurrence in patients with primary intracerebral hemorrhage. Stroke 2000;31:123. [\[PMID: 10625726\]](#)

4. Subarachnoid Hemorrhage

Essentials of Diagnosis

- Sudden severe headache.
- Signs of meningeal irritation usually present.
- Obtundation is common.
- Focal deficits frequently absent.

General Considerations

Between 5% and 10% of strokes are due to subarachnoid hemorrhage. Although hemorrhage is usually from rupture of an aneurysm or arteriovenous malformation, no specific cause can be found in 20% of cases.

Clinical Findings

A. Symptoms and Signs

Subarachnoid hemorrhage has a characteristic clinical picture. Its onset is with sudden headache of a severity never experienced previously by the patient. This may

be followed by nausea and vomiting and by a loss or impairment of consciousness that can either be transient or progress inexorably to deepening coma and death. If consciousness is regained, the patient is often confused and irritable and may show other symptoms of an altered mental status. Neurologic examination generally reveals nuchal rigidity and other signs of meningeal irritation, except in deeply comatose patients. A focal neurologic deficit is occasionally present and may suggest the site of the underlying lesion.

B. Imaging

A CT scan should be performed immediately to confirm that hemorrhage has occurred and to search for clues regarding its source. It is preferable to MRI because it is faster and more sensitive in detecting hemorrhage in the first 24 hours. CT findings sometimes are normal in patients with suspected hemorrhage, and the cerebrospinal fluid must then be examined for the presence of blood or xanthochromia before the possibility of subarachnoid hemorrhage is discounted.

Cerebral arteriography may be undertaken to determine the source of bleeding; it is not performed unless or until the patient's condition has stabilized and is good enough so that operative treatment is feasible. In general, bilateral carotid and vertebral arteriography are necessary because aneurysms are often multiple, while arteriovenous malformations may be supplied from several sources. MR angiography may also permit these vascular anomalies to be visualized but is less sensitive than conventional arteriography.

Treatment

The measures outlined below in the section on stupor and coma are applied to comatose patients. Conscious patients are confined to bed, advised against any exertion or straining, treated symptomatically for headache and anxiety, and given laxatives or stool softeners. If there is severe hypertension, the blood pressure can be lowered gradually, but not below a diastolic level of 100 mm Hg. Phenytoin is generally prescribed routinely to prevent seizures. Further comment concerning the specific operative management of arteriovenous malformations and aneurysms follows.

5. Intracranial Aneurysm

Saccular aneurysms ("berry" aneurysms) tend to occur at arterial bifurcations, are frequently multiple (20% of cases), and are usually asymptomatic. They may be associated with polycystic kidney disease and coarctation of the aorta. Risk factors for aneurysm formation include smoking, hypertension, and hypercholesterolemia. Most aneurysms are located on the anterior part of the circle of Willis—particularly on the anterior or posterior communicating arteries, at the bifurcation of the middle cerebral artery, and at the bifurcation of the internal carotid artery.

Clinical Findings

A. Symptoms and Signs

Aneurysms may cause a focal neurologic deficit by compressing adjacent structures. However, most are asymptomatic or produce only nonspecific symptoms until they rupture, at which time subarachnoid hemorrhage results. There is often a paucity of focal neurologic signs in patients with subarachnoid hemorrhage, but when present, such signs may relate either to a focal hematoma or to ischemia in the territory of the vessel with the ruptured aneurysm. Hemiplegia or other focal deficit sometimes occurs after a delay of 4-14 days and is due to focal arterial spasm in the vicinity of the ruptured aneurysm. This spasm is of uncertain, probably multifactorial, cause, but it sometimes leads to significant cerebral ischemia or infarction, and it may further aggravate any existing increase in intracranial pressure. Subacute hydrocephalus due to interference with the flow of cerebrospinal fluid may occur after 2 or more weeks, and this leads to a delayed clinical deterioration that is relieved by shunting.

In some patients, "warning leaks" of a small amount of blood from the aneurysm precede the major hemorrhage by a few hours or days. They lead to headaches, sometimes accompanied by nausea and neck stiffness, but the true cause of these symptoms is often not appreciated until massive hemorrhage occurs.

B. Imaging

The CT scan generally confirms that subarachnoid hemorrhage has occurred, but occasionally it is normal. Angiography (bilateral carotid and vertebral studies) generally indicates the size and site of the lesion, sometimes reveals multiple aneurysms, and may show arterial spasm. If subarachnoid hemorrhage is confirmed by lumbar puncture or CT scanning but arteriograms show no abnormality, the examination should be repeated after 2 weeks, because vasospasm may have prevented detection of an aneurysm during the initial study.

C. Laboratory and Other Studies

The cerebrospinal fluid is bloodstained. The electroencephalogram sometimes indicates the side or site of hemorrhage but frequently shows only a diffuse abnormality. Electrocardiographic evidence of arrhythmias or myocardial ischemia has been well described and probably relates to excessive sympathetic activity. Peripheral leukocytosis and transient glycosuria are also common findings.

Treatment

The major aim of treatment is to prevent further hemorrhages. Definitive treatment requires a surgical approach to the aneurysm and ideally consists of clipping of its base. Alternatively, endovascular treatment (coil embolization) by interventional radiologists may be undertaken and is sometimes feasible even for inoperable aneurysms. Otherwise, medical management as outlined above for subarachnoid hemorrhage is continued for about 6 weeks and is followed by gradual mobilization.

The risk of further hemorrhage is greatest within a few days of the first hemorrhage; approximately 20% of patients will have further bleeding within 2 weeks and 40% within 6 months. Attempts have been made to reduce this risk pharmacologically. Treatment with an antifibrinolytic agent such as aminocaproic acid during the first 14 days reduces the risk of recurrent hemorrhage but is associated with such an increase in cerebral ischemic complications that the mortality rate and the degree of disability among survivors are unchanged. Thus, early operation (ie, within about 2 days of hemorrhage) is preferred for good operative candidates.

Calcium channel-blocking agents have helped to reduce or reverse experimental vasospasm, and nimodipine has been shown to reduce, in neurologically normal patients, the incidence of ischemic deficits from arterial spasm without producing any side effects. The dose of nimodipine is 60 mg every 4 hours for 21 days. After surgical obliteration of any aneurysms, symptomatic vasospasm may also be treated by intravascular volume expansion, induced hypertension, or transluminal balloon angioplasty of involved intracranial vessels.

With regard to unruptured aneurysms, those that are symptomatic merit prompt treatment, either surgically or by endovascular coil embolization, whereas small asymptomatic ones discovered incidentally are often followed arteriographically and corrected surgically only if they increase in size to over 10 mm. The natural history of unruptured aneurysms is not clearly defined.

6. Arteriovenous Malformations

Arteriovenous malformations are congenital vascular malformations that result from a localized maldevelopment of part of the primitive vascular plexus and consist of abnormal arteriovenous communications without intervening capillaries. They vary in size, ranging from massive lesions that are fed by multiple vessels and involve a large part of the brain to lesions so small that they are hard to identify at arteriography, surgery, or autopsy. In approximately 10% of cases, there is an associated arterial aneurysm, while 1-2% of patients presenting with aneurysms have associated arteriovenous malformations. Clinical presentation may relate to hemorrhage from the malformation or an associated aneurysm or may relate to cerebral ischemia due to diversion of blood by the anomalous arteriovenous shunt or due to venous stagnation. Regional maldevelopment of the brain, compression or distortion of adjacent cerebral tissue by enlarged anomalous vessels, and progressive gliosis due to mechanical and ischemic factors may also be contributory. In addition, communicating or obstructive hydrocephalus may occur and lead to symptoms.

Clinical Findings

A. Symptoms and Signs

1. Supratentorial lesions—Most cerebral arteriovenous malformations are supratentorial, usually lying in the territory of the middle cerebral artery. Initial symptoms consist of hemorrhage in 30-60% of cases, recurrent seizures in 20-40%, headache in 5-25%, and miscellaneous complaints (including focal deficits) in 10-15%. Up to 70% of arteriovenous malformations bleed at some point in their natural history, most commonly before the patient reaches the age of 40 years. This tendency to bleed is unrelated to the lesion site or to the patient's sex, but small arteriovenous malformations are more likely to bleed than large ones. Arteriovenous malformations that have bled once are more likely to bleed again. Hemorrhage is commonly intracerebral as well as into the subarachnoid space, and it has a fatal outcome in about 10% of cases. Focal or generalized seizures may accompany or follow hemorrhage, or they may be the initial presentation, especially with frontal or parietal arteriovenous

malformations. Headaches are especially likely when the external carotid arteries are involved in the malformation. These sometimes simulate migraine but more commonly are nonspecific in character, with nothing about them to suggest an underlying structural lesion.

In patients presenting with subarachnoid hemorrhage, examination may reveal an abnormal mental status and signs of meningeal irritation. Additional findings may help to localize the lesion and sometimes indicate that intracranial pressure is increased. A cranial bruit always suggests the possibility of a cerebral arteriovenous malformation, but bruits may also be found with aneurysms, meningiomas, acquired arteriovenous fistulas, and arteriovenous malformations involving the scalp, calvarium, or orbit. Bruits are best heard over the ipsilateral eye or mastoid region and are of some help in lateralization but of no help in localization. Absence of a bruit in no way excludes the possibility of arteriovenous malformation.

2. Infratentorial lesions—Brain stem arteriovenous malformations are often clinically silent, but they may hemorrhage, cause obstructive hydrocephalus, or lead to progressive or relapsing brain stem deficits. Cerebellar arteriovenous malformations may also be clinically inconspicuous but sometimes lead to cerebellar hemorrhage.

B. Imaging

In patients presenting with suspected hemorrhage, CT scanning indicates whether subarachnoid or intracerebral bleeding has recently occurred, helps to localize its source, and may reveal the arteriovenous malformation. If the CT scan shows no evidence of bleeding but subarachnoid hemorrhage is diagnosed clinically, the cerebrospinal fluid should be examined.

When intracranial hemorrhage is confirmed but the source of hemorrhage is not evident on the CT scan, arteriography is necessary to exclude aneurysm or arteriovenous malformation. MR angiography is not sensitive enough for this purpose. Even if the findings on CT scan suggest arteriovenous malformation, arteriography is required to establish the nature of the lesion with certainty and to determine its anatomic features so that treatment can be planned. The examination must generally include bilateral opacification of the internal and external carotid arteries and the vertebral arteries. Arteriovenous malformations typically appear as a tangled vascular mass with distended tortuous afferent and efferent vessels, a rapid circulation time, and arteriovenous shunting. Findings on plain radiographs of the skull are often normal unless an intracerebral hematoma is present, in which case there may be changes suggestive of raised intracranial pressure and displacement of a calcified pineal gland.

In patients presenting without hemorrhage, CT scan or MRI usually reveals the underlying abnormality, and MRI frequently also shows evidence of old or recent hemorrhage that may have been asymptomatic. The nature and detailed anatomy of any focal lesion identified by these means are delineated by angiography, especially if operative treatment is under consideration.

C. Laboratory and Other Studies

Electroencephalography is usually indicated in patients presenting with seizures and may show consistently focal or lateralized abnormalities resulting from the underlying cerebral arteriovenous malformation. This should be followed by CT scanning.

Treatment

Surgical treatment to prevent further hemorrhage is justified in patients with arteriovenous malformations that have bled, provided that the lesion is accessible and the patient has a reasonable life expectancy. Surgical treatment is also appropriate if intracranial pressure is increased and to prevent further progression of a focal neurologic deficit. In patients presenting solely with seizures, anticonvulsant drug treatment is usually sufficient, and operative treatment is unnecessary unless there are further developments.

Definitive operative treatment consists of excision of the arteriovenous malformation if it is surgically accessible. Arteriovenous malformations that are inoperable because of their location are sometimes treated solely by embolization; although the risk of hemorrhage is not reduced, neurologic deficits may be stabilized or even reversed by this procedure. Two other techniques for the treatment of intracerebral arteriovenous malformations are injection of a vascular occlusive polymer through a flow-guided microcatheter and permanent occlusion of feeding vessels by positioning detachable balloon catheters in the desired sites and then inflating them with quickly solidifying contrast material. Stereotactic radiosurgery with the gamma knife is also useful in the management of inoperable cerebral arteriovenous malformations.

Ogilvy CS et al: AHA Scientific Statement: recommendations for the management of intracranial arteriovenous malformations. *Stroke* 2001;32:1458. [\[PMID: 11387517\]](#)

7. Intracranial Venous Thrombosis

Intracranial venous thrombosis may occur in association with intracranial or maxillofacial infections, hypercoagulable states, polycythemia, sickle cell disease, and cyanotic congenital heart disease and in pregnancy or during the puerperium. It is characterized by headache, focal or generalized convulsions, drowsiness, confusion, increased intracranial pressure, and focal neurologic deficits—and sometimes by evidence of meningeal irritation. The diagnosis is confirmed by CT scanning and MRI, MR venography, or angiography.

Treatment includes anticonvulsant drugs if seizures have occurred and antiedema agents (eg, dexamethasone, 4 mg four times daily and continued as necessary) to reduce intracranial pressure. Anticoagulation with dose-adjusted intravenous heparin followed by oral anticoagulation for 6 months reduces morbidity and mortality of venous sinus thrombosis.

8. Spinal Cord Vascular Diseases

Essentials of Diagnosis

- Sudden onset of back or limb pain and neurologic deficit in limbs.
- Motor, sensory, or reflex changes in limbs depending on level of lesion.
- Imaging studies distinguish between infarct and hematoma.

Infarction of the Spinal Cord

Infarction of the spinal cord is rare. It occurs only in the territory of the anterior spinal artery because this vessel, which supplies the anterior two-thirds of the cord, is itself supplied by only a limited number of feeders. Infarction usually results from interrupted flow in one or more of these feeders, eg, with aortic dissection, aortography, polyarteritis, or severe hypotension, or after surgical resection of the thoracic aorta. The paired posterior spinal arteries, by contrast, are supplied by numerous arteries at different levels of the cord.

Since the anterior spinal artery receives numerous feeders in the cervical region, infarcts almost always occur caudally. Clinical presentation is characterized by acute onset of flaccid, areflexive paraplegia that evolves after a few days or weeks into a spastic paraplegia with extensor plantar responses. There is an accompanying dissociated sensory loss, with impairment of appreciation of pain and temperature but preservation of sensations of vibration and position. Treatment is symptomatic.

Goodin DS: Neurological complications of aortic disease and surgery. In: *Neurology and General Medicine*, 3rd ed. Aminoff MJ (editor). Churchill Livingstone, 2001.

Epidural or Subdural Hemorrhage

Epidural or subdural hemorrhage may lead to sudden severe back pain followed by an acute compressive myelopathy necessitating urgent myelography and surgical evacuation. It may occur in patients with bleeding disorders or those who are taking anticoagulant drugs, sometimes following trauma or lumbar puncture. Epidural hemorrhage may also be related to a vascular malformation or tumor deposit.

Arteriovenous Malformation of the Spinal Cord

Arteriovenous malformations of the cord are congenital lesions that present with spinal subarachnoid hemorrhage or myeloradiculopathy. Since most of these malformations are located in the thoracolumbar region, they lead to motor and sensory disturbances in the legs and to sphincter disorders. Pain in the legs or back is often severe. Examination reveals an upper, lower, or mixed motor deficit in the legs; sensory deficits are also present and are usually extensive, although occasionally they are confined to radicular distribution. Cervical arteriovenous malformations lead also to symptoms and signs in the arms. Spinal MRI may not detect the arteriovenous malformation, and negative findings do not exclude the diagnosis. In general, the diagnosis is suggested at myelography (performed with the patient

prone and supine) when serpiginous filling defects due to enlarged vessels are found. Selective spinal arteriography confirms the diagnosis. Most lesions are extramedullary, are posterior to the cord (lying either intra- or extradurally), and can easily be treated by ligation of feeding vessels and excision of the fistulous anomaly or by embolization procedures. Delay in treatment may lead to increased and irreversible disability or to death from recurrent subarachnoid hemorrhage.

INTRACRANIAL & SPINAL SPACE-OCCUPYING LESIONS

1. Primary Intracranial Tumors

Essentials of Diagnosis

- Generalized or focal disturbance of cerebral function, or both.
- Increased intracranial pressure in some patients.
- Neuroradiologic evidence of space-occupying lesion.

General Considerations

Half of all primary intracranial neoplasms ([Table 24-3](#)) are gliomas and the remainder meningiomas, pituitary adenomas, neurofibromas, and other tumors. Certain tumors, especially neurofibromas, hemangioblastomas, and retinoblastomas, may have a familial basis, and congenital factors bear on the development of craniopharyngiomas. Tumors may occur at any age, but certain gliomas show particular age predilections ([Table 24-3](#)).

Clinical Findings

A. Symptoms and Signs

Intracranial tumors may lead to a generalized disturbance of cerebral function and to symptoms and signs of increased intracranial pressure. In consequence, there may be personality changes, intellectual decline, emotional lability, seizures, headaches, nausea, and malaise. If the pressure is increased in a particular cranial compartment, brain tissue may herniate into a compartment with lower pressure. The most familiar syndrome is herniation of the temporal lobe uncus through the tentorial hiatus, which causes compression of the third cranial nerve, midbrain, and posterior cerebral artery. The earliest sign of this is ipsilateral pupillary dilation, followed by stupor, coma, decerebrate posturing, and respiratory arrest. Another important herniation syndrome consists of displacement of the cerebellar tonsils through the foramen magnum, which causes medullary compression leading to apnea, circulatory collapse, and death. Other herniation syndromes are less common and of less clear clinical importance.

Intracranial tumors also lead to focal deficits depending on their location.

1. Frontal lobe lesions—Tumors of the frontal lobe often lead to progressive intellectual decline, slowing of mental activity, personality changes, and contralateral grasp reflexes. They may lead to expressive aphasia if the posterior part of the left inferior frontal gyrus is involved. Anosmia may also occur as a consequence of pressure on the olfactory nerve. Precentral lesions may cause focal motor seizures or contralateral pyramidal deficits.

2. Temporal lobe lesions—Tumors of the uncinate region may be manifested by seizures with olfactory or gustatory hallucinations, motor phenomena such as licking or smacking of the lips, and some impairment of external awareness without actual loss of consciousness. Temporal lobe lesions also lead to depersonalization, emotional changes, behavioral disturbances, sensations of déjà vu or jamais vu, micropsia or macropsia (objects appear smaller or larger than they are), visual field defects (crossed upper quadrantanopia), and auditory illusions or hallucinations. Left-sided lesions may lead to dysnomia and receptive aphasia, while right-sided involvement sometimes disturbs the perception of musical notes and melodies.

3. Parietal lobe lesions—Tumors in this location characteristically cause contralateral disturbances of sensation and may cause sensory seizures, sensory loss or inattention, or some combination of these symptoms. The sensory loss is cortical in type and involves postural sensibility and tactile discrimination, so that the appreciation of shape, size, weight, and texture is impaired. Objects placed in the hand may not be recognized (astereognosis). Extensive parietal lobe lesions may produce contralateral hyperpathia and spontaneous pain (thalamic syndrome). Involvement of the optic radiation leads to a contralateral homonymous field defect that sometimes consists solely of lower quadrantanopia. Lesions of the left angular gyrus cause Gerstmann's syndrome (a combination of alexia, agraphia, acalculia, right-left confusion, and finger agnosia), whereas involvement of the left submarginal gyrus causes ideational apraxia. Anosognosia (the denial, neglect, or rejection of a paralyzed limb) is seen in patients with lesions of the nondominant (right) hemisphere. Constructional apraxia and dressing apraxia may also occur with right-sided lesions.

4. Occipital lobe lesions—Tumors of the occipital lobe characteristically produce crossed homonymous hemianopia or a partial field defect. With left-sided or bilateral lesions, there may be visual agnosia both for objects and for colors, while irritative lesions on either side can cause unformed visual hallucinations. Bilateral occipital lobe involvement causes cortical blindness in which there is preservation of pupillary responses to light and lack of awareness of the defect by the patient. There may also be loss of color perception, prosopagnosia (inability to identify a familiar face), simultagnosia (inability to integrate and interpret a composite scene as opposed to its individual elements), and Balint's syndrome (failure to turn the eyes to a particular point in space, despite preservation of spontaneous and reflex eye movements). The denial of blindness or a field defect constitutes Anton's syndrome.

5. Brain stem and cerebellar lesions—Brain stem lesions lead to cranial nerve palsies, ataxia, incoordination, nystagmus, and pyramidal and sensory deficits in the limbs on one or both sides. Intrinsic brain stem tumors, such as gliomas, tend to produce an increase in intracranial pressure only late in their course. Cerebellar tumors produce marked ataxia of the trunk if the vermis cerebelli is involved and ipsilateral appendicular deficits (ataxia, incoordination and hypotonia of the limbs) if the cerebellar hemispheres are affected.

6. False localizing signs—Tumors may lead to neurologic signs other than by direct compression or infiltration, thereby leading to errors of clinical localization. These false localizing signs include third or sixth nerve palsy and bilateral extensor plantar responses produced by herniation syndromes, and an extensor plantar response occurring ipsilateral to a hemispheric tumor as a result of compression of the opposite cerebral peduncle against the tentorium.

B. Imaging

CT scanning or MRI with gadolinium enhancement may detect the lesion and may also define its location, shape, and size; the extent to which normal anatomy is distorted; and the degree of any associated cerebral edema or mass effect. CT scanning is less helpful with tumors in the posterior fossa, but MRI is of particular value there. The characteristic appearance of meningiomas on CT scanning is virtually diagnostic; ie, a lesion in a typical site (parasagittal and sylvian regions, olfactory groove, sphenoidal ridge, tuberculum sellae) that appears as a homogeneous area of increased density in noncontrast CT scans and enhances uniformly with contrast.

Arteriography may show stretching or displacement of normal cerebral vessels by the tumor and the presence of tumor vascularity. The presence of an avascular mass is a nonspecific finding that could be due to tumor, hematoma, abscess, or any space-occupying lesion. In patients with normal hormone levels and an intrasellar mass, angiography is necessary to distinguish with confidence between a pituitary adenoma and an arterial aneurysm.

C. Laboratory and Other Studies

The electroencephalogram provides supporting information concerning cerebral function and may show either a focal disturbance due to the neoplasm or a more diffuse change reflecting altered mental status. Lumbar puncture is rarely necessary; the findings are seldom diagnostic, and the procedure carries the risk of causing a herniation syndrome.

Treatment

Treatment depends on the type and site of the tumor ([Chapter 5](#)).

2. Metastatic Intracranial Tumors

Cerebral Metastases

Metastatic brain tumors present in the same way as other cerebral neoplasms, ie, with increased intracranial pressure, with focal or diffuse disturbance of cerebral function, or with both of these manifestations. Indeed, in patients with a single cerebral lesion, the metastatic nature of the lesion may only become evident on histopathologic examination. In other patients, there is evidence of widespread metastatic disease, or an isolated cerebral metastasis develops during treatment of the primary neoplasm.

The most common source of intracranial metastasis is carcinoma of the lung; other primary sites are the breast, kidney, and gastrointestinal tract. Most cerebral metastases are located supratentorially. Laboratory and radiologic studies used to evaluate patients with metastases are those described for primary neoplasms. They include MRI and CT scanning performed both with and without contrast material. Lumbar puncture is necessary only in patients with suspected carcinomatous meningitis (see below). In patients with verified cerebral metastasis from an unknown primary, investigation is guided by symptoms and signs. In women, mammography is indicated; in men under 50, germ cell origin is sought since both have therapeutic implications.

In patients with only a single cerebral metastasis who are otherwise well, it may be possible to remove the lesion and then treat with irradiation; the latter may also be selected as the sole treatment. In patients with multiple metastases or widespread systemic disease, the prognosis is poor, and treatment is palliative only.

Leptomeningeal Metastases (Carcinomatous Meningitis)

The neoplasms metastasizing most commonly to the leptomeninges are carcinoma of the breast, lymphomas, and leukemia. Leptomeningeal metastases lead to multifocal neurologic deficits, which may be associated with infiltration of cranial and spinal nerve roots, direct invasion of the brain or spinal cord, obstructive hydrocephalus, or some combination of these factors.

The diagnosis is confirmed by examination of the cerebrospinal fluid. Findings may include elevated cerebrospinal fluid pressure, pleocytosis, increased protein concentration, and decreased glucose concentration. Cytologic studies may indicate that malignant cells are present; if not, spinal tap should be repeated at least twice to obtain further samples for analysis.

CT scans showing contrast enhancement in the basal cisterns or showing hydrocephalus without any evidence of a mass lesion support the diagnosis. Gadolinium-enhanced MRI frequently shows enhancing foci in the leptomeninges. Myelography may show deposits on multiple nerve roots.

Treatment is by irradiation to symptomatic areas, combined with intrathecal methotrexate. The long-term prognosis is poor—only about 10% of patients survive for 1 year—and palliative care is therefore important ([Chapter 5](#)).

3. Intracranial Mass Lesions in AIDS Patients

AIDS patients may present with **primary cerebral lymphoma**. This leads to disturbances in cognition or consciousness, focal motor or sensory deficits, aphasia, seizures, and cranial neuropathies. Similar clinical disturbances may result from **cerebral toxoplasmosis**, which is also a common complication in patients with AIDS. Neither CT nor MRI findings distinguish these two disorders, and serologic tests for toxoplasmosis are unreliable in AIDS patients. Accordingly, for neurologically stable patients, a trial of treatment for toxoplasmosis with sulfadiazine (100 mg/kg/d up to 8 g/d in four divided doses) and pyrimethamine (75 mg/d for 3 days, then 25 mg/d) is recommended for 3 weeks; the imaging studies are then repeated, and if any lesion has improved, the regimen is continued indefinitely. If any lesion does not improve, cerebral biopsy is necessary. Primary cerebral lymphoma is treated with whole-brain irradiation.

Cryptococcal meningitis is also a commonly opportunistic infection in AIDS patients. Clinically, it may resemble cerebral toxoplasmosis or lymphoma, but cranial CT scans are usually normal. The diagnosis is made on the basis of cerebrospinal fluid studies, with positive India ink staining in 75-80% and cryptococcal antigen tests in 95% of cases. Treatment is with amphotericin B, sometimes accompanied by flucytosine, as set forth in [Table 36-1](#).

Berger JR: AIDS and the nervous system. In: *Neurology and General Medicine*, 3rd ed. Aminoff MJ (editor). Churchill Livingstone, 2001.

4. Primary & Metastatic Spinal Tumors

Approximately 10% of spinal tumors are intramedullary. Ependymoma is the most common type of intramedullary tumor; the remainder are other types of glioma. Extradurellary tumors may be extradural or intradural in location. Among the primary extradurellary tumors, neurofibromas and meningiomas are relatively common, are benign, and may be intra- or extradural. Carcinomatous metastases, lymphomatous or leukemic deposits, and myeloma are usually extradural; in the case of metastases, the prostate, breast, lung, and kidney are common primary sites.

Tumors may lead to spinal cord dysfunction by direct compression, by ischemia secondary to arterial or venous obstruction, and, in the case of intramedullary lesions, by invasive infiltration.

Clinical Findings

A. Symptoms and Signs

Symptoms usually develop insidiously. Pain is often conspicuous with extradural lesions; is characteristically aggravated by coughing or straining; may be radicular, localized to the back, or felt diffusely in an extremity; and may be accompanied by motor deficits, paresthesias, or numbness, especially in the legs. When sphincter disturbances occur, they are usually particularly disabling. Pain, however, often precedes specific neurologic symptoms from epidural metastases.

Examination may reveal localized spinal tenderness. A segmental lower motor neuron deficit or dermatomal sensory changes (or both) are sometimes found at the level of the lesion, while an upper motor neuron deficit and sensory disturbance are found below it.

B. Imaging

Findings on plain radiography of the spine may be normal but are commonly abnormal when there are metastatic deposits. CT myelography or MRI may be necessary to identify and localize the site of cord compression. The combination of known tumor elsewhere in the body, back pain, and either abnormal plain films of the spine or neurologic signs of cord compression is an indication to perform these studies on an urgent basis. Some clinicians proceed to myelography based solely on new back pain in a cancer patient. If a complete block is present at lumbar myelography, a cisternal myelogram is performed to determine the upper level of the block and to investigate the possibility of block higher in the cord.

C. Laboratory Findings

The cerebrospinal fluid removed at myelography is often xanthochromic and contains a greatly increased protein concentration with normal cell content and glucose concentration.

Treatment

Intramedullary tumors are treated by decompression and surgical excision (when feasible) and by irradiation. The prognosis depends upon the cause and severity of cord compression before it is relieved.

Treatment of epidural spinal metastases consists of irradiation, irrespective of cell type. Dexamethasone is also given in a high dosage (eg, 25 mg four times daily for 3 days, followed by rapid tapering of the dosage, depending on response) to reduce cord swelling and relieve pain. Surgical decompression is reserved for patients with tumors that are unresponsive to irradiation or have previously been irradiated and for cases in which there is some uncertainty about the diagnosis. The long-term outlook is poor, but radiation treatment may at least delay the onset of major disability.

5. Brain Abscess

Essentials of Diagnosis

- Symptoms and signs of expanding intracranial mass.
- May be signs of primary infection or congenital heart disease.
- Fever may be absent.

General Considerations

Brain abscess presents as an intracranial space-occupying lesion and arises as a sequela of disease of the ear or nose, may be a complication of infection elsewhere in the body, or may result from infection introduced intracranially by trauma or surgical procedures. The most common infective organisms are streptococci, staphylococci, and anaerobes; mixed infections are not uncommon. Headache, drowsiness, inattention, confusion, and seizures are early symptoms, followed by signs of increasing intracranial pressure and then a focal neurologic deficit. There may be little or no systemic evidence of infection.

A CT scan of the head characteristically shows an area of contrast enhancement surrounding a low-density core. Similar abnormalities may be found in patients with metastatic neoplasms. MRI findings often permit earlier recognition of focal cerebritis or an abscess. Arteriography indicates the presence of a space-occupying lesion, which appears as an avascular mass with displacement of normal cerebral vessels, but this procedure provides no clue to the nature of the lesion. Examination of the cerebrospinal fluid does not help in diagnosis and may precipitate a herniation syndrome.

Treatment consists of intravenous antibiotics, combined with surgical drainage (aspiration or excision) if necessary to reduce the mass effect, or sometimes to establish the diagnosis. Abscesses smaller than 2 cm can often be cured medically. Broad-spectrum antibiotics are used if the infecting organism is unknown. A common regimen is penicillin G (2 million units every 2 hours intravenously) plus either chloramphenicol (1-2 g intravenously every 6 hours), metronidazole (750 mg intravenously every 6 hours), or both. Nafcillin is added if *Staphylococcus aureus* infection is suspected. Antimicrobial treatment is usually continued parenterally for 6-8 weeks, followed by orally for a further 2-3 weeks. The patient should be monitored by serial CT scans or MRI every 2 weeks and at deterioration. Dexamethasone (4-25 mg four times daily, depending on severity, followed by tapering of dose, depending on response) may reduce any associated edema, but intravenous mannitol is sometimes required.

NONMETASTATIC NEUROLOGIC COMPLICATIONS OF MALIGNANT DISEASE

A variety of nonmetastatic neurologic complications of malignant disease ([Table 40-6](#)) can be recognized. Metabolic encephalopathy due to electrolyte abnormalities, infections, drug overdose, or the failure of some vital organ may be reflected by drowsiness, lethargy, restlessness, insomnia, agitation, confusion, stupor, or coma. The mental changes are usually associated with tremor, asterixis, and multifocal myoclonus. The electroencephalogram is generally diffusely slowed. Laboratory studies are necessary to detect the cause of the encephalopathy, which must then be treated appropriately.

Immune suppression resulting from either the malignant disease or its treatment (eg, by chemotherapy) predisposes patients to brain abscess, progressive multifocal leukoencephalopathy, meningitis, herpes zoster infection, and other opportunistic infectious diseases. Moreover, an overt or occult cerebrospinal fluid fistula, as occurs with some tumors, may also increase the risk of infection. CT scanning aids in the early recognition of a brain abscess, but metastatic brain tumors may have a similar appearance. Examination of the cerebrospinal fluid is essential in the evaluation of patients with meningitis but is of no help in the diagnosis of brain abscess.

Cerebrovascular disorders that cause neurologic complications in patients with systemic cancer include nonbacterial thrombotic endocarditis and septic embolization. Cerebral, subarachnoid, or subdural hemorrhages may occur in patients with myelogenous leukemia and may be found in association with metastatic tumors, especially malignant melanoma. Spinal subdural hemorrhage sometimes occurs after lumbar puncture in patients with marked thrombocytopenia.

Disseminated intravascular coagulation occurs most commonly in patients with acute promyelocytic leukemia or with some adenocarcinomas and is characterized by a fluctuating encephalopathy, often with associated seizures, that frequently progresses to coma or death. There may be few accompanying neurologic signs. Venous sinus thrombosis, which usually presents with convulsions and headaches, may also occur in patients with leukemia or lymphoma. Examination commonly reveals papilledema and focal or diffuse neurologic signs. Anticonvulsants, anticoagulants, and drugs to lower the intracranial pressure may be of value.

Paraneoplastic cerebellar degeneration occurs most commonly in association with carcinoma of the lung. Symptoms may precede those due to the neoplasm itself, which may be undetected for several months or even longer. Typically, there is a pancerebellar syndrome causing dysarthria, nystagmus, and ataxia of the trunk and limbs. The disorder probably has an autoimmune basis. Treatment is of the underlying malignant disease.

Encephalopathy, characterized by impaired recent memory, disturbed affect, hallucinations, and seizures, occurs in some patients with carcinomas. The cerebrospinal fluid is often abnormal. EEGs may show diffuse slow-wave activity, especially over the temporal regions. Pathologic changes are most marked in the inferomedian portions of the temporal lobes. There is no specific treatment.

Malignant disease may be associated with sensorimotor polyneuropathy and less commonly with pure sensory neuropathy (ie, dorsal root ganglionitis) or autonomic neuropathy. A subacute motor neuronopathy may be associated with lymphomas.

Dermatomyositis or a myasthenic syndrome may be seen in patients with underlying carcinoma (see [Chapter 20](#)). The myasthenic syndrome may have an autoimmune basis and differs clinically from myasthenia gravis.

PSEUDOTUMOR CEREBRI (BENIGN INTRACRANIAL HYPERTENSION)

Essentials of Diagnosis

- Headache, worse on straining.
- Visual obscurations or diplopia may occur.
- Level of consciousness may be impaired.
- Other deficits depend on cause of intracranial hypertension or on herniation syndrome.
- Examination reveals papilledema.

General Considerations

Symptoms of pseudotumor cerebri consist of headache, diplopia, and other visual disturbances due to papilledema and abducens nerve dysfunction. Examination reveals the papilledema and some enlargement of the blind spots, but patients otherwise look well. Investigations reveal no evidence of a space-occupying lesion, and the CT scan shows small or normal ventricles. Lumbar puncture confirms the presence of intracranial hypertension, but the cerebrospinal fluid is normal.

There are many causes of pseudotumor cerebri. Thrombosis of the transverse venous sinus as a noninfectious complication of otitis media or chronic mastoiditis is one cause, and sagittal sinus thrombosis may lead to a clinically similar picture. MR venography is helpful in screening for these disorders. Other causes include chronic pulmonary disease, endocrine disturbances such as hypoparathyroidism or Addison's disease, vitamin A toxicity, and the use of tetracycline or oral contraceptives. Cases have also followed withdrawal of corticosteroids after long-term use. In many instances, however, no specific cause can be found, and the disorder remits spontaneously after several months.

Untreated pseudotumor cerebri leads to secondary optic atrophy and permanent visual loss. Acetazolamide (250 mg orally three times daily) reduces formation of cerebrospinal fluid and can be used to start treatment. Oral corticosteroids (eg, prednisone, 60-80 mg daily) may also be necessary. Obese patients should be advised to lose weight. Repeated lumbar puncture to lower the intracranial pressure by removal of cerebrospinal fluid is effective, but pharmacologic approaches to treatment are now more satisfactory. Treatment is monitored by checking visual acuity and visual fields, funduscopic appearance, and pressure of the cerebrospinal fluid.

If medical treatment fails to control the intracranial pressure, surgical placement of a lumboperitoneal or other shunt—or subtemporal decompression or optic nerve sheath fenestration—should be undertaken to preserve vision.

In addition to the above measures, any specific cause of pseudotumor cerebri requires appropriate treatment. Thus, hormone therapy should be initiated if there is an underlying endocrine disturbance. Discontinuing the use of tetracycline, oral contraceptives, or vitamin A will allow for resolution of pseudotumor cerebri due to these agents. If corticosteroid withdrawal is responsible, the medication should be reintroduced and then tapered more gradually.

SELECTED NEUROCUTANEOUS DISEASES

Tuberous Sclerosis

Tuberous sclerosis may occur sporadically or on a familial basis with autosomal dominant inheritance. The responsible gene is located on the long arm of chromosome

9 in at least some cases. Its pathogenesis is unknown. Neurologic presentation is with seizures and progressive psychomotor retardation beginning in early childhood. The cutaneous abnormality, adenoma sebaceum, becomes manifest usually between 5 and 10 years of age and typically consists of reddened nodules on the face (cheeks, nasolabial folds, sides of the nose, and chin) and sometimes on the forehead and neck. Other typical cutaneous lesions include subungual fibromas, shagreen patches (leathery plaques of subepidermal fibrosis, situated usually on the trunk), and leaf-shaped hypopigmented spots. Associated abnormalities include retinal lesions and tumors, benign rhabdomyomas of the heart, lung cysts, benign tumors in the viscera, and bone cysts.

The disease is slowly progressive and leads to increasing mental deterioration. There is no specific treatment, but anticonvulsant drugs may help in controlling seizures.

Neurofibromatosis

Neurofibromatosis may occur either sporadically or on a familial basis with autosomal dominant inheritance. Two distinct forms are recognized: Type 1 (**Recklinghausen's disease**) is characterized by multiple hyperpigmented macules and neurofibromas and type 2 by **eighth nerve tumors**, often accompanied by other intracranial or intraspinal tumors. Among familial cases, the gene for type 1 is located on chromosome 17 and that for type 2 on chromosome 22.

Neurologic presentation is usually with symptoms and signs of tumor. Multiple neurofibromas characteristically are present and may involve spinal or cranial nerves, especially the eighth nerve. Examination of the superficial cutaneous nerves usually reveals palpable mobile nodules. In some cases, there is an associated marked overgrowth of subcutaneous tissues (plexiform neuromas), sometimes with an underlying bony abnormality. Associated cutaneous lesions include axillary freckling and patches of cutaneous pigmentation (cafe au lait spots). Malignant degeneration of neurofibromas occasionally occurs and may lead to peripheral sarcomas. Meningiomas, gliomas (especially optic nerve gliomas), bone cysts, pheochromocytomas, scoliosis, and obstructive hydrocephalus may also occur.

It may be possible to correct disfigurement by plastic surgery. Intraspinal or intracranial tumors and tumors of peripheral nerves should be treated surgically if they are producing symptoms.

Wolkenstein P et al: Quality-of-life impairment in neurofibromatosis type 1: a cross-sectional study of 128 cases. Arch Dermatol 2001;137:1421. [\[PMID: 11708944\]](#)

Sturge-Weber Syndrome

Sturge-Weber syndrome consists of a congenital, usually unilateral, cutaneous capillary angioma involving the upper face, leptomeningeal angiomatosis, and, in many patients, choroidal angioma. It has no sex predilection and usually occurs sporadically. The cutaneous angioma sometimes has a more extensive distribution over the head and neck and is often quite disfiguring, especially if there is associated overgrowth of connective tissue. Focal or generalized seizures are the usual neurologic presentation and may commence at any age. There may be contralateral homonymous hemianopia, hemiparesis and hemisensory disturbance, ipsilateral glaucoma, and mental subnormality. Skull x-rays taken after the first 2 years of life usually reveal gyriform ("tramline") intracranial calcification, especially in the parieto-occipital region, due to mineral deposition in the cortex beneath the intracranial angioma.

Treatment is aimed at controlling seizures pharmacologically. Ophthalmologic advice should be sought concerning the management of choroidal angioma and of increased intraocular pressure.

MOVEMENT DISORDERS

1. Benign Essential (Familial) Tremor

Essentials of Diagnosis

- Postural tremor of hands, head, or voice.
- Family history common.
- May improve temporarily with alcohol.
- No abnormal findings other than tremor.

General Considerations

The cause of benign essential tremor is uncertain, but it is sometimes inherited in an autosomal dominant manner. Tremor may begin at any age and is enhanced by emotional stress. The tremor usually involves one or both hands, the head, or the hands and head, while the legs tend to be spared. Examination reveals no other abnormalities. Ingestion of a small quantity of alcohol commonly provides remarkable but short-lived relief by an unknown mechanism.

Although the tremor may become more conspicuous with time, it generally leads to little disability, and treatment is often unnecessary. Occasionally, it interferes with manual skills and leads to impairment of handwriting. Speech may also be affected if the laryngeal muscles are involved. In such circumstances, propranolol may be helpful but will need to be continued indefinitely in daily doses of 60-240 mg. However, intermittent therapy is sometimes useful in patients whose tremor becomes exacerbated in specific predictable situations. Primidone may be helpful when propranolol is ineffective, but patients with essential tremor are often very sensitive to it. They are therefore started on 50 mg daily, and the daily dose is increased by 50 mg every 2 weeks depending on the response; a maintenance dose of 125 mg three times daily is commonly effective. Occasional patients fail to respond to these measures but are helped by alprazolam (up to 3 mg daily in divided doses), clozapine (30-50 mg twice daily), or mirtazapine (15 or 30 mg at night).

Disabling tremor unresponsive to medical treatment may be helped by contralateral thalamotomy. Unilateral high-frequency thalamic stimulation is an alternative approach that is equally effective, is associated with only mild and transient side effects, and is therefore preferred. Bilateral thalamotomy has significant morbidity, whereas the risks of bilateral stimulation are appreciably lower.

2. Parkinsonism

Essentials of Diagnosis

- Any combination of tremor, rigidity, bradykinesia, progressive postural instability.
- Seborrhea of skin quite common.
- Mild intellectual deterioration may occur.

General Considerations

Parkinsonism is a relatively common disorder that occurs in all ethnic groups, with an approximately equal sex distribution. The most common variety, idiopathic Parkinson's disease (paralysis agitans), begins most often between 45 and 65 years of age.

Etiology

Parkinsonism may rarely occur on a familial basis, and the parkinsonian phenotype may result from mutations of several different genes. Postencephalitic parkinsonism is becoming increasingly rare. Exposure to certain toxins (eg, manganese dust, carbon disulfide) and severe carbon monoxide poisoning may lead to parkinsonism. Typical parkinsonism has occurred in individuals who have taken 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine (MPTP) for recreational purposes. This compound is converted in the body to a neurotoxin that selectively destroys dopaminergic neurons in the substantia nigra. Reversible parkinsonism may develop in patients receiving neuroleptic drugs (see [Chapter 25](#)), reserpine, or metoclopramide. Only rarely is hemiparkinsonism the presenting feature of a progressive space-occupying lesion.

In idiopathic parkinsonism, dopamine depletion due to degeneration of the dopaminergic nigrostriatal system leads to an imbalance of dopamine and acetylcholine, which are neurotransmitters normally present in the corpus striatum. Treatment is directed at redressing this imbalance by blocking the effect of acetylcholine with anticholinergic drugs or by the administration of levodopa, the precursor of dopamine.

Clinical Findings

Tremor, rigidity, bradykinesia, and postural instability are the cardinal features of parkinsonism and may be present in any combination. There may also be a mild decline in intellectual function. The tremor of about four to six cycles per second is most conspicuous at rest, is enhanced by emotional stress, and is often less severe during voluntary activity. Although it may ultimately be present in all limbs, the tremor is commonly confined to one limb or to the limbs on one side for months or years before it becomes more generalized. In some patients, tremor is absent.

Rigidity (an increase in resistance to passive movement) is responsible for the characteristically flexed posture seen in many patients, but the most disabling symptoms of parkinsonism are due to bradykinesia, manifested as a slowness of voluntary movement and a reduction in automatic movements such as swinging of the arms while walking. Curiously, however, effective voluntary activity may briefly be regained during an emergency (eg, the patient is able to leap aside to avoid an oncoming motor vehicle).

Clinical diagnosis of the well-developed syndrome is usually simple. The patient has a relatively immobile face with widened palpebral fissures, infrequent blinking, and a certain fixity of facial expression. Seborrhea of the scalp and face is common. There is often mild blepharoclonus, and a tremor may be present about the mouth and lips. Repetitive tapping (about twice per second) over the bridge of the nose produces a sustained blink response (Myerson's sign). Other findings may include saliva drooling from the mouth, perhaps due to impairment of swallowing; soft and poorly modulated voice; a variable rest tremor and rigidity in some or all of the limbs; slowness of voluntary movements; impairment of fine or rapidly alternating movements; and micrographia. There is typically no muscle weakness (provided that sufficient time is allowed for power to be developed) and no alteration in the tendon reflexes or plantar responses. It is difficult for the patient to arise from a sitting position and begin walking. The gait itself is characterized by small shuffling steps and a loss of the normal automatic arm swing; there may be unsteadiness on turning, difficulty in stopping, and a tendency to fall.

Differential Diagnosis

Diagnostic problems may occur in mild cases, especially if tremor is minimal or absent. For example, mild hypokinesia or slight tremor is commonly attributed to old age. Depression, with its associated expressionless face, poorly modulated voice, and reduction in voluntary activity, can be difficult to distinguish from mild parkinsonism, especially since the two disorders may coexist; in some cases, a trial of antidepressant drug therapy is necessary. The family history, the character of the tremor, and lack of other neurologic signs should distinguish essential tremor from parkinsonism. Wilson's disease can be distinguished by its early age at onset, the presence of other abnormal movements, Kayser-Fleischer rings, and chronic hepatitis, and by increased concentrations of copper in the tissues. Huntington's disease presenting with rigidity and bradykinesia may be mistaken for parkinsonism unless the family history and accompanying dementia are recognized. In Shy-Drager syndrome, the clinical features of parkinsonism are accompanied by autonomic insufficiency (leading to postural hypotension, anhidrosis, disturbances of sphincter control, impotence, etc) and more widespread neurologic deficits (pyramidal, lower motor neuron, or cerebellar signs). In progressive supranuclear palsy, bradykinesia and rigidity are accompanied by a supranuclear disorder of eye movements, pseudobulbar palsy, and axial dystonia. Creutzfeldt-Jakob disease may be accompanied by features of parkinsonism, but dementia is usual, myoclonic jerking is common, ataxia and pyramidal signs may be conspicuous, and the

electroencephalographic findings are usually characteristic. In cortical-basal ganglionic degeneration, parkinsonism is accompanied by conspicuous signs of cortical dysfunction (eg, apraxia, sensory inattention, dementia, aphasia).

Treatment

A. Medical Measures

Drug treatment is not required early in the course of parkinsonism, but the nature of the disorder and the availability of medical treatment for use when necessary should be discussed with the patient.

1. Amantadine—Patients with mild symptoms but no disability may be helped by amantadine. This drug improves all of the clinical features of parkinsonism, but its mode of action is unclear. Side effects include restlessness, confusion, depression, skin rashes, edema, nausea, constipation, anorexia, postural hypotension, and disturbances of cardiac rhythm. However, these are relatively uncommon with the usual dose (100 mg twice daily).

2. Anticholinergic drugs—Anticholinergics are more helpful in alleviating tremor and rigidity than bradykinesia. Treatment is started with a small dose ([Table 24-4](#)) and gradually increased until benefit occurs or side effects limit further increments. If treatment is ineffective, the drug is gradually withdrawn and another preparation then tried.

Common side effects include dryness of the mouth, nausea, constipation, palpitations, cardiac arrhythmias, urinary retention, confusion, agitation, restlessness, drowsiness, mydriasis, increased intraocular pressure, and defective accommodation.

Anticholinergic drugs are contraindicated in patients with prostatic hypertrophy, narrow-angle glaucoma, or obstructive gastrointestinal disease and are often tolerated poorly by the elderly.

3. Levodopa—Levodopa, which is converted in the body to dopamine, improves all of the major features of parkinsonism, including bradykinesia, but does not stop progression of the disorder. The commonest early side effects of levodopa are nausea, vomiting, and hypotension, but cardiac arrhythmias may also occur. Dyskinesias, restlessness, confusion, and other behavioral changes tend to occur somewhat later and become more common with time. Levodopa-induced dyskinesias may take any conceivable form, including chorea, athetosis, dystonia, tremor, tics, and myoclonus. An even later complication is the "on-off phenomenon," in which abrupt but transient fluctuations in the severity of parkinsonism occur unpredictably but frequently during the day. The "off" period of marked bradykinesia has been shown to relate in some instances to falling plasma levels of levodopa. During the "on" phase, dyskinesias are often conspicuous but mobility is increased.

Carbidopa, which inhibits the enzyme responsible for the breakdown of levodopa to dopamine, does not cross the blood-brain barrier. When levodopa is given in combination with carbidopa, the extracerebral breakdown of levodopa is diminished. This reduces the amount of levodopa required daily for beneficial effects, and it lowers the incidence of nausea, vomiting, hypotension, and cardiac irregularities. Such a combination does not prevent the development of the "on-off phenomenon," and the incidence of other side effects (dyskinesias or psychiatric complications) may actually be increased.

Sinemet, a commercially available preparation that contains carbidopa and levodopa in a fixed ratio (1:10 or 1:4), is generally used. Treatment is started with a small dose—eg, one tablet of Sinemet 25/100 (containing 25 mg of carbidopa and 100 mg of levodopa) three times daily—and gradually increased depending on the response. Sinemet CR is a controlled-release formulation (containing 25 or 50 mg of carbidopa and 100 or 200 mg of levodopa). It is sometimes helpful in reducing fluctuations in clinical response to treatment and in reducing the frequency with which medication must be taken. Response fluctuations are also reduced by keeping the daily intake of protein at the recommended minimum and taking the main protein meal as the last meal of the day.

The dyskinesias and behavioral side effects of levodopa are dose-related, but reduction in dose may eliminate any therapeutic benefit.

Levodopa therapy is contraindicated in patients with psychotic illness or narrow-angle glaucoma. It should not be given to patients taking monoamine oxidase A inhibitors or within 2 weeks of their withdrawal, because hypertensive crises may result. Levodopa should be used with care in patients with suspected malignant melanomas or with active peptic ulcers because of concerns that it may exacerbate these disorders.

4. Dopamine agonists—Dopamine agonists act directly on dopamine receptors, and their use in parkinsonism is associated with a lower incidence of the response fluctuations and dyskinesias that occur with long-term levodopa therapy. They were previously reserved for patients who had either become refractory to levodopa or developed the "on-off phenomenon." However, they are now best given either before the introduction of levodopa or with a low dose of Sinemet-25/100 (carbidopa 25 mg and levodopa 100 mg), one tablet three times daily when dopaminergic therapy is first introduced; the dose of Sinemet is kept constant, while the dose of the agonist is gradually increased. Two widely used agonists are bromocriptine and pergolide, which are equally effective ergot derivatives. The initial dosage of bromocriptine is 1.25 mg twice daily; this is increased by 2.5 mg at 2-week intervals until benefit occurs or side effects limit further increments. The usual daily maintenance dose in patients with parkinsonism is between 10 and 30 mg. Pergolide is similarly started in a low dose (eg, 0.05 mg daily) and built up gradually depending on the response and tolerance.

Side effects include anorexia, nausea, vomiting, constipation, postural hypotension, digital vasospasm, cardiac arrhythmias, various dyskinesias and mental disturbances, headache, nasal congestion, erythromelalgia, and pulmonary infiltrates. Bromocriptine and pergolide are contraindicated in patients with a history of mental illness or recent myocardial infarction and are probably best avoided in those with peripheral vascular disease or peptic ulcers as bleeding from the latter has been reported.

Pramipexole and ropinirole are two newer dopamine agonists that are not ergot derivatives. It is not clear that they have any benefit over the older agents, except that ergot-related side effects are unlikely. They are effective in early Parkinson's disease as well as in advanced stages of the disease. In each case, the daily dose is built up gradually. Pramipexole is started at a dosage of 0.125 mg three times daily, and the dose is doubled after 1 week and again after another week; the daily dose is then increased by 0.75 mg at weekly intervals depending on response and tolerance. Most patients require between 0.5 and 1.5 mg three times daily. Ropinirole is begun in a dosage of 0.25 mg three times daily, and the total daily dose is increased at weekly intervals by 0.75 mg until the fourth week and by 1.5 mg thereafter. Most patients require between 2 and 8 mg three times daily for benefit. Adverse effects include fatigue, somnolence, nausea, peripheral edema, dyskinesias, confusion, and postural hypotension. Less commonly, an irresistible urge to sleep may occur, sometimes in inappropriate and hazardous circumstances.

5. Selegiline—Selegiline is a monoamine oxidase B inhibitor that is sometimes used as adjunctive treatment for parkinsonism in patients receiving levodopa. By inhibiting the metabolic breakdown of dopamine, selegiline has been used to improve fluctuations or declining response to levodopa. In general, however, the response to treatment with it has been disappointing. The drug is taken in a standard dose of 5 mg with breakfast and 5 mg with lunch. It may increase any adverse effects of levodopa.

There are reasons to believe that selegiline may arrest the progression of Parkinson's disease. Studies have failed to establish this conclusively, but this remains an important consideration for patients who are young or have mild disease.

6. COMT inhibitors—Catecholamine-O-methyltransferase inhibitors reduce the metabolism of levodopa to 3-O-methyldopa and thereby alter the plasma pharmacokinetics of levodopa, leading to more sustained plasma levels and more constant dopaminergic stimulation of the brain. Two such agents, tolcapone and entacapone, are currently available and may be used as an adjunct to levodopa-carbidopa in patients with response fluctuations or an otherwise inadequate response and who either have failed with other adjunctive therapies or are not candidates for such therapies. Treatment results in reduced response fluctuations, with a greater period of responsiveness to administered levodopa. Tolcapone is given in a dosage of 100 mg or 200 mg three times daily, and entacapone is given as 200 mg with each dose of Sinemet (levodopa-carbidopa). With either preparation, the dose of Sinemet taken concurrently may have to be reduced by up to one-third to avoid side effects such as dyskinesias, confusion, hypotension, and syncope. Diarrhea is sometimes troublesome. Because rare cases of fulminant hepatic failure have followed its use, tolcapone should be avoided in patients with preexisting liver disease. Serial liver function tests should be performed at 2-week intervals for the first year and at longer intervals thereafter in patients receiving the drug—as recommended by the manufacturer. Hepatotoxicity has not been reported with entacapone, and serial liver function tests are not required.

7. Atypical antipsychotics—Confusion and psychotic symptoms, which may be iatrogenic, often respond to atypical antipsychotic agents, which have few extrapyramidal side effects and do not block the effects of dopaminergic medication. Olanzapine, quetiapine, and risperidone may be tried, but the most effective of these agents is clozapine, a dibenzodiazepine derivative. Clozapine may rarely cause marrow suppression, and weekly blood counts are therefore necessary for patients taking it. The patient is started on 6.25 mg at bedtime and the dosage increased to 25-100 mg/d as needed. In low doses, it may also improve iatrogenic dyskinesias.

B. General Measures

Physical therapy or speech therapy helps many patients. The quality of life can often be improved by the provision of simple aids to daily living, eg, rails or banisters placed strategically about the home, special table cutlery with large handles, nonslip rubber table mats, and devices to amplify the voice.

C. Surgical Measures

Thalamotomy or pallidotomy may be helpful for patients who become unresponsive to medical treatment or have intolerable side effects from antiparkinsonian agents,

especially if they have no evidence of diffuse vascular disease or significant cognitive decline. Surgery should generally be confined to one side because the morbidity is considerably greater after bilateral procedures. Surgical implantation of adrenal medullary or fetal substantia nigra tissue into the caudate nucleus has been reported to benefit some patients, but other investigators have failed to substantiate such claims or have found only modest benefits or major adverse effects, and the procedure is still being evaluated.

D. Brain Stimulation

High-frequency thalamic stimulation is effective in suppressing the rest tremor of Parkinson's disease, and chronic bilateral stimulation of the subthalamic nuclei or globus pallidus internus may benefit all the major features of the disease. Electrical stimulation of the brain has the advantage of being reversible and of causing minimal or no damage to the brain, and its utility is being explored in several centers. There is no evidence that the natural history of Parkinson's disease is affected.

3. Huntington's Disease

Essentials of Diagnosis

- Gradual onset and progression of chorea and dementia or behavioral change.
- Family history of the disorder.
- Responsible gene identified on chromosome 4.

General Considerations

Huntington's disease is characterized by chorea and dementia. It is inherited in an autosomal dominant manner and occurs throughout the world, in all ethnic groups, with a prevalence rate of about 5 per 100,000. The gene responsible for the disease has been located on the short arm of chromosome No. 4. At 4p16.3 there is an expanded and unstable CAG trinucleotide repeat.

Clinical Findings

Clinical onset is usually between 30 and 50 years of age. The disease is progressive and usually leads to a fatal outcome within 15-20 years. The initial symptoms may consist of either abnormal movements or intellectual changes, but ultimately both occur. The earliest mental changes are often behavioral, with irritability, moodiness, antisocial behavior, or a psychiatric disturbance, but a more obvious dementia subsequently develops. The dyskinesia may initially be no more than an apparent fidgetiness or restlessness, but eventually choreiform movements and some dystonic posturing occur. Progressive rigidity and akinesia (rather than chorea) sometimes occur in association with dementia, especially in cases with childhood onset. CT scanning usually demonstrates cerebral atrophy and atrophy of the caudate nucleus in established cases. MRI and positron emission tomography (PET) have shown reduced glucose utilization in an anatomically normal caudate nucleus.

Chorea developing with no family history of choreoathetosis should not be attributed to Huntington's disease, at least not until other causes of chorea have been excluded clinically and by appropriate laboratory studies. In younger patients, self-limiting Sydenham's chorea develops after group A streptococcal infections on rare occasions. If a patient presents solely with progressive intellectual failure, it may not be possible to distinguish Huntington's disease from other causes of dementia unless there is a characteristic family history or a dyskinesia develops.

A clinically similar autosomal dominant disorder (**dentatorubral-pallidolysian atrophy**), manifested by chorea, dementia, ataxia, and myoclonic epilepsy, is uncommon except in persons of Japanese ancestry. It is due to a mutant gene mapping to 12p13.31. Treatment is as for Huntington's disease.

Treatment

There is no cure for Huntington's disease; progression cannot be halted; and treatment is purely symptomatic. The reported biochemical changes suggest a relative underactivity of neurons containing gamma-aminobutyric acid (GABA) and acetylcholine or a relative overactivity of dopaminergic neurons. Treatment with drugs blocking dopamine receptors, such as phenothiazines or haloperidol, may control the dyskinesia and any behavioral disturbances. Haloperidol treatment is usually begun with a dose of 1 mg once or twice daily, which is then increased every 3 or 4 days depending on the response. Tetrabenazine, a drug that depletes central monoamines, is widely used in Europe to treat dyskinesia but is not available in the United States. Reserpine is similar in its actions to tetrabenazine and may be helpful; the daily dose is built up gradually to between 2 and 5 mg, depending on the response. Behavioral disturbances may respond to clozapine. Attempts to compensate for the relative GABA deficiency by enhancing central GABA activity or to compensate for the relative cholinergic underactivity by giving choline chloride have not been therapeutically helpful. High levels of somatostatin (a neuropeptide) have recently been reported in certain areas of the brain in patients with Huntington's disease, and the therapeutic response to cysteamine (a selective depleter of somatostatin in the brain) is currently under study. Neuroprotective strategies are also being explored.

Offspring should be offered genetic counseling. Genetic testing permits presymptomatic detection and definitive diagnosis of the disease.

4. Idiopathic Torsion Dystonia

Essentials of Diagnosis

- Dystonic movements and postures.
- Normal birth and developmental history. No other neurologic signs.
- Investigations (including CT scan or MRI) reveal no cause of dystonia.

General Considerations

Idiopathic torsion dystonia may occur sporadically or on a hereditary basis, with autosomal dominant, autosomal recessive, and X-linked recessive modes of transmission. The responsible gene is located at 9q34 (and has been named *DYT1*) and involves a unique mutation consisting of a GAG deletion in the dominantly inherited disorder, and maps to the long arm of the X chromosome in the X-linked recessive form; the responsible gene in the autosomal recessive disorder is unknown. Other autosomal dominant forms have also been recognized, with different or unidentified genetic loci. Symptoms may begin in childhood or later and persist throughout life.

Clinical Findings

The disorder is characterized by the onset of abnormal movements and postures in a patient with a normal birth and developmental history, no relevant past medical illness, and no other neurologic signs. Investigations (including CT scan) reveal no cause for the abnormal movements. Dystonic movements of the head and neck may take the form of torticollis, blepharospasm, facial grimacing, or forced opening or closing of the mouth. The limbs may also adopt abnormal but characteristic postures. The age at onset influences both the clinical findings and the prognosis. With onset in childhood, there is usually a family history of the disorder, symptoms commonly commence in the legs, and progression is likely until there is severe disability from generalized dystonia. In contrast, when onset is later, a positive family history is unlikely, initial symptoms are often in the arms or axial structures, and severe disability does not usually occur, although generalized dystonia may ultimately develop in some patients. If all cases are considered together, about one-third of patients eventually become so severely disabled that they are confined to chair or bed, while

another one-third are affected only mildly.

Before a diagnosis of idiopathic torsion dystonia is made, it is imperative to exclude other causes of dystonia. For example, perinatal anoxia, birth trauma, and kernicterus are common causes of dystonia, but abnormal movements usually then develop before the age of 5, the early development of the patient is usually abnormal, and a history of seizures is not unusual. Moreover, examination may reveal signs of mental retardation or pyramidal deficit in addition to the movement disorder. Dystonic posturing may also occur in Wilson's disease, Huntington's disease, or parkinsonism; as a sequela of encephalitis lethargica or previous neuroleptic drug therapy; and in certain other disorders. In these cases, diagnosis is based on the history and accompanying clinical manifestations.

Treatment

Idiopathic torsion dystonia usually responds poorly to drugs. Levodopa, diazepam, baclofen, carbamazepine, amantadine, or anticholinergic medication (in high dosage) is occasionally helpful; if not, a trial of treatment with phenothiazines or haloperidol may be worthwhile. In each case, the dose has to be individualized, depending on response and tolerance. However, the doses of these latter drugs that are required for benefit lead usually to mild parkinsonism. Stereotactic thalamotomy is sometimes helpful in patients with predominantly unilateral dystonia, especially when this involves the limbs.

A distinct variety of dominantly inherited dystonia, mapping to a genetic locus on chromosome 14q, is remarkably responsive to levodopa.

Bressman SB et al: Diagnostic criteria for dystonia in DYT1 families. *Neurology* 2002;59:1780. [PMID: 12473770]

Kanovsky P: Dystonia: a disorder of motor programming or motor execution? *Mov Disord* 2002;17:1143. [PMID: 12465050]

5. Focal Torsion Dystonia

A number of the dystonic manifestations that occur in idiopathic torsion dystonia may also occur as isolated phenomena. They are best regarded as focal dystonias that either occur as formes frustes of idiopathic torsion dystonia in patients with a positive family history or represent a focal manifestation of the adult-onset form of that disorder when there is no family history. Mapping of responsible genes to chromosome 8 (*DYT6*) and chromosome 18 (*DYT7*) has been reported in some instances of cervical or cranial dystonia. Medical treatment is generally unsatisfactory. A trial of the drugs used in idiopathic torsion dystonia is worthwhile, however, since a few patients do show some response. In addition, with restricted dystonias such as blepharospasm or torticollis, local injection of botulinum A toxin into the overactive muscles may produce worthwhile benefit for several weeks or months and can be repeated as needed.

Both blepharospasm and oromandibular dystonia may occur as an isolated focal dystonia. The former is characterized by spontaneous involuntary forced closure of the eyelids for a variable interval. Oromandibular dystonia is manifested by involuntary contraction of the muscles about the mouth causing, for example, involuntary opening or closing of the mouth, roving or protruding tongue movements, and retraction of the platysma.

Spasmodic torticollis, usually with onset between 25 and 50 years of age, is characterized by a tendency for the neck to twist to one side. This initially occurs episodically, but eventually the neck is held to the side. Spontaneous resolution may occur in the first year or so. The disorder is otherwise usually lifelong. Selective section of the spinal accessory nerve and the upper cervical nerve roots is sometimes helpful if medical treatment is unsuccessful. Local injection of botulinum A toxin provides benefit in most cases.

Writer's cramp is characterized by dystonic posturing of the hand and forearm when the hand is used for writing and sometimes when it is used for other tasks, eg, playing the piano, using a screwdriver or eating utensils. Drug treatment is usually unrewarding, and patients are often best advised to learn to use the other hand for activities requiring manual dexterity. Injections of botulinum A toxin are helpful in some instances.

6. Myoclonus

Occasional myoclonic jerks may occur in anyone, especially when drifting into sleep. General or multifocal myoclonus is common in patients with idiopathic epilepsy and is especially prominent in certain hereditary disorders characterized by seizures and progressive intellectual decline, such as the lipid storage diseases. It is also a feature of various rare degenerative disorders, notably Ramsay Hunt syndrome, and is common in subacute sclerosing panencephalitis and Creutzfeldt-Jakob disease. Generalized myoclonic jerking may accompany uremic and other metabolic encephalopathies, result from levodopa therapy, occur in alcohol or drug withdrawal states, or follow anoxic brain damage. It also occurs on a hereditary or sporadic basis as an isolated phenomenon in otherwise healthy subjects.

Segmental myoclonus is a rare manifestation of a focal spinal cord lesion. It may also be the clinical expression of **epilepsia partialis continua**, a disorder in which a repetitive focal epileptic discharge arises in the contralateral sensorimotor cortex, sometimes from an underlying structural lesion. An electroencephalogram is often helpful in clarifying the epileptic nature of the disorder, and CT or MRI scan may reveal the causal lesion.

Myoclonus may respond to certain anticonvulsant drugs, especially valproic acid, or to one of the benzodiazepines, particularly clonazepam (Table 24-2). It may also respond to piracetam (up to 16.8 g daily). Myoclonus following anoxic brain damage is often responsive to oxitriptan (5-hydroxytryptophan), an investigational agent that is the precursor of serotonin, and sometimes to clonazepam. Oxitriptan is given in gradually increasing doses up to 1-1.5 mg daily. In patients with segmental myoclonus, a localized lesion should be searched for and treated appropriately.

7. Wilson's Disease

In this metabolic disorder, abnormal movement and posture may occur with or without coexisting signs of liver involvement. It is discussed in Chapter 15.

8. Drug-Induced Abnormal Movements

Phenothiazines and butyrophenones may produce a wide variety of abnormal movements, including parkinsonism, akathisia (ie, motor restlessness), acute dystonia, chorea, and tardive dyskinesia. These complications are discussed in Chapter 25. Chorea may also develop in patients receiving levodopa, bromocriptine, anticholinergic drugs, phenytoin, carbamazepine, lithium, amphetamines, or oral contraceptives, and it resolves with withdrawal of the offending substance. Similarly, dystonia may be produced by levodopa, bromocriptine, lithium, metoclopramide, or carbamazepine; and parkinsonism by reserpine, tetrabenazine, and metoclopramide. Postural tremor may occur with a variety of drugs, including epinephrine, isoproterenol, theophylline, caffeine, lithium, thyroid hormone, tricyclic antidepressants, and valproic acid.

9. Gilles de la Tourette's Syndrome

Essentials of Diagnosis

- Multiple motor and phonic tics.
- Symptoms begin before age 21 years.
- Tics occur frequently for at least 1 year.
- Tics vary in number, frequency, and nature over time.

Clinical Findings

Motor tics are the initial manifestation in 80% of cases and most commonly involve the face whereas in the remaining 20%, the initial symptoms are phonic tics; all patients ultimately develop a combination of different motor and phonic tics. These are noted first in childhood, generally between the ages of 2 and 15. Motor tics occur especially about the face, head, and shoulders (eg, sniffing, blinking, frowning, shoulder shrugging, head thrusting, etc). Phonic tics commonly consist of grunts, barks, hisses, throat-clearing, coughs, etc, but sometimes also of verbal utterances including coprolalia (obscene speech). There may also be echolalia (repetition of the speech of others), echopraxia (imitation of others' movements), and palilalia (repetition of words or phrases). Some tics may be self-mutilating in nature, such as nail-biting, hair-pulling, or biting of the lips or tongue. The disorder is chronic, but the course may be punctuated by relapses and remissions. Obsessive-compulsive behaviors are commonly associated and may be more disabling than the tics themselves.

Examination usually reveals no abnormalities other than the tics. In addition to obsessive-compulsive behavior disorders, psychiatric disturbances may occur because of the associated cosmetic and social embarrassment. Electroencephalography may show minor nonspecific abnormalities of no diagnostic relevance.

The diagnosis of the disorder is often delayed for years, the tics being interpreted as psychiatric illness or some other form of abnormal movement. Patients are thus often subjected to unnecessary treatment before the disorder is recognized. The tic-like character of the abnormal movements and the absence of other neurologic signs should differentiate this disorder from other movement disorders presenting in childhood. Wilson's disease, however, can simulate the condition and should be

excluded.

Treatment

Treatment is symptomatic and may need to be continued indefinitely. Haloperidol is generally regarded as the drug of choice. It is started in a low daily dose (0.25 mg) that is gradually increased (by 0.25 mg every 4 or 5 days) until there is maximum benefit with a minimum of side effects or until side effects limit further increments. A total daily dose of between 2 and 8 mg is usually optimal, but higher doses are sometimes necessary. Treatment with clonazepam (in a dose that depends on response and tolerance) or clonidine (2-5 ug/kg/d) may also be helpful, and it seems sensible to begin with one of these drugs in order to avoid some of the long-term extrapyramidal side effects of haloperidol. Phenothiazines, such as fluphenazine (2-15 mg daily), have been used, but patients unresponsive to haloperidol are usually unresponsive to these as well.

Pimozide, an oral dopamine-blocking drug related to haloperidol, may be helpful in patients who cannot tolerate or have not responded to haloperidol. Treatment is started with 1 mg daily and the daily dose increased by 1-2 mg every 10 days; the average dose is between 7 and 16 mg daily.

Treatment with risperidone, calcium channel blockers, tetrabenazene, or clomipramine has yielded mixed results.

Jankovic J: Tourette's syndrome. N Engl J Med 2001;345:1184. [\[PMID: 11642235\]](#)

DEMENTIA

Dementia, the symptom complex of progressive global impairment of intellectual function, is a major medical, social, and economic problem that is worsening as the number of elderly people in the general population increases. It is discussed in [Chapter 4](#), and the only point to be reiterated here is the importance of recognizing early any treatable or reversible causes of dementia, such as normal-pressure hydrocephalus, intracranial mass lesions, vascular disease, hypothyroidism, thiamin or vitamin B₁₂ deficiency, Wilson's disease, hepatic or renal failure, neurosyphilis, and the chronic meningitides.

MULTIPLE SCLEROSIS

Essentials of Diagnosis

- Episodic neurologic symptoms.
- Patient usually under 55 years of age at onset.
- Single pathologic lesion cannot explain clinical findings.
- Multiple foci best visualized by MRI.

General Considerations

This common neurologic disorder, which probably has an autoimmune basis, has its greatest incidence in young adults. Epidemiologic studies indicate that multiple sclerosis is much more common in persons of western European lineage who live in temperate zones. No population with a high risk for multiple sclerosis exists between latitudes 40 °N and 40 °S. Genetic, dietary, and climatic factors cannot account for these differences. Nevertheless, a genetic susceptibility to the disease is likely, based on twin studies, familial cases, and an association with specific HLA antigens (HLA-DR2). Pathologically, focal—often perivenular—areas of demyelination with reactive gliosis are found scattered in the white matter of brain and spinal cord and in the optic nerves.

Clinical Findings

A. Symptoms and Signs

The common initial presentation is weakness, numbness, tingling, or unsteadiness in a limb; spastic paraparesis; retrobulbar neuritis; diplopia; disequilibrium; or a sphincter disturbance such as urinary urgency or hesitancy. Symptoms may disappear after a few days or weeks, although examination often reveals a residual deficit.

Several forms of the disease are recognized. In most patients, there is an interval of months or years after the initial episode before new symptoms develop or the original ones recur (**relapsing-remitting disease**). Eventually, however, relapses and usually incomplete remissions lead to increasing disability, with weakness, spasticity, and ataxia of the limbs, impaired vision, and urinary incontinence. The findings on examination at this stage commonly include optic atrophy, nystagmus, dysarthria, and pyramidal, sensory, or cerebellar deficits in some or all of the limbs. In some of these patients, the clinical course changes so that a steady deterioration occurs, unrelated to acute relapses (**secondary progressive disease**).

Less commonly, symptoms are steadily progressive from their onset, and disability develops at a relatively early stage (**primary progressive disease**). The diagnosis cannot be made with confidence unless the total clinical picture indicates involvement of different parts of the central nervous system at different times.

A number of factors (eg, infection, trauma) may precipitate or trigger exacerbations. Relapses are also more likely during the 2 or 3 months following pregnancy, possibly because of the increased demands and stresses that occur in the postpartum period.

B. Imaging

MRI of the brain or cervical cord is often helpful in demonstrating the presence of a multiplicity of lesions. CT scans are less helpful.

In patients presenting with myelopathy alone and in whom there is no clinical or laboratory evidence of more widespread disease, myelography or MRI may be necessary to exclude a congenital or acquired surgically treatable lesion. The foramen magnum region must be visualized to exclude the possibility of Arnold-Chiari malformation, in which parts of the cerebellum and the lower brain stem are displaced into the cervical canal and produce mixed pyramidal and cerebellar deficits in the limbs.

C. Laboratory and Other Studies

A definitive diagnosis can never be based solely on the laboratory findings. If there is clinical evidence of only a single lesion in the central nervous system, multiple sclerosis cannot properly be diagnosed unless it can be shown that other regions are affected subclinically. The electrocerebral responses evoked by monocular visual stimulation with a checkerboard pattern stimulus, by monaural click stimulation, and by electrical stimulation of a sensory or mixed peripheral nerve have been used to detect subclinical involvement of the visual, brain stem auditory, and somatosensory pathways, respectively. Other disorders may also be characterized by multifocal electrophysiologic abnormalities.

There may be mild lymphocytosis or a slightly increased protein concentration in the cerebrospinal fluid, especially soon after an acute relapse. Elevated IgG in cerebrospinal fluid and discrete bands of IgG (oligoclonal bands) are present in many patients. The presence of such bands is not specific, however, since they have been found in a variety of inflammatory neurologic disorders and occasionally in patients with vascular or neoplastic disorders of the nervous system.

D. Diagnosis

Multiple sclerosis should not be diagnosed unless there is evidence that two or more different regions of the central white matter have been affected at different times. A diagnosis of clinically definite disease can be made in patients with a relapsing-remitting course and evidence on examination of at least two lesions involving different regions of the central white matter. The diagnosis is probable in patients with multifocal white matter disease but only one clinical attack, or with a history of at least two clinical attacks but signs of only a single lesion.

Treatment

At least partial recovery from acute exacerbations can reasonably be expected, but further relapses may occur without warning, and there is no means of preventing progression of the disorder. Some disability is likely to result eventually, but about half of all patients are without significant disability even 10 years after onset of symptoms.

Recovery from acute relapses may be hastened by treatment with corticosteroids, but the extent of recovery is unchanged. A high dose (eg, prednisone, 60 or 80 mg) is given daily for 1 week, after which medication is tapered over the following 2 or 3 weeks. Such a regimen is often preceded by methylprednisolone, 1 g intravenously for 3 days. Long-term treatment with steroids provides no benefit and does not prevent further relapses.

In patients with relapsing-remitting or secondary progressive disease, treatment with beta interferon or with daily subcutaneous administration of glatiramer acetate reduces the frequency of exacerbations. Several recent studies have suggested that immunosuppressive therapy with cyclophosphamide, azathioprine, methotrexate,

cladribine, or mitoxantrone may help to arrest the course of secondary progressive multiple sclerosis. The evidence of benefit is incomplete, however. There is little evidence that plasmapheresis enhances any beneficial effects of immunosuppression in multiple sclerosis. Intravenous immunoglobulins may reduce the clinical attack rate in relapsing-remitting disease, but the available studies are inadequate to permit treatment recommendations.

Treatment for spasticity (see below) and for neurogenic bladder may be needed in advanced cases. Excessive fatigue must be avoided, and patients should rest during periods of acute relapse.

Goodin DS et al: Disease modifying therapies in multiple sclerosis: subcommittee of the American Academy of Neurology and the MS Council for Clinical Practice Guidelines. *Neurology* 2002;58;169. [\[PMID: 11805241\]](#)

VITAMIN E DEFICIENCY

Vitamin E deficiency may produce a disorder somewhat similar to Friedreich's ataxia (see below). There is spinocerebellar degeneration involving particularly the posterior columns of the spinal cord and leading to limb ataxia, sensory loss, absent tendon reflexes, slurring of speech, and, in some cases, pigmentary retinal degeneration. The disorder may occur as a consequence of malabsorption or on a hereditary basis. Treatment is with alpha-tocopheryl acetate (eg, Aquasol E capsules or drops) as discussed in [Chapter 29](#).

SPASTICITY

The term "spasticity" is commonly used for an upper motor neuron deficit, but it properly refers to a velocity-dependent increase in resistance to passive movement that affects different muscles to a different extent, is not uniform in degree throughout the range of a particular movement, and is commonly associated with other features of pyramidal deficit. It is often a major complication of stroke, cerebral or spinal injury, static perinatal encephalopathy, and multiple sclerosis.

Physical therapy with appropriate stretching programs is important during rehabilitation after the development of an upper motor neuron lesion and in subsequent management of the patient. The aim is to prevent joint and muscle contractures and perhaps to modulate spasticity.

Drug management is important also, but treatment may increase functional disability when increased extensor tone is providing additional support for patients with weak legs. Dantrolene weakens muscle contraction by interfering with the role of calcium. It is best avoided in patients with poor respiratory function or severe myocardial disease. Treatment is begun with 25 mg once daily, and the daily dose is built up by 25 mg increments every 3 days, depending on tolerance, to a maximum of 100 mg four times daily. Side effects include diarrhea, nausea, weakness, hepatic dysfunction (that may rarely be fatal, especially in women older than 35), drowsiness, light-headedness, and hallucinations.

Lioresal is an effective drug for treating spasticity of spinal origin and painful flexor (or extensor) spasms. The maximum recommended daily dose is 80 mg; treatment is started with a dose of 5 or 10 mg twice daily and then built up gradually. Side effects include gastrointestinal disturbances, lassitude, fatigue, sedation, unsteadiness, confusion, and hallucinations. Diazepam may modify spasticity by its action on spinal interneurons and perhaps also by influencing supraspinal centers, but effective doses often cause intolerable drowsiness and vary with different patients. Tizanidine, a centrally acting α_2 -adrenergic agonist, is as effective as these other agents but is probably better tolerated. The daily dose is built up gradually, usually to 8 mg taken three times daily. Side effects include sedation, lassitude, hypotension, and dryness of the mouth.

Motor-point blocks by intramuscular phenol have been used to reduce spasticity selectively in one or a few important muscles and may permit return of function in patients with incomplete myelopathies. Intramuscular administration of botulinum toxin may also be helpful. Intrathecal injection of phenol or absolute alcohol may be helpful in more severe cases, but greater selectivity can be achieved by nerve root or peripheral nerve neurolysis. These procedures should not be undertaken until the spasticity syndrome is fully evolved, ie, only after about 1 year or so, and only if long-term drug treatment either has been unhelpful or carries a significant risk to the patient.

In patients with severe spasticity and limited use of the legs, a surgically implanted lioresal pump may provide significant relief and improve hygiene. A number of surgical procedures, eg, adductor or heel cord tenotomy, may also help in the management of spasticity and facilitate patient management. For example, obturator neurectomy is helpful in patients with marked adductor spasms that interfere with personal hygiene or cause gait disturbances. Posterior rhizotomy reduces spasticity, but its effect may be short-lived, whereas anterior rhizotomy produces permanent wasting and weakness in the muscles that are denervated.

Spasticity may be exacerbated by decubitus ulcers, urinary or other infections, and nociceptive stimuli.

Auff E et al: Clinical applications of botulinum toxin type A. *Eur J Neurol* 1999;6:Suppl 4.

MYELOPATHIES IN AIDS

A variety of myelopathies may occur in patients with AIDS. These are discussed in [Chapter 31](#).

MYELOPATHY OF HUMAN T CELL LEUKEMIA VIRUS

Human T cell leukemia virus (HTLV-1), a human retrovirus, is transmitted by breast feeding, sexual contact, blood transfusion, and contaminated needles. Most patients are asymptomatic, but after a variable latent period (may be as long as several years) a myelopathy develops in some instances. The MRI, electrophysiologic, and cerebrospinal fluid findings are similar to those of multiple sclerosis, but HTLV-1 antibodies are present in serum and spinal fluid. There is no specific treatment.

Engstrom JW: HTLV-I infection and the nervous system. In: *Neurology and General Medicine*, 3rd ed. Aminoff MJ (editor). Churchill Livingstone, 2001.

SUBACUTE COMBINED DEGENERATION OF THE SPINAL CORD

Subacute combined degeneration of the spinal cord is due to vitamin B₁₂ deficiency, such as occurs in pernicious anemia. It is characterized by myelopathy with predominant pyramidal and posterior column deficits, sometimes in association with polyneuropathy, mental changes, or optic neuropathy. Megaloblastic anemia may also occur, but this does not parallel the neurologic disorder, and the former may be obscured if folic acid supplements have been taken. Treatment is with vitamin B₁₂. For pernicious anemia, a convenient therapeutic regimen is 100 mg cyanocobalamin intramuscularly daily for 1 week, then weekly for 1 month, and then monthly for the remainder of the patient's life.

WERNICKE'S ENCEPHALOPATHY

Wernicke's encephalopathy is characterized by confusion, ataxia, and nystagmus leading to ophthalmoplegia (lateral rectus muscle weakness, conjugate gaze palsies); peripheral neuropathy may also be present. It is due to thiamin deficiency and in the United States occurs most commonly in alcoholics. It may also occur in patients with AIDS. In suspected cases, thiamin (50 mg) is given intravenously immediately and then intramuscularly on a daily basis until a satisfactory diet can be ensured. Intravenous glucose given before thiamin may precipitate the syndrome or worsen the symptoms. The diagnosis is confirmed by the response in 1 or 2 days to treatment, which must not be delayed while laboratory confirmation is obtained.

Messing RO: Alcohol and the nervous system. In: *Neurology and General Medicine*, 3rd ed. Aminoff MJ (editor). Churchill Livingstone, 2001.

STUPOR & COMA

The patient who is stuporous is unresponsive except when subjected to repeated vigorous stimuli, while the comatose patient is unarousable and unable to respond to external events or inner needs, although reflex movements and posturing may be present.

Coma is a major complication of serious central nervous system disorders. It can result from seizures, hypothermia, metabolic disturbances, or structural lesions causing bilateral cerebral hemispheric dysfunction or a disturbance of the brain stem reticular activating system. A mass lesion involving one cerebral hemisphere may cause coma by compression of the brain stem.

Assessment & Emergency Measures

The diagnostic workup of the comatose patient must proceed concomitantly with management. Supportive therapy for respiration or blood pressure is initiated; in hypothermia, all vital signs may be absent and all such patients should be rewarmed before the prognosis is assessed.

The patient can be positioned on one side with the neck partly extended, dentures removed, and secretions cleared by suction; if necessary, the patency of the airways is maintained with an oropharyngeal airway. Blood is drawn for serum glucose, electrolyte, and calcium levels; arterial blood gases; liver and renal function tests; and toxicologic studies as indicated. Dextrose 50% (25 g), naloxone (0.4-1.2 mg), and thiamine (50 mg) are given intravenously.

Further details are then obtained from attendants of the patient's medical history, the circumstances surrounding the onset of coma, and the time course of subsequent events. Abrupt onset of coma suggests subarachnoid hemorrhage, brain stem stroke, or intracerebral hemorrhage, whereas a slower onset and progression occur with other structural or mass lesions. A metabolic cause is likely with a preceding intoxicated state or agitated delirium. On examination, attention is paid to the behavioral response to painful stimuli, the pupils and their response to light, the position of the eyes and their movement in response to passive movement of the head and ice-water caloric stimulation, and the respiratory pattern.

A. Response to Painful Stimuli

Purposive limb withdrawal from painful stimuli implies that sensory pathways from and motor pathways to the stimulated limb are functionally intact. Unilateral absence of responses despite application of stimuli to both sides of the body in turn implies a corticospinal lesion; bilateral absence of responsiveness suggests brain stem involvement, bilateral pyramidal tract lesions, or psychogenic unresponsiveness. Inappropriate responses may also occur. Decorticate posturing may occur with lesions of the internal capsule and rostral cerebral peduncle, decerebrate posturing with dysfunction or destruction of the midbrain and rostral pons, and decerebrate posturing in the arms accompanied by flaccidity or slight flexor responses in the legs in patients with extensive brain stem damage extending down to the pons at the trigeminal level.

B. Ocular Findings

1. Pupils—Hypothalamic disease processes may lead to unilateral Horner's syndrome, while bilateral diencephalic involvement or destructive pontine lesions may lead to small but reactive pupils. Ipsilateral pupillary dilation with no direct or consensual response to light occurs with compression of the third cranial nerve, eg, with uncal herniation. The pupils are slightly smaller than normal but responsive to light in many metabolic encephalopathies; however, they may be fixed and dilated following overdosage with atropine, scopolamine, or glutethimide, and pinpoint (but responsive) with opiates. Pupillary dilation for several hours following cardiopulmonary arrest implies a poor prognosis.

2. Eye movements—Conjugate deviation of the eyes to the side suggests the presence of an ipsilateral hemispheric lesion or a contralateral pontine lesion. A mesencephalic lesion leads to downward conjugate deviation. Dysconjugate ocular deviation in coma implies a structural brain stem lesion unless there was preexisting strabismus.

The oculomotor responses to passive head turning and to caloric stimulation relate to each other and provide complementary information. In response to brisk rotation of the head from side to side and to flexion and extension of the head, normally conscious patients with open eyes do not exhibit contraversive conjugate eye deviation (doll's-head eye response) unless there is voluntary visual fixation or bilateral frontal pathology. With cortical depression in lightly comatose patients, a brisk doll's-head eye response is seen. With brain stem lesions, this oculocephalic reflex becomes impaired or lost, depending on the site of the lesion.

The oculovestibular reflex is tested by caloric stimulation using irrigation with ice water. In normal subjects, jerk nystagmus is elicited for about 2 or 3 minutes, with the slow component toward the irrigated ear. In unconscious patients with an intact brain stem, the fast component of the nystagmus disappears, so that the eyes tonically deviate toward the irrigated side for 2-3 minutes before returning to their original position. With impairment of brain stem function, the response becomes perverted and finally disappears. In metabolic coma, oculocephalic and oculovestibular reflex responses are preserved, at least initially.

C. Respiratory Patterns

Diseases causing coma may lead to respiratory abnormalities. Cheyne-Stokes respiration may occur with bihemispheric or diencephalic disease or in metabolic disorders. Central neurogenic hyperventilation occurs with lesions of the brain stem tegmentum; apneustic breathing (in which there are prominent end-inspiratory pauses) suggests damage at the pontine level (eg, due to basilar artery occlusion); and atactic breathing (a completely irregular pattern of breathing with deep and shallow breaths occurring randomly) is associated with lesions of the lower pontine tegmentum and medulla.

1. Stupor & Coma Due to Structural Lesions

Supratentorial mass lesions tend to affect brain function in an orderly way. There may initially be signs of hemispheric dysfunction, such as hemiparesis. As coma develops and deepens, cerebral function becomes progressively disturbed, producing a predictable progression of neurologic signs that suggest rostrocaudal deterioration.

Thus, as a supratentorial mass lesion begins to impair the diencephalon, the patient becomes drowsy, then stuporous, and finally comatose. There may be Cheyne-Stokes respiration; small but reactive pupils; doll's-head eye responses with side-to-side head movements but sometimes an impairment of reflex upward gaze with brisk flexion of the head; tonic ipsilateral deviation of the eyes in response to vestibular stimulation with cold water; and initially a positive response to pain but subsequently only decorticate posturing. With further progression, midbrain failure occurs. Motor dysfunction progresses from decorticate to bilateral decerebrate posturing in response to painful stimuli; Cheyne-Stokes respiration is gradually replaced by sustained central hyperventilation; the pupils become middle-sized and fixed; and the oculocephalic and oculovestibular reflex responses become impaired, perverted, or lost. As the pons and then the medulla fail, the pupils remain unresponsive; oculovestibular responses are unobtainable; respiration is rapid and shallow; and painful stimuli may lead only to flexor responses in the legs. Finally, respiration becomes irregular and stops, the pupils often then dilating widely.

In contrast, a subtentorial (ie, brain stem) lesion may lead to an early, sometimes abrupt disturbance of consciousness without any orderly rostrocaudal progression of neurologic signs. Compressive lesions of the brain stem, especially cerebellar hemorrhage, may be clinically indistinguishable from intraparenchymal processes.

A structural lesion is suspected if the findings suggest focality. In such circumstances, a CT scan should be performed before, or instead of, a lumbar puncture in order to avoid any risk of cerebral herniation. Further management is of the causal lesion and is considered separately under the individual disorders.

2. Stupor & Coma Due to Metabolic Disturbances

Patients with a metabolic cause of coma generally have signs of patchy, diffuse, and symmetric neurologic involvement that cannot be explained by loss of function at any single level or in a sequential manner, although focal or lateralized deficits may occur in hypoglycemia. Moreover, pupillary reactivity is usually preserved, while other brain stem functions are often grossly impaired. Comatose patients with meningitis, encephalitis, or subarachnoid hemorrhage may also exhibit little in the way of focal neurologic signs, however, and clinical evidence of meningeal irritation is sometimes very subtle in comatose patients. Examination of the cerebrospinal fluid in such patients is essential to establish the correct diagnosis.

In patients with coma due to cerebral ischemia and hypoxia, the absence of pupillary light reflexes at the time of initial examination indicates that there is little chance of regaining independence; by contrast, preserved pupillary light responses, the development of spontaneous eye movements (roving, conjugate, or better), and extensor, flexor, or withdrawal responses to pain at this early stage imply a relatively good prognosis.

Treatment of metabolic encephalopathy is of the underlying disturbance and is considered in other chapters. If the cause of the encephalopathy is obscure, all drugs except essential ones may have to be withdrawn in case they are responsible for the altered mental status.

Wilson FC et al: Vegetative state and minimally responsive patients—regional survey, long-term case outcomes and service recommendations. *Neurorehabilitation* 2002;17:231. [\[PMID: 12237504\]](#)

3. Brain Death

The definition of brain death is controversial, and diagnostic criteria have been published by many different professional organizations. In order to establish brain death, the irreversibly comatose patient must be shown to have lost all brain stem reflex responses, including the pupillary, corneal, oculovestibular, oculocephalic, oropharyngeal, and respiratory reflexes, and should have been in this condition for at least 6 hours. Spinal reflex movements do not exclude the diagnosis, but ongoing seizure activity or decerebrate or decorticate posturing is not consistent with brain death. The apnea test (presence or absence of spontaneous respiratory activity at a PaCO₂ of at least 60 mm Hg) serves to determine whether the patient is capable of respiratory activity.

Reversible coma simulating brain death may be seen with hypothermia (temperature < 32°C) and overdosage with central nervous system depressant drugs, and these conditions must be excluded. Certain ancillary tests may assist the determination of brain death but are not essential. An isoelectric electroencephalogram, when the recording is made according to the recommendations of the American Electroencephalographic Society, is especially helpful in confirming the diagnosis. Alternatively, the demonstration of an absent cerebral circulation by intravenous radioisotope cerebral angiography or by four-vessel contrast cerebral angiography can be confirmatory.

Wijdicks EFM: Brain death worldwide. Neurology 2002;58:20. [\[PMID: 11781400\]](#)

4. Persistent Vegetative State

Patients with severe bilateral hemispheric disease may show some improvement from an initially comatose state, so that, after a variable interval, they appear to be awake but lie motionless and without evidence of awareness or higher mental activity. This persistent vegetative state has been variously referred to as akinetic mutism, apallic state, or coma vigil. Most patients in this persistent vegetative state will die in months or years, but partial recovery has occasionally occurred and in rare instances has been sufficient to permit communication or even independent living.

5. Locked-In Syndrome (De-efferented State)

Acute destructive lesions (eg, infarction, hemorrhage, demyelination, encephalitis) involving the ventral pons and sparing the tegmentum may lead to a mute, quadriparetic but conscious state in which the patient is capable of blinking and of voluntary eye movement in the vertical plane, with preserved pupillary responses to light. Such a patient can mistakenly be regarded as comatose. Physicians should recognize that "locked-in" individuals are fully aware of their surroundings. The prognosis is variable, but recovery has occasionally been reported—in some cases including resumption of independent daily life, though this may take up to 2 or 3 years.

HEAD INJURY

Trauma is the most common cause of death in young people, and head injury accounts for almost half of these trauma-related deaths. The prognosis following head injury depends upon the site and severity of brain damage. Some guide to prognosis is provided by the mental status, since loss of consciousness for more than 1 or 2 minutes implies a worse prognosis than otherwise. Similarly, the degree of retrograde and posttraumatic amnesia provides an indication of the severity of injury and thus of the prognosis. Absence of skull fracture does not exclude the possibility of severe head injury. During the physical examination, special attention should be given to the level of consciousness and extent of any brain stem dysfunction.

Note: Patients who have lost consciousness for 2 minutes or more following head injury should be admitted to the hospital for observation, as should patients with focal neurologic deficits, lethargy, or skull fractures. If admission is declined, responsible family members should be given clear instructions about the need for, and manner of, checking on them at regular (hourly) intervals and for obtaining additional medical help if necessary.

Skull radiographs or CT scans may provide evidence of fractures. Because injury to the spine may have accompanied head trauma, cervical spine radiographs (especially in the lateral projection) should always be obtained in comatose patients and in patients with severe neck pain or a deficit possibly related to cord compression. CT scanning has an important role in demonstrating intracranial hemorrhage and may also provide evidence of cerebral edema and displacement of midline structures.

Cerebral Injuries

These are summarized in [Table 24-5](#) along with comments about treatment. Increased intracranial pressure may result from ventilatory obstruction, abnormal neck position, seizures, dilutional hyponatremia, or cerebral edema; an intracranial hematoma requiring surgical evacuation may also be responsible. Other measures that may be necessary to reduce intracranial pressure include induced hyperventilation, intravenous mannitol infusion, and intravenous furosemide; corticosteroids provide no benefit in this context.

Scalp Injuries & Skull Fractures

Scalp lacerations and depressed or compound depressed skull fractures should be treated surgically as appropriate. Simple skull fractures require no specific treatment.

The clinical signs of basilar skull fracture include bruising about the orbit (raccoon sign), blood in the external auditory meatus (Battle's sign), and leakage of cerebrospinal fluid (which can be identified by its glucose content) from the ear or nose. Cranial nerve palsies (involving especially the first, second, third, fourth, fifth, seventh, and eighth nerves in any combination) may also occur. If there is any leakage of cerebrospinal fluid, conservative treatment, with elevation of the head, restriction of fluids, and administration of acetazolamide (250 mg four times daily), is often helpful; but if the leak continues for more than a few days, lumbar subarachnoid drainage may be necessary. Antibiotics are given if infection occurs, based on culture and sensitivity studies. Only very occasional patients require intracranial repair of the dural defect because of persistence of the leak or recurrent meningitis.

Late Complications of Head Injury

The relationship of chronic subdural hemorrhage to head injury is not always clear. In many elderly persons there is no history of trauma, but in other cases a head injury, often trivial, precedes the onset of symptoms by several weeks. The clinical presentation is usually with mental changes such as slowness, drowsiness, headache, confusion, memory disturbances, personality change, or even dementia. Focal neurologic deficits such as hemiparesis or hemisensory disturbance may also occur but are less common. CT scan is an important means of detecting the hematoma, which is sometimes bilateral. Treatment is by surgical evacuation to prevent cerebral compression and tentorial herniation. There is no clear evidence that prophylactic anticonvulsant therapy reduces the incidence of posttraumatic seizures.

Normal-pressure hydrocephalus may follow head injury, subarachnoid hemorrhage, or meningoencephalitis.

Other late complications of head injury include posttraumatic seizure disorder and posttraumatic headache.

SPINAL TRAUMA

While spinal cord damage may result from whiplash injury, severe injury usually relates to fracture-dislocation causing compression or angular deformity of the cord either cervically or in the lower thoracic and upper lumbar regions. Extreme hypotension following injury may also lead to cord infarction.

Total cord transection results in immediate flaccid paralysis and loss of sensation below the level of the lesion. Reflex activity is lost for a variable period, and there is urinary and fecal retention. As reflex function returns over the following days and weeks, spastic paraplegia or quadriplegia develops, with hyperreflexia and extensor plantar responses, but a flaccid atrophic (lower motor neuron) paralysis may be found depending on the segments of the cord that are affected. The bladder and bowels also regain some reflex function, permitting urine and feces to be expelled at intervals. As spasticity increases, flexor or extensor spasms (or both) of the legs become troublesome, especially if the patient develops bed sores or a urinary tract infection. Paraplegia with the legs in flexion or extension may eventually result.

With lesser degrees of injury, patients may be left with mild limb weakness, distal sensory disturbance, or both. Sphincter function may also be impaired, urinary urgency and urgency incontinence being especially common. More particularly, a unilateral cord lesion leads to an ipsilateral motor disturbance with accompanying impairment of proprioception and contralateral loss of pain and temperature appreciation below the lesion (Brown-Sequard's syndrome). A central cord syndrome may lead to a lower motor neuron deficit and loss of pain and temperature appreciation, with sparing of posterior column functions. A radicular deficit may occur at the level of the injury—or, if the cauda equina is involved, there may be evidence of disturbed function in several lumbosacral roots.

Treatment of the injury consists of immobilization and—if there is cord compression—decompressive laminectomy and fusion. Early treatment with high doses of corticosteroids (eg, methylprednisolone, 30 mg/kg by intravenous bolus, followed by 5.4 mg/kg/h for 23 hours) has been shown to improve neurologic recovery if commenced within 8 hours after injury. Treatment with G_{M1} ganglioside for 3 or 4 weeks is an experimental approach that has also been helpful. Anatomic realignment of the spinal cord by traction and other orthopedic procedures is also important. Subsequent care of the residual neurologic deficit—paraplegia or quadriplegia—requires treatment of spasticity and care of the skin, bladder, and bowels.

SYRINGOMYELIA

Destruction or degeneration of gray and white matter adjacent to the central canal of the cervical spinal cord leads to cavitation and accumulation of fluid within the spinal cord. The precise pathogenesis is unclear, but many cases are associated with Arnold-Chiari malformation, in which there is displacement of the cerebellar

tonsils, medulla, and fourth ventricle into the spinal canal, sometimes with accompanying meningocele. In such circumstances, the cord cavity connects with and may merely represent a dilated central canal. In other cases, the cause of cavitation is less clear. There is a characteristic clinical picture, with segmental atrophy and areflexia and loss of pain and temperature appreciation in a "cape" distribution owing to the destruction of fibers crossing in front of the central canal. Thoracic kyphoscoliosis is usually present. With progression, involvement of the long motor and sensory tracts occurs as well, so that a pyramidal and sensory deficit develops in the legs. Upward extension of the cavitation (syringobulbia) leads to dysfunction of the lower brain stem and thus to bulbar palsy, nystagmus, and sensory impairment over one or both sides of the face.

Syringomyelia, ie, cord cavitation, may also occur in association with an intramedullary tumor or following severe cord injury, and the cavity then does not communicate with the central canal.

In patients with Arnold-Chiari malformation, there are commonly skeletal abnormalities on plain x-rays of the skull and cervical spine. CT scans show caudal displacement of the fourth ventricle. MRI or positive contrast myelography may demonstrate the malformation itself. Focal cord enlargement is found at myelography or by MRI in patients with cavitation related to past injury or intramedullary neoplasms.

Treatment of Arnold-Chiari malformation with associated syringomyelia is by suboccipital craniectomy and upper cervical laminectomy, with the aim of decompressing the malformation at the foramen magnum. The cord cavity should be drained, and if necessary an outlet for the fourth ventricle can be made. In cavitation associated with intramedullary tumor, treatment is surgical, but radiation therapy may be necessary if complete removal is not possible. Posttraumatic syringomyelia is also treated surgically if it leads to increasing neurologic deficits or to intolerable pain.

MOTOR NEURON DISEASES

Essentials of Diagnosis

- Weakness.
- No sensory loss or sphincter disturbance.

General Considerations

This group of disorders is characterized clinically by weakness and variable wasting of affected muscles, without accompanying sensory changes.

Motor neuron disease in adults generally commences between 30 and 60 years of age. There is degeneration of the anterior horn cells in the spinal cord, the motor nuclei of the lower cranial nerves, and the corticospinal and corticobulbar pathways. The disorder is usually sporadic, but familial cases may occur.

Classification

Five varieties have been distinguished on clinical grounds.

A. Progressive Bulbar Palsy

Bulbar involvement predominates owing to disease processes affecting primarily the motor nuclei of the cranial nerves.

B. Pseudobulbar Palsy

Bulbar involvement predominates in this variety also, but it is due to bilateral corticobulbar disease and thus reflects upper motor neuron dysfunction.

C. Progressive Spinal Muscular Atrophy

This is characterized primarily by a lower motor neuron deficit in the limbs due to degeneration of the anterior horn cells in the spinal cord.

D. Primary Lateral Sclerosis

There is a purely upper motor neuron deficit in the limbs.

E. Amyotrophic Lateral Sclerosis

A mixed upper and lower motor neuron deficit is found in the limbs. This disorder is sometimes associated with dementia or parkinsonism.

Clinical Findings

A. Symptoms and Signs

Difficulty in swallowing, chewing, coughing, breathing, and talking (dysarthria) occur with bulbar involvement. In progressive bulbar palsy, there is drooping of the palate, a depressed gag reflex, pooling of saliva in the pharynx, a weak cough, and a wasted, fasciculating tongue. In pseudobulbar palsy, the tongue is contracted and spastic and cannot be moved rapidly from side to side. Limb involvement is characterized by motor disturbances (weakness, stiffness, wasting, fasciculations) reflecting lower or upper motor neuron dysfunction; there are no objective changes on sensory examination, though there may be vague sensory complaints. The sphincters are generally spared.

The disorder is progressive, and amyotrophic lateral sclerosis is usually fatal within 3-5 years; death usually results from pulmonary infections. Patients with bulbar involvement generally have the poorest prognosis.

B. Laboratory and Other Studies

Electromyography may show changes of chronic partial denervation, with abnormal spontaneous activity in the resting muscle and a reduction in the number of motor units under voluntary control. In patients with suspected spinal muscular atrophy or amyotrophic lateral sclerosis, the diagnosis should not be made with confidence unless such changes are found in at least three extremities. Motor conduction velocity is usually normal but may be slightly reduced, and sensory conduction studies are also normal. Biopsy of a wasted muscle shows the histologic changes of denervation. The serum creatine kinase may be slightly elevated but never reaches the extremely high values seen in some of the muscular dystrophies. The cerebrospinal fluid is normal.

A familial form of amyotrophic lateral sclerosis has been described with autosomal dominant inheritance, related to mutations in the copper-zinc superoxide dismutase gene on the long arm of chromosome 21. X-linked bulbospinal neuronopathy is associated with an expanded trinucleotide repeat sequence on the androgen receptor gene and carries a more benign prognosis than other forms of motor neuron disease. There have been recent reports of juvenile spinal muscular atrophy due to hexosaminidase deficiency, with abnormal findings on rectal biopsy and reduced hexosaminidase A in serum and leukocytes. Pure motor syndromes resembling motor neuron disease may also occur in association with monoclonal gammopathy or multifocal motor neuropathies with conduction block. A motor neuronopathy may also develop in Hodgkin's disease and has a relatively benign prognosis.

Treatment

Riluzole, which reduces the presynaptic release of glutamate, may slow progression of amyotrophic lateral sclerosis. There is otherwise no specific treatment except in patients with gammopathy, in whom plasmapheresis and immunosuppression may lead to improvement. Therapeutic trials of various neurotrophic factors to slow disease progression have yielded generally disappointing results. Symptomatic and supportive measures may include prescription of anticholinergic drugs (such as trihexyphenidyl, amitriptyline, or atropine) if drooling is troublesome, braces or a walker to improve mobility, and physical therapy to prevent contractures. Spasticity may be helped by baclofen or diazepam. A semiliquid diet or nasogastric tube feeding may be needed if dysphagia is severe. Gastrostomy or cricopharyngomyotomy is sometimes resorted to in extreme cases of predominant bulbar involvement, and tracheostomy may be necessary if respiratory muscles are severely affected; however, in the terminal stages of these disorders, the aim of treatment should be to keep patients as comfortable as possible.

PERIPHERAL NEUROPATHIES

Peripheral neuropathies can be categorized on the basis of the structure primarily affected. The predominant pathologic feature may be axonal degeneration (axonal or

neuronal neuropathies) or paranodal or segmental demyelination. The distinction may be possible on the basis of neurophysiologic findings. Motor and sensory conduction velocity can be measured in accessible segments of peripheral nerves. In axonal neuropathies, conduction velocity is normal or reduced only mildly and needle electromyography provides evidence of denervation in affected muscles. In demyelinating neuropathies, conduction may be slowed considerably in affected fibers, and in more severe cases, conduction is blocked completely, without accompanying electromyographic signs of denervation.

Nerves may be injured or compressed by neighboring anatomic structures at any point along their course. Common **mononeuropathies** of this sort are considered below. They lead to a sensory, motor, or mixed deficit that is restricted to the territory of the affected nerve. A similar clinical disturbance is produced by peripheral nerve tumors, but these are rare except in patients with Recklinghausen's disease. Multiple mononeuropathies suggest a patchy multifocal disease process such as vasculopathy (eg, diabetes, arteritis), an infiltrative process (eg, leprosy, sarcoidosis), radiation damage, or an immunologic disorder (eg, brachial plexopathy). Diffuse **polyneuropathies** lead to a symmetric sensory, motor, or mixed deficit, often most marked distally. They include the hereditary, metabolic, and toxic disorders; idiopathic inflammatory polyneuropathy (Guillain-Barre syndrome); and the peripheral neuropathies that may occur as a nonmetastatic complication of malignant diseases. Involvement of motor fibers leads to flaccid weakness that is most marked distally; dysfunction of sensory fibers causes impaired sensory perception. Tendon reflexes are depressed or absent. Paresthesias, pain, and muscle tenderness may also occur.

1. Polyneuropathies & Mononeuritis Multiplex

Essentials of Diagnosis

- Weakness, sensory disturbances, or both in the extremities.
- Pain sometimes common.
- Depressed or absent tendon reflexes.
- May be family history of neuropathy.
- May be history of systemic illness or toxic exposure.

General Considerations

The cause of polyneuropathy or mononeuritis multiplex is suggested by the history, mode of onset, and predominant clinical manifestations. Laboratory workup includes a complete blood count and sedimentation rate, serum protein electrophoresis, determination of plasma urea and electrolytes, liver and thyroid function tests, tests for rheumatoid factor and antinuclear antibody, HBsAg determination, a serologic test for syphilis, fasting blood glucose level, urinary heavy metal levels, cerebrospinal fluid examination, and chest radiography. These tests should be ordered selectively, as guided by symptoms and signs. Measurement of nerve conduction velocity is important in confirming the peripheral nerve origin of symptoms and providing a means of following clinical changes, as well as indicating the likely disease process (ie, axonal or demyelinating neuropathy). Cutaneous nerve biopsy may help establish a precise diagnosis (eg, polyarteritis, amyloidosis). In about half of cases, no specific cause can be established; of these, slightly less than half are subsequently found to be hereditary.

Treatment is of the underlying cause, when feasible, and is discussed below under the individual disorders. Physical therapy helps prevent contractures, and splints can maintain a weak extremity in a position of useful function. Anesthetic extremities must be protected from injury. To guard against burns, patients should check the temperature of water and hot surfaces with a portion of skin having normal sensation, measure water temperature with a thermometer, and use cold water for washing or lower the temperature setting of their hot-water heaters. Shoes should be examined frequently during the day for grit or foreign objects in order to prevent pressure lesions.

Patients with polyneuropathies or mononeuritis multiplex are subject to additional nerve injury at pressure points and should therefore avoid such behavior as leaning on elbows or sitting with crossed legs for lengthy periods.

Neuropathic pain is sometimes troublesome and may respond to simple analgesics such as aspirin. Narcotics or narcotic substitutes may be necessary for severe hyperpathia or pain induced by minimal stimuli, but their use should be avoided as far as possible. The use of a frame or cradle to reduce contact with bedclothes may be helpful. Many patients experience episodic stabbing pains, which may respond to phenytoin, carbamazepine, gabapentin, or tricyclic antidepressants.

Symptoms of autonomic dysfunction are occasionally troublesome. Postural hypotension is often helped by wearing waist-high elastic stockings and sleeping in a semierect position at night. Fludrocortisone reduces postural hypotension, but doses as high as 1 mg/d are sometimes necessary in diabetics and may lead to recumbent hypertension. Midodrine, an alpha agonist, is sometimes helpful in a dose of 2.5-10 mg three times daily. Impotence and diarrhea are difficult to treat; a flaccid neuropathic bladder may respond to parasympathomimetic drugs such as bethanechol chloride, 10-50 mg three or four times daily.

Inherited Neuropathies

A. Charcot-Marie-Tooth Disease

Several distinct varieties of Charcot-Marie-Tooth disease can be recognized. There is usually an autosomal dominant mode of inheritance, but occasional cases occur on a sporadic, recessive, or X-linked basis. The responsible gene is commonly located on the short arm of chromosome 17 and less often shows linkage to chromosome 1 or the X chromosome. Clinical presentation may be with foot deformities or gait disturbances in childhood or early adult life. Slow progression leads to the typical features of polyneuropathy, with distal weakness and wasting that begin in the legs, a variable amount of distal sensory loss, and depressed or absent tendon reflexes. Tremor is a conspicuous feature in some instances. Electrodiagnostic studies show a marked reduction in motor and sensory conduction velocity (hereditary motor and sensory neuropathy [HMSN] type I).

In other instances (HMSN type II), motor conduction velocity is normal or only slightly reduced, sensory nerve action potentials may be absent, and signs of chronic partial denervation are found in affected muscles electromyographically. The predominant pathologic change is axonal loss rather than segmental demyelination.

A similar disorder may occur in patients with progressive distal spinal muscular atrophy, but there is no sensory loss; electrophysiologic investigation reveals that motor conduction velocity is normal or only slightly reduced, and nerve action potentials are normal.

B. Dejerine-Sottas Disease (HMSN Type III)

Most cases are sporadic or autosomal recessive. The recessive form has its onset in infancy or childhood and leads to a progressive motor and sensory polyneuropathy with weakness, ataxia, sensory loss, and depressed or absent tendon reflexes. The peripheral nerves may be palpably enlarged and are characterized pathologically by segmental demyelination, Schwann cell hyperplasia, and thin myelin sheaths. Electrophysiologically, there is slowing of conduction, and sensory action potentials may be unrecordable.

C. Friedreich's Ataxia

Patients generally present in childhood or early adult life with this autosomal recessive disorder, which has been related to an unstable mutation of the X25 gene on chromosome 9q13-q21.1. The gait becomes atactic, the hands become clumsy, and other signs of cerebellar dysfunction develop accompanied by weakness of the legs and extensor plantar responses. Involvement of peripheral sensory fibers leads to sensory disturbances in the limbs and depressed tendon reflexes. There is bilateral pes cavus. Pathologically, there is a marked loss of cells in the posterior root ganglia and degeneration of peripheral sensory fibers. In the central nervous system, changes are conspicuous in the posterior and lateral columns of the cord. Electrophysiologically, conduction velocity in motor fibers is normal or only mildly reduced, but sensory action potentials are small or absent.

D. Refsum's Disease (HMSN Type IV)

This autosomal recessive disorder is due to a disturbance in phytanic acid metabolism. Clinically, pigmentary retinal degeneration is accompanied by progressive sensorimotor polyneuropathy and cerebellar signs. Auditory dysfunction, cardiomyopathy, and cutaneous manifestations may also occur. Motor and sensory conduction velocity are reduced, often markedly, and there may be electromyographic evidence of denervation in affected muscles. Dietary restriction of phytanic acid and its precursors may be helpful therapeutically.

E. Porphyrria

Peripheral nerve involvement may occur during acute attacks in both variegate porphyria and acute intermittent porphyria. Motor symptoms usually occur first, and weakness is often most marked proximally and in the upper limbs rather than the lower. Sensory symptoms and signs may be proximal or distal in distribution. Autonomic involvement is sometimes pronounced. The electrophysiologic findings are in keeping with the results of neuropathologic studies suggesting that the neuropathy is axonal in type. Hematin (4 mg/kg intravenously over 15 minutes once or twice daily) may lead to rapid improvement. A high-carbohydrate diet and, in severe cases, intravenous glucose or levulose may also be helpful. Propranolol (up to 100 mg every 4 hours) may control tachycardia and hypertension in acute attacks. Porphyrria is discussed further in [Chapter 40](#).

Neuropathies Associated With Systemic & Metabolic Disorders

A. Diabetes Mellitus

In this disorder, involvement of the peripheral nervous system may lead to symmetric sensory or mixed polyneuropathy, asymmetric motor radiculoneuropathy or plexopathy (diabetic amyotrophy), thoracoabdominal radiculopathy, autonomic neuropathy, or isolated lesions of individual nerves. These may occur singly or in any combination and are discussed in [Chapter 27](#).

B. Uremia

Uremia may lead to a symmetric sensorimotor polyneuropathy that tends to affect the lower limbs more than the upper limbs and is more marked distally than proximally ([Chapter 22](#)). The diagnosis can be confirmed electrophysiologically, for motor and sensory conduction velocity is moderately reduced. The neuropathy improves both clinically and electrophysiologically with renal transplantation and to a lesser extent with chronic dialysis.

C. Alcoholism and Nutritional Deficiency

Many alcoholics have an axonal distal sensorimotor polyneuropathy that is frequently accompanied by painful cramps, muscle tenderness, and painful paresthesias and is often more marked in the legs than in the arms. Symptoms of autonomic dysfunction may also be conspicuous. Motor and sensory conduction velocity may be slightly reduced, even in subclinical cases, but gross slowing of conduction is uncommon. A similar distal sensorimotor polyneuropathy is a well-recognized feature of beriberi (thiamin deficiency). In vitamin B₁₂ deficiency, distal sensory polyneuropathy may develop but is usually overshadowed by central nervous system manifestations (eg, myelopathy, optic neuropathy, or intellectual changes).

D. Paraproteinemias

A symmetric sensorimotor polyneuropathy that is gradual in onset, progressive in course, and often accompanied by pain and dysesthesias in the limbs may occur in patients (especially men) with multiple myeloma. The neuropathy is of the axonal type in classic lytic myeloma, but segmental demyelination (primary or secondary) and axonal loss may occur in sclerotic myeloma and lead to predominantly motor clinical manifestations. Both demyelinating and axonal neuropathies are also observed in patients with paraproteinemias without myeloma. A small fraction will develop myeloma if serially followed. The demyelinating neuropathy in these patients may be due to the monoclonal protein's reacting to a component of the nerve myelin. The neuropathy of classic multiple myeloma is poorly responsive to therapy. The polyneuropathy of benign monoclonal gammopathy may respond to immunosuppressant drugs and plasmapheresis.

Polyneuropathy may also occur in association with macroglobulinemia and cryoglobulinemia and sometimes responds to plasmapheresis. Entrapment neuropathy, such as carpal tunnel syndrome, is more common than polyneuropathy in patients with (nonhereditary) generalized amyloidosis. With polyneuropathy due to amyloidosis, sensory and autonomic symptoms are especially conspicuous, whereas distal wasting and weakness occur later; there is no specific treatment.

Neuropathies Associated With Infectious & Inflammatory Diseases

A. Leprosy

Leprosy is an important cause of peripheral neuropathy in certain parts of the world. Sensory disturbances are mainly due to involvement of intracutaneous nerves. In tuberculoid leprosy, they develop at the same time and in the same distribution as the skin lesion but may be more extensive if nerve trunks lying beneath the lesion are also involved. In lepromatous leprosy, there is more extensive sensory loss, and this develops earlier and to a greater extent in the coolest regions of the body, such as the dorsal surfaces of the hands and feet, where the bacilli proliferate most actively. Motor deficits result from involvement of superficial nerves where their temperature is lowest, eg, the ulnar nerve in the region proximal to the olecranon groove, the median nerve as it emerges from beneath the forearm flexor muscle to run toward the carpal tunnel, the peroneal nerve at the head of the fibula, and the posterior tibial nerve in the lower part of the leg; patchy facial muscular weakness may also occur owing to involvement of the superficial branches of the seventh cranial nerve.

Motor disturbances in leprosy are suggestive of multiple mononeuropathy, whereas sensory changes resemble those of distal polyneuropathy. Examination, however, relates the distribution of sensory deficits to the temperature of the tissues; in the legs, for example, sparing frequently occurs between the toes and in the popliteal fossae, where the temperature is higher. Treatment is with antileprotic agents (see [Chapter 33](#)).

B. AIDS

A variety of neuropathies occur in HIV-infected patients (see [Chapter 31](#)). Patients with AIDS may develop a chronic symmetric sensorimotor axonal **polyneuropathy** associated usually with no abnormal cerebrospinal fluid findings. Treatment is symptomatic. AIDS patients may also develop progressive **polyradiculopathy** or radiculomyelopathy that leads to leg weakness and urinary retention; sensory loss is less conspicuous than in polyneuropathy. The cerebrospinal fluid may show mononuclear pleocytosis and increased protein and low glucose concentrations. Cytomegalovirus is responsible in at least some cases. The prognosis is generally poor, but some patients respond to intravenous ganciclovir (2.5 mg/kg every 8 hours for 10 days, then 7.5 mg/kg daily 5 days per week).

An inflammatory **demyelinating polyradiculoneuropathy** sometimes occurs in HIV-seropositive patients without AIDS and may follow an acute, subacute, or chronic course. Weakness is usually more conspicuous distally than proximally and tends to overshadow sensory symptoms. Tendon reflexes are depressed or absent. The cerebrospinal fluid shows an increased cell count and protein concentration. Treatment with plasmapheresis has helped some patients. Spontaneous improvement may also occur. Seropositive patients without AIDS may also develop a **mononeuropathy multiplex** that sometimes responds to treatment with plasmapheresis.

C. Lyme Borreliosis

The neurologic manifestations of Lyme disease include meningitis, meningoencephalitis, polyradiculoneuropathy, mononeuropathy multiplex, and cranial neuropathy. Serologic tests establish the underlying disorder. Treatment is as described in [Chapter 34](#).

D. Sarcoidosis

Cranial nerve palsies (especially facial palsy), multiple mononeuropathy, and, less commonly, symmetric polyneuropathy may all occur, the latter sometimes preferentially affecting either motor or sensory fibers. Improvement may occur with use of corticosteroids.

E. Polyarteritis

Involvement of the vasa nervorum by the vasculitic process may result in infarction of the nerve. Clinically, one encounters an asymmetric sensorimotor polyneuropathy (mononeuritis multiplex) that pursues a waxing and waning course. Steroids and cytotoxic agents—especially cyclophosphamide—may be of benefit in severe cases.

F. Rheumatoid Arthritis

Compressive or entrapment neuropathies, ischemic neuropathies, mild distal sensory polyneuropathy, and severe progressive sensorimotor polyneuropathy can occur in rheumatoid arthritis.

Neuropathy Associated With Critical Illness

Patients in intensive care units with sepsis and multiorgan failure sometimes develop polyneuropathies. This may be manifested initially by unexpected difficulty in weaning patients from a mechanical ventilator and in more advanced cases by wasting and weakness of the extremities and loss of tendon reflexes. Sensory abnormalities are relatively inconspicuous. The neuropathy is axonal in type. Its pathogenesis is obscure, and treatment is supportive. The prognosis is good provided patients recover from the underlying critical illness.

Toxic Neuropathies

Axonal polyneuropathy may follow exposure to industrial agents or pesticides such as acrylamide, organophosphorus compounds, hexacarbon solvents, methyl bromide, and carbon disulfide; metals such as arsenic, thallium, mercury, and lead; and drugs such as phenytoin, perhexiline, isoniazid, nitrofurantoin, vincristine, and pyridoxine in high doses. Detailed occupational, environmental, and medical histories and recognition of clusters of cases are important in suggesting the diagnosis. Treatment is by preventing further exposure to the causal agent. Isoniazid neuropathy is prevented by pyridoxine supplementation.

Diphtheritic neuropathy results from a neurotoxin released by the causative organism and is common in many areas. Palatal weakness may develop 2-4 weeks after infection of the throat, and infection of the skin may similarly be followed by focal weakness of neighboring muscles. Disturbances of accommodation may occur about 4-5 weeks after infection and distal sensorimotor demyelinating polyneuropathy after 1-3 months.

Neuropathies Associated With Malignant Diseases ([Table 40-6](#))

Both a sensorimotor and a purely sensory polyneuropathy may occur as a nonmetastatic complication of malignant diseases. The sensorimotor polyneuropathy may be mild and occur in the course of known malignant disease, or it may have an acute or subacute onset, lead to severe disability, and occur before there is any clinical evidence of the cancer, occasionally following a remitting course.

Acute Idiopathic Polyneuropathy (Guillain-Barre Syndrome)

This acute or subacute polyradiculoneuropathy sometimes follows infective illness, inoculations, or surgical procedures. There is an association with preceding

Campylobacter jejuni enteritis. The disorder probably has an immunologic basis, but the precise mechanism is unclear. The main complaint is of weakness that varies widely in severity in different patients and often has a proximal emphasis and symmetric distribution. It usually begins in the legs, spreading to a variable extent but frequently involving the arms and often one or both sides of the face. The muscles of respiration or deglutition may also be affected. Sensory symptoms are usually less conspicuous than motor ones, but distal paresthesias and dysesthesias are common, and neuropathic or radicular pain is present in many patients. Autonomic disturbances are also common, may be severe, and are sometimes life-threatening; they include tachycardia, cardiac irregularities, hypotension or hypertension, facial flushing, abnormalities of sweating, pulmonary dysfunction, and impaired sphincter control.

The cerebrospinal fluid characteristically contains a high protein concentration with a normal cell content, but these changes may take 2 or 3 weeks to develop. Electrophysiologic studies may reveal marked abnormalities, which do not necessarily parallel the clinical disorder in their temporal course. Pathologic examination has shown primary demyelination or, less commonly, axonal degeneration.

When the diagnosis is made, the history and appropriate laboratory studies should exclude the possibility of porphyric, diphtheritic, or toxic (heavy metal, hexacarbon, organophosphate) neuropathies. Poliomyelitis, botulism, and tick paralysis must also be considered. The presence of pyramidal signs, a markedly asymmetric motor deficit, a sharp sensory level, or early sphincter involvement should suggest a focal cord lesion.

Most patients eventually make a good recovery, but this may take many months, and 10-20% patients are left with persisting disability. Treatment with prednisone is ineffective and may prolong recovery time. Plasmapheresis is of value; it is best performed within the first few days of illness and is best reserved for clinically severe or rapidly progressive cases or those with ventilatory impairment. Intravenous immunoglobulin (400 mg/kg/d for 5 days) is also helpful and imposes less stress on the cardiovascular system than plasmapheresis. Patients should be admitted to intensive care units if their forced vital capacity is declining, and intubation is considered if the forced vital capacity reaches 15 mL/kg, dyspnea becomes evident, or the oxygen saturation declines. Respiratory toilet and chest physical therapy help prevent atelectasis. Marked hypotension may respond to volume replacement or pressor agents. Low-dose heparin to prevent pulmonary embolism should be considered.

Approximately 3% of patients with acute idiopathic polyneuropathy have one or more clinically similar relapses, sometimes several years after the initial illness. Plasma exchange therapy may produce improvement in chronic and relapsing inflammatory polyneuropathy.

Chronic Inflammatory Polyneuropathy

Chronic inflammatory demyelinating polyneuropathy, an acquired immunologically mediated disorder, is clinically similar to Guillain-Barre syndrome except that it has a relapsing or steadily progressive course over months or years. In the relapsing form, partial recovery may occur after some relapses, but in other instances there is no recovery between exacerbations. Although remission may occur spontaneously with time, the disorder frequently follows a progressive downhill course leading to severe functional disability.

Electrodiagnostic studies show marked slowing of motor and sensory conduction, and focal conduction block. Signs of partial denervation may also be present owing to secondary axonal degeneration. Nerve biopsy may show chronic perivascular inflammatory infiltrates in the endoneurium and epineurium, without accompanying evidence of vasculitis. However, a normal nerve biopsy result or the presence of nonspecific abnormalities does not exclude the diagnosis.

Corticosteroids may be effective in arresting or reversing the downhill course. Treatment is usually begun with prednisone, 60 mg daily, continued for 2-3 months or until a definite response has occurred. If no response has occurred despite 3 months of treatment, a higher dose may be tried. In responsive cases, the dose is gradually tapered, but most patients become corticosteroid-dependent, often requiring prednisone, 20 mg daily on alternate days, on a long-term basis. Patients unresponsive to corticosteroids may benefit instead from treatment with a cytotoxic drug such as azathioprine. There are increasing anecdotal reports of short-term benefit with plasmapheresis; high-dose intravenous immunoglobulin treatment (eg, 400 mg/kg/d) may produce clinical improvement lasting for weeks to months.

2. Mononeuropathies

An individual nerve may be injured along its course or may be compressed, angulated, or stretched by neighboring anatomic structures, especially at a point where it passes through a narrow space (entrapment neuropathy). The relative contributions of mechanical factors and ischemia to the local damage are not clear. With involvement of a sensory or mixed nerve, pain is commonly felt distal to the lesion. Symptoms never develop with some entrapment neuropathies, resolve rapidly and spontaneously in others, and become progressively more disabling and distressing in yet other cases. The precise neurologic deficit depends on the nerve involved. Percussion of the nerve at the site of the lesion may lead to paresthesias in its distal distribution.

Entrapment neuropathy may be the sole manifestation of subclinical polyneuropathy, and this must be borne in mind and excluded by nerve conduction studies. Such studies are also indispensable for the accurate localization of the focal lesion.

In patients with acute compression neuropathy such as may occur in intoxicated individuals ("Saturday night palsy"), no treatment is necessary. Complete recovery generally occurs, usually within 2 months, presumably because the underlying pathology is demyelination. However, axonal degeneration can occur in severe cases, and recovery then takes longer and may never be complete.

In chronic compressive or entrapment neuropathies, avoidance of aggravating factors and correction of any underlying systemic conditions are important. Local infiltration of the region about the nerve with corticosteroids may be of value; in addition, surgical decompression may help if there is a progressively increasing neurologic deficit or if electrodiagnostic studies show evidence of partial denervation in weak muscles.

Peripheral nerve tumors are uncommon, except in Recklinghausen's disease, but also give rise to mononeuropathy. This may be distinguishable from entrapment neuropathy only by noting the presence of a mass along the course of the nerve and by demonstrating the precise site of the lesion with appropriate electrophysiologic studies. Treatment of symptomatic lesions is by surgical removal if possible.

Carpal Tunnel Syndrome

See [Chapter 20](#).

Pronator Teres or Anterior Interosseous Syndrome

The median nerve gives off its motor branch, the anterior interosseous nerve, below the elbow as it descends between the two heads of the pronator teres muscle. A lesion of either nerve may occur in this region, sometimes after trauma or owing to compression from, for example, a fibrous band. With anterior interosseous nerve involvement, there is no sensory loss, and weakness is confined to the pronator quadratus, flexor pollicis longus, and the flexor digitorum profundus to the second and third digits. Weakness is more widespread and sensory changes occur in an appropriate distribution when the median nerve itself is affected. The prognosis is variable. If improvement does not occur spontaneously, decompressive surgery may be helpful.

Ulnar Nerve Lesions

Ulnar nerve lesions are likely to occur in the elbow region as the nerve runs behind the medial epicondyle and descends into the cubital tunnel. In the condylar groove, the ulnar nerve is exposed to pressure or trauma. Moreover, any increase in the carrying angle of the elbow, whether congenital, degenerative, or traumatic, may cause excessive stretching of the nerve when the elbow is flexed. Ulnar nerve lesions may also result from thickening or distortion of the anatomic structures forming the cubital tunnel, and the resulting symptoms may also be aggravated by flexion of the elbow, because the tunnel is then narrowed by tightening of its roof or inward bulging of its floor. A severe lesion at either site causes sensory changes in the medial 1 1/2 digits and along the medial border of the hand. There is weakness of the ulnar-innervated muscles in the forearm and hand. With a cubital tunnel lesion, however, there may be relative sparing of the flexor carpi ulnaris muscle. Electrophysiologic evaluation using nerve stimulation techniques allows more precise localization of the lesion.

If conservative measures are unsuccessful in relieving symptoms and preventing further progression, surgical treatment may be necessary. This consists of nerve

transposition if the lesion is in the condylar groove, or a release procedure if it is in the cubital tunnel.

Ulnar nerve lesions may also develop at the wrist or in the palm of the hand, usually owing to repetitive trauma or to compression from ganglia or benign tumors. They can be subdivided depending upon their presumed site. Compressive lesions are treated surgically. If repetitive mechanical trauma is responsible, this is avoided by occupational adjustment or job retraining.

Radial Nerve Lesions

The radial nerve is particularly liable to compression or injury in the axilla (eg, by crutches or by pressure when the arm hangs over the back of a chair). This leads to weakness or paralysis of all the muscles supplied by the nerve, including the triceps. Sensory changes may also occur but are often surprisingly inconspicuous, being marked only in a small area on the back of the hand between the thumb and index finger. Injuries to the radial nerve in the spiral groove occur characteristically during deep sleep, as in intoxicated individuals (Saturday night palsy), and there is then sparing of the triceps muscle, which is supplied more proximally. The nerve may also be injured at or above the elbow; its purely motor posterior interosseous branch, supplying the extensors of the wrist and fingers, may be involved immediately below the elbow, but then there is sparing of the extensor carpi radialis longus, so that the wrist can still be extended. The superficial radial nerve may be compressed by handcuffs or a tight watch strap.

Femoral Neuropathy

The clinical features of femoral nerve palsy consist of weakness and wasting of the quadriceps muscle, with sensory impairment over the anteromedian aspect of the thigh and sometimes also of the leg to the medial malleolus, and a depressed or absent knee jerk. Isolated femoral neuropathy may occur in diabetics or from compression by retroperitoneal neoplasms or hematomas (eg, expanding aortic aneurysm). Femoral neuropathy may also result from pressure from the inguinal ligament when the thighs are markedly flexed and abducted, as in the lithotomy position.

Meralgia Paresthetica

The lateral femoral cutaneous nerve, a sensory nerve arising from the L2 and L3 roots, may be compressed or stretched in obese or diabetic patients and during pregnancy. The nerve usually runs under the outer portion of the inguinal ligament to reach the thigh, but the ligament sometimes splits to enclose it. Hyperextension of the hip or increased lumbar lordosis—such as occurs during pregnancy—leads to nerve compression by the posterior fascicle of the ligament. However, entrapment of the nerve at any point along its course may cause similar symptoms, and several other anatomic variations predispose the nerve to damage when it is stretched. Pain, paresthesia, or numbness occurs about the outer aspect of the thigh, usually unilaterally, and is sometimes relieved by sitting. Examination shows no abnormalities except in severe cases when cutaneous sensation is impaired in the affected area. Symptoms are usually mild and commonly settle spontaneously. Hydrocortisone injections medial to the anterosuperior iliac spine often relieve symptoms temporarily, while nerve decompression by transposition may provide more lasting relief.

Sciatic & Common Peroneal Nerve Palsies

Misplaced deep intramuscular injections are probably still the most common cause of sciatic nerve palsy. Trauma to the buttock, hip, or thigh may also be responsible. The resulting clinical deficit depends on whether the whole nerve has been affected or only certain fibers. In general, the peroneal fibers of the sciatic nerve are more susceptible to damage than those destined for the tibial nerve. A sciatic nerve lesion may therefore be difficult to distinguish from peroneal neuropathy unless there is electromyographic evidence of involvement of the short head of the biceps femoris muscle. The common peroneal nerve itself may be compressed or injured in the region of the head and neck of the fibula, eg, by sitting with crossed legs or wearing high boots. There is weakness of dorsiflexion and eversion of the foot, accompanied by numbness or blunted sensation of the anterolateral aspect of the calf and dorsum of the foot.

Tarsal Tunnel Syndrome

The tibial nerve, the other branch of the sciatic, supplies several muscles in the lower extremity, gives origin to the sural nerve, and then continues as the posterior tibial nerve to supply the plantar flexors of the foot and toes. It passes through the tarsal tunnel behind and below the medial malleolus, giving off calcaneal branches and the medial and lateral plantar nerves that supply small muscles of the foot and the skin on the plantar aspect of the foot and toes. Compression of the posterior tibial nerve or its branches between the bony floor and ligamentous roof of the tarsal tunnel leads to pain, paresthesias, and numbness over the bottom of the foot, especially at night, with sparing of the heel. Muscle weakness may be hard to recognize clinically. Compressive lesions of the individual plantar nerves may also occur more distally, with clinical features similar to those of the tarsal tunnel syndrome. Treatment is surgical decompression.

Aminoff MJ: *Electromyography in Clinical Practice: Clinical and Electrodiagnostic Aspects of Neuromuscular Disease*, 3rd ed. Churchill Livingstone, 1998.

Facial Neuropathy

An isolated facial palsy may occur in patients with HIV seropositivity, sarcoidosis, or Lyme disease ([Chapter 34](#)), but most often it is idiopathic (Bell's palsy).

3. Bell's Palsy

Bell's palsy is an idiopathic facial paresis of lower motor neuron type that has been attributed to an inflammatory reaction involving the facial nerve near the stylomastoid foramen or in the bony facial canal. Reactivation of herpes simplex virus has been postulated, but there is limited evidence to support that view.

The clinical features of Bell's palsy are characteristic. The facial paresis generally comes on abruptly, but it may worsen over the following day or so. Pain about the ear precedes or accompanies the weakness in many cases but usually lasts for only a few days. The face itself feels stiff and pulled to one side. There may be ipsilateral restriction of eye closure and difficulty with eating and fine facial movements. A disturbance of taste is common, owing to involvement of chorda tympani fibers, and hyperacusis due to involvement of fibers to the stapedius occurs occasionally.

The management of Bell's palsy is controversial. Approximately 60% of cases recover completely without treatment, presumably because the lesion is so mild that it leads merely to conduction block. Considerable improvement occurs in most other cases, and only about 10% of all patients have permanent disfigurement or other long-term sequelae. Treatment is unnecessary in most cases but is indicated for patients in whom an unsatisfactory outcome can be predicted. The best clinical guide to progress is the severity of the palsy during the first few days after presentation. Patients with clinically complete palsy when first seen are less likely to make a full recovery than those with an incomplete one. A poor prognosis for recovery is also associated with advanced age, hyperacusis, and severe initial pain. Electromyography and nerve excitability or conduction studies provide a guide to prognosis but not early enough to aid in the selection of patients for treatment.

The only medical treatment that may influence the outcome is administration of corticosteroids with or without acyclovir, but studies supporting this concept have been criticized. Many clinicians nevertheless routinely prescribe corticosteroids for patients with Bell's palsy seen within 5 days of onset. The author prescribes them only when the palsy is clinically complete or there is severe pain. Treatment with prednisone, 60 or 80 mg daily in divided doses for 4 or 5 days, followed by tapering of the dose over the next 7-10 days, is a satisfactory regimen. It is helpful to protect the eye with lubricating drops (or lubricating ointment at night) and a patch if eye closure is not possible. There is no evidence that surgical procedures to decompress the facial nerve are of benefit.

Grogan PM et al: Practice parameter: steroids, acyclovir, and surgery for Bell's palsy (an evidenced-based review): report of the Quality Standards Subcommittee of the American Academy of Neurology. *Neurology* 2001;56:830. [\[PMID: 11294918\]](#)

DISCOGENIC NECK PAIN*

*Low back pain is discussed in [Chapter 20](#).

Essentials of Diagnosis

- Neck pain, sometimes radiating to arms.
- Restricted neck movements.
- Motor, sensory, or reflex changes in arms with root involvement.
- Neurologic deficit in legs, gait disorder, or sphincter disturbance with cord involvement.

General Considerations

A variety of congenital abnormalities may involve the cervical spine and lead to neck pain; these include hemivertebrae, fused vertebrae, basilar impression, and instability of the atlantoaxial joint. Traumatic, degenerative, infective, and neoplastic disorders may also lead to pain in the neck. When rheumatoid arthritis involves the

spine, it tends to affect especially the cervical region, leading to pain, stiffness, and reduced mobility; displacement of vertebrae or atlantoaxial subluxation may lead to cord compression that can be life-threatening if not treated by fixation. Further details are given in [Chapter 20](#), and discussion here is restricted to disk disease.

Acute Cervical Disk Protrusion

Acute cervical disk protrusion leads to pain in the neck and radicular pain in the arm, exacerbated by head movement. With lateral herniation of the disk, motor, sensory, or reflex changes may be found in a radicular (usually C6 or C7) distribution on the affected side ([Figure 24-1 A](#), [24-1 B](#)); with more centrally directed herniations, the spinal cord may also be involved, leading to spastic paraparesis and sensory disturbances in the legs, sometimes accompanied by impaired sphincter function. The diagnosis is confirmed by MRI or CT myelography. In mild cases, bed rest or intermittent neck traction may help, followed by immobilization of the neck in a collar for several weeks. If these measures are unsuccessful or the patient has a significant neurologic deficit, surgical removal of the protruding disk may be necessary.

Cervical Spondylosis

Cervical spondylosis results from chronic cervical disk degeneration, with herniation of disk material, secondary calcification, and associated osteophytic outgrowths. One or more of the cervical nerve roots may be compressed, stretched, or angulated; and myelopathy may also develop as a result of compression, vascular insufficiency, or recurrent minor trauma to the cord. Patients present with neck pain and restricted head movement, occipital headaches, radicular pain and other sensory disturbances in the arms, weakness of the arms or legs, or some combination of these symptoms. Examination generally reveals that lateral flexion and rotation of the neck are limited. A segmental pattern of weakness or dermatomal sensory loss (or both) may be found unilaterally or bilaterally in the upper limbs, and tendon reflexes mediated by the affected root or roots are depressed. The C5 and C6 nerve roots are most commonly involved, and examination frequently then reveals weakness of muscles supplied by these roots (eg, deltoids, supra- and infraspinatus, biceps, brachioradialis), pain or sensory loss about the shoulder and outer border of the arm and forearm, and depressed biceps and brachioradialis reflexes. Spastic paraparesis may also be present if there is an associated myelopathy, sometimes accompanied by posterior column or spinothalamic sensory deficits in the legs.

Plain radiographs of the cervical spine show osteophyte formation, narrowing of disk spaces, and encroachment on the intervertebral foramina, but such changes are common in middle-aged persons and may be unrelated to the presenting complaint. CT or MRI helps to confirm the diagnosis and exclude other structural causes of the myelopathy.

Restriction of neck movements by a cervical collar may relieve pain. Operative treatment may be necessary to prevent further progression if there is a significant neurologic deficit or if root pain is severe, persistent, and unresponsive to conservative measures.

BRACHIAL & LUMBAR PLEXUS LESIONS

Brachial Plexus Neuropathy

Brachial plexus neuropathy may be idiopathic, sometimes occurring in relationship to a number of different nonspecific illnesses or factors. In other instances, brachial plexus lesions follow trauma or result from congenital anomalies, neoplastic involvement, or injury by various physical agents. In rare instances, the disorder occurs on a familial basis.

Idiopathic brachial plexus neuropathy (neuralgic amyotrophy) characteristically begins with severe pain about the shoulder, followed within a few days by weakness, reflex changes, and sensory disturbances involving especially the C5 and C6 segments. Symptoms and signs are usually unilateral but may be bilateral. Wasting of affected muscles is sometimes profound. The disorder relates to disturbed function of cervical roots or part of the brachial plexus, but its precise cause is unknown. Recovery occurs over the ensuing months but may be incomplete. Treatment is purely symptomatic.

Cervical Rib Syndrome

Compression of the C8 and T1 roots or the lower trunk of the brachial plexus by a cervical rib or band arising from the seventh cervical vertebra leads to weakness and wasting of intrinsic hand muscles, especially those in the thenar eminence, accompanied by pain and numbness in the medial two fingers and the ulnar border of the hand and forearm. The subclavian artery may also be compressed, and this forms the basis of Adson's test for diagnosing the disorder; the radial pulse is diminished or obliterated on the affected side when the seated patient inhales deeply and turns the head to one side or the other. Electromyography, nerve conduction studies, and somatosensory evoked potential studies may help confirm the diagnosis. X-rays sometimes show the cervical rib or a large transverse process of the seventh cervical vertebra, but normal findings do not exclude the possibility of a cervical band. Treatment of the disorder is by surgical excision of the rib or band.

Lumbosacral Plexus Lesions

A lumbosacral plexus lesion may develop in association with diseases such as diabetes, cancer, or bleeding disorders or in relation to injury. It occasionally occurs as an isolated phenomenon similar to idiopathic brachial plexopathy, and pain and weakness then tend to be more conspicuous than sensory symptoms. The distribution of symptoms and signs depends on the level and pattern of neurologic involvement.

DISORDERS OF NEUROMUSCULAR TRANSMISSION

1. Myasthenia Gravis

Essentials of Diagnosis

- Fluctuating weakness of commonly used voluntary muscles, producing symptoms such as diplopia, ptosis, and difficulty in swallowing.
- Activity increases weakness of affected muscles.
- Short-acting anticholinesterases transiently improve the weakness.

General Considerations

Myasthenia gravis occurs at all ages, sometimes in association with a thymic tumor or thyrotoxicosis, as well as in rheumatoid arthritis and lupus erythematosus. It is commonest in young women with HLA-DR3; if thymoma is associated, older men are more commonly affected. Onset is usually insidious, but the disorder is sometimes unmasked by a coincidental infection that leads to exacerbation of symptoms. Exacerbations may also occur before the menstrual period and during or shortly after pregnancy. Symptoms are due to a variable degree of block of neuromuscular transmission caused by autoantibodies binding to acetylcholine receptors; these are found in most patients with the disease and have a primary role in reducing the number of functioning acetylcholine receptors. Additionally, cellular immune activity against the receptor is found. Clinically, this leads to weakness; initially powerful movements fatigue readily. The external ocular muscles and certain other cranial muscles, including the masticatory, facial, and pharyngeal muscles, are especially likely to be affected, and the respiratory and limb muscles may also be involved.

Clinical Findings

A. Symptoms and Signs

Patients present with ptosis, diplopia, difficulty in chewing or swallowing, respiratory difficulties, limb weakness, or some combination of these problems. Weakness may remain localized to a few muscle groups, especially the ocular muscles, or may become generalized. Symptoms often fluctuate in intensity during the day, and this diurnal variation is superimposed on a tendency to longer-term spontaneous relapses and remissions that may last for weeks. Nevertheless, the disorder follows a slowly progressive course and may have a fatal outcome owing to respiratory complications such as aspiration pneumonia.

Clinical examination confirms the weakness and fatigability of affected muscles. In most cases, the extraocular muscles are involved, and this leads to ocular palsies and ptosis, which are commonly asymmetric. Pupillary responses are normal. The bulbar and limb muscles are often weak, but the pattern of involvement is variable. Sustained activity of affected muscles increases the weakness, which improves after a brief rest. Sensation is normal, and there are usually no reflex changes.

The diagnosis can generally be confirmed by the response to a short-acting anticholinesterase. Edrophonium can be given intravenously in a dose of 10 mg (1 mL), 2 mg being given initially and the remaining 8 mg about 30 seconds later if the test dose is well tolerated; in myasthenic patients, there is an obvious improvement in strength of weak muscles lasting for about 5 minutes. Alternatively, 1.5 mg of neostigmine can be given intramuscularly, and the response then lasts for about 2 hours; atropine sulfate (0.6 mg) should be available to reverse muscarinic side effects.

B. Imaging

Lateral and anteroposterior x-rays of the chest and CT scans should be obtained to demonstrate a coexisting thymoma, but normal studies do not exclude this possibility.

C. Laboratory and Other Studies

Electrophysiologic demonstration of a decrementing muscle response to repetitive 2- or 3-Hz stimulation of motor nerves indicates a disturbance of neuromuscular transmission. Such an abnormality may even be detected in clinically strong muscles with certain provocative procedures. Needle electromyography of affected muscles shows a marked variation in configuration and size of individual motor unit potentials, and single-fiber electromyography reveals an increased jitter, or variability, in the time interval between two muscle fiber action potentials from the same motor unit.

Assay of serum for elevated levels of circulating acetylcholine receptor antibodies is another approach—increasingly used—to the laboratory diagnosis of myasthenia gravis and has a sensitivity of 80-90%.

Treatment

Medication such as aminoglycosides that may exacerbate myasthenia gravis should be avoided. Anticholinesterase drugs provide symptomatic benefit without influencing the course of the disease. Neostigmine, pyridostigmine, or both can be used, the dose being determined on an individual basis. The usual dose of neostigmine is 7.5-30 mg (average, 15 mg) taken four times daily; of pyridostigmine, 30-180 mg (average, 60 mg) four times daily. Overmedication may temporarily increase weakness, which is then unaffected or enhanced by intravenous edrophonium.

Thymectomy usually leads to symptomatic benefit or remission and should be considered in all patients younger than age 60, unless weakness is restricted to the extraocular muscles. If the disease is of recent onset and only slowly progressive, operation is sometimes delayed for a year or so, in the hope that spontaneous remission will occur.

Treatment with corticosteroids is indicated for patients who have responded poorly to anticholinesterase drugs and have already undergone thymectomy. It is introduced with the patient in the hospital, since weakness may initially be aggravated. Once weakness has stabilized after 2-3 weeks or any improvement is sustained, further management can be on an outpatient basis. Alternate-day treatment is usually well tolerated, but if weakness is enhanced on the nontreatment day it may be necessary for medication to be taken daily. The dose of corticosteroids is determined on an individual basis, but an initial high daily dose (eg, prednisone, 60-100 mg) can gradually be tapered to a relatively low maintenance level as improvement occurs; total withdrawal is difficult, however. Treatment with azathioprine may also be effective. The usual dose is 2- 3 mg/kg orally daily after a lower initial dose.

In patients with major disability in whom conventional treatment is either unhelpful or contraindicated, plasmapheresis or intravenous immunoglobulin therapy may be beneficial. It may also be useful for stabilizing patients before thymectomy and for managing acute crisis. Mycophenolate mofetil, an immunosuppressant, has also been used, and preliminary studies indicate that it may provide symptomatic benefit and allow the steroid dose to be reduced.

Palace J et al: Myasthenia gravis: diagnostic and management dilemmas. *Curr Opin Neurol* 2001;14:583. [PMID: 11562569]

Vincent A et al: Myasthenia gravis. *Lancet* 2001;357:2122. [PMID: 11445126]

2. Myasthenic Syndrome (Lambert-Eaton Syndrome)

Essentials of Diagnosis

- Variable weakness, typically improving with activity.
- Dysautonomic symptoms may also be present.
- A history of malignant disease may be obtained.

General Considerations

Myasthenic syndrome (Table 40-6) may be associated with small-cell carcinoma, sometimes developing before the tumor is diagnosed, and occasionally occurs with certain autoimmune diseases. There is defective release of acetylcholine in response to a nerve impulse, and this leads to weakness, especially of the proximal muscles of the limbs. As is not the case in myasthenia gravis, however, power steadily increases with sustained contraction. The diagnosis can be confirmed electrophysiologically, because the muscle response to stimulation of its motor nerve increases remarkably if the nerve is stimulated repetitively at high rates, even in muscles that are not clinically weak.

Treatment with plasmapheresis and immunosuppressive drug therapy (prednisone and azathioprine) may lead to clinical and electrophysiologic improvement, in addition to therapy aimed at tumor when present. Prednisone is usually initiated in a daily dose of 60-80 mg and azathioprine in a daily dose of 2 mg/kg. Guanidine hydrochloride (25-50 mg/kg/d in divided doses) is occasionally helpful in seriously disabled patients, but adverse effects of the drug include marrow suppression. The response to treatment with anticholinesterase drugs such as pyridostigmine or neostigmine, either alone or in combination with guanidine, is variable.

3. Botulism

The toxin of *Clostridium botulinum* prevents the release of acetylcholine at neuromuscular junctions and autonomic synapses. Botulism occurs most commonly following the ingestion of contaminated home-canned food and should be suggested by the development of sudden, fluctuating, severe weakness in a previously healthy person. Symptoms begin within 72 hours following ingestion of the toxin and may progress for several days. Typically, there is diplopia, ptosis, facial weakness, dysphagia, and nasal speech, followed by respiratory difficulty and finally by weakness that appears last in the limbs. Blurring of vision (with unreactive dilated pupils) is characteristic, and there may be dryness of the mouth, constipation (paralytic ileus), and postural hypotension. Sensation is preserved, and the tendon reflexes are not affected unless the involved muscles are very weak. If the diagnosis is suspected, the local health authority should be notified and a sample of serum and contaminated food (if available) sent to be assayed for toxin. Support for the diagnosis may be obtained by electrophysiologic studies; with repetitive stimulation of motor nerves at fast rates, the muscle response increases in size progressively.

Patients should be hospitalized in case respiratory assistance becomes necessary. Treatment is with trivalent antitoxin, once it is established that the patient is not allergic to horse serum. Guanidine hydrochloride (25-50 mg/kg/d in divided doses) to facilitate release of acetylcholine from nerve endings sometimes helps to increase muscle strength. Anticholinesterase drugs are of no value. Respiratory assistance and other supportive measures should be provided as necessary. Further details are provided in Chapter 33.

4. Disorders Associated with Use of Aminoglycosides

Aminoglycoside antibiotics, eg, gentamicin, may produce a clinical disturbance similar to botulism by preventing the release of acetylcholine from nerve endings, but symptoms subside rapidly as the responsible drug is eliminated from the body. These antibiotics are particularly dangerous in patients with preexisting disturbances of neuromuscular transmission and are therefore best avoided in patients with myasthenia gravis.

MYOPATHIC DISORDERS

Muscular Dystrophies

Essentials of Diagnosis

- Muscle weakness, often in a characteristic distribution.
- Age at onset and inheritance pattern depend on the specific dystrophy.

General Considerations

These inherited myopathic disorders are characterized by progressive muscle weakness and wasting. They are subdivided by mode of inheritance, age at onset, and clinical features, as shown in Table 24-6. In the Duchenne type, pseudohypertrophy of muscles frequently occurs at some stage; intellectual retardation is common; and there may be skeletal deformities, muscle contractures, and cardiac involvement. The serum creatine kinase level is increased, especially in the Duchenne and

Becker varieties, and mildly increased also in limb-girdle dystrophy. Electromyography may help to confirm that weakness is myopathic rather than neurogenic. Similarly, histopathologic examination of a muscle biopsy specimen may help to confirm that weakness is due to a primary disorder of muscle and to distinguish between various muscle diseases.

A genetic defect on the short arm of the X chromosome has been identified in Duchenne dystrophy. The affected gene codes for the protein dystrophin, which is markedly reduced or absent from the muscle of patients with the disease. Dystrophin levels are generally normal in the Becker variety, but the protein is qualitatively altered.

Duchenne muscular dystrophy can now be recognized early in pregnancy in about 95% of women by genetic studies; in late pregnancy, DNA probes can be used on fetal tissue obtained for this purpose by amniocentesis. The genes causing some of the other muscular dystrophies are listed in [Table 24-6](#).

There is no specific treatment for the muscular dystrophies, but it is important to encourage patients to lead as normal lives as possible. Prolonged bed rest must be avoided, as inactivity often leads to worsening of the underlying muscle disease. Physical therapy and orthopedic procedures may help to counteract deformities or contractures.

Cohn RD et al: Molecular basis of muscular dystrophies. Muscle Nerve 2000;23:1456. [\[PMID: 11003781\]](#)

Myotonic Dystrophy

Myotonic dystrophy, a slowly progressive, dominantly inherited disorder, usually manifests itself in the third or fourth decade but occasionally appears early in childhood. The genetic defect has been localized to the long arm of chromosome 19. Myotonia leads to complaints of muscle stiffness and is evidenced by the marked delay that occurs before affected muscles can relax after a contraction. This can often be demonstrated clinically by delayed relaxation of the hand after sustained grip or by percussion of the belly of a muscle. In addition, there is weakness and wasting of the facial, sternocleidomastoid, and distal limb muscles. Associated clinical features include cataracts, frontal baldness, testicular atrophy, diabetes mellitus, cardiac abnormalities, and intellectual changes. Electromyographic sampling of affected muscles reveals myotonic discharges in addition to changes suggestive of myopathy.

Myotonia can be treated with phenytoin (100 mg three times daily), quinine sulfate (300-400 mg three times daily), or procainamide (0.5-1 g four times daily). More recently, tocainide and mexiletine have been used. Phenytoin is preferred, since the other drugs may have undesirable effects on cardiac conduction. Neither the weakness nor the course of the disorder is influenced by treatment.

Meola G: Clinical and genetic heterogeneity in myotonic dystrophies. Muscle Nerve 2000;23:1789. [\[PMID: 11102902\]](#)

Myotonia Congenita

Myotonia congenita is commonly inherited as a dominant trait. The responsible gene may be on the long arm of chromosome 7. Generalized myotonia without weakness is usually present from birth, but symptoms may not appear until early childhood. Patients complain of muscle stiffness that is enhanced by cold and inactivity and relieved by exercise. Muscle hypertrophy, at times pronounced, is also a feature. A recessive form with later onset is associated with slight weakness and atrophy of distal muscles. Treatment with quinine sulfate, procainamide, tocainide, mexiletine, or phenytoin may help the myotonia, as in myotonic dystrophy.

Polymyositis & Dermatomyositis

See [Chapter 20](#).

Inclusion Body Myositis

This disorder, of unknown cause, begins insidiously, usually after middle age, with progressive proximal weakness of first the lower and then the upper extremities. Distal weakness is usually mild. Serum creatine kinase levels may be normal or increased. The diagnosis is confirmed by muscle biopsy. In contrast to polymyositis, corticosteroid therapy is usually ineffective. The role of intravenous immunoglobulin therapy is unclear.

Dalakas MC et al: A controlled study of intravenous immunoglobulin combined with prednisone in the treatment of IBM. Neurology 2001;56:323. [\[PMID: 11171896\]](#)

Mitochondrial Myopathies

The mitochondrial myopathies are a clinically diverse group of disorders that on pathologic examination of skeletal muscle with the modified Gomori stain show characteristic "ragged red fibers" containing accumulations of abnormal mitochondria. Patients may present with progressive external ophthalmoplegia or with limb weakness that is exacerbated or induced by activity. Other patients present with central neurologic dysfunction, eg, myoclonic epilepsy (myoclonic epilepsy, ragged red fiber syndrome, or MERRF), or the combination of myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (MELAS). These disorders result from separate abnormalities of mitochondrial DNA. (See also [Chapter 19](#).)

Myopathies Associated With Other Disorders

Myopathy may occur in association with chronic hypokalemia, any endocrinopathy, and in patients taking corticosteroids, chloroquine, colchicine, clofibrate, emetine, aminocaproic acid, lovastatin, bretylium tosylate, or drugs causing potassium depletion. Weakness is mainly proximal, and serum creatine kinase is typically normal, except in hypothyroidism and some of the toxic myopathies. Treatment is of the underlying cause. Myopathy also occurs with chronic alcoholism, whereas acute reversible muscle necrosis may occur shortly after acute alcohol intoxication. Inflammatory myopathy may occur in patients taking penicillamine; myotonia may be induced by clofibrate and preexisting myotonia may be exacerbated or unmasked by depolarizing muscle relaxants (eg, suxamethonium), beta-blockers (eg, propranolol), fenoterol, ritodrine, and, possibly, certain diuretics.

PERIODIC PARALYSIS SYNDROME

Periodic paralysis may have a familial (dominant inheritance) basis. Episodes of flaccid weakness or paralysis occur, sometimes in association with abnormalities of the plasma potassium level. Strength is normal between attacks. **Hypokalemic periodic paralysis** is characterized by attacks that tend to occur on awakening, after exercise, or after a heavy meal and may last for several days. Patients should avoid excessive exertion. A low-carbohydrate and low-salt diet may help prevent attacks, as may acetazolamide, 250-750 mg/d. An ongoing attack may be aborted by potassium chloride given orally or by intravenous drip, provided the ECG can be monitored and renal function is satisfactory. In young Asian men, it is commonly associated with hyperthyroidism; treatment of the endocrine disorder then prevents recurrences. In **hyperkalemic periodic paralysis**, attacks also tend to occur after exercise but usually last for less than an hour. They may be terminated by intravenous calcium gluconate (1-2 g) or by intravenous diuretics (furosemide, 20-40 mg), glucose, or glucose and insulin; daily acetazolamide or chlorothiazide may prevent recurrences. Genetic linkage studies suggest that many families with this disorder have a defect in the sodium channel gene on the long arm of chromosome 17. **Normokalemic periodic paralysis** is similar clinically to the hyperkalemic variety, but the plasma potassium level remains normal during attacks; treatment is with acetazolamide.

Table 24-1. Prophylactic treatment of migraine.

Drug	Usual Adult Daily Dose	Common Side Effects
Aspirin	650-1950 mg	Dyspepsia, gastrointestinal bleeding.
Propranolol	80-240 mg	Fatigue, lassitude, depression, insomnia, nausea, vomiting, constipation.
Amitriptyline	10-150 mg	Sedation, dry mouth, constipation, weight gain, blurred vision, edema, hypotension, urinary retention.
Imipramine	10-150 mg	Similar to those of amitriptyline (above).
Sertraline	50-200 mg	Anxiety, insomnia, sweating, tremor, gastrointestinal disturbances.
Fluoxetine	20-60 mg	Similar to those of sertraline (above).
Ergonovine maleate	0.6-2 mg	Nausea, vomiting, abdominal pain, diarrhea.
Cyproheptadine	12-20 mg	Sedation, dry mouth, epigastric discomfort, gastrointestinal disturbances.
Clonidine	0.2-0.6 mg	Dry mouth, drowsiness, sedation, headache, constipation.
Methysergide	4-8 mg	Nausea, vomiting, diarrhea, abdominal pain, cramps, weight gain, insomnia, edema, peripheral vasoconstriction. Retroperitoneal and pleuropulmonary fibrosis and fibrous thickening of cardiac valves may occur.
Verapamil ¹	80-160 mg	Headache, hypotension, flushing, edema, constipation. May aggravate atrioventricular nodal heart block and congestive heart failure.

¹Other calcium channel antagonists (eg, nimodipine, nifedipine, and diltiazem) may also be used.

Table 24-2. Drug treatment for seizures.

Drug	Usual Adult Daily Dose	Minimum No. of Daily Doses	Time to Steady-State Drug Levels	Optimal Drug Level	Selected Side Effects and Idiosyncratic Reactions
Generalized tonic-clonic (grand mal) or partial (focal) seizures					
Phenytoin	200-400 mg	1	5-10 days	10-20 µg/mL	Nystagmus, ataxia, dysarthria, sedation, confusion, gingival hyperplasia, hirsutism, megaloblastic anemia, blood dyscrasias, skin rashes, fever, systemic lupus erythematosus, lymphadenopathy, peripheral neuropathy, dyskinesias.
Carbamazepine	600-1200 mg	2-3	3-4 days	4-8 µg/mL	Nystagmus, dysarthria, diplopia, ataxia, drowsiness, nausea, blood dyscrasias, hepatotoxicity, hyponatremia. May exacerbate myoclonic seizures.
(extended-release formulation)		(2)			
Valproic acid	1500-2000 mg	3	2-4 days	50-100 µg/mL	Nausea, vomiting, diarrhea, drowsiness, alopecia, weight gain, hepatotoxicity, thrombocytopenia, tremor.
Phenobarbital	100-200 mg	1	14-21 days	10-40 µg/mL	Drowsiness, nystagmus, ataxia, skin rashes, learning difficulties, hyperactivity.
Primidone	750-1500 mg	3	4-7 days	5-15 µg/mL	Sedation, nystagmus, ataxia, vertigo, nausea, skin rashes, megaloblastic anemia, irritability.
Felbamate ^{1,2}	1200-3600 mg	3	4-5 days	?	Anorexia, nausea, vomiting, headache, insomnia, weight loss, dizziness, hepatotoxicity, aplastic anemia.
Gabapentin ²	900-1800 mg	3	1 day	?	Sedation, fatigue, ataxia, nystagmus, weight loss.
Lamotrigine	100-500 mg	2	4-5 days	?	Sedation, skin rash, visual disturbances, dyspepsia, ataxia.
Topiramate ²	200-400 mg	2	4 days	?	Somnolence, nausea, dyspepsia, irritability, dizziness, ataxia, nystagmus, diplopia, renal calculi, weight loss.
Oxycarbamazepine ²	900-1800 mg	2	2-3 days	?	As for carbamazepine.
Levetiracetam ²	1000-3000 mg	2	2 days	?	Somnolence, ataxia, headache.
Zonisamide ²	200-600 mg	1-2	10 days	?	Somnolence, ataxia, anorexia, nausea, vomiting, rach, confusion, renal calculi. Do not use in patients with sulfonamide allergy.
Tiagabine ³	32-56 mg	2	2 days	?	Somnolence, anxiety, dizziness, poor concentration, tremor, diarrhea.
Absence (petit mal) seizures					
Ethosuximide	100-1500 mg	2	5-10 days	40-100 µg/mL	Nausea, vomiting, anorexia, headache, lethargy, unsteadiness, blood dyscrasias, systemic lupus erythematosus, urticaria, pruritus.
Valproic acid	1500-2000 mg	3	2-4 days	50-100 µg/mL	See above.
Clonazepam	0.04-0.2 mg/kg	2	?	20-80 ng/mL	Drowsiness, ataxia, irritability, behavioral changes, exacerbation of tonic-clonic seizures.
Myoclonic seizures					
Valproic acid	1500-2000 mg	3	2-4 days	50-100 µg/mL	See above.
Clonazepam	0.04-0.2 mg/kg	2	?	20-80 ng/mL	See above.

¹Not to be used as a first-line drug; when used, blood counts should be performed regularly (every 2-4 weeks). Should be used only in selected patients because of risk of aplastic anemia and hepatic failure.

²Approved as adjunctive therapy for partial and secondarily generalized seizures.

³Approved as adjunctive therapy for partial seizures.

Table 24-3. Primary intracranial tumors.

Tumor	Clinical Features	Treatment and Prognosis
Glioblastoma multiforme	Presents commonly with nonspecific complaints and increased intracranial pressure. As it grows, focal deficits develop.	Course is rapidly progressive, with poor prognosis. Total surgical removal is usually not possible. Radiation therapy and chemotherapy may prolong survival.
Astrocytoma	Presentation similar to glioblastoma multiforme but course more protracted, often over several years. Cerebellar astrocytoma may have a more benign course.	Prognosis is variable. By the time of diagnosis, total excision is usually impossible; tumor often is not radiosensitive. In cerebellar astrocytoma, total surgical removal is often possible.
Medulloblastoma	Seen most frequently in children. Generally arises from roof of fourth ventricle and leads to increased intracranial pressure accompanied by brainstem and cerebellar signs. May seed subarachnoid space.	Treatment consists of surgery combined with radiation therapy and chemotherapy.
Ependymoma	Glioma arising from the ependyma of a ventricle, especially the fourth ventricle; leads early to signs of increased intracranial pressure. Arises also from central canal of cord.	Tumor is not radiosensitive and is best treated surgically if possible.
Oligodendroglioma	Slow-growing. Usually arises in cerebral hemisphere in adults. Calcification may be visible on skull x-ray.	Treatment is surgical and usually successful.
Brainstem glioma	Presents during childhood with cranial nerve palsies and then with long tract signs in the limbs. Signs of increased intracranial pressure occur late.	Tumor is inoperable; treatment is by irradiation and shunt for increased intracranial pressure.
Cerebellar hemangioblastoma	Presents with dysequilibrium, ataxia of trunk or limbs, and signs of increased intracranial pressure. Sometimes familial. May be associated with retinal and spinal vascular lesions, polycythemia, and renal cell carcinoma.	Treatment is surgical.
Pineal tumor	Presents with increased intracranial pressure, sometimes associated with impaired upward gaze (Parinaud's syndrome) and other deficits indicative of midbrain lesion.	Ventricular decompression by shunting is followed by surgical approach to tumor; irradiation is indicated if tumor is malignant. Prognosis depends on histopathologic findings and extent of tumor.
Craniopharyngioma	Originates from remnants of Rathke's pouch above the sella, depressing the optic chiasm. May present at any age but usually in childhood, with endocrine dysfunction and bitemporal field defects.	Treatment is surgical, but total removal may not be possible.
Acoustic neurinoma	Ipsilateral hearing loss is most common initial symptom. Subsequent symptoms may include tinnitus, headache, vertigo, facial weakness or numbness, and long tract signs. (May be familial and bilateral when related to neurofibromatosis.) Most sensitive screening tests are MRI and brainstem auditory evoked potential.	Treatment is excision by translabyrinthine surgery, craniectomy, or a combined approach. Outcome is usually good.
Meningioma	Originates from the dura mater or arachnoid; compresses rather than invades adjacent neural structures. Increasingly common with advancing age. Tumor size varies greatly. Symptoms vary with tumor siteeg, unilateral exophthalmos (sphenoidal ridge); anosmia and optic nerve compression (olfactory groove). Tumor is usually benign and readily detected by CT scanning; may lead to calcification and bone erosion visible on plain x-rays of skull.	Treatment is surgical. Tumor may recur if removal is incomplete.
Primary cerebral lymphoma	Associated with AIDS and other immunodeficient states. Presentation may be with focal deficits or with disturbances of cognition and consciousness. May be indistinguishable from cerebral toxoplasmosis.	Treatment is by whole brain irradiation; chemotherapy may have an adjunctive role. Prognosis depends upon CD4 count at diagnosis.

Table 24-5. Acute cerebral sequelae of head injury.

Sequelae	Clinical Features	Pathology
Concussion	Transient loss of consciousness with bradycardia, hypotension, and respiratory arrest for a few seconds followed by retrograde and posttraumatic amnesia. Occasionally followed by transient neurologic deficit.	Bruising on side of impact (coup injury) or contralaterally (contrecoup injury).
Cerebral contusion or laceration	Loss of consciousness longer than with concussion. May lead to death or severe residual neurologic deficit.	Cerebral contusion, edema, hemorrhage, and necrosis. May have subarachnoid bleeding.
Acute epidural hemorrhage	Headache, confusion, somnolence, seizures, and focal deficits occur several hours after injury and lead to coma, respiratory depression, and death unless treated by surgical evacuation.	Tear in meningeal artery, vein, or dural sinus, leading to hematoma visible on CT scan.
Acute subdural hemorrhage	Similar to epidural hemorrhage, but interval before onset of symptoms is longer. Treatment is by surgical evacuation.	Hematoma from tear in veins from cortex to superior sagittal sinus or from cerebral laceration, visible on CT scan.
Cerebral hemorrhage	Generally develops immediately after injury. Clinically resembles hypertensive hemorrhage. Surgical evacuation is sometimes helpful.	Hematoma, visible on CT scan.

Introduction

Psychiatric disorders are functional impairments that may result from disturbance of one or more of the following interrelated factors: (1) biologic function, (2) psychodynamic adaptation, (3) learned behavior, and (4) social and environmental conditions. Although the clinical situation at a given time determines which area of dysfunction will be emphasized, proper patient care requires an approach that adequately evaluates all factors.

Biologic Function

Psychiatric disorders of biologic origin may be secondary to identifiable physical illness or caused by biochemical disturbances of the brain. A wide variety of psychiatric disorders (eg, psychosis, depression, delirium, anxiety) as well as nonspecific symptoms are caused by organic brain disease or by derangement of cerebral metabolism resulting from illness, biochemical aberrations (usually neurotransmitter dysfunction), nutritional deficiencies, or toxic agents.

Neurotransmitter functions have been correlated with the major psychiatric disorders. Cholinergic deficiency is present in some dementias, and adrenergic imbalance is important in some psychoses. Serotonergic mechanisms are significantly involved in affective disorders, aggression, autism, and the anxiety disorders, particularly obsessive-compulsive disorders and panic disorder.

Psychodynamic Adaptations

Psychodynamic adaptation involves a healthy balancing of intrapsychic motivations. Psychodynamic maladaptation involves intrapsychic aberrations and is usually treated by a psychotherapeutic approach. There are many forms of psychotherapy: supportive, interpretive, cognitive, persuasive, educative, or some combination of these methods. Depth, duration, intensity, and frequency of sessions may vary.

Learned Behavior

Learned behavior is part of the pathogenetic mechanism in all psychiatric disorders. For example, in somatization disorder, the patient may have learned that being sick is the only way to get attention. Altering such positive reinforcement may be critical in producing a change in behavior. Personality disorders are examples of failure to learn to incorporate patterns of behavior acceptable in social surroundings.

Social & Environmental Conditions

Social and environmental factors have always been considered of vital importance in the mental balance of the individual. Without encounter with the environment, there can be no socially recognized illness: The exigencies of everyday life contribute both to the development of a stable personality and to the deviations from the norm. There is a constantly changing cultural mix of influences that determines which types of behavior will be tolerated or considered deviant. Cultural attitudes and fears play key roles in the perception of illness and acceptance of treatment.

Hedrick SC et al: Effectiveness of collaborative care depression treatment in Veterans' Affairs primary care. J Gen Intern Med 2003;18:9. [\[PMID: 12534758\]](#)

■ PSYCHIATRIC ASSESSMENT

Psychiatric diagnosis rests upon the established principles of a thorough history and examination. All of the forces contributing to the individual's life situation must be identified, and this can be done only if the examination includes the history, mental status, medical conditions (including drugs), and pertinent social, cultural, and environmental factors impinging on the individual.

The examination of a psychiatric patient must include a complete medical history and physical examination (with emphasis on the neurologic examination) as well as all necessary laboratory and other special studies. Physical illness may frequently present as psychiatric disease, and vice versa.

Interview

Every psychiatric history should cover the following points: (1) complaint, from the patient's viewpoint; (2) the present illness, or the evolution of the symptoms; (3) neurovegetative signs such as libido, appetite, and sleep; (4) previous disorders and the nature and extent of their treatment; (5) the family history—important for genetic aspects and family influences; (6) the personal history—childhood development, adolescent adjustment, level of education, and adult coping patterns; (7) current life functioning, with attention to vocational, social, educational, and avocational areas; and (8) present or past use of alcohol and other drugs.

It is often essential to obtain additional information from the family. Observing interactions of the patient with significant others in the context of a family interview may give important diagnostic information and may even underscore the nature of the problem and suggest a therapeutic approach.

The formal mental status examination should be particularly detailed when there is any evidence or high risk of cognitive dysfunction. The mental status examination includes the following: (1) Appearance: Note unusual modes of dress, use of makeup, etc. (2) Activity and behavior: Gait, gestures, coordination of bodily movements, etc. (3) Affect: Outward manifestation of emotions such as depression, anger, elation, fear, resentment, or lack of emotional response. (4) Mood: The patient's report of feelings and observable emotional manifestations. (5) Speech: Coherence, spontaneity, articulation, hesitancy in answering, and duration of response. (6) Content of thought: Associations, preoccupations, obsessions, depersonalization, delusions, hallucinations, paranoid ideation, anger, fear, or unusual experiences; suicidal and homicidal ideation. (7) Thought process: Loose associations, flight of ideas, thought blocking, tangentiality, circumstantiality, perseveration, racing thought. (8) Cognition: (a) orientation to person, place, time, and circumstances; (b) remote and recent memory and recall; (c) calculations, digit retention (six forward is normal), serial sevens or threes; (d) general fund of knowledge (presidents, states, distances, events); (e) abstracting ability, often tested with common proverbs or with analogies and differences (eg, "How are a lie and a mistake the same, and how are they different?"); (f) ability to identify by naming, reading, and writing specified test names and objects; (g) ideomotor function, which combines understanding and the ability to perform a task (eg, "Show me how to throw a ball"); (h) ability to reproduce geometric constructions (eg, parallelogram, intersecting squares); and (i) right-left differentiation. (9) Judgment regarding commonsense problems such as what to do when one runs out of medicine. (10) Insight into the nature and extent of the current difficulty and its ramifications in the patient's daily life.

Formal cognitive screens can quantify impairments and point to the need for further evaluation. The Mini-Mental State Examination produces a numerical score with up to 30 points given for correct answers to questions (likely organic < 27 points) ([Figure 25-1](#)). Specific cognitive assessment must be performed, since many patients are able to cover a deficit in routine conversation.

Special Diagnostic Aids

Many tests and evaluation procedures are available that can be used to support and clarify initial diagnostic impressions.

A. Psychologic Testing

Testing by a psychologist may measure intelligence and cognitive functioning; provide information about personality, feelings, psychodynamics, and psychopathology; and differentiate psychic problems from organic ones. The place of such tests is similar to that of other tests in medicine—helpful in diagnostic problems but may be an unnecessary expense.

1. Objective tests—These tests provide quantitative evaluation compared to standard norms.

a. Intelligence tests—The test most frequently used is the Wechsler Adult Intelligence Scale-Revised (WAIS-R). Intelligence tests often reveal more than IQ. The results, given expert interpretation, can quantify intellectual deterioration that has occurred.

b. Minnesota Multiphasic Personality Inventory (MMPI-2)—The MMPI-2 is an empirically based test of personality assessment. The patient's scores are interpreted in comparison with data about others with the same response pattern to assess psychopathologic changes.

c. Screening instruments—These tests include the Beck Depression Inventory, which quantifies degrees of dysphoria, and the Mental Health Screener (Prime MD), which is a broad measure of the patient's concerns and assists with differential diagnosis.

d. Neuropsychologic assessment—Such an assessment is made when an organic deficit is present but information on anatomic location and extent of dysfunction is required.

2. Projective tests—These tests are unstructured, so that the patient is forced to respond in ways that reflect fantasies and individual modes of adaptation. They are particularly useful in identifying psychotic disorders and unconscious motivations.

a. Rorschach Psychodiagnostics—This test utilizes ten inkblots to provide important information on psychodynamic themes and aberrations.

b. Thematic Apperception Test (TAT)—This test uses 20 pictures of people in different situations to assess areas of interpersonal conflicts.

B. Neurologic Evaluation

Consultation is often necessary and may include specialized tests. Brain imaging is useful for detecting structural abnormalities in the patient who presents with a nondefinitive history and examination (eg, dissociative episodes, unusual psychotic episodes not explained by drug abuse, or an acute change in mental status). MRI is particularly useful in delineating lesions and identifying demyelinating and degenerative diseases (eg, Huntington's disease). Electroencephalography is particularly useful for the diagnosis of seizure disorders and in differentiating delirium from depression or dementia. Typically, delirium is associated with generalized electroencephalographic slowing, while depression and dementia do not have this change. Single photon emission computed tomography (SPECT) is a gamma imaging technology like PET, and both provide tomographic images of brain activity. SPECT is cheaper but has the disadvantages of lower image resolution and lower quantification of regional brain activity.

Formulation of the Diagnosis

A psychiatric diagnosis must be based upon positive evidence accumulated by the above techniques. It must not be based simply on the exclusion of organic findings.

A thorough psychiatric evaluation has therapeutic as well as diagnostic value and should be expressed in ways best understood by the patient, family, and other clinicians.

TREATMENT APPROACHES

The approaches to treatment of psychiatric patients are, in a broad sense, similar to those in other branches of medicine. For example, the internist treating a patient with heart disease uses not only **medical** measures such as drugs and pacemakers but also **psychologic** techniques to change attitudes and behaviors, **social** and **environmental** manipulation to mitigate deleterious influences, and **behavioral** techniques to change behavior patterns.

Regardless of the methods employed, treatment must be directed toward an objective, ie, it must be **goal-oriented**. This usually involves (1) obtaining active cooperation on the part of the patient, (2) establishing reasonable goals and modifying the goal if failure occurs, (3) emphasizing positive behavior (goals) instead of symptom behavior (problems), (4) delineating the method, and (5) setting a time frame (which can be modified later).

The clinician must resist pressures for instantaneous results. In almost all cases, psychiatric treatment involves the active participation of the significant people in the patient's life. Time must be spent with the patient, but the frequency and duration of appointments are highly variable and should be adjusted to meet both the patient's psychologic needs and financial restrictions. Adherence (collaboration) is the end product of many factors, the most important being clear communication, attention to cost, and simple dosage regimens when drugs are prescribed. The clinician can unwittingly promote chronic illness by prescribing medication inappropriately. The patient may come to believe that problems respond only to medication, and the more drugs prescribed, the stronger the misconception becomes.

Psychiatric Consultation

All clinicians are in an excellent position to meet their patients' emotional needs in an organized and competent way, referring to psychiatrists for consultation or for ongoing treatment of patients whose problems are considered beyond the expertise of the referring clinician. The most pressing problems involve evaluation of suicidal or assaultive potential and diagnostic differentiation in mood disorders and psychoses. Psychiatric problems associated with unusual psychopharmacologic therapy and with medications used in other branches of medicine may require pharmacologic consultation. When a psychiatric referral is made, it should be conducted like any other referral: in an open manner, with full explanation of the problem to the patient.

Hospitalization

Hospital care may be indicated when patients are too sick to care for themselves or when they present serious threats to themselves or others, when observation and diagnostic procedures are necessary, or when specific kinds of treatment such as complex medication trials or a hospital environment ("milieu therapy") are required. Symptoms calling for hospitalization include self-neglect, violent or bizarre behavior, suicidal risk, paranoid ideation or delusions, marked intellectual impairment, and poor judgment. The trend over recent years has been to admit patients to hospitals and treat them aggressively with the expectation of prompt discharge to the next appropriate level of care—day hospital, halfway house, outpatient therapy, etc. The decision to propose involuntary hospitalization should be taken only after weighing the potential benefits to the patient and the community against the individual's loss of autonomy.

The disadvantages of psychiatric hospitalization include decreased self-confidence as a result of needing hospitalization, the stigma of being a "psychiatric patient," possible increased dependency and regression, and the expense. Generally, there is no advantage to prolonged hospital stays for most psychiatric disorders. Partial hospitalization or "day" programs are providing many of the benefits of hospitalization without some of the disadvantages; in these programs, the patient attends daytime treatment but sleeps at home.

Bateman A et al: Effectiveness of partial hospitalization in the treatment of borderline personality disorder: a randomized controlled trial. Am J Psychiatry 1999;156:1563. [\[PMID: 10518167\]](#)

COMMON PSYCHIATRIC DISORDERS

STRESS & ADJUSTMENT DISORDERS (SITUATIONAL DISORDERS)

Essentials of Diagnosis

- Anxiety or depression clearly secondary to an identifiable stress.
- Subsequent symptoms of anxiety or depression commonly elicited by similar stress of lesser magnitude.
- Alcohol and other drugs are commonly used in self-treatment.

General Considerations

Stress exists when the adaptive capacity of the individual is overwhelmed by events. The event may be an insignificant one objectively considered, and even favorable changes (eg, promotion and transfer) requiring adaptive behavior can produce stress. For each individual, stress is subjectively defined, and the response to stress is a function of each person's personality and physiologic endowment.

Classification & Clinical Findings

Opinion differs about what events are most apt to produce stress reactions. The causes of stress are different at different ages—eg, in young adulthood, the sources of stress are found in the marriage or parent-child relationship, the employment relationship, and the struggle to achieve financial stability; in the middle years, the focus shifts to changing spousal relationships, problems with aging parents, and problems associated with having young adult offspring who themselves are encountering stressful situations; in old age, the principal concerns are apt to be retirement, loss of physical capacity, major personal losses, and thoughts of death.

An individual may react to stress by becoming anxious or depressed, by developing a physical symptom, by running away, having a drink, starting an affair, or in

limitless other ways. Common subjective responses are fear (of repetition of the stress-inducing event), rage (at frustration), guilt (over aggressive impulses), and shame (over helplessness). Acute and reactivated stress may be manifested by restlessness, irritability, fatigue, increased startle reaction, and a feeling of tension. Inability to concentrate, sleep disturbances (insomnia, bad dreams), and somatic preoccupations often lead to self-medication, most commonly with alcohol or other central nervous system depressants. Maladaptive behavior in response to stress is called adjustment disorder, with the major symptom specified (eg, "adjustment disorder with depressed mood").

Posttraumatic stress disorder (PTSD)—included among the anxiety disorders in *DSM-IV*—is a syndrome characterized by "reexperiencing" a traumatic event (eg, rape, severe burns, military combat), along with decreased responsiveness and avoidance of current events associated with the trauma. Patients experience physiologic hyperarousal, which includes startle reactions, intrusive thoughts, illusions, overgeneralized associations, sleep problems, nightmares, dreams about the precipitating event, impulsivity, difficulties in concentration, and hyperalertness. The symptoms may be precipitated or exacerbated by events that are a reminder of the original stress. Symptoms frequently arise after a long latency period (eg, child abuse can result in later-onset posttraumatic stress syndrome). The sooner the symptoms arise after the initial trauma and the sooner therapy is initiated, the better the prognosis. The therapeutic approach is to facilitate the normal recovery that was blocked at the time of the trauma. Therapy at that time should be brief and simple (catharsis and working through of the traumatic experience), expecting quick recovery and promoting a sense of mastery over the traumatic event.

Treatment initiated later, when symptoms have crystallized, includes programs for cessation of alcohol and other drug abuse, group and individual psychotherapy, and improved social support systems.

Differential Diagnosis

Adjustment disorders must be distinguished from anxiety disorders, affective disorders, and personality disorders exacerbated by stress and from somatic disorders with psychic overlay.

Treatment

A. Behavioral

Stress reduction techniques include immediate symptom reduction (eg, rebreathing in a bag for hyperventilation) or early recognition and removal from a stress source before full-blown symptoms appear. It is often helpful for the patient to keep a daily log of stress precipitators, responses, and alleviators. Relaxation and exercise techniques are also helpful in reducing the reaction to stressful events.

B. Social

The stress reactions of life crisis problems are—more than any other category—a function of psychosocial upheaval, and patients frequently present with somatic symptoms. While it is not easy for the patient to make necessary changes (or they would have been made long ago), it is important for the therapist to establish the framework of the problem, since the patient's denial system may obscure the issues. Clarifying the problem allows the patient to begin viewing it within the proper context and facilitates the sometimes difficult decisions the patient eventually must make (eg, change of job or relocation of adult-dependent offspring).

C. Psychologic

Prolonged in-depth psychotherapy is seldom necessary in cases of isolated stress response or adjustment disorder. Supportive psychotherapy (see above) with an emphasis on the here and now and strengthening of existing defenses is a helpful approach so that time and the patient's own resiliency can restore the previous level of function. Posttraumatic stress syndromes respond to early catharsis and dynamic psychotherapy oriented toward acceptance of the event, with the expectation of quick recovery and return to the previous level of function. Early cognitive behavioral interventions can also speed recovery. Psychologic debriefing in a single session, once considered a mainstay in prevention of PTSD, is being reevaluated as a therapeutic option. Marital problems are a major area of concern, and it is important that the clinician have available a dependable referral source when marriage counseling is indicated.

D. Medical

Judicious use of sedatives (eg, lorazepam, 1-2 mg orally daily) for a limited time and as part of an overall treatment plan can provide relief from acute anxiety symptoms. Problems arise when the situation becomes chronic through inappropriate treatment or when the treatment approach supports the development of chronicity (see Sedative-Hypnotic Drugs, below).

In posttraumatic stress disorder, early treatment of anxious arousal with beta-blockers (eg, propranolol, 80-160 mg daily) may lessen the peripheral symptoms of anxiety (eg, tremors, palpitations) and help prevent development of the disorder. Antidepressant drugs—particularly selective serotonin reuptake inhibitors (SSRIs)—in full dosage are helpful in ameliorating depression, panic attacks, sleep disruption, and startle responses in chronic PTSD. Sertraline is FDA-approved for this purpose. Antiseizure medications such as carbamazepine (400-800 mg daily) will often mitigate impulsivity and difficulty with anger management. Benzodiazepines such as clonazepam (1-4 mg daily) will reduce anxiety and panic attacks when used in adequate dosage, but dependency problems are a concern, particularly when the patient has had such problems in the past.

Prognosis

Return to satisfactory function after a short period is part of the clinical picture of this syndrome. Resolution may be delayed if others' responses to the patient's difficulties are thoughtlessly harmful or if the secondary gains outweigh the advantages of recovery. The longer the symptoms persist, the worse the prognosis.

ANXIETY DISORDERS & DISSOCIATIVE DISORDERS

Essentials of Diagnosis

- Overt anxiety or an overt manifestation of a defense mechanism (such as a phobia), or both.
- Not limited to an adjustment disorder.
- Somatic symptoms referable to the autonomic nervous system or to a specific organ system (eg, dyspnea, palpitations, paresthesias).
- Not a result of physical disorders, psychiatric conditions (eg, schizophrenia), or drug abuse (eg, cocaine).

General Considerations

Stress, fear, and anxiety all tend to be interactive. The principal components of anxiety are **psychologic** (tension, fears, difficulty in concentration, apprehension) and **somatic** (tachycardia, hyperventilation, palpitations, tremor, sweating). Other organ systems (eg, gastrointestinal) may be involved in multiple-system complaints. Fatigue and sleep disturbances are common. Sympathomimetic symptoms of anxiety are both a response to a central nervous system state and a reinforcement of further anxiety. Anxiety can become self-generating, since the symptoms reinforce the reaction, causing it to spiral. This is often the case when the anxiety is an epiphenomenon of other medical or psychiatric disorders.

Anxiety may be free-floating, resulting in acute anxiety attacks, occasionally becoming chronic. When one or several defense mechanisms (see above) are functioning, the consequences are well-known problems such as phobias, conversion reactions, dissociative states, obsessions, and compulsions. Lack of structure is frequently a contributing factor, as noted in those people who have "Sunday neuroses." They do well during the week with a planned work schedule but cannot tolerate the unstructured weekend. Planned-time activities tend to bind anxiety, and many people have increased difficulties when this is lost, as in retirement.

Some believe that various manifestations of anxiety are not a result of unconscious conflicts but are "habits"—persistent patterns of nonadaptive behavior acquired by learning. The "habits," being nonadaptive, are unsatisfactory ways of dealing with life's problems—hence the resultant anxiety. Help is sought only when the anxiety becomes too painful. Exogenous factors such as stimulants (eg, caffeine, cocaine) must be considered as a contributing factor.

Clinical Findings

A. Generalized Anxiety Disorder

This is the most common of the clinically significant anxiety disorders. Initial manifestations appear at age 20-35 years, and there is a slight predominance in women. The anxiety symptoms of apprehension, worry, irritability, difficulty in concentrating, insomnia, and somatic complaints are present more days than not for at least 6 months. Manifestations include cardiac (eg, tachycardia, increased blood pressure), gastrointestinal (eg, increased acidity, nausea, epigastric pain), and neurologic (eg,

headache, near-syncope) systems. The focus of the anxiety may be a number of everyday activities.

B. Panic Disorder

This is characterized by short-lived, recurrent, unpredictable episodes of intense anxiety accompanied by marked physiologic manifestations. Agoraphobia may be present. Distressing symptoms and signs such as dyspnea, tachycardia, palpitations, headaches, dizziness, paresthesias, choking, smothering feelings, nausea, and bloating are associated with feelings of impending doom (alarm response). Recurrent sleep panic attacks (not nightmares) occur in about 30% of panic disorders. Anticipatory anxiety develops in all these patients and further constricts their daily lives. Panic disorder tends to be familial, with onset usually under age 25; it affects 3-5% of the population, and the female-to-male ratio is 2:1. The premenstrual period is one of heightened vulnerability. Patients frequently undergo emergency medical evaluations (eg, for "heart attacks" or "hypoglycemia") before the correct diagnosis is made. Gastrointestinal symptoms are especially common, occurring in about one-third of cases. Myocardial infarction, pheochromocytoma, hyperthyroidism, and various recreational drug reactions can mimic panic disorder. Mitral valve prolapse may be present but is not usually a significant factor. Patients who have recurrent panic disorder often become **demoralized, hypochondriacal, agoraphobic, and depressed**. These individuals are at increased risk for major depression and the suicide attempts associated with that disorder. Alcohol abuse (about 20%) results from self-treatment and is not infrequently combined with dependence on sedatives. Some patients have atypical panic attacks associated with seizure-like symptoms that often include psychosensory phenomena (a history of stimulant abuse often emerges). About 25% of panic disorder patients also have obsessive-compulsive disorder.

C. Obsessive-Compulsive Disorder (OCD)

In the obsessive-compulsive reaction, the irrational idea or the impulse persistently intrudes into awareness. Obsessions (constantly recurring thoughts such as fears of exposure to germs) and compulsions (repetitive actions such as washing the hands many times) are recognized by the individual as absurd and are resisted, but anxiety is alleviated only by ritualistic performance of the action or by deliberate contemplation of the intruding idea or emotion. The primary underlying concern of the patient is not to lose control. Many patients do not mention the symptoms and must be asked about them. These patients are usually predictable, orderly, conscientious, and intelligent—traits that are seen in many compulsive behaviors such as food bingeing and purging and compulsive running. There is an overlapping of obsessive-compulsive disorder and other behaviors ("OCD spectrum"), including tics, trichotillomania (hair pulling), onychophagia (nail biting), hypochondriasis, Tourette's syndrome, and eating disorders (see [Chapter 29](#)). The 2-3% incidence of OCD in the general population is much higher than was previously recognized. In addition, there is a high comorbidity of OCD and major depression; two-thirds of OCD patients will develop major depression during their lifetime. Male:female ratios are similar, with the highest rates occurring in the young, divorced, separated, and unemployed (all high-stress categories). Neurologic abnormalities of fine motor coordination and involuntary movements are common. Under extreme stress, these patients sometimes exhibit paranoid and delusional behaviors, often associated with depression, and can mimic schizophrenia.

D. Phobic Disorder

Phobic ideation can be considered a mechanism of "displacement" in which patients transfer feelings of anxiety from their true object to one that can be avoided. However, since phobias are ineffective defense mechanisms, there tends to be an increase in their scope, intensity, and number. Social phobias are global or specific; in the former, all social situations are poorly tolerated, while the latter group includes performance anxiety or well-delineated phobias. Agoraphobia (fear of open places and public areas) is frequently associated with severe panic attacks. Patients often develop the agoraphobia in early adult life, making a normal lifestyle difficult.

E. Dissociative Disorder

Fugue (the sudden, unexpected travel away from one's home with inability to recall one's past), amnesia, somnambulism, dissociative identity disorder (multiple personality disorder), and depersonalization are all dissociative states. The reaction is precipitated by emotional crisis. The symptom produces anxiety reduction and a temporary solution of the crisis. Mechanisms include repression and isolation as well as particularly limited concentration as seen in hypnotic states. Dissociative symptoms are similar in many ways to symptoms seen in patients with temporal lobe dysfunction.

Treatment

In all cases, underlying medical disorders must be ruled out (eg, cardiovascular, endocrine, respiratory, and neurologic disorders and substance-related syndromes, both intoxication and withdrawal states). These and other disorders can coexist with panic disorder.

A. Medical

1. Generalized anxiety—Benzodiazepines are the anxiolytics of choice in the acute management of generalized anxiety ([Table 25-1](#)). They are almost immediately effective. Antidepressants can be efficacious for the long-term treatment of generalized anxiety disorder, panic disorder, social phobia, and obsessive-compulsive disorder.

All of the benzodiazepines may be given orally, and several are available in parenteral formulations. Benzodiazepines such as lorazepam are absorbed rapidly when given intramuscularly. In psychiatric disorders, the benzodiazepines are usually given orally; in controlled medical environments (eg, the ICU), where the rapid onset of respiratory depression can be assessed, they are often given intravenously. Onset of action is a function of the rate of absorption (related to lipophilic property) and varies, with diazepam and clorazepate being the most rapidly absorbed. This characteristic, along with high lipid solubility, may explain the popularity of diazepam. In the average case of anxiety, diazepam, 5-10 mg orally every 6-8 hours as needed, is a reasonable starting regimen.

The duration of action of the benzodiazepines varies as a function of the active metabolites they produce. Benzodiazepines such as lorazepam do not produce active metabolites and have intermediate half-lives of 10-20 hours, characteristics useful in treating elderly patients. Ultra-short-acting agents such as triazolam have half-lives of 1-3 hours and may lead to rebound withdrawal anxiety. Longer-acting benzodiazepines such as flurazepam and diazepam produce active metabolites, have half-lives of 20-120 hours, and should be avoided in the elderly. Since people vary widely in their response and since the drugs are long-lasting, one must individualize the dosage. Once this is established, an adequate dose early in the course of symptom development will obviate the need for "pill popping," which contributes to dependency problems. Panic disorder does not usually respond to benzodiazepines other than clonazepam and alprazolam. Those high-potency benzodiazepines and the antidepressants are most commonly used for panic disorder. Notably, alprazolam has a relatively short half-life and over time can lead to interdose rebound anxiety.

Whether the indications for benzodiazepines are anxiety or insomnia, the drugs should be used judiciously. The longer-acting benzodiazepines are used for the treatment of alcohol withdrawal and anxiety symptoms; the intermediate drugs are useful as sedatives for insomnia (eg, lorazepam), while short-acting agents (eg, midazolam) are used for medical procedures such as endoscopy.

The side effects of all the benzodiazepine antianxiety agents are mainly behavioral and depend on patient reaction and dosage. As the dosage exceeds the levels necessary for sedation, the side effects include disinhibition, ataxia, dysarthria, nystagmus, and errors of commission. (The patient should be told not to operate machinery until he or she is well stabilized without side effects.)

Paradoxical agitation, anxiety, psychosis, confusion, mood lability, and anterograde amnesia have been reported, particularly with the shorter-acting benzodiazepines. These agents produce cumulative clinical effects with repeated dosage (especially if the patient has not had time to metabolize the previous dose), additive effects when given with other classes of sedatives or alcohol (many apparently "accidental" deaths are the result of concomitant use of sedatives and alcohol), and residual effects after termination of treatment (particularly in the case of drugs that undergo slow biotransformation).

Overdosage results in respiratory depression, hypotension, shock syndrome, coma, and death. Flumazenil, a benzodiazepine antagonist, is effective in overdosage. Overdosage (see [Chapter 39](#)) and withdrawal states are medical emergencies. Serious side effects of chronic excessive dosage are development of tolerance, resulting in increasing dose requirements, and physiologic dependence, resulting in withdrawal symptoms similar in appearance to alcohol and barbiturate withdrawal (withdrawal effects must be distinguished from reemergent anxiety). Abrupt withdrawal of sedative drugs may cause serious and even fatal convulsive seizures. Psychosis, delirium, and autonomic dysfunction have also been described. Both duration of action and duration of exposure are major factors. Common withdrawal symptoms after low to moderate daily use of benzodiazepines are classified as **somatic** (disturbed sleep, tremor, nausea, muscle aches), **psychologic** (anxiety, poor concentration, irritability, mild depression), or **perceptual** (poor coordination, mild paranoia, mild confusion). The presentation of symptoms will vary depending on the half-life of the drug. There are no significant side effects on organ systems other than the brain, and the drugs are safe in most medical conditions. Benzodiazepine interactions with other drugs are listed in [Table 25-2](#).

Antidepressants are the first-line medications for sustained treatment of generalized anxiety, having the advantage of not causing serious physiologic dependency problems. At initiation of treatment, antidepressants can themselves be anxiogenic—thus, an initial dose, in conjunction with short-term treatment with a benzodiazepine, is often indicated. Venlafaxine (a sustained-release serotonin and norepinephrine reuptake inhibitor, is FDA-approved for the treatment of generalized anxiety disorder in usual antidepressant doses (75-225 mg). Initial daily dosing should start low (37.5-75 mg) and be tapered upward as needed. Similarly, buspirone, sometimes used as an augmenting agent in the treatment of agitated depression and compulsive behaviors, is also effective for generalized anxiety. Buspirone is usually given in a dosage of 15-60 mg/d in three divided doses. Higher doses tend to be counterproductive and produce gastrointestinal symptoms and dizziness. There is a 2- to 4-week delay before antidepressants and buspirone take effect, and patients require education regarding this lag. Sleep is sometimes negatively effected. Beta-blockers such as propranolol may help reduce peripheral somatic symptoms. Ethanol is the most frequently self-administered drug and should be interdicted. The highly addicting drugs with a narrow margin of safety such as glutethimide, ethchlorvynol, methprylon, meprobamate, and the barbiturates (with the exception of phenobarbital) should be avoided. Phenobarbital, in addition to its anticonvulsant properties, is a reasonably safe and very cheap sedative but has the disadvantage of causing hepatic microsomal enzyme stimulation (not the case with benzodiazepines), which markedly reduces its usefulness if any other relevant

medications are being used by the patient.

2. Panic attacks—Panic attacks may be treated in several ways. A sublingual dose of lorazepam (0.5-2 mg) or alprazolam (0.5-1 mg) is often effective for urgent treatment. For sustained treatment, serotonin-selective reuptake inhibitors (SSRIs) are the initial drugs of choice (adequate blood levels will require dosages similar to those used in the treatment of depression). For example, sertraline starting at 25 mg/d and increased after 1 week to 50 mg/d may be effective. Because of initial agitation in response to antidepressants, doses should start low and be very gradually increased. High-potency benzodiazepines may be used for symptomatic treatment as the antidepressant dose is titrated upward. Clonazepam (1-6 mg/d orally) and alprazolam (0.5-6 mg/d orally) are effective alternatives to antidepressants. Both drugs may produce marked withdrawal if stopped abruptly and should always be tapered. Because of chronicity of the disorders and the problem of dependency with benzodiazepine drugs, it is generally desirable to use antidepressant drugs as the principal pharmacologic approach. Antidepressants have been used in conjunction with beta-blockers in resistant cases. Propranolol (40-160 mg/d orally) can mute the peripheral symptoms of anxiety without significantly affecting motor and cognitive performance. They block symptoms mediated by sympathetic stimulation (eg, palpitations, tremulousness) but not nonadrenergic symptoms (eg, diarrhea, muscle tension). Contrary to current belief, they usually do not cause depression as a side effect and can be used cautiously in patients with depression. Valproate has been found to be as effective in panic disorder as the antidepressants and is another useful alternative.

3. Phobic disorder—Phobic disorder may be part of the panic disorder and is treated within that framework. Global social phobias may be treated with SSRIs, such as paroxetine, sertraline, and fluvoxamine, or MAO inhibitors in the same dosage as used for depression. Gabapentin, an anticonvulsant with anxiolytic properties, may be an alternative to antidepressants in the treatment of social phobia in a dosage of 900-3600 mg/d. Specific phobias such as performance anxiety may respond to moderate doses of beta-blockers, such as propranolol, 20-40 mg 1 hour prior to exposure. A sustained effect is often not obtained with drugs alone; a combination of drugs, behavioral techniques, and cognitive psychotherapy is most effective. If there is any indication of seizure-like phenomena, carbamazepine or valproic acid should be considered.

4. Obsessive-compulsive disorders—Obsessive-compulsive disorders respond to serotonergic drugs in about 60% of cases and usually require a longer response time than for depression (up to 12 weeks). Clomipramine has proved effective in doses equivalent to those used for depression. Fluoxetine (an SSRI drug) has been widely used in this disorder but in doses higher than those used in depression (up to 60-80 mg/d). The other SSRI drugs such as sertraline, paroxetine, and fluvoxamine are being used with comparable efficacy, each with its own side-effect profile. Buspirone in doses of 15-60 mg/d appears to be effective primarily as an antiobsessional augmenting agent for the SSRI drugs. Psychosurgery has a limited place in selected cases of severe unremitting obsessive-compulsive disorder. The stereotactic techniques now being used, including modified cingulotomy, are great improvements over the crude methods of the past.

B. Behavioral

Behavioral approaches are widely used in various anxiety disorders, often in conjunction with medication. Any of the behavioral techniques (see above) can be used beneficially in altering the contingencies (precipitating factors or rewards) supporting any anxiety-provoking behavior. Relaxation techniques can sometimes be helpful in reducing anxiety. Desensitization, by exposing the patient to graded doses of a phobic object or situation, is an effective technique and one that the patient can practice outside the therapy session. Emotive imagery, wherein the patient imagines the anxiety-provoking situation while at the same time learning to relax, helps to decrease the anxiety when the patient faces the real-life situation. Physiologic symptoms in panic attacks respond well to relaxation training.

C. Psychologic

Cognitive approaches have been effective in treatment of panic disorders, phobias, and obsessive-compulsive disorder when erroneous beliefs need correction. The combination of medical and cognitive therapy is more effective than either alone. Group therapy is the treatment of choice when the anxiety is clearly a function of the patient's difficulties in dealing with others, and if these other people are part of the family it is appropriate to include them and initiate family or couples therapy.

D. Social

Peer support groups for panic disorder and agoraphobia have been particularly helpful. Social modification may require measures such as family counseling to aid acceptance of the patient's symptoms and avoid counterproductive behavior in behavioral training. Any help in maintaining the social structure is anxiety-alleviating, and work, school, and social activities should be maintained. School and vocational counseling may be provided by professionals, who often need help from the clinician in defining the patient's limitations.

Prognosis

Anxiety disorders are usually of long standing and may be quite difficult to treat. All can be relieved to varying degrees with medications and behavioral techniques. The prognosis is much better if one can break the commonly observed anxiety-panic-phobia-depression cycle with a combination of the therapeutic interventions discussed above.

SOMATOFORM DISORDERS (ABNORMAL ILLNESS BEHAVIORS)

Essentials of Diagnosis

- Physical symptoms may involve one or more organ systems and are not intentional.
- Subjective complaints exceed objective findings.
- Correlations of symptom development and psychosocial stresses.
- Combination of biogenetic and developmental patterns.

General Considerations

A major source of diagnostic confusion in medicine has been to assume cause-and-effect relationships when parallel conditions exist. This problem is particularly vexing in situations where the individual exhibits psychosocial distress that could well be secondary to a chronic illness but has been assumed to be primary and causative. An example is the person with a chronic bowel disease who becomes querulous and demanding. Is this behavior a result of problems of coping with a chronic disease, or is it a personality pattern that causes the gastrointestinal problem?

Vulnerability in one or more organ systems and exposure to family members with somatization problems play a major role in the development of particular symptoms, and the "functional" versus "organic" dichotomy is a hindrance to good treatment. Clinicians should suspect psychiatric disorders in a number of conditions. For example, 45% of patients complaining of palpitations had lifetime psychiatric diagnoses including generalized anxiety, depression, panic, and somatization disorders. Similarly, 33-44% of patients who undergo coronary angiography for chest pain but have negative results have been found to have panic disorder.

In any patient presenting with a condition judged to be somatoform, depression must be considered in the diagnosis.

Clinical Findings

A. Conversion Disorder

"Conversion" (formerly "hysterical conversion") of psychic conflict into physical symptoms in parts of the body innervated by the sensorimotor system (eg, paralysis, aphonia) is a disorder that is more common in individuals from lower socioeconomic classes and certain cultures. The defense mechanisms utilized in this condition are repression (a barring from consciousness) and isolation (a splitting of the affect from the idea). The somatic manifestation that takes the place of anxiety is typically paralysis, and in some instances the organ dysfunction may have symbolic meaning (eg, arm paralysis in marked anger). Pseudoepileptic ("hysterical") seizures are often difficult to differentiate from intoxication states or panic attacks. Retention of consciousness, random flailing with asynchronous movements of the right and left sides, and resistance to having the nose and mouth pinched closed during the attack all point toward a pseudoepileptic event. Electroencephalography, particularly in a video-EEG assessment unit, during the attack is the most helpful diagnostic aid in excluding genuine seizure states. Serum prolactin levels rise abruptly in the postictal state only in true epilepsy. La belle indifference (a lack of affect) is not a significant characteristic, as commonly believed. Important criteria in diagnosis include a history of conversion or somatization disorder, modeling the symptom after someone else who had a similar presentation, a serious precipitating emotional event, associated psychopathology (eg, depression, schizophrenia, personality disorders), a temporal correlation between the precipitating event and the symptom, and a temporary "solving of the problem" by the conversion. It is important to identify physical disorders with unusual presentations (eg, multiple sclerosis).

B. Somatization Disorder (Briquet's Syndrome, Hysteria)

This is characterized by multiple physical complaints referable to several organ systems. Anxiety, panic disorder, and depression are often present, and **major depression** is an important consideration in the differential diagnosis. There is a significant relationship (20%) to a lifetime history of panic-agoraphobia-depression. It usually occurs before age 30 and is ten times more common in women. Polysurgery is often a feature of the history. Preoccupation with medical and surgical therapy becomes a lifestyle that excludes most other activities. The symptoms are a reflection of maladaptive coping techniques and reactivity of the particular organ system. There is often evidence of long-standing somatic symptoms (particularly dysmenorrhea, a lump in the throat, vomiting, shortness of breath, burning in the sex organs, painful extremities, and amnesia), often with a history of similar organ system involvement in other family members. Multiple symptoms that constantly change and inability of more than three doctors to make a diagnosis are strong clues to the problem.

C. Pain Disorder Associated With Psychologic Factors (Formerly Somatoform Pain Disorder)

This involves a long history of complaints of severe pain not consonant with anatomic and clinical signs. This diagnosis must not be one of exclusion and should be made only after extended evaluation has established a clear correlation of psychogenic factors with exacerbations and remissions of complaints.

D. Hypochondriasis

This is a fear of disease and preoccupation with the body, with perceptual amplification and heightened responsiveness. A process of social learning is usually involved, frequently with a role model who was a member of the family and may be a part of the underlying psychodynamic causation. It is common in panic disorders.

E. Factitious Disorders

These disorders, in which symptom production is intentional, are not somatoform conditions in that symptoms are produced consciously, in contrast to the unconscious process of the above conditions. They are characterized by self-induced symptoms or false physical and laboratory findings for the purpose of deceiving clinicians or other hospital personnel. The deceptions may involve self-mutilation, fever, hemorrhage, hypoglycemia, seizures, and an almost endless variety of manifestations—often presented in an exaggerated and dramatic fashion (Munchausen syndrome). "Munchausen by proxy" is the term used when a parent creates an illness in a child so the adult (usually the mother) can maintain a relationship with clinicians. The duplicity may be either simple or extremely complex and difficult to recognize. The patients are frequently connected in some way with the health professions; they are often migratory; and there is no apparent external motivation other than achieving the patient role.

Complications

A poor doctor-patient relationship, with iatrogenic disorders and "doctor shopping," tends to exacerbate the problem. Sedative and analgesic dependency is the most common iatrogenic complication.

Treatment

A. Medical

Medical support with careful attention to building a therapeutic doctor-patient relationship is the mainstay of treatment. It must be accepted that the patient's distress is real. Every problem not found to have an organic basis is not necessarily a mental disease. Diligent attempts should be made to relate symptoms to adverse developments in the patient's life. It may be useful to have the patient keep a meticulous diary, paying particular attention to various pertinent factors evident in the history. Regular, frequent, short appointments that are not symptom-contingent may be helpful. Drugs (frequently abused) should not be prescribed to replace appointments. One doctor should be the primary clinician, and consultants should be used mainly for evaluation. An empathic, realistic, optimistic approach must be maintained in the face of the expected ups and downs. Ongoing reevaluation is necessary, since somatization can coexist with a concurrent physical illness.

B. Psychologic

Psychologic approaches can be used by the primary clinician when it is clear that the patient is ready to make some changes in lifestyle in order to achieve symptomatic relief. This is often best approached on a here-and-now basis and oriented toward pragmatic changes rather than an exploration of early experiences that the patient frequently fails to relate to current distress. Group therapy with other individuals who have similar problems is sometimes of value to improve coping, allow ventilation, and focus on interpersonal adjustment. Hypnosis or lorazepam interviews used early are helpful in resolving conversion disorders. If the primary clinician has been working with the patient on psychologic problems related to the physical illness, the groundwork is often laid for successful psychiatric referral.

For patients who have been identified as having a factitious disorder, early psychiatric consultation is indicated. There are two main treatment strategies for these patients. One consists of a conjoint confrontation of the patient by both the primary clinician and the psychiatrist. The patient's disorder is portrayed as a cry for help, and psychiatric treatment is recommended. The second approach avoids direct confrontation and attempts to provide a face-saving way to relinquish the symptom without overt disclosure of the disorder's origin. Techniques such as biofeedback and self-hypnosis may foster recovery using this strategy. Another face-saving approach is to utilize a double bind with the patient. For example, the patient is told there are two possible diagnoses: (1) an organic disease that should respond to the next medical intervention (usually modest and noninvasive), or (2) factitious disorder for which the patient will need psychiatric treatment. Given these options, many patients will choose to recover and not have to admit the origin of their problem.

C. Behavioral

Behavioral therapy is probably best exemplified by biofeedback techniques. In biofeedback, the particular abnormality (eg, increased peristalsis) must be recognized and monitored by the patient and therapist (eg, by an electronic stethoscope to amplify the sounds). This is immediate feedback, and after learning to recognize it the patient can then learn to identify any change thus produced (eg, a decrease in bowel sounds) and so become a conscious originator of the feedback instead of a passive recipient. Relief of the symptom operantly conditions the patient to utilize the maneuver that relieves symptoms (eg, relaxation causing a decrease in bowel sounds). With emphasis on this type of learning, the patient is able to identify symptoms early and initiate the countermeasures, thus decreasing the symptomatic problem. Migrainoid and tension headaches have been particularly responsive to biofeedback methods.

D. Social

Social endeavors include family, work, and other interpersonal activity. Family members should come for some appointments with the patient so they can learn how best to live with the patient. This is particularly important in treatment of somatization and pain disorders. Peer support groups provide a climate for encouraging the patient to accept and live with the problem. Ongoing communication with the employer may be necessary to encourage long-term continued interest in the employee. Employers can become just as discouraged as clinicians in dealing with employees who have chronic problems.

Prognosis

The prognosis is much better if the primary clinician is able to intervene early before the situation has deteriorated. After the problem has crystallized into chronicity, it is very difficult to effect change.

CHRONIC PAIN DISORDERS

Essentials of Diagnosis

- Chronic complaints of pain.
- Symptoms frequently exceed signs.
- Minimal relief with standard treatment.
- History of having seen many clinicians.
- Frequent use of several nonspecific medications.

General Considerations

A problem in the management of pain is the lack of distinction between acute and chronic pain syndromes. Most clinicians are adept at dealing with acute pain problems but have difficulty handling the patient with a chronic pain disorder. This type of patient frequently takes too many medications, stays in bed a great deal, has seen many clinicians, has lost skills, and experiences little joy in either work or play. All relationships suffer (including those with clinicians), and life becomes a constant search for succor. The search results in complex clinician-patient relationships that usually include many drug trials, particularly sedatives, with adverse consequences (eg, irritability, depressed mood) related to long-term use. Treatment failures provoke angry responses and depression from both the patient and the clinician, and the

pain syndrome is exacerbated. When frustration becomes too great, a new clinician is found, and the cycle is repeated. The longer the existence of the pain disorder, the more important become the psychologic factors of anxiety and depression. As with all other conditions, it is counterproductive to speculate about whether the pain is "real." It is real to the patient, and acceptance of the problem must precede a mutual endeavor to alleviate the disturbance.

Clinical Findings

Components of the chronic pain syndrome consist of anatomic changes, chronic anxiety and depression, anger, and changed lifestyle. Usually, the anatomic problem is irreversible, since it has already been subjected to many interventions with increasingly unsatisfactory results. An algorithm for assessing chronic pain and differentiating it from other psychiatric conditions is illustrated in [Figure 25-2](#).

Chronic anxiety and depression produce heightened irritability and overreaction to stimuli. A marked decrease in pain threshold is apparent. This pattern develops into a hypochondriacal preoccupation with the body and a constant need for reassurance. The pressure on the clinician becomes wearing and often leads to covert rejection devices, such as not being available or making referrals to other clinicians. This is perceived by the patient, who then intensifies the effort to find help, and the typical cycle is repeated. Anxiety and depression are seldom discussed, almost as if there is a tacit agreement not to deal with these issues.

Changes in lifestyle involve some of the pain behaviors. These usually take the form of a family script in which the patient accepts the role of being sick, and this role then becomes the focus of most family interactions and may become important in maintaining the family, so that neither the patient nor the family wants the patient's role to change. Demands for attention and efforts to control the behavior of others revolve around the central issue of control of other people (including clinicians). Cultural factors frequently play a role in the behavior of the patient and how the significant people around the patient cope with the problem. Some cultures encourage demonstrative behavior, while others value the stoic role.

Another secondary gain that frequently maintains the patient in the sick role is financial compensation or other benefits ("green poultice"). Frequently, such systems are structured so that they reinforce the maintenance of sickness and discourage any attempts to give up the role. Clinicians unwittingly reinforce this role because of the very nature of the practice of medicine, which is to respond to complaints of illness. Helpful suggestions from the clinician are often met with responses like, "Yes, but. . ." Medications then become the principal approach, and drug dependency problems may develop.

Treatment

A. Behavioral

The cornerstone of a unified approach to chronic pain syndromes is a comprehensive behavioral program. This is necessary to identify and eliminate pain reinforcers, to decrease drug use, and to use effectively those positive reinforcers that shift the focus from the pain. It is critical that the patient be made a partner in the effort to alleviate pain. The clinician must shift from the idea of biomedical cure to ongoing care of the patient. The patient should agree to discuss the pain only with the clinician and not with family members; this tends to stabilize the patient's personal life, since the family is usually tired of the subject. At the beginning of treatment, the patient should be assigned self-help tasks graded up to maximal activity, as a means of positive reinforcement. The tasks should not exceed capability. The patient can also be asked to keep a self-rating chart to log accomplishments, so that progress can be measured and remembered. Instruct the patient to record degrees of pain on a self-rating scale in relation to various situations and mental attitudes so that similar circumstances can be avoided or modified.

Avoid positive reinforcers for pain such as marked sympathy and attention to pain. Emphasize a positive response to productive activities, which remove the focus of attention from the pain. Activity is also desensitizing, since the patient learns to tolerate increasing activity levels.

Biofeedback techniques (see Somatoform Disorders, above) and hypnosis have been successful in ameliorating some pain syndromes. Hypnosis tends to be most effective in patients with a high level of denial, who are more responsive to suggestion. Hypnosis can be used to lessen anxiety, alter perception of the length of time that pain is experienced, and encourage relaxation.

B. Medical

A *single clinician* in charge of the multiple treatment approach is the highest priority. Consultations as indicated and technical procedures done by others are appropriate, but the care of the patient should remain in the hands of the primary clinician. Referrals should not be allowed to raise the patient's hopes unrealistically or to become a way for the clinician to reject the case. The attitude of the doctor should be one of honesty, interest, and hopefulness—not for a cure but for control of pain and improved function. If the patient manifests narcotic addiction, detoxification may be an early treatment goal.

If analgesics or sedatives are prescribed, they should not be given on an "as-needed" schedule (see [Chapter 1](#)). A fixed schedule lessens the conditioning effects of these drugs. Tricyclic antidepressants (eg, nortriptyline) and venlafaxine in doses up to those used in depression may be helpful, particularly in neuropathic pain syndromes. In other conditions, their effects on pain may be less clear, but ameliorating depression is usually important nonetheless. Gabapentin, an anticonvulsant with possible applications in the treatment of mood and anxiety disorders, has been shown to be useful in postherpetic and diabetic neuropathy and somatoform disorders.

In addition to medications, a variety of alternative strategies may be offered, including physical therapy and acupuncture.

C. Social

Involvement of family members and other significant persons in the patient's life should be an early priority. The best efforts of both patient and therapists can be unwittingly sabotaged by other persons who may feel that they are "helping" the patient. They frequently tend to reinforce the negative aspects of the chronic pain disorder. The patient becomes more dependent and less active, and the pain syndrome becomes an immutable way of life. The more destructive pain behaviors described by many experts in chronic pain disorders are the results of well-meaning but misguided efforts of family members. Ongoing therapy with the family can be helpful in the early identification and elimination of these behavior patterns.

D. Psychologic

In addition to group therapy with family members and others, groups of patients can be helpful if properly led. The major goal, whether of individual or group therapy, is to gain patient involvement. A group can be a powerful instrument for achieving this goal, with the development of group loyalties and cooperation. People will frequently make efforts with group encouragement that they would never make alone. Individual therapy should be directed toward strengthening existing defenses and improving self-esteem. The rapport between patient and clinician, as in all psychotherapeutic efforts, is the major factor in therapeutic success.

PSYCHOSEXUAL DISORDERS

The stages of sexual activity include **excitement** (arousal), **orgasm**, and **resolution**. The precipitating excitement or arousal is psychologically determined. Arousal response leading to plateau is a physiologic and psychologic phenomenon of vasocongestion, a parasympathetic reaction causing erection in men and labial-clitoral congestion in women. The orgasmic response includes emission in men and clonic contractions of the analogous striated perineal muscles of both men and women. Resolution is a gradual return to normal physiologic status.

While the arousal stimuli—vasocongestive and orgasmic responses—constitute a single response in a well-adjusted person, they can be considered as separate stages that can produce different syndromes responding to different treatment procedures.

Clinical Findings

There are three major groups of sexual disorders.

A. Paraphilias (Sexual Arousal Disorders)

In these conditions, formerly called "deviations" or "variations," the excitement stage of sexual activity is associated with sexual objects or orientations different from those usually associated with adult sexual stimulation. The stimulus may be a woman's shoe, a child, animals, instruments of torture, or incidents of aggression. The pattern of sexual stimulation is usually one that has early psychologic roots. Poor experiences with sexual activity frequently reinforce this pattern over time.

Exhibitionism is the impulsive behavior of exposing the genitalia to unsuspecting strangers in order to achieve sexual excitation. It is a childhood sexual behavior carried into adult life.

Transvestism consists of recurrent cross-dressing behavior in a heterosexual man for the purpose of sexual excitation. Such fetishistic behavior can be part of masturbation foreplay. Transvestism in homosexuality and transsexualism is not for the purpose of sexual excitement but is a function of the homosexual preference or gender disorder.

Voyeurism involves the achievement of sexual arousal by watching the activities of an unsuspecting person, usually in various stages of undress or sexual activity. In both exhibitionism and voyeurism, excitation leads to masturbation as a replacement for sexual activity.

Pedophilia is the use of a child of either sex to achieve sexual arousal and, in many cases, gratification. Contact is frequently oral, with either participant being dominant, but pedophilia includes intercourse of any type. Adults of both sexes engage in this behavior, but because of social and cultural factors it is more commonly identified with men. The pedophile has difficulty in adult sexual relationships, and men who perform this act are frequently impotent.

Incest involves a sexual relationship with a person in the immediate family, most frequently a child. In many ways it is similar to pedophilia (intrafamilial pedophilia). Incestuous feelings are fairly common, but cultural mores are usually sufficiently strong to act as a barrier to the expression of sexual feelings.

Sexual sadism is the attainment of sexual arousal by inflicting pain upon the sexual object. Much sexual activity has aggressive components (eg, biting, scratching). However, forced sexual acquiescence (eg, rape) is considered to be primarily an act of aggression.

Sexual masochism is the achievement of erotic pleasure by being humiliated, enslaved, physically bound, and restrained. It is life-threatening, since neck binding or partial asphyxiation usually forms part of the ritual. It is estimated that bondage is responsible for about 1000 accidental deaths a year in men (the practice is much less common in women).

Necrophilia is sexual intercourse with a dead body or the use of parts of a dead body for sexual excitation, often with masturbation.

B. Gender Identity Disorder

Core gender identity reflects a biologic self-image—the conviction that "I am a boy" or "I am a girl" that is usually well developed by age 3 or 4. Gender dysphoria refers to the development of a sexual identity that is the opposite of the biologic one.

Transsexualism is an attempt to deny and reverse biologic sex by maintaining sexual identity with the opposite gender. Transsexuals do not alternate between gender roles; rather, they assume a fixed role of attitudes, feelings, fantasies, and choices consonant with those of the opposite sex, all of which clearly date back to early development. For example, male transsexuals in early childhood behave, talk, and fantasize as if they were girls. They do not grow out of feminine patterns; they do not work in professions traditionally considered to be masculine; and they have no interest in their own penises either as evidence of maleness or as organs for erotic behavior. The desire for sex change starts early and may culminate in assumption of a feminine lifestyle, hormonal treatment, and use of surgical procedures, eg, castration and vaginoplasty.

C. Psychosexual Dysfunction

This category includes a large group of vasocongestive and orgasmic disorders. Often, they involve problems of sexual adaptation, education, and technique that are often initially discussed with, diagnosed by, and treated by the primary care provider.

There are two conditions common in men: erectile dysfunction and ejaculation disturbances.

Erectile dysfunction (impotence) is inability to achieve or maintain an erection firm enough for satisfactory intercourse; patients sometimes use the term to mean premature ejaculation. Careful questioning is necessary, since causes of this vasocongestive disorder can be psychologic, physiologic, or both. The majority are pathophysiologic and, to varying degrees, treatable. After onset of the problem, a history of occasional erections—especially nocturnal penile tumescence, which may be evaluated by a simple monitoring device, or a sleep study in the sleep laboratory—is usually evidence that the dysfunction is psychologic in origin, with the caveat that decreased nocturnal penile tumescence occurs in some depressed patients. **Psychologic erectile dysfunction** is caused by interpersonal or intrapsychic factors (eg, marital disharmony, depression). **Organic factors** are discussed in [Chapter 23](#).

Ejaculation disturbances include premature ejaculation, inability to ejaculate, and retrograde ejaculation. (One may ejaculate even though impotent.) Ejaculation is usually connected with orgasm, and ejaculatory control is an acquired behavior that is minimal in adolescence and increases with experience. Pathogenic factors are those that interfere with learning control, most frequently sexual ignorance. Intrapsychic factors (anxiety, guilt, depression) and interpersonal maladaptation (marital problems, unresponsiveness of mate, power struggles) are also common. Organic causes include interference with sympathetic nerve distribution (often due to surgery or trauma) and the effects of pharmacologic agents (eg, SSRIs or sympatholytics).

In women, the two most common forms of sexual dysfunction are vaginismus and frigidity.

Vaginismus is a conditioned response in which a spasm of the perineal muscles occurs if there is any stimulation of the area. The desire is to avoid penetration. Sexual responsiveness and vasocongestion may be present, and orgasm can result from clitoral stimulation.

Frigidity is a complex condition in which there is a general lack of sexual responsiveness. The woman has difficulty in experiencing erotic sensation and does not have the vasocongestive response. Sexual activity varies from active avoidance of sex to an occasional orgasm. Orgasmic dysfunction—in which a woman has a vasocongestive response but varying degrees of difficulty in reaching orgasm—is sometimes differentiated from frigidity. Causes for the dysfunctions include poor sexual techniques, early traumatic sexual experiences, interpersonal disharmony (marital struggles, use of sex as a means of control), and intrapsychic problems (anxiety, fear, guilt). Organic causes include any conditions that might cause pain in intercourse, pelvic pathology, mechanical obstruction, and neurologic deficits. **Disorders of sexual desire** consist of diminished or absent libido in either sex and may be a function of organic or psychologic difficulties (eg, anxiety, phobic avoidance). Any chronic illness can sap desire. Hormonal disorders, including hypogonadism or use of antiandrogen compounds such as cyproterone acetate, and chronic renal failure contribute to deterioration in sexual activity. Though menopause may lead to diminution of sexual desire in some women, the relationship between menopause and libido is complicated and may be influenced by sociocultural factors. Alcohol, sedatives, narcotics, marijuana, and some medications may affect sexual drive and performance.

Treatment

A. Paraphilias and Gender Identity Disorders

1. Psychologic—Sexual arousal disorders involving variant sexual activity (paraphilia), particularly those of a more superficial nature (eg, voyeurism) and those of recent onset, are responsive to psychotherapy in a moderate percentage of cases. The prognosis is much better if the motivation comes from the individual rather than the legal system; unfortunately, however, judicial intervention is frequently the only stimulus to treatment, because the condition persists and is reinforced until conflict with the law occurs. Therapies frequently focus on barriers to normal arousal response; the expectation is that the variant behavior will decrease as normal behavior increases.

2. Behavioral—Aversive and operant conditioning techniques have been tried frequently in gender role disorders but have only occasionally been successful. In some cases, the sexual arousal disorders improve with modeling, role-playing, and conditioning procedures. Emotive imagery is occasionally helpful in lessening anxiety in fetish problems.

3. Social—Although they do not produce a change in sexual arousal patterns or gender role, self-help groups have facilitated adjustment to an often hostile society. Attention to the family is particularly important in helping persons in such groups to accept their situation and alleviate their guilt about the role they think they had in creating the problem.

4. Medical—Medroxyprogesterone acetate, a suppressor of libidinal drive, is used to mute disruptive sexual behavior in men of all ages. Onset of action is usually within 3 weeks, and the effects are generally reversible. Fluoxetine or other SSRIs may reduce some of the compulsive sexual behaviors including the paraphilias. Although some transsexuals are treated with genital reconstructive surgery, many others are screened out by trial periods of living as females prior to operation.

B. Psychosexual Dysfunction

1. Medical—Identification of a contributory reversible cause is most important. Even if the condition is not reversible, identification of the specific cause helps the patient to accept the condition. Marital disharmony, with its exacerbating effects, may thus be avoided. Of all the sexual dysfunctions, erectile dysfunction is the condition most likely to have an organic basis. Sildenafil citrate is an effective oral agent for the treatment of penile erectile dysfunction in the recommended dose of 25-100 mg 1 hour prior to intercourse. Sildenafil is effective for SSRI-induced erectile dysfunction in men and in some cases for SSRI-associated sexual dysfunction in women. Use of the medication in conjunction with any nitrates, particularly in individuals with coronary artery disease, can have significant hypotensive effects leading to death in some cases. The medication, which does not appear to impact sexual desire, should be used only once a day. Because of their common effect in delaying ejaculation, the SSRIs have been effective in premature ejaculation.

2. Behavioral—Syndromes resulting from conditioned responses have been treated by conditioning techniques, with excellent results. Vaginismus responds well to desensitization with graduated Hegar dilators along with relaxation techniques. Masters and Johnson have used behavioral approaches in all of the sexual dysfunctions, with concomitant supportive psychotherapy and with improvement of the communication patterns of the couple.

3. Psychologic—The use of psychotherapy by itself is best suited for those cases in which interpersonal difficulties or intrapsychic problems predominate. Anxiety and guilt about parental injunctions against sex may contribute to sexual dysfunction. Even in these cases, however, a combined behavioral-psychologic approach usually produces results most quickly.

4. Social—The proximity of other people (eg, a mother-in-law) in a household is frequently an inhibiting factor in sexual relationships. In such cases, some social engineering may alleviate the problem.

PERSONALITY DISORDERS

Essentials of Diagnosis

- Long history dating back to childhood.
- Recurrent maladaptive behavior.
- Low self-esteem and lack of confidence.
- Minimal introspective ability with a tendency to blame others for all problems.
- Major difficulties with interpersonal relationships or society.
- Depression with anxiety when maladaptive behavior fails.

General Considerations

Personality—a hypothetical construct—is the result of a genetic substrate and the prolonged interaction of an individual with personal drives and with outside influences (parent-child interactions, peer influences, random events). The sum of the effects produces the enduring and unique patterns of behavior that are adopted in order to cope with the environment and which characterize one as an individual. The personality structure, or character, is an integral part of self-image and is important to one's sense of personal identity.

The classification of subtypes depends upon the predominant symptoms and their severity. The most severe disorders—those that bring the patient into greatest conflict with society—tend to be classified as antisocial (psychopathic) or borderline.

Personality disorders can be considered a matrix for some of the more severe psychiatric problems (eg, schizotypal, relating to schizophrenia, and avoidance types, relating to some anxiety disorders).

Classification & Clinical Findings

See [Table 25-3](#).

Differential Diagnosis

Patients with personality disorders tend to show anxiety and depression when pathologic coping mechanisms fail, and their symptoms can be similar to those occurring with anxiety disorders. Occasionally, the more severe cases may decompensate into psychosis under stress and mimic other psychotic disorders.

Treatment

A. Social

Social and therapeutic environments such as day hospitals, halfway houses, and self-help communities utilize peer pressures to modify the self-destructive behavior. The patient with a personality disorder often has failed to profit from experience, and difficulties with authority impair the learning experience. The use of peer relationships and the repetition possible in a structured setting of a helpful community enhance the behavioral treatment opportunities and increase learning. When problems are detected early, both the school and the home can serve as foci of intensified social pressure to change the behavior, particularly with the use of behavioral techniques.

B. Behavioral

The behavioral techniques used are principally operant conditioning and aversive conditioning. The former simply emphasizes the recognition of acceptable behavior and its reinforcement with praise or other tangible rewards. Aversive responses usually mean punishment, though this can range from a mild rebuke to some specific punitive responses such as deprivation of privileges. Extinction plays a role in that an attempt is made not to respond to inappropriate behavior, and the lack of response eventually causes the person to abandon that type of behavior. Pouting and tantrums, for example, diminish quickly when such behavior elicits no reaction. Dialectical behavioral therapy is a program of individual and group therapy specifically designed for patients with chronic suicidality and borderline personality disorder. It adapts a cognitive-behavioral model to address self-awareness, interpersonal functioning, affective lability, and reactions to stress.

C. Psychologic

Psychologic intervention is best conducted in group settings. Group therapy is helpful when specific interpersonal behavior needs to be improved (eg, schizoid and inadequate types, in which involvement with people is markedly impaired). This mode of treatment also has a place with so-called acting-out patients, ie, those who frequently act in an impulsive and inappropriate way. The peer pressure in the group tends to impose restraints on rash behavior. The group also quickly identifies the patient's types of behavior and helps to improve the validity of the patient's self-assessment, so that the antecedents of the unacceptable behavior can be effectively handled, thus decreasing its frequency. Individual therapy should initially be supportive, ie, helping the patient to restabilize and mobilize defenses. If the individual has the ability to observe his or her own behavior, a longer-term and more introspective therapy may be warranted. The therapist must be able to handle countertransference feelings (which are frequently negative), maintain appropriate boundaries in the relationship (no physical contacts, however well-meaning), and refrain from premature confrontations and interpretations.

D. Medical

Hospitalization is rarely indicated except in the case of serious suicidal danger. In most cases, treatment can be accomplished in the day treatment center or self-help community. Antipsychotics may be required for short periods in conditions that have temporarily decompensated into transient psychoses (eg, haloperidol, 2-5 mg orally every 3-4 hours until the patient has quieted down and is regaining contact with reality). Olanzapine (2.5-10 mg/d) or risperidone (0.5-2 mg/d) may be given with lorazepam (1-2 mg orally every 4 hours as needed). In some cases, these drugs are required only for several days and can be discontinued after the patient has regained a previously established level of adjustment; they can also provide ongoing support. Carbamazepine, 400-800 mg orally daily in divided doses, decreases the severity of behavioral dyscontrol. Antidepressants have improved anxiety, depression, and sensitivity to rejection in some borderline patients. Selective serotonin reuptake inhibitors (SSRIs) may have a role in reducing aggressive behavior in impulsive aggressive patients.

Prognosis

Antisocial and borderline categories generally have a guarded prognosis. Those patients with poor outcomes are more likely to have a history of parental abuse and a family history of mood disorder, whereas persons with mild schizoid or passive-aggressive tendencies have a better prognosis with appropriate treatment.

Gross R et al: Borderline personality disorder in primary care. Arch Intern Med 2002;162:53. [PMID: 11784220]

Schultz S et al: Olanzapine safety and efficacy in patients with borderline personality disorder and comorbid dysthymia. Biol Psychiatry 1999;46:1429. [PMID:]

SCHIZOPHRENIC & OTHER PSYCHOTIC DISORDERS

Essentials of Diagnosis

- Social withdrawal, usually slowly progressive, often with deterioration in personal care.
- Loss of ego boundaries, with inability to perceive oneself as a separate entity.
- Loose thought associations, often with slowed thinking or overinclusive and rapid shifting from topic to topic.
- Autistic absorption in inner thoughts and frequent sexual or religious preoccupations.
- Auditory hallucinations, often of a derogatory nature.
- Delusions, frequently of a grandiose or persecutory nature.
- Symptoms of at least 6 months' duration.

Frequent additional signs:

- Flat affect and rapidly alternating mood shifts irrespective of circumstances.
- Hypersensitivity to environmental stimuli, with a feeling of enhanced sensory awareness.
- Variability or changeable behavior incongruent with the external environment.
- Concrete thinking with inability to abstract; inappropriate symbolism.
- Impaired concentration worsened by hallucinations and delusions.
- Depersonalization, wherein one behaves like a detached observer of one's own actions.

General Considerations

The schizophrenic disorders are a group of syndromes manifested by massive disruption of thinking, mood, and overall behavior as well as poor filtering of stimuli. The characterization and nomenclature of the disorders are quite arbitrary and are influenced by sociocultural factors and schools of psychiatric thought.

It is currently believed that the schizophrenic disorders are of multifactorial cause, with genetic, environmental, and neurotransmitter pathophysiologic components. At present, there is no laboratory method for confirmation of a diagnosis of schizophrenia. There may or may not be a history of a major disruption in the individual's life (failure, loss, physical illness) before gross psychotic deterioration is evident.

"Other psychotic disorders" are conditions that are similar to schizophrenic disorders in their acute symptoms but have a less pervasive influence over the long term. The individual usually attains higher levels of functioning. The acute psychotic episodes tend to be less disruptive of the person's lifestyle, with a fairly quick return to previous levels of functioning.

Classification

A. Schizophrenic Disorders

Schizophrenic disorders are subdivided on the basis of certain prominent phenomena that are frequently present. **Disorganized (hebephrenic) schizophrenia** is characterized by marked incoherence and an incongruous or silly affect. **Catatonic schizophrenia** is distinguished by a marked psychomotor disturbance of either excitement (purposeless and stereotyped) or rigidity with mutism. Infrequently, there may be rapid alternation between excitement and stupor (see under catatonic syndrome, below). **Paranoid schizophrenia** includes marked persecutory or grandiose delusions often consonant with hallucinations of similar content and with less marked disorganization of speech and behavior. **Undifferentiated schizophrenia** denotes a category in which symptoms are not specific enough to warrant inclusion of the illness in the other subtypes. **Residual schizophrenia** is a classification that includes persons who have clearly had an episode warranting a diagnosis of schizophrenia but who at present have no overt psychotic symptoms, though they show milder signs such as social withdrawal, flat affect, and eccentric behaviors.

B. Delusional Disorders

Delusional disorders are psychoses in which the predominant symptoms are persistent, nonbizarre delusions with minimal impairment of daily functioning. (The schizophrenic disorders show significant impairment.) Intellectual and occupational activities are little affected, whereas social and marital functioning tend to be markedly involved. Hallucinations are not usually present. Common delusional themes include paranoid delusions of persecution, delusions of being related to or loved by a well-known person, and delusions that one's partner is unfaithful.

C. Schizoaffective Disorders

Schizoaffective disorders are those cases that fail to fit comfortably either in the schizophrenic or in the affective categories. They are usually cases with affective symptoms that precede or develop concurrently with psychotic manifestations.

D. Schizophreniform Disorders

Schizophreniform disorders are similar in their symptoms to schizophrenic disorders except that the duration of prodromal, acute, and residual symptoms is more than 1 week but less than 6 months.

E. Brief Psychotic Disorders

These disorders last less than 1 week. They are the result of psychologic stress. The shorter duration is significant and correlates with a more acute onset and resolution as well as a much better prognosis.

F. Late Life Psychosis

Brain abnormalities occur in 40% of patients who develop psychotic symptoms after age 60. The psychotic symptoms are typical, and there are other findings such as low IQ scores and diminished cognitive function.

G. Atypical Psychoses

This group includes a wide range of conditions with psychotic symptomatology. The cause is often not clear, but later events (eg, new symptoms) may clarify the diagnosis. The most common example is chronic psychosis developing either during periods of heavy abuse of drugs or at some time after the drug use has ceased. Other conditions include temporal lobe dysfunction, HIV infection, and a number of the conditions noted in the differential diagnosis (see below). They often have a good premorbid history, a precipitous onset, and an episodic course with symptom-free intervals.

Clinical Findings

The symptoms and signs of schizophrenia vary markedly among individuals as well as in the same person at different times. The patient's **appearance** may be bizarre, though the usual finding is a mild to moderate unkempt blandness. **Motor activity** is generally reduced, though extremes ranging from catatonic stupor to frenzied excitement occur. **Social behavior** is characterized by marked withdrawal coupled with disturbed interpersonal relationships and a reduced ability to experience pleasure. Dependency and a poor self-image are common. **Verbal utterances** are variable, the language being concrete yet symbolic, with unassociated rambling statements (at times interspersed with mutism) during an acute episode. Neologisms (made-up words or phrases), echolalia (repetition of words spoken by others), and verbigeration (repetition of senseless words or phrases) are occasionally present. **Affect** is usually flattened, with occasional inappropriateness. **Depression** is present in almost all cases but may be less apparent during the acute psychotic episode and more obvious during recovery. Depression is sometimes confused with akinetic side effects of antipsychotic drugs. It is also related to **boredom**, which increases symptoms and decreases the response to treatment. Work is generally unavailable and time unfilled, providing opportunities for counterproductive activities such as drug abuse, withdrawal, and increased psychotic symptoms.

Thought content may vary from a paucity of ideas to a rich complex of delusional fantasy with archaic thinking. One frequently notes after a period of conversation that little if any information has actually been conveyed. Incoming stimuli produce varied responses. In some cases a simple question may trigger explosive outbursts, whereas at other times there may be no overt response whatsoever (catatonia). When paranoid ideation is present, the patient is often irritable and less cooperative. **Delusions** (false beliefs) are characteristic of paranoid thinking, and they usually take the form of a preoccupation with the supposedly threatening behavior exhibited by other individuals. This ideation may cause the patient to adopt active countermeasures such as locking doors and windows, taking up weapons, covering the ceiling with aluminum foil to counteract radar waves, and other bizarre efforts. Somatic delusions revolve around issues of bodily decay or infestation. **Perceptual distortions** usually include auditory hallucinations—visual hallucinations are more commonly associated with organic mental states—and may include illusions (distortions of

reality) such as figures changing in size or lights varying in intensity. Cenesthetic hallucinations (eg, a burning sensation in the brain, feeling blood flowing in blood vessels) occasionally occur. Lack of humor, feelings of dread, depersonalization (a feeling of being apart from the self), and fears of annihilation may be present. Any of the above symptoms generate higher anxiety levels, with heightened arousal and occasional panic and suicidal ideation, as the individual fails to cope.

Schizophrenic symptoms have been classified into positive and negative categories. Positive symptoms include hallucinations, delusions, and formal thought disorders. These symptoms appear to be related to increased (D_2) dopaminergic activity in the mesolimbic region. Negative symptoms include diminished sociability, restricted affect, and poverty of speech and appear to be related to decreased dopaminergic activity in the mesocortical system.

Ventricular enlargement and cortical atrophy, as seen on the CT scan, have been correlated with a chronic course, severe cognitive impairment, and nonresponsiveness to neuroleptic medications. Decreased frontal lobe activity on positron emission tomography has been associated with negative symptoms.

The development of the acute episode in schizophrenia frequently is the end product of a gradual decompensation. Frustration and anxiety appear early, followed by depression and alienation, along with decreased effectiveness in day-to-day coping. This often leads to feelings of panic and increasing disorganization, with loss of the ability to test and evaluate the reality of perceptions. The stage of so-called psychotic resolution includes delusions, autistic preoccupations, and psychotic insight, with acceptance of the decompensated state. The process is frequently complicated by the use of caffeine, alcohol, and other recreational drugs. Life expectancy of schizophrenics is as much as 20% shorter than that of cohorts in the general population (usually because of a higher mortality rate in younger people).

Polydipsia may produce water intoxication with hyponatremia—characterized by symptoms of confusion, lethargy, psychosis, seizures, and occasionally death—in any psychiatric disorder, but most commonly in schizophrenia. These problems exacerbate the schizophrenic symptoms. Possible pathogenetic factors include a hypothalamic defect, inappropriate ADH secretion, neuroleptic medications (anticholinergic effects, stimulation of hypothalamic thirst center, effect on ADH), smoking (nicotine and SIADH), psychotic thought processes (delusions), and other medications (eg, diuretics, antidepressants, lithium, alcohol). Other causes of polydipsia must be ruled out (eg, diabetes mellitus, diabetes insipidus, renal disease).

Differential Diagnosis

One should not hesitate to reconsider the diagnosis of schizophrenia in any person who has received that diagnosis in the past, particularly when the clinical course has been atypical. A number of these patients have been found to actually have atypical episodic affective disorders that have responded well to lithium. Manic episodes often mimic schizophrenia. Furthermore, many individuals have been diagnosed as schizophrenic because of inadequacies in psychiatric nomenclature. Thus, persons with brief reactive psychoses, obsessive-compulsive disorder, paranoid disorders, and schizophreniform disorders were often inappropriately diagnosed as having schizophrenia.

Psychotic depressions, psychotic organic mental states, and any illness with psychotic ideation tend to be confused with schizophrenia, partly because of the regrettable tendency to use the terms interchangeably. Adolescent phases of growth and counterculture behaviors constitute another area of diagnostic confusion. It is particularly important to avoid a misdiagnosis in these groups, because of the long-term implications arising from having such a serious diagnosis made in a formative stage of life.

Medical disorders such as thyroid dysfunction, adrenal and pituitary disorders, reactions to toxic materials (eg, mercury, PCBs), and almost all of the organic mental states in the early stages must be ruled out. Postpartum psychosis is discussed under Mood Disorders. **Complex partial seizures**, especially when psychosensory phenomena are present, are an important differential consideration. Toxic drug states arising from prescription, over-the-counter, and street drugs may mimic all of the psychotic disorders. The chronic use of amphetamines, cocaine, and other stimulants frequently produces a psychosis that is almost identical to the acute paranoid schizophrenic episode. The presence of formication and stereotypy suggests the possibility of stimulant abuse. Phencyclidine (see below), a very common street drug, may cause a reaction that is difficult to distinguish from other psychotic disorders. Cerebellar signs, excessive salivation, dilated pupils, and increased deep tendon reflexes should alert the clinician to the possibility of a toxic psychosis. Industrial chemical toxicity (both organic and metallic), degenerative disorders, and metabolic deficiencies must be considered in the differential diagnosis.

Catatonic syndrome, frequently assumed to exist solely as a component of schizophrenic disorders, is actually the end product of a number of illnesses, including various organic conditions. Neoplasms, viral and bacterial encephalopathies, central nervous system hemorrhage, metabolic derangements such as diabetic ketoacidosis, sedative withdrawal, and hepatic and renal malfunction have all been implicated. It is particularly important to realize that drug toxicity (eg, overdoses of antipsychotic medications such as fluphenazine or haloperidol) can cause catatonic syndrome, which may be misdiagnosed as a catatonic schizophrenic disorder and inappropriately treated with more antipsychotic medication.

Treatment

A. Medical

Hospitalization is often necessary, particularly when the patient's behavior shows gross disorganization. The presence of competent family members lessens the need for hospitalization, and each case should be judged individually. The major considerations are to prevent self-inflicted harm or harm to others and to provide the patient's basic needs. A full medical evaluation and CT scan or MRI should be considered in first episodes of schizophreniform disorder and other psychotic episodes of unknown cause.

Antipsychotic medications (see below) are the treatment of choice. They block the response to stimulation. The relapse rate can be reduced by 50% with proper maintenance neuroleptic therapy. Long-acting, injectable depot neuroleptics are used in noncompliant patients or nonresponders to oral medication.

Antipsychotic drugs include the "typical" neuroleptics **phenothiazines**, **thioxanthenes** (both similar in structure), **butyrophenones**, **dihydroindolones**, **dibenzoxazepines**, and **benzisoxazoles**, and the newer "atypical" neuroleptics clozapine, risperidone, olanzapine, quetiapine, and ziprasidone ([Table 25-4](#)).

Generally, increasing milligram potency of the typical neuroleptics is associated with decreasing anticholinergic and adrenergic side effects and increasing extrapyramidal symptoms ([Table 25-5](#)). For example, chlorpromazine has lower potency and more severe anticholinergic and adrenergic side effects. The increased anticholinergic effect of chlorpromazine, however, lowers the risk of extrapyramidal symptoms.

The phenothiazines comprise the bulk of the currently used typical neuroleptic drugs. The only butyrophenone commonly used in psychiatry is haloperidol, which is totally different in structure but very similar in action and side effects to the piperazine phenothiazines such as fluphenazine, perphenazine, and trifluoperazine. These drugs and haloperidol (dopamine [D_2] receptor blockers) have high potency and a paucity of autonomic side effects, and act to markedly lower arousal levels.

Molindone and loxapine, while less potent, are similar in action, side effects, and safety to the piperazine phenothiazines.

The first "atypical" (novel) antipsychotic drug developed, clozapine, a dibenzodiazepine derivative, has dopamine (D_4) receptor-blocking activity as well as central serotonergic, histaminergic, and alpha-noradrenergic receptor-blocking activity. It is effective in the treatment of about 30% of psychoses resistant to other neuroleptic drugs. Recent research suggests that clozapine may have specific efficacy in decreasing suicidality in patients with schizophrenia. It is associated with a 1% risk of agranulocytosis, which requires weekly white blood cell count monitoring for the first 6 months followed by monitoring every other week. Weekly monitoring for 1 month after discontinuation of the medication is recommended. Because of an association between clozapine and myocarditis, the drug is contraindicated in patients with severe heart disease. Risperidone is an antipsychotic that blocks some serotonin receptors ($5-HT_2$) and dopamine receptors (D_2). Risperidone causes fewer extrapyramidal side effects than the typical antipsychotics at doses less than 6 mg. It appears to be as effective as haloperidol and possibly as effective as clozapine in treatment-resistant patients without requiring weekly white cell counts. Risperidone-induced hyperprolactinemia, even on low doses, has been reported, and that effect is thought to be more common with risperidone than with other atypical antipsychotics.

Olanzapine is a potent blocker of muscarinic, anticholinergic, $5-HT_2$, and dopamine D_1 , D_2 , and D_4 receptors. High doses of olanzapine (12.5-17.5 mg daily) appear to be more effective than lower doses. The drug appears to be more effective than haloperidol in the treatment of negative symptoms. It has, however, been associated with more elevated serum alanine aminotransferase than those taking haloperidol. It is associated with a much lower incidence of dystonic reaction than haloperidol and is perhaps less likely to induce tardive dyskinesia. Its most common side effects include somnolence, agitation, nervousness, headache, insomnia, dizziness, and significant weight gain. Multiple case reports have linked olanzapine and clozapine to new-onset type 2 diabetes. Further investigation is ongoing to clarify the risk, risk factors, and pathophysiology.

Quetiapine is a neuroleptic with greater $5-HT_2$ relative to D_2 receptor blockade as well as a relatively high affinity for α_1 - and α_2 -adrenergic receptors. It appears to be as efficacious as haloperidol in treating positive and negative symptoms of schizophrenia, with less extrapyramidal side effects even at high doses. More common side effects include somnolence, dizziness, and postural hypotension. Because of an association with lens changes seen in patients on long-term treatment, an eye examination to detect cataract formation is recommended at initiation of treatment and then at 6-month intervals during treatment.

Ziprasidone has both anti-dopamine receptor and anti-serotonin receptor effects, with good efficacy for both positive and negative symptoms of schizophrenia. Ziprasidone is not associated with significant weight gain, hyperlipidemia, or new-onset diabetes and offers a good alternative for some patients. It has been implicated in QTc interval delay of > 500 ms in some patients, though in several cases of overdose there were no incidents of torsade de pointes or sudden death. Patients taking ziprasidone should be screened for cardiac risk factors. A pretreatment ECG is indicated for patients at risk of cardiac sequelae (including patients taking other

medications that might prolong the QTc interval).

Aripiprazole, a new neuroleptic agent available in the United States, is the first dopamine stabilizer. A partial agonist at the dopamine D₂ and serotonin 5-HT₁ receptors and an antagonist at 5-HT₂ receptors, it is effective against positive and negative symptoms of schizophrenia. It functions as an antagonist or agonist, depending on the dopaminergic activity at the dopamine receptors. This may help decrease side effects. More activating than sedating, aripiprazole is thought to impose a low risk of extrapyramidal symptoms, weight gain, hyperprolactinemia, and delayed QT interval.

None of the antipsychotics produce true physical dependency, and they have wide safety margins between therapeutic and toxic effects. All decrease adrenergic responses. Despite higher costs, atypical neuroleptics are often considered preferable to traditional antipsychotics because they are thought to be associated with reduced extrapyramidal symptoms and a lesser risk of tardive dyskinesia.

Clinical Indications

The antipsychotics are used to treat all forms of the schizophrenias as well as psychotic ideation in organic brain psychoses, delirium and dementia, drug-induced psychoses, psychotic depression, and mania. They are also effective in Tourette's disorder. They quickly lower the arousal (activity) level and, perhaps indirectly, gradually improve socialization and thinking. The improvement rate is about 80%. Patients whose behavioral symptoms worsen with use of antipsychotic drugs may have an undiagnosed organic condition such as anticholinergic toxicity.

Symptoms that are ameliorated by these drugs include hyperactivity, hostility, aggression, delusions, hallucinations, irritability, and poor sleep. Individuals with acute psychosis and good premorbid function respond quite well. The most common cause of failure in the treatment of acute psychosis is inadequate dosage, and the most common cause of relapse is noncompliance.

Though typical antipsychotics are efficacious in the treatment of so-called positive symptoms of schizophrenia such as hallucinations and delusions, atypical antipsychotics are thought to have efficacy in reducing both positive symptoms and negative symptoms such as withdrawal, psychomotor retardation, and poor interpersonal relationships. Antidepressant drugs may be used in conjunction with neuroleptics if significant depression is present. Resistant cases may require concomitant use of lithium, carbamazepine, or valproic acid. The addition of a benzodiazepine drug to the neuroleptic regimen may prove helpful in treating the agitated or catatonic psychotic patient who has not responded to neuroleptics alone—lorazepam, 1-2 mg orally, can produce a rapid resolution of catatonic symptoms and may allow maintenance with a lower neuroleptic dose. ECT has also been effective in treating catatonia.

Dosage Forms & Patterns

The dosage range is quite broad. For example, risperidone, 0.5-1 mg orally at bedtime, may be sufficient for the elderly person with mild dementia, whereas up to 6 mg/d may be used in a young patient with acute schizophrenia. For quick response, one may start with an atypical antipsychotic in combination with a benzodiazepine (eg, risperidone oral solution, 2 mg, or olanzapine, 10 mg orally, and lorazepam, 2 mg orally, every 2-4 hours as needed). In an acutely distressed, psychotic patient one might use haloperidol, 10 mg intramuscularly, which is absorbed rapidly and achieves an initial tenfold plasma level advantage over equal oral doses. Psychomotor agitation, racing thoughts, and general arousal are quickly reduced. The dose can be repeated every 3-4 hours; when the patient is less symptomatic, oral doses can replace parenteral administration in most cases.

Various factors play a role in the absorption of oral medications. Of particular importance are previous gastrointestinal surgery and concomitant administration of other drugs. There are racial differences in metabolizing the neuroleptic drugs—eg, many Asians require only about half the usual dosage. Bioavailability is influenced by other factors such as smoking or hepatic microsomal enzyme stimulation with alcohol or barbiturates and enzyme-altering drugs such as carbamazepine or methylphenidate. Neuroleptic plasma drug level determinations are not currently of major clinical assistance.

Divided daily doses are not necessary after a maintenance dose has been established, and most patients can then be maintained on a single daily dose, usually taken at bedtime. This is particularly appropriate in a case where the sedative effect of the drug is desired for nighttime sleep, and undesirable sedative effects can be avoided during the day. Risperidone is an exception, being given twice daily. First-episode patients especially should be tapered off medications after about 6 months of stability and carefully monitored; their rate of relapse is lower than that of multiple-episode patients.

Psychiatric patients—particularly paranoid individuals—often neglect to take their medication. In these cases and in nonresponders to oral medication, the enanthate and decanoate (the latter is slightly longer-lasting and has fewer extrapyramidal side effects) forms of fluphenazine or the decanoate form of haloperidol may be given by deep subcutaneous injection or intramuscularly to achieve an effect that will usually last 7-28 days. A patient who cannot be depended on to take oral medication (or who overdoses on minimal provocation) will generally agree to come to the clinician's office for a "shot." The usual dose of the fluphenazine long-acting preparations is 25 mg every 2 weeks. Dosage and frequency of administration vary from about 100 mg weekly to 12.5 mg monthly. Use the smallest effective amount as infrequently as possible. A monthly injection of 25 mg of fluphenazine decanoate is equivalent to about 15-20 mg of oral fluphenazine daily. Concomitant use of a benzodiazepine (eg, lorazepam, 2 mg orally twice daily) may permit reduction of the required dosage of oral or parenteral antipsychotic drug.

Intravenous haloperidol, the neuroleptic most commonly used by this route, is often used in critical care units in the management of agitated, delirious patients. Intravenous haloperidol should be given no faster than 1 mg/min to reduce cardiovascular side effects, such as torsade de pointes, and is associated with a lower risk of extrapyramidal side effects.

Side Effects

For both typical and atypical neuroleptic agents, a range of side effects are reported. The most common anticholinergic side effects include dry mouth (which can lead to ingestion of caloric liquids and weight gain or hyponatremia), blurred near vision, urinary retention (particularly in elderly men with enlarged prostates), delayed gastric emptying, esophageal reflux, ileus, delirium, and precipitation of acute glaucoma in patients with narrow anterior chamber angles. Other autonomic effects include orthostatic hypotension and sexual dysfunction—problems in achieving erection, ejaculation (including retrograde ejaculation), and orgasm in men (approximately 50% of cases) and women (approximately 30%). Delay in achieving orgasm is often a factor in medication noncompliance. Electrocardiographic changes occur frequently, but clinically significant arrhythmias are much less common. Elderly patients and those with preexisting cardiac disease are at greater risk. The most frequently seen electrocardiographic changes include diminution of the T wave amplitude, appearance of prominent U waves, depression of the ST segment, and prolongation of the QT interval. Thioridazine has been given an FDA warning for dose-related QTc delay and risk of fatal cardiac arrhythmias. As noted above, ziprasidone can produce QTc prolongation. An ECG prior to treatment in some patients may be indicated. In some critical care patients, torsade de pointes has been associated with the use of high-dose intravenous haloperidol (usually > 30 mg/24 h).

Associations have been suggested between the atypical neuroleptics and new-onset diabetes, hyperlipidemia, QTc prolongation, and weight gain ([Table 25-6](#)). Neuroleptic medications in general may have metabolic and endocrine effects, including weight gain, hyperglycemia, infrequent temperature irregularities (particularly in hot weather), and water intoxication, that may be due to inappropriate antidiuretic hormone secretion. Lactation and menstrual irregularities are common (antipsychotic drugs should be avoided, if possible, in breast cancer patients because of potential trophic effects of elevated prolactin levels on the breast). Both antipsychotic and antidepressant drugs inhibit sperm motility. Bone marrow depression and cholestatic jaundice occur rarely; these are hypersensitivity reactions, and they usually appear in the first 2 months of treatment. They subside on discontinuance of the drug. There is cross-sensitivity among all of the phenothiazines, and a drug from a different group should be used when allergic reactions occur.

Clozapine is associated with a 1.6% risk of **agranulocytosis** (higher in persons of Ashkenazi Jewish ancestry), and its use must be strictly monitored with weekly blood counts during the first 6 months of treatment, with monitoring every other week thereafter. Discontinuation of the medication requires weekly monitoring of the white blood cell count for 1 month. Recently, clozapine has been associated with fatal myocarditis and is contraindicated in patients with severe heart disease. Additionally, clozapine lowers the seizure threshold and has many side effects, including sedation, hypotension, increased liver enzyme levels, hypersalivation, respiratory arrest, weight gain, and changes in both the ECG and the EEG.

Photosensitivity, retinopathy, and hyperpigmentation are associated with use of fairly high dosages of chlorpromazine and thioridazine. The appearance of particulate melanin deposits in the lens of the eye is related to the total dose given, and patients on long-term medication should have periodic eye examinations. Teratogenicity has not been causally related to these drugs, but prudence is indicated particularly in the first trimester of pregnancy. The seizure threshold is lowered, but it is safe to use these medications in epileptics controlled by anticonvulsants.

The **neuroleptic malignant syndrome (NMS)** is a catatonia-like state manifested by extrapyramidal signs, blood pressure changes, altered consciousness, and hyperpyrexia; it is an uncommon but serious complication of neuroleptic treatment. Muscle rigidity, involuntary movements, confusion, dysarthria, and dysphagia are accompanied by pallor, cardiovascular instability, fever, pulmonary congestion, and diaphoresis and may result in stupor, coma, and death. The cause may be related to a number of factors, including poor dosage control of neuroleptic medication, affective illness, decreased serum iron, dehydration, and increased sensitivity of dopamine receptor sites. Lithium in combination with a neuroleptic drug may increase vulnerability, which is already increased in patients with an affective disorder. In most cases, the symptoms develop within the first 2 weeks of antipsychotic drug treatment. The syndrome may occur with small doses of the drugs. Intramuscular administration is a risk factor. Elevated creatine kinase and leukocytosis with a shift to the left are present early in about half of cases. Treatment includes controlling fever and providing fluid support. Dopamine agonists such as bromocriptine, 2.5-10 mg orally three times a day, and amantadine, 100-200 mg orally twice a day, have

also been useful. Dantrolene, 50 mg intravenously as needed, is used to alleviate rigidity (do not exceed 10 mg/kg/d). There is ongoing controversy about the efficacy of these three agents as well as the use of calcium channel blockers and benzodiazepines. Electroconvulsive therapy has been used effectively in resistant cases. Clozapine has been used with relative safety and fair success as an antipsychotic drug for patients who have had NMS. The syndrome must be differentiated from acute lethal catatonia, malignant hyperthermia, neurotoxic syndromes (including AIDS), and a variety of other conditions such as viral encephalitis, Wilson's disease, central anticholinergic syndrome, and hypertonic states (eg, tetany, strychnine poisoning).

Akathisia is the most common (about 20%) so-called **extrapyramidal symptom**. It usually occurs early in treatment (but may persist after neuroleptics are discontinued) and is frequently mistaken for anxiety or exacerbation of psychosis. It is characterized by a subjective desire to be in constant motion followed by an inability to sit or stand still and consequent pacing. It may include suicidality or feelings of fright, rage, terror, or sexual torment. Insomnia is often present. In all cases, reevaluate the dosage requirement or the type of neuroleptic drug. One should inquire also about cigarette smoking, which in women has been associated with an increased incidence of akathisia. Antiparkinsonism drugs such as trihexyphenidyl, 2-5 mg orally three times daily, or benztropine mesylate, 1-2 mg twice daily, may be helpful. In resistant cases, symptoms may be alleviated by propranolol, 30-80 mg/d orally, diazepam, 5 mg three times daily, or amantadine, 100 mg orally three times daily.

Acute dystonias usually occur early, though a late (tardive) occurrence is reported in patients (mostly men after several years of therapy) who previously had early severe dystonic reactions and a mood disorder (see below). Younger patients are at higher risk for acute dystonias. The most common signs are bizarre muscle spasms of the head, neck, and tongue. Frequently present are torticollis, oculogyric crises, swallowing or chewing difficulties, and masseter spasms. Laryngospasm is particularly dangerous. Back, arm, or leg muscle spasms are occasionally reported. Diphenhydramine, 50 mg intramuscularly, is effective for the acute crisis; one should then give benztropine mesylate, 2 mg orally twice daily, for several weeks, and then discontinue gradually, since few of the extrapyramidal symptoms require long-term use of the antiparkinsonism drugs (all of which are about equally efficacious—though trihexyphenidyl tends to be mildly stimulating and benztropine mildly sedating).

Drug-induced parkinsonism is indistinguishable from idiopathic parkinsonism, but it is reversible, occurs later in treatment than the preceding extrapyramidal symptoms, and in some cases appears after neuroleptic withdrawal. The condition includes the typical signs of apathy and reduction of facial and arm movements (akinesia, which can mimic depression), festinating gait, rigidity, loss of postural reflexes, and pill-rolling tremor. AIDS patients seem particularly vulnerable to extrapyramidal side effects. High-potency neuroleptics often require antiparkinsonism drugs ([Table 24-5](#)). The neuroleptic dosage should be reduced, and immediate relief can be achieved with antiparkinsonism drugs in the same dosages as above. After 4-6 weeks, these antiparkinsonism drugs can often be discontinued with no recurrent symptoms. In any of the extrapyramidal symptoms, amantadine, 100-400 mg daily, may be used instead of the antiparkinsonism drugs. Neuroleptic-induced catatonia is similar to catatonic stupor with rigidity, drooling, urinary incontinence, and cogwheeling. It usually responds slowly to withdrawal of the offending medication and use of antiparkinsonism agents.

Tardive dyskinesia is a syndrome of abnormal involuntary stereotyped movements of the face, mouth, tongue, trunk, and limbs that may occur after months or (usually) years of treatment with neuroleptic agents. The syndrome affects 20-35% of patients who have undergone long-term neuroleptic therapy. Predisposing factors include older age, many years of treatment, cigarette smoking, and diabetes mellitus. Pineal calcification is higher in this condition by a margin of 3:1. There are no known differences among any of the antipsychotic drugs in the development of this syndrome, though the atypical antipsychotics appear to offer lower risk.

Early manifestations include fine worm-like movements of the tongue at rest, difficulty in sticking out the tongue, facial tics, increased blink frequency, or jaw movements of recent onset. Later manifestations may include bucco-linguo-masticatory movements, lip smacking, chewing motions, mouth opening and closing, disturbed gag reflex, puffing of the cheeks, disrupted speech, respiratory distress, or choreoathetoid movements of the extremities (the last being more prevalent in younger patients). The symptoms do not necessarily worsen and in rare cases may lessen even though neuroleptic drugs are continued. The dyskinesias do not occur during sleep and can be voluntarily suppressed for short periods. Stress and movements in other parts of the body will often aggravate the condition.

Early signs of dyskinesia must be differentiated from those reversible signs produced by ill-fitting dentures or nonneuroleptic drugs such as levodopa, tricyclic antidepressants (TCAs), antiparkinsonism agents, anticonvulsants, and antihistamines. Other neurologic conditions such as Huntington's chorea can be differentiated by history and examination.

The emphasis should be on prevention. Use the least amount of neuroleptic drug necessary to mute the psychotic symptoms. Detect early manifestations of dyskinesias. When these occur, stop anticholinergic drugs and gradually discontinue neuroleptic drugs. Weight loss and cachexia sometimes appear on withdrawal of neuroleptics. In an indeterminate number of cases, the dyskinesias will remit. Keep the patient off the drugs until reemergent psychotic symptoms dictate their resumption, at which point they are restarted in low doses and gradually increased until there is clinical improvement. If neuroleptic drugs are restarted, clozapine and olanzapine appear to offer less risk of recurrence. The use of adjunctive agents such as benzodiazepines or lithium may help directly or indirectly by allowing control of psychotic symptoms with a low dosage of neuroleptics. If the dyskinesic syndrome recurs and it is necessary to continue neuroleptic drugs to control psychotic symptoms, informed consent should be obtained. Benzodiazepines, buspirone (in doses of 15-60 mg/d), phosphatidylcholine, clonidine, calcium channel blockers, vitamin E, and propranolol all have had limited usefulness in treating the dyskinetic side effects.

B. Social

Environmental considerations are most important in the individual with a chronic illness, who usually has a history of repeated hospitalizations, a continued low level of functioning, and symptoms that never completely remit. Family rejection and work failure are common. In these cases, board and care homes staffed by personnel experienced in caring for psychiatric patients are most important. There is frequently an inverse relationship between stability of the living situation and the amounts of required antipsychotic drugs, since the most salutary environment is one that reduces stimuli. Nonresidential self-help groups such as Recovery, Inc., should be utilized whenever possible. They provide a setting for sharing, learning, and mutual support and are frequently the only social involvement with which this type of patient is comfortable. Vocational rehabilitation and work agencies (eg, Goodwill Industries, Inc.) provide assessment, training, and job opportunities at a level commensurate with the person's clinical condition.

C. Psychologic

The need for psychotherapy varies markedly depending on the patient's current status and history. In a person with a single psychotic episode and a previously good level of adjustment, supportive psychotherapy may help the patient reintegrate the experience, gain some insight into antecedent problems, and become a more self-observant individual who can recognize early signs of stress. Insight-oriented psychotherapy is often counterproductive in this type of disorder. Early research suggests that cognitive behavioral therapy—in conjunction with medication management, may have some efficacy in the treatment of symptoms of schizophrenia. Family therapy should be given concomitantly to help alleviate the patient's stress and to assist relatives in coping with the patient.

D. Behavioral

Behavioral techniques (see above) are most frequently used in therapeutic settings such as day treatment centers, but there is no reason why they cannot be incorporated into family situations or any therapeutic setting. Many behavioral techniques are used unwittingly (eg, positive reinforcement—whether it be a word of praise or an approving nod—after some positive behavior), and with some careful thought this approach can be a powerful instrument for helping a person learn behaviors that will facilitate social acceptance. Music from portable cassette players with earphones is one of many ways to divert the patient's attention from auditory hallucinations.

Prognosis

In any psychosis in the large majority of patients, the prognosis is excellent for alleviation of positive symptoms such as hallucinations or delusions treated with medication. Negative symptoms such as diminished affect and sociability are much more difficult to treat but appear responsive to atypical antipsychotics. Unavailability of structured work situations and lack of family therapy are two other reasons why the prognosis is so guarded in such a large percentage of schizophrenic patients. Psychosis connected with a history of serious drug abuse has a guarded prognosis because of the central nervous system damage, usually from the drugs themselves and associated medical illnesses.

MOOD DISORDERS (DEPRESSION & MANIA)

Essentials of Diagnosis

Present in most depressions:

- Lowered mood, varying from mild sadness to intense feelings of guilt, worthlessness, and hopelessness.
- Difficulty in thinking, including inability to concentrate, ruminations, and lack of decisiveness.
- Loss of interest, with diminished involvement in work and recreation.
- Somatic complaints such as headache; disrupted, lessened, or excessive sleep; loss of energy; change in appetite; decreased sexual drive.
- Anxiety.

Present in some severe depressions:

- Psychomotor retardation or agitation.
- Delusions of a hypochondriacal or persecutory nature.
- Withdrawal from activities.
- Physical symptoms of major severity, eg, anorexia, insomnia, reduced sexual drive, weight loss, and various somatic complaints.
- Suicidal ideation.

Present in mania:

- Mood ranging from euphoria to irritability.
- Sleep disruption.
- Hyperactivity.
- Racing thoughts.
- Grandiosity.
- Variable psychotic symptoms.

General Considerations

Depression is extremely common, with up to 30% of primary care patients having depressive symptoms. Depression may be the final expression of (1) genetic factors (neurotransmitter dysfunction), (2) developmental problems (personality defects, childhood events), or (3) psychosocial stresses (divorce, unemployment). It frequently presents in the form of somatic complaints with negative medical workups. Although sadness and grief are normal responses to loss, depression is not. Patients experiencing normal grief tend to produce sympathy and sadness in the clinician caregiver; depression often produces frustration and irritation in the clinician. Grief is usually accompanied by intact self-esteem, whereas depression is marked by a sense of guilt and worthlessness.

Mania is often combined with depression and may occur alone, together with mania in a mixed episode, or in cyclic fashion with depression.

Clinical Findings

In general, there are four major types of depressions, with similar symptoms in each group.

A. Adjustment Disorder with Depressed Mood

Depression may occur in reaction to some identifiable stressor or adverse life situation, usually loss of a person by death (grief reaction), divorce, etc; financial reversal (crisis); or loss of an established role, such as being needed. Anger is frequently associated with the loss, and this in turn often produces a feeling of guilt. The disorder occurs within 3 months of the stressor and causes significant impairment in social or occupational functioning. The symptoms range from mild sadness, anxiety, irritability, worry, lack of concentration, discouragement, and somatic complaints to the more severe symptoms of the next group.

B. Depressive Disorders

The subclassifications include major depressive disorder and dysthymia.

1. Major depressive disorder—A major depressive disorder (eg, "endogenous" unipolar disorder, melancholia) consists of at least one episode of serious mood depression that occurs at any time of life. Many consider a physiologic or metabolic aberration to be causative. Complaints vary widely but most frequently include a loss of interest and pleasure (anhedonia), withdrawal from activities, and feelings of guilt. Also included are inability to concentrate, some cognitive dysfunction, anxiety, chronic fatigue, feelings of worthlessness, somatic complaints (unidentifiable somatic complaints frequently indicate depression), loss of sexual drive, and thoughts of death. Diurnal variation with improvement as the day progresses is common. Vegetative signs that frequently occur are insomnia, anorexia with weight loss, and constipation. Occasionally, severe agitation and psychotic ideation (paranoid thinking, somatic delusions) are present. These symptoms are more common in postmenopausal depression (involutional melancholia). Paranoid symptoms may range from general suspiciousness to ideas of reference with delusions. The somatic delusions frequently revolve around feelings of impending annihilation or hypochondriacal beliefs (eg, that the body is rotting away with cancer). Hallucinations are uncommon.

Subcategories include **major depression with atypical features** characterized by hypersomnia, overeating, lethargy, and rejection sensitivity. **Major depression with a seasonal onset (seasonal affective disorder)** is a dysfunction of circadian rhythms that occurs more commonly in the winter months and is believed to be due to decreased exposure to full-spectrum light. Common symptoms include carbohydrate craving, lethargy, hyperphagia, and hypersomnia. **Major depression with postpartum onset** usually occurs 2 weeks to 6 months postpartum.

Most women (up to 80%) experience some mild letdown of mood in the postpartum period. For some of these (10-15%), the symptoms are more severe and similar to those usually seen in serious depression, with an increased emphasis on concerns related to the baby (obsessive thoughts about harming it or inability to care for it). When psychotic symptoms occur, there is frequently associated sleep deprivation, volatility of behavior, and manic-like symptoms. Postpartum psychosis is much less common (< 2%), often occurs within the first 2 weeks, and requires early and aggressive management. Biologic vulnerability with hormonal changes and psychosocial stressors all play a role. The chances of a second episode are about 25% and may be reduced with prophylactic treatment.

2. Dysthymia—Dysthymia is a chronic depressive disturbance. Sadness, loss of interest, and withdrawal from activities over a period of 2 or more years with a relatively persistent course is necessary for this diagnosis. Generally, the symptoms are milder but longer-lasting than those in a major depressive episode.

3. Premenstrual dysphoric disorder—Depressive symptoms during the late luteal phase of the menstrual cycles may occur throughout the year.

C. Bipolar Disorders

Bipolar disorders consist of episodic mood shifts into mania, major depression, hypomania, and mixed mood states. The ability of bipolar disorder to mimic aspects of many other Axis I disorders and a high comorbidity with substance abuse can make the initial diagnosis of bipolar disorder difficult.

1. Mania—A manic episode is a mood change characterized by elation with hyperactivity, overinvolvement in life activities, increased irritability, flight of ideas, easy distractibility, and little need for sleep. The overenthusiastic quality of the mood and the expansive behavior initially attract others, but the irritability, mood lability with swings into depression, aggressive behavior, and grandiosity usually lead to marked interpersonal difficulties. Activities may occur that are later regretted, eg, excessive spending, resignation from a job, a hasty marriage, sexual acting out, and exhibitionistic behavior, with alienation of friends and family. Atypical manic episodes can include gross delusions, paranoid ideation of severe proportions, and auditory hallucinations usually related to some grandiose perception. The episodes begin abruptly (sometimes precipitated by life stresses) and may last from several days to months. Spring and summer tend to be the peak periods. Generally, the manic episodes are of shorter duration than the depressive episodes. In almost all cases, the manic episode is part of a broader bipolar (manic-depressive) disorder. Patients with four or more discrete episodes of a mood disturbance in 1 year are called "rapid cyclers." (Substance abuse, particularly cocaine, can mimic rapid cycling.) These patients have a higher incidence of hypothyroidism. Manic patients differ from schizophrenics in that the former use more effective interpersonal maneuvers, are more sensitive to the social maneuvers of others, and are more able to utilize weakness and vulnerability in others to their own advantage. Creativity has been positively correlated with mood disorders, but the best work done is between episodes of mania and depression.

2. Cyclothymic disorders—These are chronic mood disturbances with episodes of depression and hypomania. The symptoms must have at least a 2-year duration and are milder than those that occur in depressive or manic episodes. Occasionally, the symptoms will escalate into a full-blown manic or depressive episode, in which case reclassification as bipolar I or bipolar II disorder would be warranted.

D. Mood Disorders Secondary to Illness and Drugs

Any illness, severe or mild, can cause significant depression. Conditions such as rheumatoid arthritis, multiple sclerosis, and chronic heart disease are particularly likely to be associated with depression, as are other chronic illnesses. Hormonal variations clearly play a role in some depressions. Varying degrees of depression occur at various times in schizophrenic disorders, central nervous system disease, and organic mental states. **Alcohol dependency** frequently coexists with serious depression.

The classic model of drug-induced depression occurs with the use of reserpine, both in a clinical and a neurochemical sense. Corticosteroids and oral contraceptives are commonly associated with affective changes. Antihypertensive medications such as methyldopa, guanethidine, and clonidine have been associated with the development of depressive syndromes, as have digitalis and antiparkinsonism drugs (eg, levodopa). It is unusual for beta-blockers to produce depression when given for short periods, such as in the treatment of performance anxiety. Sustained use of beta-blockers for medical conditions such as hypertension may produce depression in some patients, though the literature is unclear on this subject. It is also unclear whether non-lipid-soluble beta-blockers are less likely to be associated with depression than lipid-soluble ones. Infrequently, disulfiram and anticholinesterase drugs may be associated with symptoms of depression. All stimulant use results in a depressive syndrome when the drug is withdrawn. Alcohol, sedatives, opiates, and most of the psychedelic drugs are depressants and, paradoxically, are often used in self-treatment of depression.

Differential Diagnosis

Since depression may be a part of any illness—either reactively or as a secondary symptom—careful attention must be given to personal life adjustment problems and the role of medications (eg, reserpine, corticosteroids, levodopa). Schizophrenia, partial complex seizures, organic brain syndromes, panic disorders, and anxiety disorders must be differentiated. Subtle thyroid dysfunction must be ruled out.

Complications

The longer the depression continues, the more crystallized it becomes—particularly when there is an element of secondary reinforcement. The most important complication is suicide, which often includes some elements of aggression. Suicide rates in the general population vary from 9 per 100,000 in Spain to 20 per 100,000 in the United States to 58 per 100,000 in Hungary. In individuals with depression, the lifetime risk rises to 10-15%. Men tend toward successful suicide, particularly in older age groups, whereas women make more attempts with lower mortality rates. An increased suicide rate is being observed in the younger population, ages 15-35. Patients with cancer, respiratory illnesses, AIDS, and those being maintained on hemodialysis have higher suicide rates. Alcohol is a significant factor in many suicide attempts.

There are four major groups of people who make suicide attempts. By far the greatest number fall into the category of **situational problems** (the despair of ordinary people). There is often great ambivalence—they don't really want to die, but they don't want to go on as before either. A suicide attempt in such cases may be an impulsive or aggressive act not associated with significant depression. In other cases a suicide attempt is clearly a stratagem for **controlling or hurting others**.

The high-risk groups are those with severe depressions or psychotic illnesses. **Severe depression** may be due to exogenous conditions (eg, AIDS, whose victims have a suicide rate over 30 times that of the general population) or endogenous conditions (eg, panic disorders). This group includes also those who may not be diagnosed as having depression but who are overwhelmed by a serious stressful situation (eg, the man charged with child molestation who hangs himself in his cell). Anxiety, panic, and fear are major findings in suicidal behavior. A patient may seem to make a dramatic improvement, but the lifting of depression may be due to the patient's decision to commit suicide. Those with **psychotic illness** tend not to verbalize their concerns, are unpredictable, and are often successful but make up only a small percentage of the total.

Suicide is ten times more prevalent in schizophrenics than in the general population, and jumping from bridges is a more common means of attempted suicide by schizophrenics than by others. In one study of 100 jumpers, 47% were schizophrenic.

The immediate goal of psychiatric evaluation is to assess the current suicidal risk and the need for hospitalization versus outpatient management. The intent is less likely to be truly suicidal, for example, if small amounts of poison or drugs were ingested or scratching of wrists was superficial, if the act was performed in the vicinity of others or with early notification of others, or if the attempt was arranged so that early detection would be anticipated. Alcohol, hopelessness, delusional thoughts, and complete or nearly complete loss of interest in life or ability to experience pleasure are all positively correlated with suicide attempts. Other risk factors are previous attempts, a family history of suicide, medical or psychiatric illness (eg, anxiety, depression, psychosis), male sex, older age, contemplation of violent methods, a humiliating social stressor, and drug use (including long-term sedative or alcohol use), which contributes to impulsiveness or mood swings. Successful treatment of the patient at risk for suicide cannot be achieved if the patient continues to abuse drugs.

The patient's current mood status is best evaluated by direct evaluation of plans and concerns about the future, personal reactions to the attempt, and thoughts about the reactions of others. The patient's immediate resources should be assessed—people who can be significantly involved (most important), family support, job situation, financial resources, etc.

If hospitalization is not indicated (eg, gestures, impulsive attempts; see above), the clinician must formulate and institute a treatment plan or make an adequate referral. Medication should be dispensed in small amounts to at-risk patients. Although tricyclics and SSRIs are associated with an equal incidence of suicide attempts, the risk of successful suicide is higher with tricyclic overdose. Guns and drugs should be removed from the patient's household. Driving should be interdicted until the patient improves. The problem is often worsened by the long-term complications of the suicide attempt, eg, brain damage due to hypoxia, peripheral neuropathies caused by staying for long periods in one position, causing nerve compressions, and medical or surgical problems such as esophageal strictures and tendon dysfunctions.

The reasons for self-mutilation, most commonly wrist cutting (but also autocastration, autoamputation, and autoenucleation, which are associated with psychoses), may be very different from the reasons for a suicide attempt. The initial treatment plan, however, should presume suicidal ideation, and conservative treatment should be initiated.

Sleep disturbances in the depressions are discussed below.

Treatment of Depression

A. Medical

Depression associated with reactive disorders usually does not call for drug therapy and can be managed by psychotherapy and the passage of time. In severe cases—particularly when vegetative signs are significant and symptoms have persisted for more than a few weeks—antidepressant drug therapy is often effective. Drug therapy is also suggested by a family history of major depression in first-degree relatives or a past history of prior episodes.

The antidepressant drugs may be conveniently classified into three groups: (1) the newer antidepressants, including the serotonin-selective reuptake inhibitors (SSRIs) and bupropion, venlafaxine, nefazodone, and mirtazapine, (2) the tricyclic antidepressants (TCAs) and clinically similar drugs, and (3) the monoamine oxidase (MAO) inhibitors. These groups are described in greater detail below. Electroconvulsive therapy is effective in all types of depression (particularly involuntional melancholia) and will also rapidly resolve a manic episode. It is also very effective for postpartum depression. Megavitamin treatment, acupuncture, and electrosleep are of unproved usefulness for any psychiatric condition.

Hospitalization is necessary if suicide is a major consideration or if complex treatment modalities are required.

Drug selection is influenced by the history of previous responses if that information is available. If a relative has responded to a particular drug, this suggests that the patient may respond similarly. If no background information is available, a drug such as desipramine, starting with 50 mg and gradually increasing to 150 mg daily, or sertraline, 50 mg daily, can be selected and a *full trial* instituted. The medication trial should be monitored every 1-2 weeks until week 6. If successful, the medication should be continued for 6-12 months at the full therapeutic dose before tapering is considered. Antidepressants should be continued indefinitely at full dosage in individuals with more than two episodes after age 40 or one episode after age 50. If the response is inadequate despite a diagnosis supported by review and adequate drug levels, a second drug (eg, citalopram) should be substituted and given a trial. If the second drug fails, augmentation with lithium (eg, 600-900 mg/d) or thyroid medication (eg, liothyronine, 25 ug/d) should be considered. Dysthymia is also treated in this way. The Agency for Health Care Policy and Research has produced clinical practice guidelines that outline one algorithm of treatment decisions ([Figure 25-3](#)).

Psychotic depression can be treated with a combination of an antipsychotic such as perphenazine (used initially) and an antidepressant such as an SSRI at their usual doses. Recent research has suggested that use of mifepristone may have specific and early activity against psychotic depression.

Major depression with atypical features or seasonal onset can be treated with an MAO inhibitor or an SSRI with good results.

Stimulants such as dextroamphetamine (5-30 mg/d) and methylphenidate (10-45 mg/d) have enjoyed a resurgence of interest for the short-term treatment of depression in medically ill and geriatric patients. Their 50-60% efficacy rate is slightly below that of other agents. The stimulants are notable for rapid onset of action (hours) and a paucity of side effects (tachycardia, agitation) in most patients. They are usually given in two divided doses early in the day (eg, 7 AM and noon) so as to avoid interfering with sleep. These agents may also be useful as adjunctive agents in refractory depression.

Caution: Depressed patients may have suicidal thoughts, and the amount of drug dispensed should be appropriately controlled. The older tricyclic agents have a narrow therapeutic index, and one advantage of the newer drugs is their wider margin of safety. In all cases of pharmacologic management of depressed states, caution is indicated until the risk of suicide is considered minimal.

1. SSRIs and atypical antidepressants—The chief advantages of these agents are that they do not generally cause significant cardiovascular or anticholinergic side effects, as do the tricyclic agents. The serotonin-selective reuptake inhibitors (SSRIs) include fluoxetine, sertraline, paroxetine, fluvoxamine, and citalopram and its recently introduced enantiomer, escitalopram. The atypical antidepressants are bupropion, which appears to exert its effect through the dopamine neurotransmitter system; venlafaxine, which inhibits the reuptake of both serotonin and norepinephrine; nefazodone, which blocks the reuptake of serotonin but also inhibits the 5-HT₂ postsynaptic receptors; and mirtazapine, which selectively blocks presynaptic α₂-adrenergic receptors and enhances both noradrenergic and serotonergic transmission. All of these antidepressants are effective in the treatment of depression, both typical and atypical. The SSRI drugs have been effective in the treatment of panic attacks, bulimia, and obsessive-compulsive disorders, while bupropion may have some particular effectiveness in the treatment of rapid-cycling bipolar disorder. They do not seem to be as clearly effective in some pain syndromes as the tricyclics, though venlafaxine may have some efficacy in the treatment of neuropathic pain.

Most of the drugs in this group tend to be activating and are given in the morning so as not to interfere with sleep. Some patients, however, may have sedation, requiring that the drug be given at bedtime. This reaction occurs most commonly with paroxetine, fluvoxamine, and mirtazapine. The SSRIs can be given in once-daily dosage. Bupropion is usually given in two divided doses daily. Nefazodone and venlafaxine are usually given twice daily. Bupropion and venlafaxine are available in extended-release formulations. There is usually some delay in response; fluoxetine, for example, requires 2-6 weeks to act in depression, 4-8 weeks to be effective in panic disorder, and 6-12 weeks in treatment of obsessive-compulsive disorder. The starting dose (10-20 mg) is the usual daily dose for depression, while obsessive-compulsive disorder may require up to 80 mg daily. Some patients, particularly the elderly, may tolerate and benefit from as little as 10 mg/d or every other day. The other SSRIs have shorter half-lives and a lesser effect on hepatic enzymes, which reduces their impact on the metabolism of other drugs (thus not increasing significantly the serum concentrations of other drugs as much as fluoxetine). The shorter half-lives also allow for more rapid clearing if adverse side effects appear. Venlafaxine appears to be more effective with doses greater than 200 mg/d, although some individuals respond at 75 mg/d.

The side effects common to all of these drugs are headache, nausea, tinnitus, insomnia, and nervousness. Akathisia has been common with the SSRIs; other extrapyramidal symptoms (eg, dystonias) have occurred infrequently but particularly in withdrawal states. Sexual side effects of erectile dysfunction, retrograde ejaculation, and dysorgasmia are very common with the SSRIs. Antidotes to SSRI-induced sexual dysfunction are occasionally helpful. Sildenafil, 25-50 mg 2 hours prior to sexual activity, can improve erectile dysfunction in some patients. Cyproheptadine, 4 mg orally prior to sexual activity, may be helpful in countering drug-induced anorgasmia. Adjunctive bupropion (75-150 mg daily) may also help with restoring erectile function. Because of early research with bulimic patients, bupropion has been burdened with an unwarranted reputation for causing seizures. The SSRIs are strong serotonin uptake blockers and may in high dosage or in combination with MAO inhibitors, including the antiparkinsonian drug selegiline, cause a "serotonin syndrome." This syndrome is manifested by rigidity, hyperthermia, autonomic instability, myoclonus, confusion, delirium, and coma. This syndrome can be a particularly troublesome problem in the elderly. Several cases of angina have been reported in association with SSRIs. However, current research indicates that SSRIs are safer agents to use than tricyclic antidepressants in patients with cardiac disease. A new study suggests that sertraline is a safe and effective antidepressant treatment in patients with acute myocardial infarction or unstable angina.

Withdrawal syndromes have been reported for the SSRIs and venlafaxine. These include dysphoric mood, agitation, and a flu-like state. These medications should be discontinued gradually over a period of weeks or months to reduce the risk of withdrawal phenomena.

Fluoxetine, fluvoxamine, paroxetine, sertraline, venlafaxine, and citalopram in customary antidepressant doses do not appear to increase the risk of major fetal malformation when used during pregnancy. Postpartum developmental effects are thought to be minimal, but this question calls for ongoing investigation. The risk of depression to the mother and fetus needs to be part of the discussion with the patient about treatment options. The decision to use SSRIs and other psychotropic agents during pregnancy must be based on a risk-benefit analysis for each individual.

Venlafaxine is reported to be well tolerated without significant anticholinergic or cardiovascular side effects. Nausea, nervousness, and profuse sweating appear to be the major side effects. Venlafaxine appears to have few drug-drug interactions. It does require monitoring of blood pressure because some individuals develop a dose-related hypertension. Nefazodone appears to lack the anticholinergic effects of the TCAs and the agitation sometimes induced by SSRIs. Nefazodone should not be given with terfenadine, astemizole, or cisapride. Because nefazodone inhibits the liver's cytochrome P450 3A4 isoenzymes, concurrent use of these medications can lead to serious QT prolongation, ventricular tachycardia, or death. Through the same mechanism of enzyme inhibition, nefazodone can elevate cyclosporine levels sixfold to tenfold. Nefazodone has been given an FDA warning because it has been implicated in liver failure in rare cases. Pretreatment and ongoing monitoring of liver enzymes are indicated.

Mirtazapine is thought to enhance central noradrenergic and serotonergic activity with minimal sexual side effects as compared with the SSRIs. Its action as a potent antagonist of histaminergic receptors may make it a useful agent for patients with depression and insomnia. Its most common adverse side effects include somnolence, increased appetite, weight gain, lipid abnormalities, and dizziness. There have been reports of agranulocytosis in two of 2796 patients. Although it is metabolized by P450 isoenzymes, it is not an inhibitor of this system. It is given in a single dose at bedtime starting at 15 mg and increasing in 15-mg increments every week or every other week up to 45 mg.

2. Tricyclic antidepressants and clinically similar drugs—These drugs were the mainstay of drug therapy for depression for many years. They have also been effective in panic disorders, pain syndromes, and anxiety states. Specific ones have been effective in obsessive-compulsive disorder (clomipramine), enuresis (imipramine), psychotic depression (amoxapine), and reduction of craving in cocaine withdrawal (desipramine).

The tricyclics are characterized more by their similarities than by their differences. There is a lag in clinical response for up to several weeks, partly as a result of side effects that prevent rapid increase in dosage and partly because of their neurotransmitter effects. They tend to affect both serotonin and norepinephrine reuptake; some drugs act mainly on the former and others principally on the latter neurotransmitter system. Individuals receiving the same dosages vary markedly in therapeutic drug levels achieved (elderly patients require smaller doses), and determination of plasma drug levels is helpful when clinical response has been disappointing. Nortriptyline is usually effective when plasma levels are between 50 and 150 ng/mL; imipramine at plasma levels of 200-250 ng/mL; and desipramine at plasma levels of 100-250 ng/mL. High blood levels are not more effective than moderate levels and may be counterproductive (eg, delirium, seizures). Patients with gastrointestinal side effects benefit from plasma level monitoring to assess absorption of the drug. Most of the tricyclics can be given in a single dose at bedtime, starting at fairly low doses (eg, nortriptyline 25 mg orally) and increasing by 25 mg every several days as tolerated until the therapeutic response is achieved (eg, nortriptyline, 100-150 mg) or to maximum dose if necessary (eg, nortriptyline, 150 mg). The most common cause of treatment failure is an inadequate trial. A full trial consists of giving maximum daily dosage for at least 6 weeks. To reach maximum dosage, the trial encompasses a total of about 8 weeks. Because of marked anticholinergic and sedating side effects, clomipramine is started at a low dose (25 mg/d orally) and increased slowly in divided doses up to 100 mg/d, held at that level for several days, and then gradually increased as necessary up to 250 mg/d. Any of the TCA-like drugs should be started at very low doses (eg, 10-25 mg/d) and increased slowly in the treatment of panic disorder.

The tricyclic antidepressants have anticholinergic side effects to varying degrees (amitriptyline 100 mg is equivalent to atropine 5 mg). One must be particularly wary of the effect in elderly men with prostatic hyperplasia. The anticholinergic effects also predispose to other medical problems such as heat stroke or dental problems from xerostomia. Orthostatic hypotension is fairly common, may not remit with time, and may predispose to falls and hip fractures in the elderly. Cardiac effects of the TCAs are functions of the anticholinergic effect, direct myocardial depression (quinidine-like effect), and interference with adrenergic neurons. These factors may produce altered rate, rhythm, and contractility, particularly in patients with preexisting cardiac disease, such as bundle-branch or bifascicular block. Electrocardiographic changes range from benign ST segment and T wave changes and sinus tachycardia to a variety of complex and serious arrhythmias, the latter requiring a change in medication. Because TCAs have class I antiarrhythmic effects, they should be used with caution in patients with ischemic heart disease, arrhythmias, or conduction disturbances. SSRIs or the atypical antidepressants may be better initial choices for this population. TCAs lower the seizure threshold so this is of particular concern in patients with a propensity for seizures (eg, previous head injury, alcohol withdrawal). Loss of libido and erectile, ejaculatory, and orgasmic dysfunction are fairly common and can compromise compliance. Trazodone rarely causes priapism, which requires treatment within 12 hours (epinephrine 1:1000 injected into the corpus cavernosum). Delirium, agitation, and mania are infrequent complications. Sudden discontinuation of some of these drugs can produce "cholinergic rebound," manifested by headaches and nausea with abdominal cramps. Overdoses of the tricyclic compounds are often serious because of the narrow therapeutic index and quinidine-like effects (see [Chapter 39](#)).

3. Monoamine oxidase inhibitors—The MAO inhibitors are now generally used as third-line drugs for depression (after a failure of SSRIs, TCAs, or the atypical antidepressants) because of the dietary and other restrictions required (see below and [Table 25-7](#)). They should be considered third-line drugs for refractory panic disorder and depression.

MAO inhibitors are administered in gradual stepwise dosage and may be given in the morning or evening, depending upon their effect on sleep. They tend to take effect in a fairly low dosage range ([Table 25-8](#)). Blood levels are not congruent with therapeutic response.

The MAO inhibitors commonly cause symptoms of orthostatic hypotension (which may persist) and sympathomimetic effects of tachycardia, sweating, and tremor. Nausea, insomnia (often associated with intense afternoon drowsiness), and sexual dysfunction are common. Trazodone, 25-75 mg orally at bedtime, may ameliorate the MAO-induced insomnia. Central nervous system effects include agitation and toxic psychoses. Dietary limitations ([Table 25-7](#)) and abstinence from drug products containing phenylpropanolamine, phenylephrine, meperidine, dextromethorphan, and pseudoephedrine are mandatory for MAO-A type inhibitors (those marketed for

treatment of depression), since the reduction of available monoamine oxidase leaves the patient vulnerable to exogenous amines (eg, tyramine in foodstuffs).

Treatment for a resultant hypertensive crisis has been the same as for pheochromocytoma (see [Chapter 26](#)), but there have been reports of success with nifedipine, 10 mg chewed and placed under the tongue, normalizing blood pressure in 1-5 minutes. The restrictions on the proscribed foodstuffs and sympathomimetic drugs are in effect during treatment and for 2-3 weeks after cessation of therapy. Termination of therapy with MAO inhibitors may be associated with anxiety, agitation, cognitive slowing, and headache. Very gradual withdrawal and short-term benzodiazepine therapy will ameliorate symptoms.

4. Switching and combination therapy—If the therapeutic response has been poor after an adequate trial with the chosen drug, one should reassess the diagnosis. Assuming that the trial has been adequate and the diagnosis is correct, a trial with a drug from another group is appropriate. In switching from one group to another, an adequate "washout time" must be allowed. This is critical in certain situations—eg, in switching from an MAO inhibitor to a tricyclic, allow 2-3 weeks between stopping one drug and starting another; in switching from an SSRI to an MAO inhibitor, allow 4-5 weeks. In switching within groups—eg, from one tricyclic to another (amitriptyline to desipramine, etc)—no washout time is needed, and one can rapidly decrease the dosage of one drug while increasing the other. Combining two antidepressants requires caution and is usually reserved for refractory patients after psychiatric consultation.

However, in any of the three groups, one can augment the antidepressant drug if the therapeutic response has been less than satisfactory. Psychiatric consultation may be helpful in selecting the augmenting agent. Lithium and thyroid hormone (eg, 25 ug daily of liothyronine) are the most commonly used augmenting agents. Lithium is an excellent augmentation agent for the 25-40% of depressed patients who fail to respond to an adequate trial of an antidepressant. One-half of these patients will respond to the addition of lithium (600-900 mg/d) with an enhanced antidepressant effect. An empirical trial of liothyronine, 25 ug, may produce effects within a week in certain patients irrespective of whether or not thyroid function is normal at baseline.

5. Maintenance and tapering—When clinical relief of symptoms is obtained, medication is continued for 12 months in the effective maintenance dosage, which is the dosage required in the acute stage. The full dosage should be continued indefinitely when the individual has a first episode before age 20 or after age 50, is over age 40 with two episodes, or has had three episodes at any age. Major depression should often be considered as a chronic disease. If the medication is being tapered, it should be done gradually over several months, monitoring closely for relapse.

6. Drug interactions—Interactions with other drugs are listed in [Table 25-9](#).

7. Electroconvulsive therapy (ECT)—ECT causes a generalized central nervous system seizure (peripheral convulsion is not necessary) by means of electric current. The key objective is to exceed the seizure threshold, which can be accomplished by a variety of means. Electrical stimulation is more reliable and simpler than the use of chemical convulsants. The mechanism of action is not known, but it is thought to involve major neurotransmitter responses at the cell membrane. Current insufficient to cause a seizure produces no therapeutic benefit.

ECT is the most effective (about 70-85%) treatment of severe depression—particularly the delusions and agitation commonly seen with depression in the involuntal period. It is indicated when medical conditions preclude the use of antidepressants or in cases of nonresponsiveness to these medications. Comparative controlled studies of electroconvulsive therapy in severe depression show that it is more effective than chemotherapy. It is also effective in the manic disorders and psychoses during pregnancy (when drugs may be contraindicated). It has not been shown to be helpful in chronic schizophrenic disorders, and it is generally not used in acute schizophrenic episodes unless drugs are not effective and it is urgent that the psychosis be controlled (eg, a catatonic stupor complicating an acute medical condition).

The most common side effects are memory disturbance and headache. Memory loss or confusion is usually related to the number and frequency of ECT treatments and proper oxygenation during treatment. Unilateral ECT is associated with less memory loss than bilateral ECT. Some memory loss is occasionally permanent, but most memory faculties return to full capacity within several weeks. There have been reports that lithium administration concurrent with ECT resulted in greater memory loss. Before anesthesia was used, spinal compression fractures and severe anticipatory anxiety were common.

Increased intracranial pressure is a serious contraindication. Other problems such as cardiac disorders, aortic aneurysms, bronchopulmonary disease, and venous thrombosis are relative contraindications and must be evaluated in light of the severity of the medical problem versus the need for electroconvulsive therapy. Serious complications arising from electroconvulsive therapy occur in less than one in 1000 cases. Most of these problems are cardiovascular or respiratory in nature (eg, aspiration of gastric contents). Poor patient understanding and lack of acceptance of the technique by the public are the biggest obstacles to the use of electroconvulsive therapy.

8. Phototherapy—Phototherapy is used in major depression with seasonal onset. It consists of exposure (at a 3-foot distance) to a light source of 2500 lux for 2 hours daily. Light visors are an adaptation that provides greater mobility and an adjustable light intensity. The price of these full-spectrum light sources ranges between \$300 and \$400. The dosage varies, with some patients requiring morning and night exposure. One effect is alteration of biorhythm through melatonin mechanisms.

9. Experimental treatments—In preliminary studies, transcranial magnetic stimulation has appeared to be effective in nonpsychotic depression. Vagal nerve stimulation has shown promise in extremely refractory cases.

B. Psychologic

It is seldom possible to engage an individual in penetrating psychotherapeutic endeavors during the acute stage of a severe depression. While medications may be taking effect, a supportive approach to strengthen existing defenses and appropriate consideration of the patient's continuing need to function at work, to engage in recreational activities, etc, are necessary as the severity of the depression lessens. If the patient is not seriously depressed, it is often quite appropriate to initiate intensive psychotherapeutic efforts, since flux periods are a good time to effect change. A catharsis of repressed anger and guilt may be beneficial. Therapy during or just after the acute stage may focus on coping techniques, with some practice of alternative choices. When lack of self-confidence and identity problems are factors in the depression, individual psychotherapy can be oriented to ways of improving self-esteem, increasing assertiveness, and lessening dependency. Interpersonal psychotherapy for depression has shown efficacy in the treatment of acute depression, helping patients master interpersonal stresses and develop new coping strategies. Cognitive psychotherapy addresses patients' patterns of negative thoughts, called cognitive distortions, that lead to feelings of depression and anxiety. Treatment usually includes homework assignments such as keeping a journal of cognitive distortions and of positive responses to them. As previously noted, numerous studies have shown that the combination of drug therapy plus interpersonal psychotherapy or cognitive psychotherapy is more effective than either modality alone. It is usually helpful to involve the spouse or other significant family members early in treatment.

C. Social

Flexible use of appropriate social services can be of major importance in the treatment of depression. Since alcohol is often associated with depression, early involvement in alcohol treatment programs such as Alcoholics Anonymous can be important to future success (see Alcohol Dependency and Abuse, below). The structuring of daily activities during severe depression is often quite difficult for the patient, and loneliness is often a major factor. The help of family, employer, or friends is often necessary to mobilize the patient who experiences no joy in daily activities and tends to remain uninvolved and to deteriorate. Insistence on sharing activities will help involve the patient in simple but important daily functions. In some severe cases, the use of day treatment centers or support groups of a specific type (eg, mastectomy groups) is indicated. It is not unusual for a patient to have multiple legal, financial, and vocational problems requiring legal and vocational assistance.

D. Behavioral

When depression is a function of self-defeating coping techniques such as passivity, the role-playing approach can be useful. Behavioral techniques, including desensitization, may be used in problems such as phobias where depression is a by-product. When depression is a regularly used interpersonal style, behavioral counseling to family members or others can help in extinguishing the behavior in the patient.

Treatment of Mania

Acute manic or hypomanic symptoms will respond to lithium therapy after several days of treatment, but it is common to use neuroleptic drugs or high-potency benzodiazepines (eg, clonazepam) to immediately treat the excited or psychotic manic stage. Some schizoaffective disorders and some cases of so-called schizophrenia are probably atypical bipolar affective disorder, for which lithium treatment may be effective.

A. Neuroleptics

Acute manic symptoms of agitation and psychosis may be initially treated with the atypical antipsychotic olanzapine, 5-20 mg orally in conjunction with a benzodiazepine if indicated. Alternatively, haloperidol, 5-10 mg orally or intramuscularly every 2-3 hours until symptoms subside, may be used. The dosage of olanzapine or haloperidol is gradually reduced after lithium or another mood stabilizer is started (see below).

B. Clonazepam

Clonazepam can be an alternative or adjunct to a neuroleptic in controlling acute behavioral symptoms. Clonazepam has the advantage of causing no extrapyramidal side effects. Although 1-2 mg orally every 4-6 hours may be effective, up to 16 mg/d may be necessary.

C. Lithium

As a prophylactic drug for bipolar affective disorder, lithium significantly decreases the frequency and severity of both manic and depressive attacks in about 70% of patients. A positive response is more predictable if the patient has a low frequency of episodes (no more than two per year with intervals free of psychopathology). A

positive response occurs more frequently in individuals who have blood relatives with a diagnosis of manic or hypomanic attacks. Patients who swing rapidly back and forth between manic and depressive attacks (at least four cycles per year) usually respond poorly to lithium prophylaxis initially, but some improve with continued long-term treatment. Carbamazepine (see below) has been used with success in this group.

In addition to its use in manic states, lithium is sometimes useful in the prophylaxis of recurrent unipolar depressions (perhaps undiagnosed bipolar disorder). Lithium may ameliorate nonspecific aggressive behaviors and dyscontrol syndromes. The dosages are the same as used in bipolar disorder. Most patients with bipolar disease can be managed long-term with lithium alone, though some will require continued or intermittent use of a neuroleptic, antidepressant, or carbamazepine. An excellent resource for information pertaining to lithium is the Information Centers, Madison Institute of Medicine, 7617 Mineral Point Road, Suite 300, Madison, WI 53717-1914.

Before treatment, the clinical workup should include a medical history and physical examination; complete blood count; T_4 , TSH, blood urea nitrogen, serum creatinine, and serum electrolyte determinations; urinalysis; and electrocardiography in patients over age 45 or with a history of cardiac disease.

1. Dosage—Lithium carbonate is generally prescribed in the 300-mg unit. In a small minority of patients, a slow-release form or units of different dosage may be required. Lithium citrate is available as a syrup. The dosage is that required to maintain blood levels in the therapeutic range. For acute attacks, this ranges from 1 to 1.5 meq/L. Although there is controversy about the optimal chronic maintenance dose, many clinicians reduce the acute level to 0.6-1 meq/L in order to reduce side effects. The dose required to meet this need will vary in different individuals. For acute mania, doses of 1200-1800 mg/d are generally recommended. Augmentation of antidepressants is usually achieved with one-half of these doses. Once-a-day dosage is acceptable, but most patients have less nausea when they take the drug in divided doses with meals.

Lithium is readily absorbed, with peak serum levels occurring within 1-3 hours and complete absorption in 8 hours. Half of the total body lithium is excreted in 18-24 hours (95% in the urine). Blood for lithium levels should be drawn 12 hours after the last dose. Serum levels should be measured 5-7 days after initiation of treatment and changes in dose. For maintenance treatment, lithium levels should be monitored initially every 1-2 months but may be measured every 6-12 months in stable, long-term patients. Levels should be monitored more closely when there is any condition that causes volume depletion (eg, diarrhea, dehydration, use of diuretics).

2. Side effects—Mild gastrointestinal symptoms (take lithium with food), fine tremors (treat with propranolol, 20-60 mg/d orally, only if persistent), slight muscle weakness, and some degree of somnolence are early side effects that are usually transient. Moderate polyuria (reduced renal responsiveness to antidiuretic hormone) and polydipsia (associated with increased plasma renin concentration) are often present. Potassium administration can blunt this effect, as may once-daily dosing of lithium. Weight gain (often a result of calories in fluids taken for polydipsia) and leukocytosis not due to infection are fairly common.

Other side effects include goiter (3%; often euthyroid), hypothyroidism (10%; concomitant administration of lithium and iodide or lithium and carbamazepine enhances the hypothyroid and goitrogenic effect of either drug), changes in the glucose tolerance test toward a diabetes-like curve, nephrogenic diabetes insipidus (usually resolving about 8 weeks after cessation of lithium therapy), nephrotic syndrome, edema, folate deficiency, and pseudotumor cerebri (ophthalmoscopy is indicated if there are complaints of headache or blurred vision). A metallic taste, hair loss, and Raynaud's phenomenon have been reported in a few cases. Thyroid and kidney function should be checked at 3- to 4-month intervals. Most of these side effects subside when lithium is discontinued; when residual side effects exist, they are usually not serious. Most clinicians treat lithium-induced hypothyroidism (more common in women) with thyroid hormone while continuing lithium therapy. Hypercalcemia and elevated parathyroid hormone levels occur in some patients. Electrocardiographic abnormalities (principally T wave flattening or inversion) may occur during lithium administration but are not of major clinical significance. Sinoatrial block may occur, particularly in the elderly. It is important that other drugs which prolong intraventricular conduction, such as tricyclics, be used with caution in conjunction with lithium. Lithium impairs ventilatory function in patients with airway obstruction. Lithium alone does not have a significant effect on sexual function, but when combined with benzodiazepines (clonazepam in most symptomatic patients) it causes sexual dysfunction in about 50% of men. Lithium may precipitate or exacerbate psoriasis in some patients.

Patients receiving long-term lithium therapy may have cogwheel rigidity and, occasionally, other extrapyramidal signs. Lithium potentiates the parkinsonian effects of haloperidol. Long-term lithium therapy has also been associated with a relative lowering of the level of memory and perceptual processing (affecting compliance in some cases). Some impairment of attention and emotional reactivity has also been noted. Lithium-induced delirium with therapeutic lithium levels is an infrequent complication usually occurring in the elderly and may persist for several days after serum levels have become negligible. Encephalopathy has occurred in patients receiving combined lithium and neuroleptic therapy and in those who have cerebrovascular disease, thus requiring careful evaluation of patients who develop neurotoxic signs at subtoxic blood levels.

Some reports have suggested that the long-term use of lithium may have adverse effects on renal function (with interstitial fibrosis or tubular atrophy). A rise in serum creatinine levels is an indication for in-depth evaluation of renal function. Incontinence has been reported in women, apparently related to changes in bladder cholinergic-adrenergic balance.

Lithium exposure in early pregnancy increases the frequency of congenital anomalies, especially Ebstein's and other major cardiovascular anomalies. As with any woman taking psychotropic medications who has a planned or unplanned pregnancy, the decision to make a change in medication is complex and requires informed consent regarding the relative risks to the patient and fetus. Recent prospective studies suggest that the risk imposed by lithium in pregnancy may be overemphasized. Indeed, the risk of untreated bipolar disorder carries its own risks for pregnancy. Formula feeding should be considered in mothers using lithium, since concentration in breast milk is one-third to one-half that in serum.

Frank toxicity usually occurs at blood lithium levels above 2 meq/L. Because sodium and lithium are reabsorbed at the same loci in the proximal renal tubules, any sodium loss (diarrhea, use of diuretics, or excessive perspiration) results in increased lithium levels. Symptoms and signs include vomiting and diarrhea, the latter exacerbating the problem since more sodium is lost and more lithium is absorbed. Other symptoms and signs, some of which may not be reversible, include tremors, marked muscle weakness, confusion, dysarthria, vertigo, choreoathetosis, ataxia, hyperreflexia, rigidity, lack of coordination, myoclonus, seizures, opisthotonos, and coma. Toxicity is more severe in the elderly, who should be maintained on slightly lower serum levels. Lithium overdosage may be accidental or intentional or may occur as a result of poor monitoring.

Patients with massive ingestions of lithium or blood lithium levels above 2.5 meq/L should be treated with induced emesis and gastric lavage. If renal function is normal, osmotic and saline diuresis increases renal lithium clearance. Urinary alkalization is also helpful, since sodium bicarbonate decreases lithium reabsorption in the proximal tubule, as does acetazolamide as well. Aminophylline potentiates the diuretic effect by increasing the clearance of lithium. Drugs affecting the distal loop have no effect on lithium reabsorption. Blood lithium levels above 2.5 meq/L (confirmed by cerebrospinal fluid lithium levels) should be considered an indication for hemodialysis.

Compliance with lithium therapy is adversely affected by the loss of some hypomanic experiences valued by the patient. These include social extroversion and a sense of heightened enjoyment in many activities such as sex and business dealings, often with increased productivity in the latter.

3. Drug interactions—Patients receiving lithium should use diuretics with caution and only under close medical supervision. The thiazide diuretics cause increased lithium reabsorption from the proximal renal tubules, resulting in increased serum lithium levels ([Table 25-10](#)), and adjustment of lithium intake must be made to compensate for this. Reduce lithium dosage by 25-40% when the patient is receiving 50 mg of hydrochlorothiazide daily. Potassium-sparing diuretics (spironolactone, amiloride, triamterene) may also increase serum lithium levels and require careful monitoring of lithium levels. Loop diuretics (furosemide, ethacrynic acid, bumetanide) do not appear to alter serum lithium levels. Concurrent use of lithium and ACE inhibitors requires a 50-75% reduction in lithium intake to achieve therapeutic lithium levels.

D. Valproic Acid

Valproic acid (divalproex) is an antiseizure drug whose activity is at least partially related to GABA neurotransmission. It is gaining favor as a first-line treatment for mania because it has a broader index of safety than lithium. This issue is particularly important in AIDS or other medically ill patients prone to dehydration or malabsorption with wide swings in serum lithium levels. Valproic acid has also been utilized effectively in panic disorder and migraine headache. Treatment is often started at a dose of 750 mg/d orally in divided doses, and dosage is then titrated to achieve therapeutic serum levels. Oral loading in acutely manic bipolar patients in an inpatient setting (initiated at a dosage of 20 mg/kg/d) can safely achieve serum therapeutic levels in 2-3 days. Concomitant use of aspirin, carbamazepine, warfarin, or phenytoin may affect serum levels. Gastrointestinal symptoms are the main side effects. Liver function tests and complete blood counts should be monitored, and teratogenic effects are a concern.

E. Carbamazepine

Carbamazepine, an antiseizure drug that stabilizes the activity of cell membranes, has been used with increasing frequency in the treatment of bipolar patients who cannot be satisfactorily treated with lithium (nonresponsive, excessive side effects, or rapid cycling). It is often effective at 800-1600 mg/d orally. It has also been used in the treatment of resistant depressions, alcohol withdrawal, and hallucinations (in conjunction with neuroleptics) and in patients with behavioral dyscontrol or panic attacks. It suppresses some phases of kindling (see Stimulants) and has been used to treat residual symptoms in previous stimulant abusers (eg, posttraumatic stress disorder with impulse control problems). Dose-related side effects include sedation and ataxia. Dosages start at 400-600 mg orally daily and are increased slowly to therapeutic levels. Skin rashes and a mild reduction in white count are common. SIADH occurs rarely. Nonsteroidal anti-inflammatory drugs (except aspirin), the antibiotics erythromycin and isoniazid, the calcium channel blockers verapamil and diltiazem (but not nifedipine), fluoxetine, propoxyphene, and cimetidine all increase carbamazepine levels. Carbamazepine can be effective in conjunction with lithium, though there have been reports of reversible neurotoxicity with the combination. Carbamazepine stimulates hepatic microsomal enzymes and so tends to decrease levels of haloperidol and oral contraceptives. It also lowers T_4 , free T_4 , and T_3 .

levels. Cases of fetal malformation (particularly spina bifida) have been reported along with growth deficiency and developmental delay. Liver tests and complete blood counts should be monitored in patients taking carbamazepine. **Oxcarbazepine**, a derivative of carbamazepine, does not appear to induce its own metabolism and is associated with fewer drug interactions and a lower risk of hepatotoxicity than carbamazepine, though it may impose a higher risk of hyponatremia. FDA-approved for partial seizures, oxcarbazepine may have efficacy in acute mania.

F. Newer Anticonvulsants

Lamotrigine is thought to inhibit neuronal sodium channels and the release of the excitatory amino acids, glutamate and aspartate. Two double-blind studies support its efficacy in the treatment of bipolar depression as adjunctive therapy or as monotherapy. One double-blind study suggests that it may have efficacy as maintenance monotherapy for patients with rapid-cycling bipolar disorder. Its metabolism is inhibited by coadministration of valproic acid—doubling its half-life—and accelerated by hepatic enzyme-inducing agents such as carbamazepine. More frequent mild side effects include headache, dizziness, nausea, and diplopia. Rash occurring in 10% of patients is an indication for immediate cessation of dosing, since lamotrigine has been associated with Stevens-Johnson syndrome (1:1000) and, rarely, toxic epidermal necrolysis. Dosing starts at 25-50 mg/d and is titrated upward slowly to decrease the likelihood of rash. Slower titration and a lower total dose are indicated for patients taking valproic acid. **Topiramate**, which has been labeled for use as an anticonvulsant, has been found efficacious in the adjunctive treatment of bipolar disorder in a series of open-label studies. It has the unique feature of promoting weight loss as a side effect. Other common side effects include somnolence, difficulty with memory, dizziness, and anxiety.

G. Calcium Channel Blockers

Calcium channel blockers (eg, verapamil) have been used in bipolar states that have failed to respond to lithium, carbamazepine, or valproic acid. This has come about with the realization that a number of drugs used in psychiatry (eg, lithium, antidepressants, neuroleptics, and carbamazepine) have calcium channel-blocking activity. There is also preliminary evidence that these drugs may be useful in the treatment of tardive dyskinesia and panic attacks. Verapamil may be safer than lithium or carbamazepine during pregnancy, though it decreases uterine contractility and must be discontinued before delivery.

Prognosis

Reactive depressions are usually time-limited, and the prognosis with treatment is good if a pathologic pattern of adjustment does not intervene. Major affective disorders frequently respond well to a full trial of drug treatment.

Mania and bipolar disorder have a good prognosis with adequate treatment.

SLEEP DISORDERS

Sleep consists of two distinct states as shown by electroencephalographic studies: REM (rapid eye movement) sleep, also called dream sleep, D state sleep, paradoxical sleep, and NREM (non-REM) sleep, also called S stage sleep, which is divided into stages 1, 2, 3, and 4 recognizable by different electroencephalographic patterns. Stages 3 and 4 are "delta" sleep. Dreaming occurs mostly in REM and to a lesser extent in NREM sleep.

Sleep is a cyclic phenomenon, with four or five REM periods during the night accounting for about one-fourth of the total night's sleep (11/2-2 hours). The first REM period occurs about 80-120 minutes after onset of sleep and lasts about 10 minutes. Later REM periods are longer (15-40 minutes) and occur mostly in the last several hours of sleep. Most stage 4 (deepest) sleep occurs in the first several hours.

Age-related changes in normal sleep include an unchanging percentage of REM sleep and a marked decrease in stage 3 and stage 4 sleep, with an increase in wakeful periods during the night. These normal changes, early bedtimes, and daytime naps play a role in the increased complaints of insomnia in older people. Variations in sleep patterns may be due to circumstances (eg, "jet lag") or to idiosyncratic patterns ("night owls") in persons who perhaps because of different "biologic rhythms" habitually go to bed late and sleep late in the morning. Creativity and rapidity of response to unfamiliar situations are impaired by loss of sleep. There are also rare individuals who have chronic difficulty in adapting to a 24-hour sleep-wake cycle (desynchronization sleep disorder), which can be resynchronized by altering exposure to light.

The three major sleep disorders are discussed below.

1. *Dyssomnias (Insomnia)*

Classification & Clinical Findings

Patients may complain of difficulty getting to sleep or staying asleep, intermittent wakefulness during the night, early morning awakening, or combinations of any of these. Transient episodes are usually of little significance. Stress, caffeine, physical discomfort, daytime napping, and early bedtimes are common factors.

Psychiatric disorders are often associated with persistent insomnia. **Depression** is usually associated with fragmented sleep, decreased total sleep time, earlier onset of REM sleep, a shift of REM activity to the first half of the night, and a loss of slow wave sleep—all of which are nonspecific findings. In **manic disorders**, sleeplessness is a cardinal feature and an important early sign of impending mania in bipolar cases. Total sleep time is decreased, with shortened REM latency and increased REM activity. Sleep-related panic attacks occur in the transition from stage 2 to stage 3 sleep in some patients with a longer REM latency in the sleep pattern preceding the attacks.

Abuse of alcohol may cause or be secondary to the sleep disturbance. There is a tendency to use alcohol as a means of getting to sleep without realizing that it disrupts the normal sleep cycle. Acute alcohol intake produces a decreased sleep latency with reduced REM sleep during the first half of the night. REM sleep is increased in the second half of the night, with an increase in total amount of slow wave sleep (stages 3 and 4). Vivid dreams and frequent awakenings are common. Chronic alcohol abuse increases stage 1 and decreases REM sleep (most drugs delay or block REM sleep), with symptoms persisting for many months after the individual has stopped drinking. Acute alcohol or other sedative withdrawal causes delayed onset of sleep and REM rebound with intermittent awakening during the night.

Heavy smoking (more than a pack a day) causes difficulty falling asleep—apparently independently of the often associated increase in coffee drinking. Excess intake near bedtime of caffeine, cocaine, and other stimulants (eg, OTC cold remedies) causes decreased total sleep time—mostly NREM sleep—with some increased sleep latency.

Sedative-hypnotics—specifically, the benzodiazepines, which are the prescription drugs of choice to promote sleep—tend to increase total sleep time, decrease sleep latency, and decrease nocturnal awakening, with variable effects on NREM sleep. Withdrawal causes just the opposite effects and results in continued use of the drug for the purpose of preventing withdrawal symptoms. Antidepressants decrease REM sleep (with marked rebound on withdrawal in the form of nightmares) and have varying effects on NREM sleep. The effect on REM sleep correlates with reports that REM sleep deprivation produces improvement in some depressions.

Persistent insomnias are also related to a wide variety of medical conditions, particularly delirium, pain, respiratory distress syndromes, uremia, asthma, and thyroid disorders. Adequate analgesia and proper treatment of medical disorders will reduce symptoms and decrease the need for sedatives.

Treatment

In general, there are two broad classes of treatment for insomnia, and the two may be combined: psychologic (cognitive-behavioral) and pharmacologic. In situations of acute distress, such as a grief reaction, pharmacologic measures may be most appropriate. With primary insomnia, however, initial efforts should be psychologically

based. This is particularly true in the elderly to avoid the potential adverse reactions of medications. The elderly population is at risk for complaints of insomnia because sleep becomes lighter and more easily disrupted with aging. Medical disorders that become more common with age may also predispose to insomnia.

A. Psychologic

Psychologic strategies should include educating the patient regarding good sleep hygiene: (1) Go to bed only when sleepy. (2) Use the bed and bedroom only for sleeping and sex. (3) If still awake after 20 minutes, leave the bedroom and only return when sleepy. (4) Get up at the same time every morning regardless of the amount of sleep during the night. (5) Discontinue caffeine and nicotine, at least in the evening if not completely. (6) Establish a daily exercise regimen. (7) Avoid alcohol as it may disrupt continuity of sleep. (8) Limit fluids in the evening. (9) Learn and practice relaxation techniques.

The clinician should also discuss any myths or misconceptions about sleep that the patient may hold.

B. Medical

When the above measures are insufficient, medications may be useful. Pharmacologic measures currently rely primarily on safe hypnotic medications that are difficult to overdose with. Lorazepam (0.5 mg nightly), temazepam (7.5-15 mg nightly), zolpidem (5-10 mg nightly), and zaleplon (5-10 mg nightly) are often effective for the elderly population and can be given in larger doses—twice what is prescribed for the elderly—in younger patients. It is important to note that short-acting agents like triazolam or zolpidem may lead to amnestic episodes if used on a daily ongoing basis. Longer-acting agents such as flurazepam (half-life of > 48 hours) may accumulate in the elderly and lead to cognitive slowing, ataxia, falls, and somnolence. In general, it is appropriate to use medications for short courses of 1-2 weeks. The medications described above have largely replaced barbiturates as hypnotic agents because of their greater safety in overdose and their lesser hepatic enzyme induction effects. Antihistamines such as diphenhydramine (25 mg nightly) or hydroxyzine (25 mg nightly) may also be useful for sleep, as they produce no pharmacologic dependency; their anticholinergic effects may, however, produce confusion or urinary symptoms in the elderly. Trazodone, an atypical antidepressant, is a non-habit-forming, effective sleep medication in lower than antidepressant doses (25-150 mg at bedtime). Priapism is a rare side effect requiring emergent treatment.

Triazolam has achieved popularity as a hypnotic drug because of its very short duration of action. Because it has been associated with dependency, transient psychotic reactions, anterograde amnesia, and rebound anxiety, it has been removed from the market in several European countries. If used, it must be prescribed only for short periods of time.

2. Hypersomnias (Disorders of Excessive Sleepiness)

The hypersomnias are a more severe problem than insomnia.

Classification & Clinical Findings

A. Sleep Apnea

This disorder is characterized by cessation of breathing for at least 30 episodes (each lasting about 10 seconds) during the night. There are two types: obstructive and central. (See [Chapter 9](#).)

B. Narcolepsy

Narcolepsy consists of a tetrad of symptoms: (1) Sudden, brief (about 15 minutes) sleep attacks that may occur during any type of activity; (2) cataplexy—sudden loss of muscle tone involving specific small muscle groups or generalized muscle weakness that may cause the person to slump to the floor, unable to move, often associated with emotional reactions and sometimes confused with seizure disorder; (3) sleep paralysis—a generalized flaccidity of muscles with full consciousness in the transition zone between sleep and waking; and (4) hypnagogic hallucinations, visual or auditory, which may precede sleep or occur during the sleep attack. The attacks are characterized by an abrupt transition into REM sleep—a necessary criterion for diagnosis. The disorder begins in early adult life, affects both sexes equally, and usually levels off in severity at about 30 years of age.

REM sleep behavior disorder, characterized by motor dyscontrol and often violent dreams during REM sleep, may be related to narcolepsy.

C. Kleine-Levin Syndrome

This syndrome, which occurs mostly in young men, is characterized by hypersomnic attacks three or four times a year lasting up to 2 days, with hyperphagia, hypersexuality, irritability, and confusion on awakening. It has often been associated with antecedent neurologic insults. It usually remits after age 40.

D. Nocturnal Myoclonus

Periodic lower leg movements occur during sleep with subsequent daytime sleepiness, anxiety, depression, and cognitive impairment.

Treatment

Narcolepsy can be managed by daily administration of a stimulant such as dextroamphetamine sulfate, 10 mg in the morning, with increased dosage as necessary. Modafinil is a schedule IV medication FDA-approved for treating the excessive daytime fatigue of narcolepsy. Usual dosing is 200 mg each morning. Its mechanism of action is unknown, yet it is thought to be less of an abuse risk than stimulants that are primarily dopaminergic. Common side effects include headache and anxiety; however, Modafinil appears to be generally well tolerated. Modafinil may reduce the efficacy of cyclosporine, oral contraceptives, and other medications by inducing their hepatic metabolism. Imipramine, 75-100 mg daily, has been effective in treatment of cataplexy but not narcolepsy.

Nocturnal myoclonus and REM sleep behavior disorder can be treated with clonazepam with variable results. There is no treatment for Kleine-Levin syndrome.

Treatment of sleep apnea is discussed in [Chapter 9](#).

3. Parasomnias (Abnormal Behaviors During Sleep)

These disorders are fairly common in children and less so in adults.

Classification & Clinical Findings

A. Sleep Terror

Sleep terror (pavor nocturnus) is an abrupt, terrifying arousal from sleep, usually in preadolescent boys though it may occur in adults as well. It is distinct from sleep panic attacks. Symptoms are fear, sweating, tachycardia, and confusion for several minutes, with amnesia for the event.

B. Nightmares

Nightmares occur during REM sleep; sleep terrors in stage 3 or stage 4 sleep.

C. Sleepwalking

Sleepwalking (somnambulism) includes ambulation or other intricate behaviors while still asleep, with amnesia for the event. It affects mostly children aged 6-12 years, and episodes occur during stage 3 or stage 4 sleep in the first third of the night and in REM sleep in the later sleep hours. Sleepwalking in elderly people may be a feature of dementia. Idiosyncratic reactions to drugs (eg, marijuana, alcohol) and medical conditions (eg, partial complex seizures) may be causative factors in adults.

D. Enuresis

Enuresis is involuntary micturition during sleep in a person who usually has voluntary control. Like other parasomnias, it is more common in children, usually in the 3-4 hours after bedtime, but is not limited to a specific stage of sleep. Confusion during the episode and amnesia for the event are common.

Treatment

Treatment for sleep terrors is with benzodiazepines (eg, diazepam, 5-20 mg at bedtime), since it will suppress stage 3 and stage 4 sleep. Somnambulism responds to the same treatment for the same reason, but simple safety measures should not be neglected. Enuresis may respond to imipramine, 50-100 mg at bedtime, though desmopressin nasal spray (an antidiuretic hormone preparation) has increasingly become the treatment of choice for nocturnal enuresis. Behavioral approaches (eg, bells that ring when the pad gets wet) have also been successful.

DISORDERS OF AGGRESSION

Acts performed with the deliberate intent of causing physical harm to persons or property have a wide variety of causative features. Aggression and violence are symptoms rather than diseases, and most frequently they are not associated with an underlying medical condition. Clinicians are unable to predict dangerous behavior with greater than chance accuracy. In terms of demographic characteristics, the perpetrator of an act of aggression is often a male under age 25, a member of a socioeconomically deprived group, and a resident of an inner city area. Depression, schizophrenia, personality disorders, mania, paranoia, temporal lobe dysfunction, and organic mental states may be associated. Anabolic steroid usage by athletes has been associated with increased tendencies toward violent behavior.

In the United States, a significant proportion of all violent deaths are alcohol-related. The ingestion of even small amounts of alcohol can result in pathologic intoxication that resembles an acute organic mental condition. Amphetamines, crack cocaine, and other stimulants are frequently associated with aggressive behavior. Phencyclidine is a drug commonly associated with violent behavior that is occasionally of a bizarre nature, partly due to lowering of the pain threshold. Impulse control disorders are characterized by physical abuse, usually of the aggressor's domestic partner or children, pathologic intoxication, impulsive sexual activities, and reckless driving.

Domestic violence and rape are much more widespread than heretofore recognized. Awareness of the problem is to some degree due to increasing recognition of the rights of women and the understanding by women that they do not have to accept abuse. Acceptance of this kind of aggression inevitably leads to more, with the ultimate aggression being murder—20-50% of murders in the United States occur within the family. Police are called in more domestic disputes than all other criminal incidents combined. Children living in such family situations frequently become victims of abuse.

Features of individuals who have been subjected to chronic physical or sexual abuse are as follows: trouble expressing anger, staying angry longer, general passivity in relationships, feeling "marked for life" with an accompanying feeling of deserving to be victimized, lack of trust, and dissociation of affect from experiences. They are prone to express their psychologic distress with somatization symptoms, often pain complaints. They may also have symptoms related to posttraumatic stress, as discussed above. The clinician should be suspicious about the origin of any injuries not fully explained, particularly if such incidents recur.

Treatment

A. Psychologic

Management of any violent individual includes appropriate psychologic maneuvers. Move slowly, talk slowly with clarity and reassurance, and evaluate the situation. Strive to create a setting that is minimally disturbing and eliminate people or things threatening to the violent individual. Do not threaten or abuse and do not touch or crowd the person. Allow no weapons in the area (an increasing problem in hospital emergency rooms). Proximity to a door is comforting to both the patient and the examiner. Use a negotiator the violent person can relate to comfortably. Food and drink are helpful in defusing the situation (as are cigarettes for those who smoke). Honesty is important. Make no false promises, bolster the patient's self-esteem, and continue to engage the subject verbally until the situation is under control. This type of individual does better with strong external controls to replace the lack of inner controls over the long term. Close probationary supervision and judicially mandated restrictions can be most helpful. There should be a major effort to help the individual avoid drug use (eg, Alcoholics Anonymous). Victims of abuse are essentially treated as any victim of trauma and, not infrequently, have evidence of posttraumatic stress disorder.

B. Pharmacologic

Pharmacologic means are often necessary whether or not psychologic approaches have been successful. This is particularly true in the agitated or psychotic patient. The drug of choice in psychotic aggressive states is haloperidol, 5-10 mg intramuscularly every hour until symptoms are alleviated. Benzodiazepine sedatives (eg, diazepam, 5 mg orally or intravenously every several hours) can be used for mild to moderate agitation, but an antipsychotic drug is preferred for management of the seriously violent and psychotic patient. Chronic aggressive states, particularly in retardation and brain damage (rule out causative organic conditions and medications such as anticholinergic drugs in amounts sufficient to cause confusion), have been ameliorated with propranolol, 40-240 mg/d orally, or pindolol, 5 mg twice daily orally (pindolol causes less bradycardia and hypotension). Carbamazepine and valproic acid are effective in the treatment of aggression and explosive disorders, particularly when associated with known or suspected brain lesions. Lithium and SSRIs are also effective for some intermittent explosive outbursts. Buspirone (10-45 mg/d orally) is helpful for aggression, particularly in mentally retarded patients.

C. Physical

Physical management is necessary if psychologic and pharmacologic means are not sufficient. It requires the active and visible presence of an adequate number of personnel (five or six) to reinforce the idea that the situation is under control despite the patient's lack of inner controls. Such an approach often precludes the need for actual physical restraint. When adequate personnel are not available, however, two people shielded by a mattress (single-bed size) can usually corner and subdue the patient without injury to anyone. Seclusion rooms and restraints should be used only when necessary (ambulatory restraints are an alternative), and the patient must then be observed at frequent intervals. Design of corridors and seclusion rooms is important. Narrow corridors, small spaces, and crowded areas exacerbate the potential for violence in an anxious patient.

D. Other

The treatment of victims (eg, battered women) is challenging and often complicated by their reluctance to leave the situation. Reasons for staying vary, but common themes include the fear of more violence because of leaving, the hope that the situation may ameliorate (in spite of steady worsening), and the financial aspects of the situation, which are seldom to the woman's advantage. Concerns for the children often finally compel the woman to seek help. An early step is to get the woman into a therapeutic situation that provides the support of others in similar straits. Al-Anon is frequently a valuable asset and quite appropriate when alcohol is a factor. The group can support the victim while she gathers strength to consider alternatives without being paralyzed by fear. Many cities now offer temporary emergency centers and counseling. Use the available resources, attend to any medical or psychiatric problems, and maintain a compassionate interest. Some states now require physicians to report injuries caused by abuse to police authorities.

■ **SUBSTANCE USE DISORDERS (DRUG DEPENDENCY, DRUG ABUSE)**

The term "drug dependency" is used in a broad sense here to include both addictions and habituations. It involves the triad of compulsive drug use referred to as drug addiction, which includes (1) a **psychologic dependence** or craving and the behavior involved included in procurement of the drug; (2) **physiologic dependence**, with withdrawal symptoms on discontinuance of the drug; and (3) **tolerance**, ie, the need to increase the dose to obtain the desired effects. Drug dependency is a function of the amount of drug used and the duration of usage. The amount needed to produce dependency varies with the nature of the drug and the idiosyncratic nature of the user. The frequency of use is usually daily, and the duration is inevitably greater than 2-3 weeks. Polydrug abuse is very common. Transgenerational continuity of drug abuse is also common.

There is accumulating evidence that an impairment syndrome exists in many former (and current) drug users. It is believed that drug use produces damaged neurotransmitter receptor sites and that the consequent imbalance produces symptoms that may mimic other psychiatric illnesses. **"Kindling"**—repeated stimulation of the brain—renders the individual more susceptible to focal brain activity with minimal stimulation. Stimulants and depressants can produce kindling, leading to relatively spontaneous effects no longer dependent on the original stimulus. These effects may be manifested as mood swings, panic, psychosis, and occasionally overt seizure activity. The imbalance also results in personal nonproductivity: frequent job changes, marital problems, and generally erratic behavior. Patients with posttraumatic stress disorder frequently have treated themselves with a variety of drugs. Chronic abusers of a wide variety of drugs exhibit cerebral atrophy on CT scans, a finding that may relate to the above symptoms. Early recognition is important, mainly to establish realistic treatment programs that are chiefly symptom-directed.

The clinician faces three problems with substance abuse: (1) the prescribing of substances such as sedatives, stimulants, or narcotics that might produce dependency; (2) the treatment of individuals who have already abused drugs, most commonly alcohol; and (3) the detection of illicit drug use in patients presenting with psychiatric symptoms. The usefulness of urinalysis for detection of drugs varies markedly with different drugs and under different circumstances (pharmacokinetics is a major factor). Water-soluble drugs (eg, alcohol, stimulants, opioids) are eliminated in a day or so. Lipophilic substances (eg, barbiturates, tetrahydrocannabinol) appear in the urine over longer periods of time: several days in most cases, 1-2 months in chronic marijuana users. Sedative drug determinations are quite variable, amount of drug and duration of use being important determinants. False-positives can be a problem related to ingestion of some legitimate drugs (eg, phenytoin for barbiturates, phenylpropanolamine for amphetamines, chlorpromazine for opioids) and some foods (eg, poppy seeds for opioids, coca leaf tea for cocaine). Manipulations can alter the legitimacy of the testing. Dilution, either in vivo or in vitro, can be detected by checking urine specific gravity. Addition of ammonia, vinegar, or salt may invalidate the test, but odor and pH determinations are simple. Hair analysis can determine drug use over longer periods, particularly sequential drug-taking patterns. The sensitivity and reliability of such tests are considered good, and the method may be complementary to urinalysis.

ALCOHOL DEPENDENCY & ABUSE (ALCOHOLISM)

Essentials of Diagnosis

Major criteria:

- Physiologic dependence as manifested by evidence of withdrawal when intake is interrupted.
- Tolerance to the effects of alcohol.
- Evidence of alcohol-associated illnesses, such as alcoholic liver disease, cerebellar degeneration.
- Continued drinking despite strong medical and social contraindications and life disruptions.
- Impairment in social and occupational functioning.
- Depression.
- Blackouts.

Other signs:

- Alcohol stigmas: alcohol odor on breath, alcoholic facies, flushed face, scleral injection, tremor, ecchymoses, peripheral neuropathy.
- Surreptitious drinking.
- Unexplained work absences.
- Frequent accidents, falls, or injuries of vague origin; in smokers, cigarette burns on hands or chest.
- Laboratory tests: elevated values of liver function tests, mean corpuscular volume, serum uric acid and triglycerides.

General Considerations

Alcoholism is a syndrome consisting of two phases: problem drinking and alcohol addiction. Problem drinking is the repetitive use of alcohol, often to alleviate anxiety or solve other emotional problems. Alcohol addiction is a true addiction similar to that which occurs following the repeated use of other sedative-hypnotics. Alcohol and other drug abuse patients have a much higher prevalence of lifetime psychiatric disorders. While male-to-female ratios in alcoholic treatment agencies remain at 4:1, there is evidence that the rates are converging. Women delay seeking help, and when they do they tend to seek it in medical or mental health settings. Adoption and twin studies indicate some genetic influence. Ethnic distinctions are important—eg, 40% of Japanese have aldehyde dehydrogenase deficiency and are more susceptible to the effects of alcohol. Depression is often present and should be evaluated carefully. The majority of suicides and intrafamily homicides involve alcohol, and alcohol is a major factor in rapes and other assaults also.

There are several screening instruments that may help identify alcoholism. One of the most useful is the CAGE questionnaire ([Table 1-10](#)).

Clinical Findings

A. Acute Intoxication

The signs of alcoholic intoxication are the same as those of overdosage with any other central nervous system depressant: drowsiness, errors of commission, psychomotor dysfunction, disinhibition, dysarthria, ataxia, and nystagmus. For a 70-kg person, an ounce of whiskey, a 4- to 6-oz glass of wine, or a 12-oz bottle of beer (roughly 15, 11, and 13 grams of alcohol, respectively) may raise the level of alcohol in the blood by 25 mg/dL. For a 50-kg person, the blood alcohol level would rise even higher (35 mg/dL) with the same consumption. Blood alcohol levels below 50 mg/dL rarely cause significant motor dysfunction. Intoxication as manifested by ataxia, dysarthria, and nausea and vomiting indicates a blood level above 150 mg/dL, and lethal blood levels range from 350 to 900 mg/dL. In severe cases, overdosage is marked by respiratory depression, stupor, seizures, shock syndrome, coma, and death. Serious overdoses are frequently due to a combination of alcohol with other sedatives.

B. Withdrawal

There is a wide spectrum of manifestations of alcoholic withdrawal, ranging from anxiety, decreased cognition, and tremulousness through increasing irritability and hyperreactivity to full-blown **delirium tremens**. Symptoms of mild withdrawal, including tremor, elevated vital signs, and anxiety, begin within about 8 hours after the last drink and usually have passed by day 3. Generalized seizures occur within the first 24-38 hours and are more prevalent in persons who have a history of withdrawal syndromes. Delirium tremens is an acute organic psychosis that is usually manifest within 24-72 hours after the last drink (but may occur up to 7-10 days later). It is characterized by mental confusion, tremor, sensory hyperacuity, visual hallucinations (often of snakes, bugs, etc), autonomic hyperactivity, diaphoresis, dehydration, electrolyte disturbances (hypokalemia, hypomagnesemia), seizures, and cardiovascular abnormalities. The acute withdrawal syndrome is often completely unexpected and occurs when the patient has been hospitalized for some unrelated problem and presents as a diagnostic problem. Suspect alcohol withdrawal in every unexplained delirium. The mortality rate from delirium tremens has steadily decreased with early diagnosis and improved treatment.

In addition to the immediate withdrawal symptoms, there is evidence of persistent longer-term ones, including sleep disturbances, anxiety, depression, excitability, fatigue, and emotional volatility. These symptoms may persist for 3-12 months, and in some cases they become chronic.

C. Alcoholic (Organic) Hallucinosis

This syndrome occurs either during heavy drinking or on withdrawal and is characterized by a paranoid psychosis without the tremulousness, confusion, and clouded

sensorium seen in withdrawal syndromes. The patient appears normal except for the auditory hallucinations, which are frequently persecutory and may cause the patient to behave aggressively and in a paranoid fashion.

D. Chronic Alcoholic Brain Syndromes

These encephalopathies are characterized by increasing erratic behavior, memory and recall problems, and emotional instability—the usual signs of organic brain injury due to any cause. Wernicke-Korsakoff syndrome due to thiamin deficiency may develop with a series of episodes. Wernicke's encephalopathy consists of the triad of confusion, ataxia, and ophthalmoplegia (typically sixth nerve). Early recognition and treatment with thiamine can minimize damage. One of the possible sequelae is Korsakoff's psychosis, characterized by both anterograde and retrograde amnesia, with confabulation early in the course. Early recognition and treatment of the alcoholic with intravenous thiamine and B complex vitamins can minimize damage.

Differential Diagnosis

The differential diagnosis of problem drinking is essentially between primary alcoholism (when no other major psychiatric diagnosis exists) and secondary alcoholism, when alcohol is used as self-medication for major underlying psychiatric problems such as schizophrenia or affective disorder. The differentiation is important, since the latter group requires treatment for the specific psychiatric problem.

The differential diagnosis of alcohol withdrawal includes other sedative withdrawals and other causes of delirium. Acute alcoholic hallucinosis must be differentiated from other acute paranoid states such as amphetamine psychosis or paranoid schizophrenia. An accurate history is the most important differentiating factor. The history and laboratory test results (elevated liver function tests, increased mean corpuscular volume, increased serum uric acid and triglycerides, decreased serum potassium and magnesium) are the most important features in differentiating chronic organic brain syndromes due to alcohol from those due to other causes. The form of the brain syndrome is of little help—eg, chronic brain syndromes from lupus erythematosus may be associated with confabulation similar to that resulting from long-standing alcoholism.

Complications

The medical, economic, and psychosocial problems of alcoholism are staggering. The central and peripheral nervous system complications include chronic brain syndromes, cerebellar degeneration, cardiomyopathy, and peripheral neuropathies. Direct effects on the liver include cirrhosis, esophageal varices, and eventual hepatic failure. Indirect effects include protein abnormalities, coagulation defects, hormone deficiencies, and an increased incidence of liver neoplasms.

Fetal alcohol syndrome includes one or more of the following developmental defects in the offspring of alcoholic women: (1) low birth weight and small size with failure to catch up in size or weight, (2) mental retardation, with an average IQ in the 60s, and (3) a variety of birth defects, with a large percentage of facial and cardiac abnormalities. The fetuses are very quiet in utero, and there is an increased frequency of breech presentations. There is a higher incidence of delayed postnatal growth and behavior development. The risk is appreciably higher the more alcohol ingested by the mother each day. Cigarette and marijuana smoking as well as cocaine use can produce similar effects on the fetus.

Treatment of Problem Drinking

A. Psychologic

The most important consideration for the clinician is to suspect the problem early and take a nonjudgmental attitude, though this does not mean a passive one. The problem of **denial** must be faced, preferably with significant family members at the first meeting. This means dealing from the beginning with any enabling behavior of the spouse or other significant people. Enabling behavior allows the alcoholic to avoid facing the consequences of his or her behavior.

There must be an emphasis on the things that can be done. This approach emphasizes the fact that the clinician cares and strikes a positive and hopeful note early in treatment. Valuable time should not be wasted trying to find out why the patient drinks; come to grips early with the immediate problem of how to stop the drinking. Though total abstinence should be the ultimate goal, a harm reduction model indicates that gradual progress toward abstinence can be a useful treatment stratagem.

B. Social

Get the patient into Alcoholics Anonymous (AA) and the spouse into Al-Anon. Success is usually proportionate to the utilization of AA, religious counseling, and other resources. The patient should be seen frequently for short periods and charged an appropriate fee.

Do not underestimate the importance of religion, particularly since the alcoholic is often a dependent person who needs a great deal of support. Early enlistment of the help of a concerned religious adviser can often provide the turning point for a personal conversion to sobriety.

One of the most important considerations is the patient's job—fear of losing a job is one of the most powerful motivations for giving up drink. The business community has become painfully aware of the problem, with the result that about 70% of the Fortune 500 companies offer programs to their employees to help with the problem of alcoholism. In the latter case, some specific recommendations to employers can be offered: (1) Avoid placement in jobs where the alcoholic must be alone, eg, as a traveling buyer or sales executive. (2) Use supervision but not surveillance. (3) Keep competition with others to a minimum. (4) Avoid positions that require quick decision making on important matters (high-stress situations).

C. Medical

Hospitalization is not usually necessary. It is sometimes used to dramatize a situation and force the patient to face the problem of alcoholism, but generally it should be used on medical indications.

Because of the many medical complications of alcoholism, a complete physical examination with appropriate laboratory tests is mandatory, with special attention to the liver and nervous system. Two tests that may provide clues to an alcohol problem are γ -glutamyl transpeptidase measurement (levels above 30 units/L are suggestive of heavy drinking) and mean corpuscular volume (> 95 fL in men and > 100 fL in women). If both are elevated, a serious drinking problem is likely. Use of other recreational drugs with alcohol skews and negates the significance of these tests. HDL cholesterol elevations combined with elevated γ -glutamyl transpeptidase concentrations also can help to identify heavy drinkers.

Use of sedatives as a replacement for alcohol is not desirable. The usual result is concomitant use of sedatives and alcohol and worsening of the problem. Lithium is not helpful in the treatment of alcoholism.

Disulfiram (250-500 mg/d orally) has been used for many years as an aversive drug to discourage alcohol use. Disulfiram inhibits alcohol dehydrogenase, causing toxic reactions when alcohol is consumed. The results have generally been of limited effectiveness and depend on the motivation of the individual to be compliant.

Naltrexone, an opiate antagonist, in a dosage of 50 mg daily, has been helpful in lowering relapse rates over the 3-6 months after cessation of drinking, apparently by lessening the pleasurable effects of alcohol. One study suggests that naltrexone is most efficacious when given during periods of drinking in combination with therapy that supports abstinence but accepts the fact that relapses occur. Naltrexone is FDA-approved for maintenance therapy. Studies indicate that it reduces alcohol craving when used as part of a comprehensive treatment program.

D. Behavioral

Conditioning approaches have been used in some settings in the treatment of alcoholism, most commonly as a type of aversion therapy. For example, the patient is given a drink of whiskey and then a shot of apomorphine, and proceeds to vomit. In this way a strong association is built up between the vomiting and the drinking. Although this kind of treatment has been successful in some cases, many people do not sustain the learned aversive response.

Treatment of Hallucinosis & Withdrawal

A. Medical

1. Alcoholic hallucinosis—Alcoholic hallucinosis, which can occur either during or on cessation of a prolonged drinking period, is not a typical withdrawal syndrome and is handled differently. Since the symptoms are primarily those of a psychosis in the presence of a clear sensorium, they are handled like any other psychosis: hospitalization (when indicated) and adequate amounts of antipsychotic drugs. Haloperidol, 5 mg orally twice a day for the first day or so, usually ameliorates symptoms quickly, and the drug can be decreased and discontinued over several days as the patient improves. It then becomes necessary to deal with the chronic alcohol abuse, which has been discussed.

2. Withdrawal symptoms—The onset of withdrawal symptoms is usually 8-12 hours and the peak intensity of symptoms is 48-72 hours after alcohol consumption is stopped. Providing adequate central nervous system depressants (eg, benzodiazepines) is important to counteract the excitability resulting from sudden cessation of alcohol intake. The choice of a specific sedative is less important than using adequate doses to bring the patient to a level of moderate sedation, and this will vary from person to person. Mild dependency requires "drying out." In some instances for outpatients, a short course of tapering benzodiazepines—eg, 20 mg of diazepam initially, decreasing by 5 mg daily—may be a useful adjunct. In moderate to severe withdrawal, hospitalize the patient and use diazepam orally in a dosage of 5-10 mg hourly depending on the clinical need as judged by withdrawal symptoms, including nausea, tremor, autonomic hyperactivity, agitation; tactile, visual, and auditory

hallucinations; and disorientation. This type of symptom-driven medication regimen for withdrawal appears to reduce total benzodiazepine usage over fixed-dose schedules. Antipsychotic drugs should not be used. Monitoring of vital signs and fluid and electrolyte levels is essential for the severely ill patient.

In very severe withdrawal, intravenous administration is necessary. After stabilization, the amount of diazepam required to maintain a sedated state may be given orally every 8-12 hours. If restlessness, tremulousness, and other signs of withdrawal persist, the dosage is increased until moderate sedation occurs. The dosage is then gradually reduced by 20% every 24 hours until withdrawal is complete. This usually requires a week or so of treatment. Clonidine, 5 ug/kg orally every 2 hours, or the patch formulation of appropriate dosage strength, suppresses cardiovascular signs of withdrawal and has some anxiolytic effect. Carbamazepine, 400-800 mg daily orally, compares favorably with benzodiazepines for alcohol withdrawal.

Atenolol, as an adjunct to benzodiazepines, can reduce symptoms of alcohol withdrawal. The daily oral atenolol dose is 100 mg when the heart rate is above 80 beats per minute and 50 mg for a heart rate between 50 and 80 beats per minute. Atenolol should not be used when bradycardia is present.

Meticulous examination for other medical problems is necessary. Alcoholic hypoglycemia can occur with low blood alcohol levels (see [Chapter 27](#)). Alcoholics commonly have liver disease and associated clotting problems and are also prone to injury—and the combination all too frequently leads to undiagnosed subdural hematoma.

Phenytoin does not appear to be useful in managing alcohol withdrawal seizures per se. Sedating doses of benzodiazepines are effective in treating alcohol withdrawal seizures. Thus, other anticonvulsants are not usually needed unless there is a preexisting seizure disorder.

A general diet should be given, and vitamins in high doses: thiamine, 50 mg intravenously initially, then intramuscularly on a daily basis; pyridoxine, 100 mg/d; folic acid, 1 mg/d; and ascorbic acid, 100 mg twice a day. Intravenous glucose solutions should not be given prior to thiamine for fear of precipitation of Wernicke's syndrome. Thiamine is necessary as a ketolase enzyme cofactor. Concurrent administration is satisfactory, and hydration should be meticulously assessed on an ongoing basis.

Chronic brain syndromes secondary to a long history of alcohol intake are not clearly responsive to thiamine and vitamin replenishment. Attention to the social and environmental care of this type of patient is paramount.

B. Psychologic and Behavioral

The comments in the section on problem drinking apply here also; these methods of treatment become the primary consideration after successful treatment of withdrawal or alcoholic hallucinosis. Psychologic and social measures should be initiated in the hospital shortly before discharge. This increases the possibility of continued posthospitalization treatment.

OTHER DRUG & SUBSTANCE DEPENDENCIES

Opioids

The terms "opioids" and "narcotics" are used interchangeably and include a group of drugs with actions that mimic those of morphine. The group includes natural derivatives of opium (opiates), synthetic surrogates (opioids), and a number of polypeptides, some of which have been discovered to be natural neurotransmitters. The principal narcotic of abuse is heroin (metabolized to morphine), which is not used as a legitimate medication. The other common narcotics are prescription drugs and differ in milligram potency, duration of action, and agonist and antagonist capabilities (see [Chapter 1](#)). All of the narcotic analgesics can be reversed by the narcotic antagonist naloxone.

The clinical symptoms and signs of mild narcotic intoxication include changes in mood, with feelings of euphoria; drowsiness; nausea with occasional emesis; needle tracks; and miosis. The incidence of snorting and inhaling heroin ("smoking") is increasing, particularly among cocaine users. This coincides with a decrease in the availability of methaqualone (no longer marketed) and other sedatives used to temper the cocaine "high" (see discussion of cocaine under Stimulants, below). Overdosage causes respiratory depression, peripheral vasodilation, pinpoint pupils, pulmonary edema, coma, and death.

Dependency is a major concern when continued use of narcotics occurs, though withdrawal causes only moderate morbidity (similar in severity to a bout of "flu"). Addicted patients sometimes consider themselves more addicted than they really are and may not require a withdrawal program. Grades of withdrawal are categorized from 0 to 4: grade 0 includes craving and anxiety; grade 1, yawning, lacrimation, rhinorrhea, and perspiration; grade 2, previous symptoms plus mydriasis, piloerection, anorexia, tremors, and hot and cold flashes with generalized aching; grades 3 and 4, increased intensity of previous symptoms and signs, with increased temperature, blood pressure, pulse, and respiratory rate and depth. In withdrawal from the most severe addiction, vomiting, diarrhea, weight loss, hemoconcentration, and spontaneous ejaculation or orgasm commonly occur. Complications of heroin administration include infections (eg, pneumonia, septic emboli, hepatitis, and HIV infection from using nonsterile needles), traumatic insults (eg, arterial spasm due to drug injection, gangrene), and pulmonary edema. BR> Treatment for overdosage (or suspected overdosage) is naloxone, 2 mg intravenously. If an overdose has been taken, the results are dramatic and occur within 2 minutes. Since the duration of action of naloxone is much shorter than that of the narcotics, the patient must be under close observation. Hospitalization, supportive care, repeated naloxone administration, and observation for withdrawal from other drugs should be maintained for as long as necessary.

Treatment for withdrawal begins if grade 2 signs develop. If a withdrawal program is necessary, use methadone, 10 mg orally (use parenteral administration if the patient is vomiting), and observe. If signs (piloerection, mydriasis, cardiovascular changes) persist for more than 4-6 hours, give another 10 mg; continue to administer methadone at 4- to 6-hour intervals until signs are not present (rarely more than 40 mg of methadone in 24 hours). Divide the total amount of drug required over the first 24-hour period by 2 and give that amount every 12 hours. Each day, reduce the total 24-hour dose by 5-10 mg. Thus, a moderately addicted patient initially requiring 30-40 mg of methadone could be withdrawn over a 4- to 8-day period. Clonidine, 0.1 mg several times daily over a 10- to 14-day period, is both an alternative and an adjunct to methadone detoxification; it is not necessary to taper the dose. Clonidine is helpful in alleviating cardiovascular symptoms but does not significantly relieve anxiety, insomnia, or generalized aching. There is a protracted abstinence syndrome of metabolic, respiratory, and blood pressure changes over a period of 3-6 months.

Alternative strategies for the treatment of opioid withdrawal include rapid and ultrarapid detoxification techniques. In rapid detoxification, withdrawal is precipitated by opioid antagonists followed by naltrexone maintenance. Ultrarapid detoxification precipitates withdrawal with opioid antagonists under general anesthesia in a hospital and remains experimental. Research on the impact of rapid detoxification on relapse rates—compared with more traditional methods—is limited at this time. Methadone maintenance programs are of some value in chronic recidivism. Under carefully controlled supervision, the narcotic addict is maintained on fairly high doses of methadone (40-120 mg/d) that satisfy craving and block the effects of heroin to a great degree.

Narcotic antagonists (eg, naltrexone) can also be used successfully for treatment of the patient who has been free of opioids for 7-10 days. Naltrexone blocks the narcotic "high" of heroin when 50 mg is given orally every 24 hours initially for several days and then 100 mg is given every 48-72 hours. Liver disorders are a major contraindication. Compliance tends to be poor, partly because of the dysphoria that can persist long after opioid discontinuance.

Sedatives (Anxiolytics)

See Anxiety Disorders, this chapter.

Psychedelics

About 6000 species of plants have psychoactive properties. All of the common psychedelics (LSD, mescaline, psilocybin, dimethyltryptamine, and other derivatives of phenylalanine and tryptophan) can produce similar behavioral and physiologic effects. An initial feeling of tension is followed by emotional release such as crying or laughing (1-2 hours). Later, perceptual distortions occur, with visual illusions and hallucinations, and occasionally there is fear of ego disintegration (2-3 hours). Major changes in time sense and mood lability then occur (3-4 hours). A feeling of detachment and a sense of destiny and control occur (4-6 hours). Of course, reactions vary among individuals, and some of the drugs produce markedly different time frames. Occasionally, the acute episode is terrifying (a "bad trip") which may include panic, depression, confusion, or psychotic symptoms. Preexisting emotional problems, the attitude of the user, and the setting where the drug is used affect the experience.

Treatment of the acute episode primarily involves protection of the individual from erratic behavior that may lead to injury or death. A structured environment is usually sufficient until the drug is metabolized. In severe cases, antipsychotic drugs with minimal side effects (eg, haloperidol, 5 mg intramuscularly) may be given every several hours until the individual has regained control. In cases where "flashbacks" occur (mental imagery from a "bad trip" that is later triggered by mild stimuli such as marijuana, alcohol, or psychic trauma), a short course of an antipsychotic drug—eg, olanzapine, 5-10 mg/d, or risperidone, 2 mg/d, initially, and up to 20 mg/d and 6 mg/d, respectively—is usually sufficient. Lorazepam, 1-2 mg orally or intramuscularly every 2 hours as needed for acute agitation, may be a useful adjunct. An occasional patient may have "flashbacks" for much longer periods and require small doses of neuroleptic drugs over the longer term.

Phencyclidine

Phencyclidine (PCP, angel dust, peace pill, hog), developed as an anesthetic agent, first appeared as a street drug deceptively sold as tetrahydrocannabinol (THC). Because it is simple to produce and mimics to some degree the traditional psychedelic drugs, PCP has become a common deceptive substitute for LSD, THC, and mescaline. It is available in crystals, capsules, and tablets to be inhaled, injected, swallowed, or smoked (it is commonly sprinkled on marijuana).

Absorption after smoking is rapid, with onset of symptoms in several minutes and peak symptoms in 15-30 minutes. Mild intoxication produces euphoria accompanied by a feeling of numbness. Moderate intoxication (5-10 mg) results in disorientation, detachment from surroundings, distortion of body image, combativeness, unusual feats of strength (partly due to its anesthetic activity), and loss of ability to integrate sensory input, especially touch and proprioception. Physical symptoms include dizziness, ataxia, dysarthria, nystagmus, retracted upper eyelid with blank stare, hyperreflexia, and tachycardia. There are increases in blood pressure, respiration, muscle tone, and urine production. Usage in the first trimester of pregnancy is associated with an increase in spontaneous abortion and congenital defects. Severe intoxication (20 mg or more) produces an increase in degree of moderate symptoms, with the addition of seizures, deepening coma, hypertensive crisis, and severe psychotic ideation. The drug is particularly long-lasting (several days to several weeks) owing to high lipid solubility, gastroenteric recycling, and the production of active metabolites. Overdosage may be fatal, with the major causes of death being hypertensive crisis, respiratory arrest, and convulsions. Acute rhabdomyolysis has been reported and can result in myoglobinuric renal failure.

Differential diagnosis involves the whole spectrum of street drugs, since in some ways phencyclidine mimics sedatives, psychedelics, and marijuana in its effects. Blood and urine testing can detect the acute problem.

Treatment is discussed in [Chapter 39](#).

Marijuana

Cannabis sativa, a hemp plant, is the source of marijuana. The parts of the plant vary in potency. The resinous exudate of the flowering tops of the female plant (hashish, charas) is the most potent, followed by the dried leaves and flowering shoots of the female plant (bhang) and the resinous mass from small leaves of inflorescence (ganja). The least potent parts are the lower branches and the leaves of the female plant and all parts of the male plant. Mercury may be a contaminant in marijuana grown in volcanic soil. The drug is usually inhaled by smoking. Effects occur in 10-20 minutes and last 2-3 hours. "Joints" of good quality contain about 500 mg of marijuana (which contains approximately 5-15 mg of tetrahydrocannabinol with a half-life of 7 days). Marijuana soaked in formaldehyde and dried ("AMP") has produced unusual effects, including autonomic discharge and severe though transient cognitive impairment.

With moderate dosage, marijuana produces two phases: mild euphoria followed by sleepiness. In the acute state, the user has an altered time perception, less inhibited emotions, psychomotor problems, impaired immediate memory, and conjunctival injection. High doses produce transient psychotomimetic effects. No specific treatment is necessary except in the case of the occasional "bad trip," in which case the person is treated in the same way as for psychedelic usage. Marijuana frequently aggravates existing mental illness and adversely affects motor performance.

Studies of long-term effects have conclusively shown abnormalities in the pulmonary tree. Laryngitis and rhinitis are related to prolonged use, along with chronic obstructive pulmonary disease. Electrocardiographic abnormalities are common, but no long-term cardiac disease has been linked to marijuana use. Chronic usage has resulted in depression of plasma testosterone levels and reduced sperm counts. Abnormal menstruation and failure to ovulate have occurred in some women. Cognitive impairments are common. Health care utilization for a variety of health problems is increased in chronic marijuana smokers. Sudden withdrawal produces insomnia, nausea, myalgia, and irritability. Psychologic effects of chronic marijuana usage are still unclear. Urine testing is reliable if samples are carefully collected and tested. Detection periods span 4-6 days in acute users and 20-50 days in chronic users.

Stimulants: Amphetamines & Cocaine

Stimulant abuse is quite common, either alone or in combination with abuse of other drugs. The **amphetamines**, including Methedrine ("speed")—one variant is a smokable form called "ice," which gives an intense and fairly long-lasting high—methylphenidate, and phenmetrazine, are under prescription control, but street availability remains high. Moderate usage of any of the stimulants produces hyperactivity, a sense of enhanced physical and mental capacity, and sympathomimetic effects. The clinical picture of acute stimulant intoxication includes sweating, tachycardia, elevated blood pressure, mydriasis, hyperactivity, and an acute brain syndrome with confusion and disorientation. Tolerance develops quickly and, as the dosage is increased, hypervigilance, paranoid ideation (with delusions of parasitosis), stereotypy, bruxism, tactile hallucinations of insect infestation, and full-blown psychoses occur, often with persecutory ideation and aggressive responses. Stimulant withdrawal is characterized by depression with symptoms of hyperphagia and hypersomnia.

People who have used stimulants chronically (eg, anorexigenics) occasionally become sensitized ("**kindling**") to future use of stimulants. In these individuals, even small amounts of mild stimulants such as caffeine can cause symptoms of paranoia and auditory hallucinations.

Cocaine is a stimulant. It is a product of the coca plant. The derivatives include seeds, leaves, coca paste, cocaine hydrochloride, and the free base of cocaine. Coca paste is a crude extract that contains 40-80% cocaine sulfate and other impurities. Cocaine hydrochloride is the salt and the most commonly used form. Free base, a purer (and stronger) derivative called "crack," is prepared by simple extraction from cocaine hydrochloride.

There are various modes of use. Coca leaf chewing involves toasting the leaves and chewing with alkaline material (eg, the ash of other burned leaves) to enhance buccal absorption. One achieves a mild high, with onset in 5-10 minutes and lasting for about an hour. Intranasal use is simply snorting cocaine through a straw. Absorption is slowed somewhat by vasoconstriction (which may eventually cause tissue necrosis and septal perforation); the onset of action is in 2-3 minutes, with a moderate high (euphoria, excitement, increased energy) lasting about 30 minutes. The purity of the cocaine is a major determinant of the high. Intravenous use of cocaine hydrochloride or "freebase" is effective in 30 seconds and produces a short-lasting, fairly intense high of about 15 minutes' duration. The combined use of cocaine and ethanol results in the metabolic production of cocaethylene by the liver. This substance produces more intense and long-lasting cocaine-like effects. Smoking freebase (volatilized cocaine because of the lower boiling point) acts in seconds and results in an intense high lasting several minutes. The intensity of the reaction is related to the marked lipid solubility of the freebase form and produces by far the most severe medical and psychiatric symptoms.

Cardiovascular collapse, arrhythmias, myocardial infarction, and transient ischemic attacks have been reported. Seizures, strokes, migraine symptoms, hyperthermia, and lung damage may occur, and there are several obstetric complications, including spontaneous abortion, abruptio placentae, teratogenic effects, delayed fetal growth, and prematurity. Cocaine can cause anxiety, mood swings, and delirium, and chronic use can cause the same problems as other stimulants (see above).

Clinicians should be alert to cocaine use in patients presenting with unexplained nasal bleeding, headaches, fatigue, insomnia, anxiety, depression, and chronic hoarseness. Sudden withdrawal of the drug is not life-threatening but usually produces craving, sleep disturbances, hyperphagia, lassitude, and severe depression (sometimes with suicidal ideation) lasting days to weeks.

Treatment is imprecise and difficult. Since the high is related to blockage of dopamine reuptake, the dopamine agonist bromocriptine, 1.5 mg orally three times a day, alleviates some of the symptoms of craving associated with acute cocaine withdrawal. Other dopamine agonists such as apomorphine, levodopa, and amantadine are under study for this purpose. Carbamazepine may be a useful adjunct in treating symptoms of alcohol withdrawal, and desipramine in moderate doses has been useful in helping maintain abstinence in the early stages of treatment. Treatment of psychosis is the same as that of any psychosis: antipsychotic drugs in dosages sufficient to alleviate the symptoms. Any medical symptoms (eg, hyperthermia, seizures, hypertension) are treated specifically. These approaches should be used in conjunction with a structured program, most often based on the Alcoholics Anonymous model. Hospitalization may be required if self-harm or violence toward others is a perceived threat (usually indicated by paranoid delusions).

Caffeine

Caffeine, along with nicotine and alcohol, is one of the most commonly used drugs worldwide. About 10 billion pounds of coffee (the richest source of caffeine) are consumed yearly throughout the world. Tea, cocoa, and cola drinks also contribute to an intake of caffeine that is often astoundingly high in a large number of people. Low to moderate doses (30-200 mg/d) tend to improve some aspects of performance (eg, vigilance). The approximate content of caffeine in a (180-mL) cup of beverage is as follows: brewed coffee, 80-140 mg; instant coffee, 60-100 mg; decaffeinated coffee, 1-6 mg; black leaf tea, 30-80 mg; tea bags, 25-75 mg; instant tea, 30-60 mg; cocoa, 10-50 mg; and 12-oz cola drinks, 30-65 mg. A 2-oz chocolate candy bar has about 20 mg. Some herbal teas (eg, "morning thunder") contain caffeine. Caffeine-containing analgesics usually contain approximately 30 mg per unit. Symptoms of caffeineism (usually associated with ingestion of over 500 mg/d) include anxiety, agitation, restlessness, insomnia, a feeling of being "wired," and somatic symptoms referable to the heart and gastrointestinal tract. It is common for a

case of caffeinism to present as an anxiety disorder. It is also common for caffeine and other stimulants to precipitate severe symptoms in compensated schizophrenic and manic-depressive patients. Chronically depressed patients often use caffeine drinks as self-medication. This diagnostic clue may help distinguish some major affective disorders. Withdrawal from caffeine (> 250 mg/d) can produce headaches, irritability, lethargy, and occasional nausea.

Miscellaneous Drugs, Solvents

The principal OTC drugs of concern have been phenylpropanolamine and an assortment of antihistaminic agents, frequently in combination with a mild analgesic promoted as cold remedies (eg, Dristan, Triaminic). Appetite suppressant combinations of phenylpropanolamine and caffeine were also heavily marketed as "stay-awake" drugs. Practically all of the so-called sleep aids are now antihistamines. Scopolamine and bromides have generally been removed from OTC products.

The major problem in the use of all these drugs related to phenylpropanolamine, which had all the side effects of any stimulant, including precipitation of anxiety states, increased pressor effect, auditory and visual hallucinations, paranoid ideation, and occasionally delirium. Aggressiveness and some loss of impulse control were reported, as well as sleep disturbances even with small doses. Medications containing phenylpropanolamine have been removed from sale due to an FDA ban.

Antihistamines usually produce some central nervous system depression—thus their use as OTC sedatives. Drowsiness may be a problem. The mixture of antihistamines with alcohol usually exacerbates the central nervous system effects.

The abuse of laxatives sometimes can lead to electrolyte disturbances that may contribute to the manifestations of a delirium. The greatest use of laxatives tends to be in the elderly and in those with eating disorders, both of whom are the most vulnerable to physiologic changes.

Anabolic steroids are being abused by people who wish to increase muscle mass for cosmetic reasons or for greater strength. In addition to the medical problems, the practice is associated with significant mood swings, aggressiveness, and paranoid delusions. Alcohol and stimulant use is higher in these individuals. Withdrawal symptoms of steroid dependency include fatigue, depressed mood, restlessness, and insomnia.

Amyl nitrite has been used in recent years as an "orgasm expander." The changes in time perception, "rush," and mild euphoria caused by the drug prompted its nonmedical use, and popular lore concerning the effects of inhalation just prior to orgasm has led to increased use. Subjective effects last from 5 seconds to 15 minutes. Tolerance develops readily, but there are no known withdrawal symptoms. Abstinence for several days reestablishes the previous level of responsiveness. Long-term effects may include damage to the immune system and respiratory difficulties.

Sniffing of solvents and inhaling of gases (including aerosols) produce a form of inebriation similar to that of the volatile anesthetics. Agents include gasoline, toluene, petroleum ether, lighter fluids, cleaning fluids, paint thinners, and solvents that are present in many household products (eg, nail polish, typewriter correction fluid). Typical intoxication states include euphoria, slurred speech, hallucinations, and confusion, and with high doses, acute manifestations are unconsciousness and cardiorespiratory depression or failure; chronic exposure produces a variety of symptoms related to the liver, kidney, bone marrow, or heart. Lead encephalopathy can be associated with sniffing leaded gasoline. In addition, studies of workers chronically exposed to jet fuel showed significant increases in neurasthenic symptoms, including fatigue, anxiety, mood changes, memory difficulties, and somatic complaints. These same problems have been noted in long-term solvent abuse.

The so-called designer drugs are synthetic substitutes for commonly used recreational drugs and are produced in small, clandestine laboratories. The most common designer drugs have been methyl analogues of fentanyl and have been used as heroin substitutes. MDMA (methylenedioxymethamphetamine), an amphetamine derivative sometimes called "ecstasy," is also a designer drug with high abuse potential and neurotoxicity. Often not detected by standard toxicology screens, these substances can present a vexing problem for clinicians faced with symptoms from a totally unknown cause.

■ DELIRIUM, DEMENTIA, & OTHER COGNITIVE DISORDERS (FORMERLY: ORGANIC BRAIN SYNDROME [OBS])

Essentials of Diagnosis

- Transient or permanent brain dysfunction.
- Cognitive impairment to varying degrees: may include impaired recall and recent memory, inability to focus attention, random psychomotor activity such as stereotypy, and problems in perceptual processing, often with psychotic ideation.
- Emotional disorders frequently present: depression, anxiety, irritability.
- Behavioral disturbances may include problems of impulse control, sexual acting-out, attention deficits, aggression, and exhibitionism.

General Considerations

The organic problem may be a primary brain disease or a secondary manifestation of some general disorder. All of the cognitive disorders show some degree of impaired thinking depending on the site of involvement, the rate of onset and progression, and the duration of the underlying brain lesion. Emotional disturbances (eg, depression) are often present as significant comorbidities. The behavioral disturbances tend to be more common with chronicity, more directly related to the underlying personality or central nervous system vulnerability to drug side effects, and not necessarily correlated with cognitive dysfunction.

The causes of cognitive disorders are listed in [Table 25-11](#).

Clinical Findings

The manifestations are many and varied and include problems with orientation, short or fluctuating attention span, loss of recent memory and recall, impaired judgment, emotional lability, lack of initiative, impaired impulse control, inability to reason through problems, depression (worse in mild to moderate types), confabulation (not limited to alcohol organic brain syndrome), constriction of intellectual functions, visual and auditory hallucinations, and delusions. Physical findings will naturally vary according to the cause. The EEG usually shows generalized slowing in delirium.

A. Delirium

Delirium (acute confusional state) is a transient global disorder of attention, with clouding of consciousness, usually a result of systemic problems (eg, drugs, hypoxemia). Onset is usually rapid. The mental status fluctuates (impairment is usually least in the morning), with varying inability to concentrate, maintain attention, and sustain purposeful behavior. ("Sundowning"—mild to moderate delirium at night—is more common in patients with preexisting dementia and may be precipitated by hospitalization, drugs, and sensory deprivation.) There is a marked deficit of short-term memory and recall. Anxiety and irritability are common. Amnesia is retrograde (impaired recall of past memories) and anterograde (inability to recall events after the onset of the delirium). Orientation problems follow the inability to retain information. Perceptual disturbances (often visual hallucinations) and psychomotor restlessness with insomnia are common. Autonomic changes include tachycardia, dilated pupils, and sweating. The average duration is about 1 week, with full recovery in most cases. Delirium can coexist with dementia.

B. Dementia

(See also [Chapter 3](#).) Dementia is characterized by chronicity and deterioration of selective mental functions. Onset is insidious over months to years in most cases. Dementia is usually progressive, more common in the elderly, and rarely reversible even if underlying disease can be corrected. Dementia can be classified as cortical or subcortical.

There are three types of cortical dementia: (1) primary degenerative dementia (eg, Alzheimer's), accounting for about 50-60% of cases; (2) atherosclerotic (multi-infarct) dementia, 15-20% of cases (this figure is probably low because of the tendency to overuse the diagnosis of Alzheimer's dementia); and (3) mixtures of the first two types or dementia due to miscellaneous causes, 15-20% of cases (see also [Chapter 3](#)). Examples of primary degenerative dementia are Alzheimer's dementia (most common) and Pick, Creutzfeldt-Jakob, and Huntington dementias (less common).

In all types, loss of impulse control (sexual and language) is common. The tenuous level of functioning makes the individual most susceptible to minor physical and psychologic stresses. The course depends on the underlying cause, and the general trend is steady deterioration.

HIV infection can produce a primary neurogenic disorder (partially due to neuronal loss) and secondary effects due to opportunistic infections, neoplasias, or the effects of drug therapy. At present there has been a reduction in dementia symptoms in both early and late stages, perhaps due to earlier use of zidovudine. The general trend

is variable, and patients require ongoing monitoring of neuropsychiatric status.

Pseudodementia is a term applied to depressed patients who appear to be demented. These patients are often identifiable by their tendency to complain about memory problems vociferously rather than try to cover them up. They usually say they can't complete cognitive tasks but with encouragement can often do so.

C. Amnestic Syndrome

This is a memory disturbance without delirium or dementia. It is usually associated with thiamin deficiency and chronic alcohol use (eg, Korsakoff's syndrome). There is an impairment in the ability to learn new information or recall previously learned information.

D. Substance-Induced Hallucinosi

This condition is characterized by persistent or recurrent hallucinations (usually auditory) without the other symptoms usually found in delirium or dementia. Alcohol or hallucinogens are often the cause. There does not have to be any other mental disorder, and there may be complete spontaneous resolution.

E. Personality Changes Due to a General Medical Condition (Formerly Organic Personality Syndrome)

This syndrome is characterized by emotional lability and loss of impulse control along with a general change in personality. Cognitive functions are preserved. Social inappropriateness is common. Loss of interest and lack of concern with the consequences of one's actions are often present. The course depends on the underlying cause (eg, frontal lobe contusion may resolve completely).

Differential Diagnosis

The differential diagnosis consists mainly of schizophrenia and the other psychoses, which are sometimes confused with cognitive disorders that are often accompanied by psychotic symptoms.

Complications

Chronicity may result from delayed correction of the defect, eg, subdural hematoma, low-pressure hydrocephalus. Accidents secondary to impulsive behavior and poor judgment are a major consideration. Secondary depression and impulsive behavior not infrequently lead to suicide attempts. Drugs—particularly sedatives—may worsen thinking abilities and contribute to the overall problems.

Treatment

(See also [Chapter 3](#).)

A. Medical

Delirium should be considered a syndrome of acute brain dysfunction analogous to acute renal failure. The first aim of treatment is to identify and correct the etiologic medical problem. Evaluation should consist of a comprehensive physical examination including a search for neurologic abnormalities, infection, or hypoxia. Routine laboratory tests may include serum electrolytes, serum glucose, BUN, serum creatinine, liver function tests, thyroid function tests, arterial blood gases, complete blood count, serum calcium, phosphorus, magnesium, vitamin B₁₂, folate, blood cultures, urinalysis, and cerebrospinal fluid analysis. Discontinue drugs that may be contributing to the problem (eg, analgesics, corticosteroids, cimetidine, lidocaine, anticholinergic drugs, central nervous system depressants, mefloquine). Do not overlook any possibility of reversible organic disease. Electroencephalography, CT, MRI, PET, and SPECT evaluations may be helpful in diagnosis. Ideally, the patient should be monitored without further medications while the evaluation is carried out. There are, however, two indications for medication in delirious states: behavioral control (eg, pulling out lines) and subjective distress (eg, pronounced fear due to hallucinations). If these indications are present, medications may be employed. If there is any hint of alcohol or substance withdrawal (the most common cause of delirium in the general hospital), a benzodiazepine such as lorazepam (1-2 mg every hour) can be given parenterally. If there is little likelihood of withdrawal syndrome, haloperidol is often used in doses of 1-10 mg every hour. Given intravenously, it appears to impose slight risk of extrapyramidal side effects. In addition to the medication, a pleasant, comfortable, nonthreatening, and physically safe environment with adequate nursing or attendant services should be provided. Once the underlying condition has been identified and treated, adjunctive medications can be tapered.

Treatment of dementia syndrome usually involves symptomatic management with one exception. Since there is a cholinergic deficiency in Alzheimer's disease, research has focused on drugs to increase cholinergic activity by inhibiting cholinesterase. Tacrine is the first reversible cholinesterase inhibitor approved by the FDA. Three newer and better-tolerated FDA-approved cholinesterase inhibitors are donepezil (5-10 mg at night), rivastigmine (3-6 mg twice daily), and galantamine (8-12 mg twice daily). Donepezil and galantamine doses need adjustment for liver disease, and the galantamine dose should be adjusted for renal failure. They are thought to be efficacious in the short-term preservation of cognitive function and activities of daily living in mild to moderate dementia and, unlike tacrine, are not thought to be hepatotoxic. Gastrointestinal side effects are common but may be least frequent with donepezil. Further research continues to clarify the long-term efficacy of these medications on cognition and behavior. None of the cholinesterase inhibitors to date are thought to slow disease progression.

Aggressiveness and rage states in central nervous system disease can be reduced with lipophilic beta-blockers (eg, propranolol, metoprolol) in moderate doses. Since the serotonergic system has been implicated in arousal conditions, drugs that affect serotonin have been found to be of some benefit in aggression and agitation. Included in this group are lithium, trazodone, buspirone, and clonazepam. Dopamine blockers (eg, the neuroleptic drugs such as haloperidol) have been used for many years to attenuate aggression. Atypical neuroleptics appear to have a role. There are also recent reports of reduced agitation in Alzheimer's disease from carbamazepine, 100-400 mg/d orally (with slow increase as needed). Emotional lability in some cases responds to small doses of imipramine (25 mg orally one to three times per day) or fluoxetine (5-20 mg/d orally); depression, which often occurs early in the course of Alzheimer's dementia, responds to the usual doses of antidepressant drugs, preferably those with the least anticholinergic side effects (eg, SSRIs and MAO inhibitors).

Cerebral vasodilators were originally used on the assumption that cerebral arteriosclerosis and ischemia were the principal causes of the dementias. Although there is a slight reduction of blood flow in primary degenerative dementia (probably as a result of the basic disorder), there is no evidence that this is a major factor in this group of disorders or that vasodilators are of value. Ergotoxine alkaloids (ergoloid mesylates: Hydergine, others) have been studied with mixed results; improvement in ambulatory self-care and depressed mood has been noted, but there has been no improvement of cognitive functioning on any standardized tests. Hyperbaric oxygen treatment has not produced significant improvement. Stimulant drugs (eg, methylphenidate) do not change cognitive function but can improve affect and mood, which helps the caretakers cope with the problem.

Failing sensory functions should be supported as necessary, with hearing aids, cataract surgery, etc.

B. Social

Substitute home care, board and care, or convalescent home care may be most useful when the family is unable to care for the patient. The setting should include familiar people and objects, lights at night, and a simple schedule. Counseling may help the family to cope with problems and may help keep the patient at home as long as possible. Information about local groups can be obtained from the Alzheimer's Disease and Related Disorders Association, 70 East Lake Street, Suite 600, Chicago, IL 60601. Volunteer services, including homemakers, visiting nurses, and adult protective services, may be helpful in maintaining the patient at home.

C. Behavioral

Behavioral techniques include operant responses that can be used to induce positive behaviors, eg, paying attention to the patient who is trying to communicate appropriately, and extinction by ignoring inappropriate responses. Alzheimer's patients can learn skills and retain them but do not recall the circumstances in which they were learned.

D. Psychologic

Formal psychologic therapies are not usually helpful and may make things worse by taxing the patient's limited cognitive resources.

Prognosis

The prognosis is good for recovery of mental functioning in delirium when the underlying condition is reversible. For most dementia syndromes, the prognosis is for gradual deterioration, though new drug treatments may prove helpful.

■ **GERIATRIC PSYCHIATRIC DISORDERS (SEE ALSO [CHAPTER 4](#).)**

There are three basic factors in the process of aging: biologic, sociologic, and psychologic.

The complex **biologic** changes depend on inherited characteristics (the best chance of long life is to have long-lived parents), nutrition, declining sensory functions such as hearing or vision, disease, trauma, and lifestyle. A definite correlation between hearing loss and paranoid ideation exists in the elderly. (See Dementia, above.) As a person ages, relatively minor disorders or combinations of disorders may cause deficits in cognition and affective response. Hypochondriasis is frequently a mechanism of compensating for decreased function (eg, preoccupation with bowel function).

The **sociologic** factors derive from stresses connected with occupation, family, and community. Any or all of these areas may be disrupted in a general phenomenon of "disengagement" and lack of intimacy that older people experience as friends die, the children move away, and the surroundings become less familiar. Retirement commonly precipitates a major disruption in a well-established life structure. This is particularly stressful in the person whose compulsive devotion to a job has inhibited the development of other interests, so that sudden loss of this outlet leaves a void that is not easily filled. New duties, such as caring for a spouse with dementia, may also lead to depression.

The **psychologic** withdrawal of the elderly person is frequently related to a loss of self-esteem, which is based on the economic insecurity of older age with its congruent loss of independence, the recognition of decreasing physical and mental ability, loneliness, and the fear of approaching death. The process of aging is often poorly accepted, and the real or imagined loss of physical attractiveness may have a traumatic impact that the plastic surgeon can only soften for a time. In a culture that stresses physical and sexual attractiveness, it is difficult for some people to accept the change.

Clinical Findings & Complications

The most common psychiatric syndrome in the elderly is dementia of varying degrees. Psychotic ideation (usually paranoid) may coexist with dementia. Frequently, in milder cases, the individual is aware of the deficiency in cognition and becomes depressed about actual or threatened loss of function. Depression may then amplify the apparent cognitive decline.

Overt depression, often presenting as a somatic complaint, is often related to life changes (80% of people over age 65 have some kind of medical problem). Alcoholism is present in approximately 15% of older patients presenting with psychiatric symptoms. The incidence of suicide is higher in elderly people—loneliness, age, and medical problems being directly related. Deprivation of full-spectrum light may be a factor in some patients (eg, nursing home residents). Anxiety, often associated with organic illness, heightens preexisting confusion in the patient with cognitive dysfunction.

Abuse of the elderly—both physical neglect (passive) and physical injury (active)—demands early recognition. Bruises, welts, fractures, and debilitation should alert the clinician. The battered elderly are probably just as numerous as battered children, but less reported, and require the same diligence in clinician recognition.

Polypharmacy (with both prescription and OTC drugs) is a major cause of accidents (often with resultant hip fracture) and illness in the elderly. Cognitive impairment increases as the number of drugs used increases; sedatives and anticholinergic drugs are the major culprits (eg, overuse in sleep problems). The increased and varied complaints are often an attempt to compensate and divert attention from decreased mental function.

Treatment

A. Social

Socialization, a structured schedule of activities, familiar surroundings, continued achievement, and avoidance of loneliness (probably the most important factor) are some of the major considerations in prevention and amelioration of the psychiatric problems of old age. The patient can be supported in the primary environment by various agencies that can help avoid a premature change of habits. For patients with disabilities that make it difficult to cope with the problems of living alone, homemaker services can assist in continuing the day-to-day activities of the household; visiting nurses can administer medications and monitor the physical condition of the patient; and geriatric social groups can help maintain socialization and human contacts. In the hospital or nursing home, attention to the kinds of people placed in the same room is most important (mix active and inactive patients).

B. Medical

Treatment of any reversible components of a dementia syndrome is obviously the major medical consideration. One commonly overlooked factor is self-medication, frequently with nonprescription drugs or herbal remedies that further impair the patient's already precarious functioning. Common culprits are antihistamines and anticholinergic drugs, sometimes mixed with ethanol abuse.

Any signs of psychosis, such as paranoid ideation, agitation, and delusions, respond very well to *small doses* of antipsychotics. Risperidone, 0.25-1 mg orally daily, or olanzapine, 1.25-5 mg orally once a day, will usually decrease psychotic ideation markedly.

Do not use drugs that cause significant orthostatic hypotension (resulting in dizziness, falls, fractures).

Antidepressants (in one-third to one-half the doses given to young adults) are used when indicated for depression. Occasionally, a stimulant in small doses (eg, methylphenidate, 5-30 mg orally usually given in two doses at 7 AM and noon) can be used to treat apathy. The stimulant may help increase the patient's energy for social involvement and help the patient to maintain life activities.

The appropriate use of wine and beer for mild sedative effects is quite rewarding in the hospital and other care facilities as well as at home.

C. Behavioral

The impaired cognitive abilities of the geriatric patient necessitate simple behavioral techniques. Positive responses to appropriate behavior encourage the patient to repeat desirable kinds of behavior, and frequent repetition offsets to some degree the defects in recent memory and recall. It also results in participation—a most important element, since there is a tendency in the older population to withdraw, thus increasing isolation and functional decline.

One must be careful not to reinforce and encourage obstreperous behavior by responding to it; in this way, extinction or at least gradual reduction of inappropriate behavior will occur. At the same time, the obstreperous behavior often represents a nondirective response to frustration and inability to function, and a structured program of activity is necessary.

D. Psychologic

Patients may require help in adjusting to changing roles and commitments and in finding new goals and viewpoints. The older person steadily loses an important commodity—the future—and may attempt to compensate by preoccupation with the past. Involvement with the present and psychotherapy on a here-and-now basis can help make the adjustment easier.

■ PSYCHIATRIC PROBLEMS ASSOCIATED WITH HOSPITALIZATION & MEDICAL & SURGICAL DISORDERS

Diagnostic Categories

A. Acute Problems

1. Delirium with psychotic features secondary to the medical or surgical problem, or compounded by effect of treatment.
2. Acute anxiety, often related to ignorance and fear of the immediate problem as well as uncertainty about the future.
3. Anxiety as an intrinsic aspect of the medical problem (eg, hyperthyroidism).
4. Denial of illness, which may present during acute or intermediate phases of illness.

B. Intermediate Problems

1. Depression as a function of the illness or acceptance of the illness, often associated with realistic or fantasied hopelessness about the future.
2. Behavioral problems, often related to denial of illness and, in extreme cases, causing the patient to leave the hospital against medical advice.

C. Recuperative Problems

1. Decreasing cooperation as the patient sees improvement and compliance are not compelled.
2. Readjustment problems with family, job, and society.

General Considerations

A. Acute Problems

1. "Intensive care unit psychosis"—The stressful ICU environment may be a cause of delirium. Critical care unit factors include sleep deprivation, increased arousal, mechanical ventilation, and social isolation. Other causes include those common to delirium and require vigorous investigation (see Delirium, above).

2. Pre- and postsurgical anxiety states—Such problems are common and commonly ignored. Presurgical anxiety is very common and is principally a fear of death (many surgical patients make out their wills). Patients may be fearful of anesthesia (improved by the preoperative anesthesia interview), the mysterious operating room, and the disease processes that might be uncovered by the surgeon. Such fears frequently cause people to delay examinations that might result in earlier surgery and a greater chance of cure.

The opposite of this is **surgery proneness**, the quest for surgery to escape from overwhelming life stresses. Polysurgery patients may be classified as "factitious" ones. Dynamic motivations include narcissism, societal pressures (eg, breast implants), unconscious guilt, a masochistic need to suffer, an attempt to deal with another family member's illness, and somatoform disorders and body dysmorphic disorder (an obsession that a body part is disfigured). More apparent reasons may include an attempt to get relief from pain and a lifestyle that has become almost exclusively medically oriented, with all of the risks entailed in such an endeavor.

Postsurgical anxiety states are usually related to pain, procedures, and loss of body image. Acute pain problems are quite different from chronic pain disorders (see Chronic Pain Disorders, above); the former are readily handled with adequate analgesic medication (see [Chapter 1](#)). Alterations in body image, as with amputations, ostomies, and mastectomies, often raise concerns about relationships with others.

3. Iatrogenic problems—These usually pertain to medications, complications of diagnostic and treatment procedures, and impersonal and unsympathetic staff behavior. Polypharmacy is often a factor. Patients with unsolved diagnostic problems are at higher risk. They are desirous of relief, and the quest engenders more diagnostic procedures with a higher incidence of complications. The upset patient and family may be very demanding. Excessive demands usually result from anxiety. Such behavior is best handled with calm and measured responses.

B. Intermediate Problems

1. Prolonged hospitalization—Prolonged hospitalization presents unique problems in certain hospital services, eg, burn units, orthopedic services, and tuberculosis wards. The acute problems of the severely burned patient are discussed in [Chapter 38](#). The problems often are behavioral difficulties related to length of hospitalization and necessary procedures. For example, in burn units, pain is a major problem in addition to anxiety about procedures. Disputes with staff are common and often concern pain medication or ward privileges. Some patients regress to infantile behavior and dependency. Staff members must agree about their approach to the patient in order to ensure the smooth functioning of the unit.

Denial of illness may present in the patient with acute myocardial infarction. Intervention by an authority figure (eg, immediate work supervisor) may help the patient accept treatment and eventually abandon the defense of denial.

2. Depression—Depression frequently occurs during this period. Therapeutic drugs (eg, corticosteroids) may be a factor. Depression can contribute to irritability and overt anger. Severe depression can lead to anorexia, which further complicates healing and metabolic balance. It is during this period that the issue of disfigurement arises—relief at survival gives way to concern about future function and appearance.

C. Recuperative Problems

1. Anxiety—Anxiety about return to the posthospital environment can cause regression to a dependent position. Complications increase, and staff forbearance again is tested. Anxiety occurring at this stage usually is handled more easily than previous behavior problems.

2. Posthospital adjustment—Adjustment difficulties after discharge are related to the severity of the deficits and the use of outpatient facilities (eg, physical therapy, rehabilitation programs, psychiatric outpatient treatment). Some patients may experience posttraumatic stress symptoms (eg, from traumatic injuries or even from necessary medical treatments). Lack of appropriate follow-up can contribute to depression in the patient, who may feel that he or she is making poor progress and may have thoughts of "giving up." Reintegration into work, educational, and social endeavors may be slow. Life is simply much more difficult when one is disfigured, disabled, or disfranchised.

Clinical Findings

The symptoms that occur in these patients are similar to those discussed in previous sections of this chapter, eg, delirium, stress and adjustment disorders, anxiety, and depression. Behavior problems may include lack of cooperation, increased complaints, demands for medication, sexual approaches to nurses, threats to leave the hospital, and actual signing out against medical recommendations. The underlying personality structure of the individual is a major factor in coping styles (eg, the compulsive individual increases indecision, the hysterical individual increases dramatic behavior).

Differential Diagnosis

Delirium and dementia (including cases associated with HIV infection and drug abuse) must always be ruled out, since they often present with symptoms resembling anxiety, depression, or psychosis. Personality disorders existing prior to hospitalization often underlie the various behavior problems, but particularly the management problems.

Complications

Prolongation of hospitalization causes increased expense, deterioration of patient-staff relationships, and increased probabilities of iatrogenic and legal problems. The possibility of increasing posthospital treatment problems is enhanced.

Treatment

A. Medical

The most important consideration by far is to have one clinician in charge, a clinician whom the patient trusts and who is able to oversee multiple treatment approaches (see Somatoform Disorders, above). In acute problems, attention must be paid to metabolic imbalance, alcohol withdrawal, and previous drug use—prescribed, recreational, or OTC. Adequate sleep and analgesia are important in the prevention of delirium.

Most clinicians are attuned to the early detection of the surgery-prone patient. Plastic and orthopedic surgeons are at particular risk. Appropriate consultations may help detect some problems and mitigate future ones.

Postsurgical anxiety states can be alleviated by personal attention from the surgeon. Anxiety is not so effectively lessened by ancillary medical personnel, whom the patient perceives as lesser authorities, until after the physician has reassured the patient. Inappropriate use of "as needed" analgesia places an unfair burden on the nurse. "Patient-controlled analgesia" can improve pain control, decrease anxiety, and minimize side effects (see [Chapter 1](#)).

Depression should be recognized early. If severe, it may be treated by antidepressant medications (see Antidepressant Drugs, above). High levels of anxiety can be lowered with judicious use of anxiolytic agents. Unnecessary medications tend to reinforce the patient's impression that there must be a serious illness or medication would not be required.

B. Psychologic

Prepare the patient and family for what is to come. This includes the types of units where the patient will be quartered, the procedures that will be performed, and any disfigurements that will result from surgery. Repetition improves understanding. The nursing staff can be helpful, since patients frequently confide a lack of understanding to a nurse but are reluctant to do so to the physician.

Denial of illness is frequently a block to acceptance of treatment. This too should be handled with family members present (to help the patient face the reality of the situation) in a series of short interviews (for reinforcement). Dependency problems resulting from long hospitalization are best handled by focusing on the changes to come as the patient makes the transition to the outside world. Key figures are teachers, vocational counselors, and physical therapists. Challenges should be realistic

and practical and handled in small steps.

Depression is usually related to the loss of familiar hospital supports, and the outpatient therapists and counselors help to lessen the impact of the loss. Some of the impact can be alleviated by anticipating, with the patient and family, the signal features of the common depression to help prevent the patient from assuming a permanent sick role (invalidism).

Suicide is always a concern when a patient is faced with despair. An honest, compassionate, and supportive approach will help sustain the patient during this trying period.

C. Behavioral

Prior desensitization can significantly allay anxiety about medical procedures. A "dry run" can be done to reinforce the oral description. Cooperation during acute problem periods can be enhanced by the use of appropriate reinforcers such as a favorite nurse or helpful family member. People who are positive reinforcers are even more helpful during the intermediate phases when the patient becomes resistant to the seemingly endless procedures (eg, debridement of burned areas).

Specific situations (eg, psychologic dependency on the respirator) can be corrected by weaning with appropriate reinforcers (eg, watching a favorite movie on a videorecorder when disconnected from the ventilator). Behavioral approaches should be employed in a positive and optimistic way for maximal reinforcement.

Relaxation techniques and attentional distraction can be used to block side effects of a necessary treatment (eg, nausea in cancer chemotherapy).

D. Social

A change in environment requires adaptation. Because of the illness, admission and hospitalization may be more easily handled than discharge. Reintegration into society can be difficult. In some cases, the family is a negative influence. A predischARGE evaluation must be made to determine whether the family will be able to cope with the physical or mental changes in the patient. Working with the family while the patient is in the acute stage may presage a successful transition later on.

Development of a new social life can be facilitated by various self-help organizations (eg, the stoma club). Sharing problems with others in similar circumstances eases the return to a social life which may be quite different from that prior to the illness.

Prognosis

The prognosis is good in all patients who have reversible medical and surgical conditions. It is guarded when there is serious functional loss that impairs vocational, educational, or societal possibilities—especially in the case of progressive and ultimately life-threatening illness.

Table 25-3. Personality disorders: Classification and clinical findings.

Personality Disorder	Clinical Findings
Paranoid	Defensive, oversensitive, secretive, suspicious, hyperalert, with limited emotional response.
Schizoid	Shy, introverted, withdrawn, avoids close relationships.
Obsessive-compulsive	Perfectionist, egocentric, indecisive, with rigid thought patterns and need for control.
Histrionic (hysterical)	Dependent, immature, seductive, egocentric, vain, emotionally labile.
Schizotypal	Superstitious, socially isolated, suspicious, with limited interpersonal ability and odd speech.
Narcissistic	Exhibitionist, grandiose, preoccupied with power, lacks interest in others, with excessive demands for attention.
Avoidant	Fears rejection, hyperreacts to rejection and failure, with poor social endeavors and low self-esteem.
Dependent	Passive, overaccepting, unable to make decisions, lacks confidence, with poor self-esteem.
Antisocial	Selfish, callous, promiscuous, impulsive, unable to learn from experience, has legal problems.
Borderline	Impulsive; has unstable and intense interpersonal relationships; is suffused with anger, fear, and guilt; lacks self-control and self-fulfillment; has identity problems and affective instability; is suicidal (a serious problem up to 80% of hospitalized borderline patients make an attempt at some time during treatment, and the incidence of completed suicide is as high as 5%); aggressive behavior, feelings of emptiness, and occasional psychotic decompensation. This group has a high drug abuse rate, which plays a role in symptomatology. There is extensive overlap with other diagnostic categories, particularly mood disorders and posttraumatic stress disorder.

Table 25-11. Etiology of delirium and other cognitive disorders

Disorder	Possible Causes
Intoxication	Alcohol, sedatives, bromides, analgesics (eg, pentazocine), psychedelic drugs, stimulants, and household solvents.
Drug withdrawal	Withdrawal from alcohol, sedative-hypnotics, corticosteroids
Long-term effects of alcohol	Wernicke-Korsakoff syndrome
Infections	Septicemia; meningitis and encephalitis due to bacterial, viral, fungal, parasitic, or tuberculous organisms or to central nervous system syphilis; acute and chronic infections due to the entire range of microbiologic pathogens.
Endocrine disorders	Thyrotoxicosis, hypothyroidism, adrenocortical dysfunction (including Addison's disease and Cushing's syndrome), pheochromocytoma, insulinoma, hypoglycemia, hyperparathyroidism, hypoparathyroidism, panhypopituitarism, diabetic ketoacidosis.
Respiratory disorders	Hypoxia, hypercapnia.
Metabolic disturbances	Fluid and electrolyte disturbances (especially hyponatremia, hypomagnesemia, and hypercalcemia), acid-base disorders, hepatic disease (hepatic encephalopathy), renal failure, porphyria.
Nutritional deficiencies	Deficiency of vitamin B ₁ (beriberi), vitamin B ₁₂ (pernicious anemia), folic acid, nicotinic acid (pellagra); protein-calorie malnutrition.
Trauma	Subdural hematoma, subarachnoid hemorrhage, intracerebral bleeding, concussion syndrome.
Cardiovascular disorders	Myocardial infarctions, cardiac arrhythmias, cerebrovascular spasms, hypertensive encephalopathy, hemorrhages, embolisms, and occlusions indirectly cause decreased cognitive function.
Neoplasms	Primary or metastatic lesions of the central nervous system, cancer-induced hypercalcemia.
Seizure disorders	Ictal, interictal, and postictal dysfunction.
Collagen-vascular and immunologic disorders	Autoimmune disorders, including systemic lupus erythematosus, Sjogren's syndrome, and AIDS.
Degenerative diseases	Alzheimer's disease, Pick's disease, multiple sclerosis, parkinsonism, Huntington's chorea, normal pressure hydrocephalus.
Medications	Anticholinergic drugs, antidepressants, H ₂ -blocking agents, digoxin, salicylates (chronic use), and a wide variety of other OTC and prescribed drugs.

■ INTRODUCTION

Hormones exert their effects by interacting with receptors on the cell surface (catecholamines and peptide hormones) or inside the cell (thyroid and steroid hormones). Endocrine disorders result from an excess or deficiency of hormonal effects.

■ COMMON PRESENTATIONS IN ENDOCRINOLOGY

Obesity

Genetics is the most important determinant for obesity. In a given environment, up to 80% of human obesity is due to genetic factors. Several novel hormones appear to act upon brain receptors to regulate appetite and metabolism, thereby determining an individual's predisposition to obesity.

Leptin is a hormone secreted by subcutaneous adipose tissue in response to fat storage or overfeeding. Leptin binds to brain α -melanocortin receptors and influences the secretion of neuropeptides, inhibiting neuropeptide Y and agouti-related peptide. It thereby promotes satiety and increases the body's metabolic rate. Leptin is also required for gonadotropin secretion. During starvation, reduced leptin secretion results in a lower metabolic rate and a reduction in gonadotropin secretion. Congenital leptin deficiency accounts for 1-2% of early-onset morbid obesity.

Ghrelin is a 28-amino-acid hormone that is secreted by the empty stomach; it stimulates appetite.

Alpha-melanocyte-stimulating hormone (α -MSH) is a neuropeptide that regulates the hypothalamic control of food intake. Defects in the α -MSH (melanocortin 4) receptor are present in up to 5% of morbidly obese patients.

Familial partial lipodystrophy (Dunnigan-Kobberling syndrome) is an autosomal dominant disorder caused by missense mutations in the lamin A/C gene. Beginning at puberty, affected patients develop atrophy of subcutaneous fat in the extremities but obese proximal thighs, trunk, and face (type I) or absence of subcutaneous fat everywhere but in the face, which is very fat (type II). Patients may have muscle hypertrophy. Affected patients, especially women, are at risk for metabolic complications associated with insulin resistance, including glucose intolerance, diabetes mellitus, hypertriglyceridemia, low HDL cholesterol, and atherosclerosis.

Therapy with leptin, injected subcutaneously twice daily, has improved triglycerides and plasmapheresis requirements. It also improves hyperglycemia and reduces hepatic steatosis.

Obesity is associated with mental retardation in several genetic syndromes expressing multiple congenital anomalies: eg, Prader-Willi syndrome (hypotonia, hypogonadism), Laurence-Moon-Bardet-Biedl syndrome (polydactyly, renal anomalies, retinitis pigmentosa, hypogonadism), Cohen's syndrome (microcephaly, hypotonia, short stature, ocular anomalies, neutropenia), and Biemond syndrome (diabetes mellitus, polydactyly, coloboma, facial anomalies, hypogonadism).

Several endocrine disorders do cause obesity. Cushing's syndrome causes central obesity (due to intraperitoneal fat) with relatively thin extremities; such patients usually have plethoric, rounded (moon) facies along with prominent supraclavicular and dorsocervical fat pads (buffalo humps). Alcoholism causes hypercortisolism and a similar syndrome. Hypothyroidism occasionally causes mild weight gain due to edema and fat accumulation. Hyperthyroidism may cause mild weight gain due to hyperphagia. Pancreatic insulinomas secrete excessive amounts of insulin, causing hypoglycemia and compensatory overeating. Growth hormone deficiency usually causes obesity in both children and adults.

Insulin or thiazolidinedione therapy for type 2 diabetes usually worsens obesity.

Menopause is associated with a decrease in the resting metabolic rate, which increases body weight. Weight gain is greatest in the perimenopausal period. Hormone replacement therapy causes negligible weight gain. Obesity may be associated with other disorders as part of several recognized syndromes. Syndrome X (the cluster of obesity, diabetes, and hypertension) has a 50% hereditary component. Polycystic ovary syndrome refers to the combination of obesity with anovulation, amenorrhea, cystic ovaries, and hirsutism. Hypothalamic lesions can cause massive obesity and are often associated with headache, lethargy, depression, diabetes insipidus, and hypopituitarism.

Unintended Weight Loss

Uncontrolled diabetes mellitus may be associated with weight loss, polyphagia, polydipsia, and polyuria. Anorexia and nausea may be seen with diabetic ketoacidosis and with adrenal insufficiency (due either to pituitary ACTH deficiency or to Addison's disease). Patients with severe diabetes insipidus may also lose weight. Patients with hyperthyroidism typically lose weight despite increased appetite; some patients with hypothyroidism lose weight because of diminished appetite. About 15% of patients with pheochromocytoma lose over 10% of their basal weight. Some patients with Cushing's syndrome lose weight as a result of muscle wasting.

A great variety of nonendocrine conditions enter into the differential diagnosis of unintended weight loss (see [Chapter 1](#)). Anorexia is frequently a side effect of medications or radiation therapy and is also seen with azotemia, AIDS, and many gastrointestinal conditions. Malignancies typically produce diminished appetite and cachexia. Tuberculosis may cause weight loss even when occult. Chronic respiratory insufficiency is often associated with weight loss. Psychiatric illnesses producing diminished appetite include depressed or agitated affective disorder, catatonia, and anorexia nervosa.

Abnormal Skin Pigmentation

Increased skin pigmentation can be caused by excessive ACTH secretion in Addison's disease and can occur after bilateral adrenalectomy for Cushing's disease (Nelson's syndrome). Pigmentation can be generalized or may be localized to palmar creases, extensor joint surfaces, tongue, nails, belt or bra lines, freckles, or new scars.

Pigmentation of the upper lip, forehead, or malar eminences, known as **chloasma** can be caused by pregnancy ("mask of pregnancy"), oral contraceptives, or estrogen replacement therapy.

Acanthosis nigricans presents as velvety brown thickened skin of the neck and axillae. It may be associated with syndromes of severe insulin resistance type A (ovarian dysfunction and hirsutism) or type B (autoimmune). It may also be familial or associated with obesity, acromegaly, or thyroid disease. Acanthosis presenting after age 40 is often a sign of an underlying malignancy.

Pretibial areas of pigmentation are common in diabetes ("diabetic shin spots") as a result of minor trauma or following necrobiosis lipoidica diabetorum.

Prominent lentigines can be a sign of Carney's complex, an autosomal dominant condition associated with atrial myxomas, schwannomas, and endocrine overactivity (eg, tumors of the thyroid, gonads, or pigmented adrenal nodular hyperplasia). Similar skin pigmentation is seen in Peutz-Jeghers syndrome with an increased risk of intestinal polyposis, adenocarcinoma, breast cancer, and tumors of the gonads and thyroid.

Diffuse hyperpigmentation is seen in POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, skin changes); adrenal insufficiency, hypoparathyroidism, diabetes, osteosclerotic bone lesions, or thiamin deficiency may occur.

Gray-brown ("bronze") hyperpigmentation is caused by hemochromatosis, which can cause endocrine deficiencies such as diabetes mellitus. An orange skin discoloration is characteristic of jaundice and carotenoderma (caused by ingestion of large amounts of carotene in vegetables, seaweed, or vitamin preparations).

Patchy hypopigmentation can be due to vitiligo, a condition sometimes associated with Addison's disease and with other endocrine deficiencies as part of the polyglandular autoimmune syndrome. Hypopigmentation can also be a manifestation of cobalamin deficiency, trisomy 13, and various dermatologic conditions.

Patients undergoing chronic hemodialysis frequently become hyperpigmented, and hypopigmentation has also been reported. Other causes of hyperpigmentation include sprue, malnutrition, HIV infection, and porphyria. Hyperpigmentation may be caused by certain drugs: amiodarone, arsenic, bleomycin, busulfan, clofazimine, hydroxychloroquine, chlorpromazine, doxorubicin (nail beds), imipramine, methimazole, minocycline, niacin, primaquine, propylthiouracil, topical tretinoin, and zidovudine (nails).

Gynecomastia

Gynecomastia is a glandular enlargement of the male breast that may be tender and is often asymmetric or unilateral. It must be distinguished from tumors and from the fatty breast enlargement of obesity.

Pubertal gynecomastia is common and is characterized by tender discoid enlargement of breast tissue 2-3 cm in diameter beneath the areola; the swelling usually subsides spontaneously within a year. Gynecomastia develops in about 50% of athletes who abuse androgens and anabolic steroids. It is seen in Klinefelter's syndrome, which affects 1:500 men. It is also common among elderly men, particularly when there is associated weight gain. Gynecomastia can be the first sign of a serious disorder. Patients with Peutz-Jeghers syndrome are prone to development of gynecomastia caused by testicular tumors.

The causes of gynecomastia are multiple and diverse ([Table 26-1](#)).

A. Diagnosis

Investigation of unclear cases should include a chest x-ray to search for metastatic or bronchogenic carcinoma. Laboratory procedures include measurements of plasma levels of prolactin (see Hyperprolactinemia) and the beta subunit of human chorionic gonadotropin (β -hCG). Detectable levels implicate a testicular tumor (germ cell or Sertoli cell) or other malignancy (usually lung or liver). Detectable low levels of serum β -hCG (< 5 mU/mL) may be reported in men with primary hypogonadism and high serum LH levels if the assay for β -hCG cross-reacts with LH. Measurements of plasma testosterone and luteinizing hormone (LH) are valuable in the diagnosis of primary or secondary hypogonadism. A low testosterone and high LH are seen in primary hypogonadism. High testosterone levels *plus* high LH levels characterize partial androgen resistance. Serum estradiol is determined but is usually normal; increased levels may result from testicular tumors, increased β -hCG, liver disease, obesity, adrenal tumors (rare), or true hermaphroditism (rare). Many estrogens and substances with estrogenic activity are not detected by estradiol assays. Serum TSH (sensitive) and free thyroxine levels are also determined. A karyotype (for Klinefelter's syndrome) is obtained in men with persistent gynecomastia without obvious cause. Needle biopsy with cytologic examination may be performed on suspicious areas of male breast enlargement (especially when unilateral or asymmetric) to distinguish gynecomastia from tumor or mastitis.

B. Treatment

The treatment of gynecomastia is that of the underlying condition. Idiopathic and pubertal gynecomastia tends to occur in boys who are taller and heavier than average; gynecomastia often resolves spontaneously within 1-2 years. Drug-induced gynecomastia resolves after the offending drug is removed. Painful gynecomastia may be treated with tamoxifen (an antiestrogen), 10 mg orally twice daily; discomfort improves, and some degree of reduction in breast size occurs in over 50%. Recurrence of gynecomastia occurs in about 28% of men after tamoxifen is stopped. Danazol, 400 mg orally daily, produces some improvement in gynecomastia in 40%; relapses are uncommon after stopping it. Danazol can cause hepatic dysfunction, so liver enzymes must be monitored. Since both tamoxifen and danazol can produce adverse reactions, it is prudent to treat gynecomastia only when it becomes a troubling and continuing problem for the patient. Surgical correction is reserved for persistent or severe gynecomastia, since results are often disappointing. Endoscopically assisted transaxillary liposuction and subcutaneous mastectomy may produce acceptable results.

Ting AC et al: Comparison of tamoxifen with danazol in the management of idiopathic gynecomastia. Am Surg 2000;66:38. [\[PMID: 10651345\]](#)

Galactorrhea

Lactation that occurs in the absence of nursing is termed galactorrhea. A small amount of breast milk can be expressed from the nipple in many parous women and is not cause for concern. Normal breast milk may be various colors besides white. Galactorrhea requires evaluation when it occurs in significant amounts or in nulliparous women or when it is associated with amenorrhea, headache, visual field abnormalities, or other symptoms implying systemic illness.

Evaluation begins with serum prolactin measurement; a persistently elevated level should prompt further investigation to determine its cause ([Table 26-4](#)). MRI of the pituitary and hypothalamus is done for nonpregnant patients with serum prolactin levels over 200 mg/dL, those with headaches or visual field defects, and women with persistently elevated prolactin levels with no discernible cause. Treatment is directed at correcting the cause of the elevated prolactin. Galactorrhea due to antipsychotic drugs may resolve if the neuroleptic is changed to clozapine, an atypical antipsychotic. Galactorrhea may occur in the absence of elevated serum prolactin levels (idiopathic). Whatever the cause, galactorrhea can be reduced with cabergoline or bromocriptine administration.

Pena KS et al: Evaluation and treatment of galactorrhea. Am Fam Physician 2001;63:1763. [\[PMID: 11352287\]](#)

Erectile Dysfunction & Diminished Libido in Men

Erectile dysfunction is a frequent problem. Psychogenic factors as well as endocrine, vascular, or neurologic abnormalities may be important. Hypogonadism of whatever origin ([Table 26-14](#)) is associated with lack of libido and erectile dysfunction. These can also be the first clinical manifestations of a hyperprolactinemic disorder ([Table 26-4](#)). Other endocrine causes include hyperthyroidism, Addison's disease, and acromegaly. Impotence in diabetes may be related to inadequate penile blood flow or autonomic neuropathy. Vascular disease is a frequent factor in impotence in elderly men. Vascular claudication of the legs along with related impotence is known as **Leriche's syndrome**.

Many pharmacologic agents are known to cause varying degrees of impotence ([Table 26-2](#)). Selective serotonin reuptake inhibitors (SSRIs, eg, fluoxetine) cause reduced libido. SSRIs and clomipramine cause delayed ejaculation.

Evaluation and treatment of erectile dysfunction are covered in [Chapter 23](#).

Cryptorchism

One or both testes may be absent from the scrotum at birth in about 20% of premature males and in 3-6% at full term. Cryptorchism is found in 1-2% of males after 1 year of age but must be distinguished from retractile testes, which require no treatment. Cryptorchism should be corrected before age 18-24 months in an attempt to reduce the risk of infertility, which occurs in up to 75% of men with bilateral cryptorchism and in 50% with unilateral cryptorchism. It is not clear, however, whether early orchiopexy improves ultimate fertility. Many patients have underlying hypogonadism.

The ultimate incidence of significant testicular neoplasia is about 0.002% in normal males, 0.06% in cryptorchid males, and up to 5% in patients with intra-abdominal testes.

If the testes are not palpable, ultrasound or MRI can be used to locate them. Alternatively, human chorionic gonadotropin, 1500 units intramuscularly daily for 3 days, causes a significant rise in testosterone if the testes are present.

Orchiopexy decreases the risk of neoplasia when performed before 10 years of age. Orchiectomy after puberty is an option for intra-abdominal testes.

Vinardi S et al: Testicular function in men treated in childhood for undescended testes. J Pediatr Surg 2001;36:385. [\[PMID: 11172441\]](#)

Bone Pain & Pathologic Fractures

Onset of pathologic fractures at an early age is seen in osteogenesis imperfecta (blue scleras may be present). Painful bowing of the bones and pseudofractures suggest rickets or osteomalacia. Hyperparathyroidism or malignancy is suspected in patients with bone pain and hypercalcemia. Back pain or pathologic fractures in hypogonadal men and women implicate osteoporosis; such pain may be relieved with calcitonin. In cases of osteopenia of unknown cause, hyperthyroidism and Cushing's syndrome should also be considered. Bone pain may occur also as a result of primary or metastatic tumors, multiple myeloma, and Paget's disease; such pain may be relieved with bisphosphonates such as pamidronate or alendronate. Treatment is that of the underlying disorder.

Muscle Cramps & Tetany

Muscle cramps are usually caused by sports or occupational muscle injury. Nocturnal leg cramps are commonly idiopathic but are seen in diabetes mellitus,

Parkinson's disease, central nervous system or spinal cord lesions, peripheral neuropathy, hemodialysis, peripheral vascular disease, and cisplatin or vincristine. Various other drugs can cause myalgias that patients describe as cramps (eg, cimetidine, cholestyramine). Alkalosis due to any cause (eg, severe vomiting or hyperventilation) may decrease ionized calcium and cause muscle cramping and paresthesias. Leg cramps during walking may be due to vascular insufficiency, hyperthyroidism, or hypothyroidism.

McArdle's disease is caused by muscle phosphorylase deficiency; patients present with muscle fatigue, cramping, and high serum CK levels; vitamin B₆ (pyridoxine) supplementation reduces muscle cramps. Carnitine palmitoyltransferase II deficiency is a genetic disorder of lipid metabolism; patients present with myalgia, cramping, myoglobinuria, and elevated serum CK levels. Other conditions that may cause muscle cramping include stiff man syndrome (abdominal and back cramping), Brody's disease, phosphoglycerate kinase deficiency (myoglobinuria), muscle phosphofructokinase deficiency (Tarui's disease), and neuromyotonia (Isaac's syndrome).

Diffuse, recurrent, or severe muscle cramping requires evaluation for hypocalcemia ([Chapter 21](#)). Magnesium deficiency must be considered in tetany unresponsive to calcium.

For patients with recurrent, severe, or prolonged muscle cramping, gabapentin, 600-1200 mg/d orally, appears to be effective. Adverse effects of gabapentin may include leukopenia and central nervous system toxicities. Quinine, long used to prevent nocturnal muscle cramps, can cause arrhythmias, dizziness, hemolytic-uremic syndrome, and agranulocytosis. Leg cramps, usually nocturnal, affect 45% of women during pregnancy; oral calcium may reduce their frequency. Exertional claudication caused by vascular insufficiency may be treated with oral pentoxifylline, cilostazol, angioplasty, or arterial bypass.

Recurrent cervicofacial and laryngeal dystonias, as well as hand cramps, have been successfully treated with injections of botulinum toxin.

Serrao M et al: Gabapentin treatment for muscle cramps: an open label trial. Clin Neuropharmacol 2000;23:45. [\[PMID: 10682230\]](#)

Mental Changes

Disturbances of mentation may be important indications of underlying endocrine disorders. Nervousness and excitability are characteristic of the menopause and hyperthyroidism. Adult cretinism is the result of prolonged hypothyroidism in infancy. In adults, hypothyroidism is accompanied by mental slowness, depression, and lethargy. Occasionally it may be manifested by delusional psychosis ("myxedema madness"). Pheochromocytoma may cause anxiety, confusion, or psychosis. Prolonged hypocalcemia from untreated hypoparathyroidism may be associated with intellectual deterioration. Hypoglycemia of any origin may cause confusion, abnormal speech, and behavioral or personality changes as well as sudden loss of consciousness, somnolence and prolonged lethargy, or coma. Frank psychosis can occur but is rare. Mild hypercalcemia causes fatigue and emotional irritability. Severe hypercalcemia can cause confusion, psychosis, and coma. Confusion may occur in hypopituitarism or Addison's disease. Confusion, lethargy, and nausea may be the presenting symptoms of hyponatremia. Insomnia, mood changes, anxiety, and psychosis can be associated with Cushing's syndrome. Rapid changes in glucocorticoid status (either a sudden increase or a sudden decrease) may be associated with acute psychosis. Porphyria may cause affective and thought disorders, particularly during acute attacks.

Mental changes may result from vitamin deficiencies caused by malnutrition, malabsorption, and other conditions. Deficiency in vitamin B₁ (thiamin) is usually seen in alcoholism and can cause Korsakoff's syndrome with typical memory loss and confabulation. Deficiency in vitamin B₂ (riboflavin) may cause personality deterioration and occurs commonly with psychotropic and antimalarial drugs and with diabetes and other diseases. Vitamin B₃ (niacin) deficiency is seen with poor nutrition, alcoholism, mercaptopurine toxicity, and malignant carcinoid syndrome and can cause irritability, dementia, dermatitis, and diarrhea. Vitamin B₆ (pyridoxine) deficiency is frequently seen in alcoholics or during treatment with isoniazid or levodopa and can cause irritability, depression, and neuropathy. Deficiency of vitamin B₁₂ (cobalamin) is caused by deficiency in gastric intrinsic factor and may be seen at any age; however, it is more common in the elderly, affecting about 10% of people over age 70 years. Vitamin B₁₂ deficiency may cause depression, irritability, paranoia, confusion, and dementia. It is usually associated with other neurologic symptoms such as paresthesias and leg weakness. Mental changes may occur in the absence of megaloblastic anemia.

■ DISEASES OF THE HYPOTHALAMUS & PITUITARY GLAND

Anterior pituitary gland function is controlled by regulating hormones produced by the hypothalamus and by direct feedback inhibition. The **posterior pituitary** receives antidiuretic hormone and oxytocin from the hypothalamus, secreting them under central nervous system control ([Table 26-3](#)). Hypothalamic hormones generally stimulate the anterior pituitary except for dopamine, which inhibits the pituitary from spontaneously secreting prolactin.

HYPOPITUITARISM

Essentials of Diagnosis

- Sexual dysfunction; weakness; easy fatigability; lack of resistance to stress, cold, and fasting; axillary and pubic hair loss.
- Low blood pressure; pituitary tumors may cause visual field defects.
- Low free thyroxine; deficient cortisol response to cosyntropin.
- Low serum testosterone (men); amenorrhea; serum prolactin may be elevated; FSH and LH are low or low normal.
- MRI may reveal a pituitary or hypothalamic lesion.

General Considerations

Hypopituitarism can be caused by either hypothalamic or pituitary dysfunction. Patients with hypopituitarism may have single or multiple hormonal deficiencies. When one hormonal deficiency is discovered, others must be sought.

Mass lesions causing hypopituitarism include pituitary adenomas, granulomas, Rathke's cleft cysts, apoplexy, metastatic carcinomas, aneurysms, and brain tumors such as craniopharyngioma, meningioma, germinoma, glioma, chondrosarcoma, and chordoma of the clivus. Langerhans cell histiocytosis usually presents in youth with diabetes insipidus or hypopituitarism; MRI may reveal a mass lesion, thickening of the pituitary stalk, or no visible abnormality. Osteolytic bone lesions are noted on skeletal x-rays. Autoimmune hypophysitis, postpartum pituitary necrosis (Sheehan's syndrome), eclampsia-preeclampsia, sickle cell disease, and African trypanosomiasis are rare causes.

A pituitary tumor may be part of the syndrome of multiple endocrine neoplasia (type 1), with tumors of the parathyroid glands and pancreatic islets.

Hypopituitarism without mass lesions may be idiopathic or may be caused by trauma, cranial radiation, surgery, encephalitis, hemochromatosis, autoimmunity, or stroke. It may also occur after coronary artery bypass grafting. Long-term intrathecal administration of opioids causes hypogonadotropic hypogonadism in the overwhelming majority of patients; GH deficiency and secondary adrenal insufficiency each occur in about 15% of such patients.

Congenital combined pituitary hormone deficiency occurs in about 1:8000 births. Depending on the genetic defect, it may be transmitted as an autosomal recessive, autosomal dominant, or X-linked recessive trait. Mutations have been found in genes such as *POU1F1* and *PIT-1* which encode transcription factors necessary for pituitary development.

Clinical Findings

Manifestations of hypopituitarism vary depending upon which specific hormones are lacking and whether their deficiency is partial or complete.

A. Symptoms and Signs

Gonadotropin deficiency includes loss of luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which causes hypogonadism and infertility. Patients with isolated gonadotropin deficiency may present as delayed adolescence. (See also discussion of primary amenorrhea.) Congenital gonadotropin deficiency may be associated with micropenis or cryptorchism.

Kallman's syndrome is the most common cause of congenital isolated gonadotropin deficiency. It is transmitted as an X-linked recessive trait with an incidence of 1:10,000 males and 1:50,000 females. It is associated with hyposmia caused by hypoplasia of the olfactory bulbs; 50% of affected patients have unilateral renal agenesis.

Congenital adrenal hypoplasia is a rare X-linked disorder caused by a mutation in the *DAX-1* gene. Boys with *DAX-1* gene mutations usually present during infancy or childhood with adrenal insufficiency caused by failure to form the permanent zone of the adrenal cortex. Boys who survive beyond childhood usually fail to enter puberty as a result of hypogonadotropic hypogonadism. However, those with partial loss-of-function mutations in *DAX-1* can present in adulthood with

hypogonadotropic hypogonadism and subtle signs of adrenal failure.

In acquired gonadotropin deficiency, both men and women lose axillary, pubic, and body hair gradually, particularly if they are also hypoadrenal. Men may note diminished beard growth. Libido is diminished. Women have amenorrhea; men note decreased erections. Most patients are infertile. Androgen deficiency predisposes patients to osteopenia and muscle atrophy. (See section on secondary amenorrhea.)

Thyroid-stimulating hormone (TSH) deficiency causes hypothyroidism with manifestations such as fatigue, weakness, weight change, and hyperlipidemia. (See Hypothyroidism and Myxedema.)

Adrenocorticotrophic hormone (ACTH) deficiency results in diminished cortisol secretion (see Adrenocortical Hypofunction). Symptoms include weakness, fatigue, weight loss, and hypotension. Adrenal mineralocorticoid secretion continues, so manifestations of adrenal insufficiency in hypopituitarism are usually less striking than in bilateral adrenal gland destruction (Addison's disease).

Growth hormone (GH) deficiency in adulthood tends to cause mild to moderate central obesity, increased systolic blood pressure, and relative increases in LDL cholesterol. GH deficiency also results in a small heart with reduced cardiac output, asthenia, and feelings of social isolation.

Panhypopituitarism is the absence of all anterior pituitary hormones. Besides the manifestations noted above, patients with long-standing hypopituitarism tend to have dry, pale, finely textured skin. The face has fine wrinkles and an apathetic countenance.

B. Laboratory Findings

The fasting blood glucose may be low. Hyponatremia is often present. Hyperkalemia usually does not occur, since aldosterone production is not affected.

The free T₄ level is low, and TSH is not elevated. Plasma levels of sex steroids (testosterone and estradiol) are low or low normal, as are the serum gonadotropins as well. Elevated prolactin levels are found in patients with prolactinomas, acromegaly, and hypothalamic disease.

In secondary hypoadrenalism, administration of cosyntropin (synthetic ACTH₁₋₂₄), 0.25 mg (intramuscularly or intravenously), usually causes serum cortisol to rise to less than 20 ug/dL by 30-60 minutes after the injection. A low-dose cosyntropin test (0.001 mg intravenously) is slightly more sensitive in detecting subtle ACTH-cortisol insufficiency. A baseline ACTH level is low or normal in secondary hypoadrenalism, distinguishing it from primary adrenal disease.

Patients with a normal cosyntropin test but with clinically suspected pituitary-adrenal insufficiency may have a metyrapone stimulation test: Metyrapone, 1.5 g orally, is administered at 11 PM; serum is collected at 8 am for 11-deoxycortisol and cortisol determinations. Patients with hypoadrenalism usually have an 11-deoxycortisol concentration under 7 ug/dL in the presence of a cortisol suppressed to less than 5 ug/dL. The metyrapone test must be performed in the absence of replacement glucocorticoid. Side effects include frequent nausea and occasional vomiting.

The diagnosis of growth hormone (GH) deficiency is made difficult by the pulsatile nature of GH secretion and individual variability. GH deficiency is present in 96% of patients with three or four other pituitary hormone deficiencies. The insulin hypoglycemia test, long considered the "gold standard," is actually somewhat unreliable, cumbersome, and uncomfortable; it is contraindicated in the elderly, in patients with cardiovascular or cerebrovascular disease, and in patients with any history of seizures, an abnormal EEG, or recent brain surgery. Other GH stimulation tests require the administration of intravenous arginine and oral carbidopa and levodopa (combination) in patients pretreated with propranolol or estrogen. However, these tests do not discriminate well between normal individuals and patients with presumed GH deficiency (patients with three or four other pituitary hormone deficiencies). Serum IGF-1 levels are in the normal range in about 50% of adults with GH deficiency. However, very low levels of IGF-1 (< 84 ug/L) are indicative of GH deficiency except in conditions that naturally suppress serum IGF-1 (eg, malnutrition, prolonged fasting, oral estrogen, hypothyroidism, uncontrolled diabetes mellitus, liver failure). In GH deficiency, exercise-stimulated serum GH levels usually fail to rise and remain at < 5 ng/mL; however, by age 40 years, most normal adults have lost their GH response to exercise.

C. Imaging

MRI provides the best visualization of parasellar lesions. In hemochromatosis, MRI shows a very hypointense anterior lobe on T1-weighted images, which is surrounded by hyperintense cerebrospinal fluid on T2-weighted images. The posterior pituitary usually has a high-intensity signal on sagittal MRI that is lacking in central diabetes insipidus.

Differential Diagnosis

Reversible hypogonadotropic hypogonadism may occur with serious illness, malnutrition, or anorexia nervosa. The clinical situation, presence of normal sex hair, and normal adrenal and thyroid function allow ready distinction from hypopituitarism. Patients receiving chronic intrathecal infusion of opioids usually develop hypogonadotropic hypogonadism; GH deficiency and secondary adrenal insufficiency each occur in 15% of such patients. Reversible secondary adrenal insufficiency may persist for many months following high-dose glucocorticoid therapy.

Severe illness causes functional suppression of TSH and thyroxine. Hyperthyroxinemia reversibly suppresses TSH. Bexarotene, used to treat cutaneous T cell lymphoma, suppresses TSH secretion, resulting in reversible central hypothyroidism. Glucocorticoids or megestrol treatment reversibly suppresses endogenous ACTH and cortisol secretion.

Serum IGF-1 may be low in patients with malnutrition, liver disease, hypothyroidism, or uncontrolled diabetes mellitus.

Complications

Patients with destructive lesions (eg, tumors) may develop complications related to them or to surgery or radiation therapy. Among patients with craniopharyngiomas, diabetes insipidus is found in 16% preoperatively and in 60% postoperatively. Hyponatremia may present abruptly during the first 2 weeks following pituitary surgery. Visual field impairment may occur. Hypothalamic damage may result in morbid obesity as well as cognitive and emotional problems. Conventional radiation therapy results in an increased incidence of small vessel ischemic strokes and second tumors.

Patients with untreated hypoadrenalism and a stressful illness may become febrile and die in shock and coma.

Adults with growth hormone deficiency have experienced an increased cardiovascular morbidity. Rarely, acute hemorrhage may occur in large pituitary tumors, manifested by rapid loss of vision, headache, and evidence of acute pituitary failure (pituitary apoplexy) requiring emergency decompression of the sella.

Treatment

Transsphenoidal removal of pituitary tumors will sometimes reverse hypopituitarism. Postoperative hyponatremia often occurs; serum sodium must be checked frequently for 2 weeks after pituitary surgery. Hypogonadism due to prolactin excess usually resolves during treatment with dopamine agonists. Endocrine substitution therapy must be used before, during, and often permanently after such procedures.

GH-secreting tumors may respond to octreotide (see section on acromegaly). Radiation therapy with x-ray, gamma knife, or heavy particles may be necessary but increases the likelihood of hypopituitarism.

The mainstay of substitution therapy for pituitary insufficiency remains lifetime hormone replacement.

A. Corticosteroids

Give hydrocortisone tablets, 15-30 mg/d orally in divided doses. Most patients do well with 15 mg in the morning and 5-10 mg in the late afternoon. Some patients feel better taking prednisone, 3-7.5 mg/d. A mineralocorticoid is rarely needed. Additional corticosteroids must be given during states of stress, eg, during infection, trauma, or surgical procedures. For mild illness, corticosteroid doses are doubled or tripled. For trauma or surgical stress, hydrocortisone is given in doses of 50 mg intramuscularly or intravenously every 6 hours and then reduced to normal doses as the stress subsides.

Patients with secondary adrenal insufficiency due to treatment with glucocorticoids at supraphysiologic doses require their usual daily dose of glucocorticoid during surgery and acute illness; supplemental hydrocortisone is not usually required.

B. Thyroid

Levothyroxine is given to correct hypothyroidism only after the patient is assessed for cortisol deficiency or is already receiving glucocorticoids. (See Hypothyroidism.) The usual maintenance dose is 0.125 mg daily (range, 0.05-0.3 mg daily).

C. Sex Hormones

Androgen replacement is discussed in the section on male hypogonadism. Estrogen replacement is discussed in the section on female hypogonadism. Women with hypopituitarism and androgen deficiency may be treated with compounded dehydroepiandrosterone (DHEA) in doses of about 30 mg/d orally. DHEA therapy tends to increase pubic and axillary hair and improve libido, alertness, and stamina.

To improve spermatogenesis, chorionic gonadotropin (equivalent to luteinizing hormone) may be given at a dosage of 2000-3000 units intramuscularly three times weekly and testosterone replacement is discontinued. The dose of hCG is adjusted to normalize serum testosterone levels. After 6-12 months of hCG treatment, if the sperm count remains low, hCG injections are continued along with injections of FSH: follitropin beta (synthetic recombinant FSH) or urofollitropins (urine-derived FSH). An alternative for patients with an intact pituitary (eg, Kallmann's syndrome) is the use of leuprolide (GnRH analog) by intermittent subcutaneous infusion. With either treatment, testicular volumes double within 5-12 months, and spermatogenesis occurs in most cases. With the help of intracytoplasmic sperm injection for some cases, the total pregnancy success rate is about 70%. Clomiphene, 25-50 mg orally daily, can sometimes stimulate a man's own pituitary gonadotropins (when his pituitary is intact), thereby increasing testosterone and sperm production.

For fertility induction in females, ovulation may be induced with clomiphene, 50 mg daily for 5 days every 2 months. Follitropins and chorionic gonadotropin can induce multiple births and should be used only by those experienced with their administration. (See [Chapter 17](#).)

D. Human Growth Hormone

hGH (somatotropin) is synthesized by recombinant DNA techniques. Symptomatic adults with severe growth hormone deficiency may be treated with subcutaneous somatotropin injection starting at a dosage of about 0.2 mg (0.6 IU) three times weekly or daily. The dosage of somatotropin is increased every 2-4 weeks by increments of 0.1 mg (0.3 IU) until side effects occur or a sufficient salutary response is achieved. A sustained-release injectable suspension of growth hormone has been developed (somatotropin depot). It can be given once monthly and is therefore more convenient than standard hGH preparations; however, its safety and dosing in adults remain to be established. If the desired effects (eg, improved energy and mentation, reduction in visceral adiposity) are not seen within 3-6 months at maximum tolerated dosage, somatotropin is discontinued.

Growth hormone may be safely administered during pregnancy to women with hypopituitarism at their usual pregestational dose during the first trimester, tapering the dose during the second trimester, and discontinuing growth hormone during the third trimester.

Oral estrogen replacement reduces hepatic IGF-1 production. Therefore, prior to commencing somatotropin therapy, oral estrogen is changed to a transdermal estradiol system.

Side effects of somatotropin therapy may include peripheral edema, hand stiffness, arthralgias, myalgias, headache, pseudotumor cerebri, gynecomastia, carpal tunnel syndrome, tarsal tunnel syndrome, hypertension, and proliferative retinopathy. Side effects are more common in older patients, those with greater weight and higher BMI, and those with adult-onset GH deficiency. Such symptoms usually remit promptly after a sufficient reduction in dosage. Excessive doses of somatotropin could cause acromegaly; patients receiving chronic therapy require careful clinical monitoring. Serum IGF-1 levels may be helpful.

GH levels normally decline with aging. However, available data do not support the use of hGH to reverse normal aging. GH should not be administered during critical illness.

GH therapy appears to benefit some patients with Crohn's disease. It also improves phosphate retention in hypophosphatemic rickets.

E. Other Drugs

Cabergoline, bromocriptine, or quinagolide may reverse the hypogonadism seen in hyperprolactinomas. (See Disorders of Prolactin Secretion.) Intravenous pamidronate may improve bone pain in Langerhans cell histiocytosis.

Prognosis

The prognosis depends on the primary cause. Hypopituitarism resulting from a pituitary tumor may be reversible with dopamine agonists or with careful selective resection of the tumor. Spontaneous recovery from hypopituitarism associated with pituitary stalk enlargement has been reported. Patients can also recover from functional hypopituitarism, eg, hypogonadism due to starvation or severe illness, suppression of ACTH by glucocorticoids, or suppression of TSH by hyperthyroidism.

Functionally, most patients with hypopituitarism do very well with hormone replacement. Men with infertility who are treated with GnRH are likely to resume spermatogenesis if they have a history of sexual maturation, descended testicles, and a baseline serum inhibin level over 60 pg/mL.

DIABETES INSIPIDUS

Essentials of Diagnosis

- Polyuria (2-20 L/d); polydipsia.
- Urine specific gravity usually < 1.006 during ad libitum fluid intake.
- Vasopressin reduces urine output (except in nephrogenic diabetes insipidus).

General Considerations

Diabetes insipidus is an uncommon disease characterized by an increase in thirst and the passage of large quantities of urine of low specific gravity. The urine is otherwise normal. It is caused by a deficiency of or resistance to vasopressin.

The causes may be classified as follows.

A. Deficiency of Vasopressin

Primary diabetes insipidus (without an identifiable organic lesion noted on MRI of the pituitary and hypothalamus) may be familial, occurring as a dominant trait, or sporadic ("idiopathic"). **Secondary diabetes insipidus** is due to damage to the hypothalamus or pituitary stalk by tumor, anoxic encephalopathy, surgical or accidental trauma, infection (eg, encephalitis, tuberculosis, syphilis), sarcoidosis, or multifocal Langerhans cell (eosinophilic) granulomatosis ("histiocytosis X"). Metastases to the pituitary are more likely to cause diabetes insipidus (33%) than are pituitary adenomas (1%).

Vasopressinase-induced diabetes insipidus may be seen in the last trimester of pregnancy and in the puerperium; it is often associated with oligohydramnios, preeclampsia, or hepatic dysfunction. A circulating enzyme destroys native vasopressin; however, synthetic desmopressin is unaffected. The condition usually responds to desmopressin therapy (see below) and subsides spontaneously.

B. "Nephrogenic" Diabetes Insipidus

This disorder is due to a defect in the kidney tubules that interferes with water reabsorption. The polyuria is unresponsive to vasopressin. These patients have normal secretion of vasopressin. Congenital nephrogenic diabetes insipidus is present from birth and is due to defective expression of renal vasopressin V2 receptors or

vasopressin-sensitive water channels. It occurs as a familial X-linked trait; adults often have hyperuricemia as well.

Acquired forms of vasopressin-resistant diabetes insipidus are usually less severe and are seen in pyelonephritis, renal amyloidosis, myeloma, potassium depletion, Sjogren's syndrome, sickle cell anemia, or chronic hypercalcemia. The disorder may occur also as a glucocorticoid effect or as an acute side effect of diuretics. Certain drugs (eg, demeclocycline, lithium, foscarnet, or methicillin) may induce nephrogenic diabetes insipidus. The recovery from acute tubular necrosis may also be associated with transient nephrogenic diabetes insipidus.

Clinical Findings

A. Symptoms and Signs

The symptoms of the disease are intense thirst, especially with a craving for ice water, and polyuria, the volume of ingested fluid varying from 2 L to 20 L daily, with correspondingly large urine volumes. Partial diabetes insipidus presents with less intense symptoms and should be suspected in patients with unremitting enuresis. Diabetes insipidus may present with hypernatremia and dehydration, especially after hypothalamic damage due to shock or anoxia.

B. Laboratory Findings

Evaluation for diabetes insipidus should include a 24-hour urine collection for volume, glucose, and creatinine and serum for glucose, urea nitrogen, calcium, uric acid, potassium, and sodium.

The diagnosis of diabetes insipidus as a cause of polyuria or hypernatremia requires clinical judgment. There is no single diagnostic laboratory test. Hyperuricemia implicates central diabetes insipidus, since reduced stimulation of the renal V1 receptor causes reduced urate clearance.

If the clinical situation implicates central diabetes insipidus (and no other causes for polyuria are present; see Differential Diagnosis, below), a supervised "vasopressin challenge test" may be given: Desmopressin acetate is given in an initial dose of 0.05-0.1 mL (5-10 ug) intranasally (or 1 ug subcutaneously or intravenously), with measurement of urine volume for 12 hours prior to and 12 hours after administration. Serum sodium must be obtained immediately in the event of symptoms of hyponatremia. The dosage of desmopressin is doubled if the response is marginal. Patients with central diabetes insipidus notice a distinct reduction in thirst and polyuria; serum sodium stays normal except in some salt-losing conditions.

When nephrogenic diabetes insipidus is a diagnostic consideration, measurement of serum vasopressin is done during modest fluid restriction; typically, the vasopressin level is high.

In nonfamilial central diabetes insipidus, MRI of the pituitary and hypothalamus and of the skull is done to look for mass lesions. The pituitary stalk may be thickened, which may be a manifestation of Langerhans cell histiocytosis, sarcoidosis, or lymphocytic hypophysitis. Absence of a posterior pituitary "bright spot" on T1-weighted MRI is suggestive of central diabetes insipidus.

Differential Diagnosis of Polyuria

Central diabetes insipidus must be distinguished from polyuria caused by Cushing's syndrome or glucocorticoid treatment, lithium, and the nocturnal polyuria of Parkinson's disease. It must also be distinguished from the excessive fluid intake seen in psychogenic polydipsia, central nervous system sarcoidosis, and intravenous fluid administration.

Central diabetes insipidus is distinguished from diabetes mellitus by checking the urine for glucose. It must also be distinguished from nephrogenic diabetes insipidus (see above).

Complications

If water is not readily available, the excessive output of urine will lead to severe dehydration. Patients with an impaired thirst mechanism are very prone to hypernatremia, particularly since they usually also have impaired mentation and forget to take their desmopressin. All the complications of the primary disease may eventually become evident. In patients who are receiving desmopressin acetate therapy, there is a danger of induced water intoxication.

Treatment

A. Desmopressin

Desmopressin acetate is the treatment of choice for central diabetes insipidus. It is also useful in diabetes insipidus associated with pregnancy or the puerperium, since desmopressin is resistant to degradation by the circulating vasopressinase. It is usually given intranasally (100 ug/mL solution) every 12-24 hours as needed for thirst and polyuria. It may be administered via metered-dose nasal inhaler containing 0.1 mL/spray or via a plastic calibrated tube. Patients are started with 0.05-0.1 mL every 12-24 hours, and the dose is then individualized according to response.

Desmopressin is also available as a parenteral preparation containing 4 ug/mL. For central diabetes insipidus, it is given intravenously, intramuscularly, or subcutaneously in doses of 1-4 ug every 12-24 hours as needed to treat thirst or hypernatremia.

Desmopressin is also available as an oral preparation (0.1- or 0.2-mg tablets) which are given in a starting dose of 0.05 mg twice daily and increased to a maximum of 0.4 mg every 8 hours, if required. Oral desmopressin is particularly useful for patients with sinusitis from the nasal preparation. Mild increases in hepatic enzymes are common, so the drug is not given to patients with liver disease. Gastrointestinal symptoms and asthenia may occur.

Adverse reactions to desmopressin have included nasal irritation, occasional agitation, and erythromelalgia. Hyponatremia is uncommon if minimum effective doses are used and the patient allows thirst to occur periodically.

B. Other Measures

Mild cases require no treatment other than adequate fluid intake. Reduction of aggravating factors (eg, glucocorticoids, which directly increase renal free water clearance) will improve polyuria. Both central and nephrogenic diabetes insipidus respond partially to hydrochlorothiazide, 50-100 mg/d (with potassium supplement or amiloride). Nephrogenic diabetes insipidus may respond to combined treatments of indomethacin-hydrochlorothiazide, indomethacin-desmopressin, or indomethacin-amiloride. Indomethacin, 50 mg every 8 hours, is effective acutely.

Psychotherapy is required for most patients with compulsive water drinking. Thioridazine and lithium are best avoided if drug therapy is needed, since they cause polyuria.

Prognosis

Central diabetes insipidus appearing after pituitary surgery usually remits after days to weeks but may be permanent if the upper pituitary stalk is cut.

Central diabetes insipidus is made transiently worse by glucocorticoids in the high doses frequently given perioperatively.

Chronic diabetes insipidus is more an inconvenience than a dire medical condition. Treatment with desmopressin allows normal sleep and activity. Hypernatremia can occur, especially when the thirst center is damaged, but diabetes insipidus itself does not reduce life expectancy, and the prognosis is that of the underlying disorder.

ACROMEGALY & GIGANTISM

Essentials of Diagnosis

- Excessive growth of hands (increased glove and ring size), feet (increased shoe width), jaw (protrusion of lower jaw), and internal organs; or gigantism before closure of epiphyses.
- Coarsening facial features; deeper voice.
- Amenorrhea, headaches, visual field loss, sweating, weakness.
- Soft, doughy, sweaty handshake.

- Serum GH not suppressed following oral glucose.
- Elevated insulin-like growth factor 1 (IGF-1).
- Imaging: Terminal phalangeal "tufting" on radiographs. CT or MRI demonstration of pituitary tumor in 90%.

General Considerations

Growth hormone exerts much of its growth-promoting effects through the release of IGF-1 produced in the liver and other tissues.

Acromegaly is nearly always caused by a pituitary adenoma. These tumors may be locally invasive, particularly into the cavernous sinus. Fewer than 1% are malignant. Most are macroadenomas (over 1 cm in diameter). Acromegaly is usually sporadic but may rarely be familial. The disease may be associated with endocrine tumors of the parathyroids or pancreas (multiple endocrine neoplasia type 1). Acromegaly may also be seen in McCune-Albright syndrome and as part of Carney's complex (atrial myxoma, acoustic neuroma, and spotty skin pigmentation). Acromegaly is rarely caused by ectopic GHRH or GH secreted by a lymphoma, hypothalamic tumor, bronchial carcinoid, or pancreatic tumor.

Clinical Findings

A. Symptoms and Signs

Excessive growth hormone causes tall stature and gigantism if it occurs before closure of epiphyses. Afterward, acromegaly develops. The term "acromegaly," meaning extremity enlargement, seriously understates the manifestations. The hands enlarge and a doughy, moist handshake is characteristic. The fingers widen, causing patients to enlarge their rings. Carpal tunnel syndrome is common. The feet also grow, particularly in width. Facial features coarsen since the bones and sinuses of the skull enlarge; hat size increases. The mandible becomes more prominent, causing prognathism and malocclusion. Tooth spacing widens.

Macroglossia occurs, as does hypertrophy of pharyngeal and laryngeal tissue; this causes a deep, coarse voice and sometimes makes intubation difficult. Obstructive sleep apnea may occur. A goiter may be noted. Hypertension (50%) and cardiomegaly are common. At diagnosis, about 10% of acromegalic patients have overt heart failure, with a dilated left ventricle and a reduced ejection fraction. Weight gain is typical, particularly of muscle and bone. Insulin resistance is usually present and frequently causes diabetes mellitus (30%). Arthralgias and degenerative arthritis occur. Overgrowth of vertebral bone can cause spinal stenosis. Colon polyps are common, especially in patients with skin papillomas. The skin may also manifest hyperhidrosis, thickening, cystic acne, and areas of acanthosis nigricans.

GH-secreting pituitary tumors usually cause some degree of hypogonadism, either by cosecretion of prolactin or by direct pressure upon normal pituitary tissue. Decreased libido and impotence are common, as are irregular menses or amenorrhea. Secondary hypothyroidism sometimes occurs; hypoadrenalism is unusual. Headaches are frequent. Temporal hemianopia may occur as a result of the optic chiasm being impinged by a suprasellar growth of the tumor.

B. Laboratory Findings

After an overnight fast, a fasting serum specimen is obtained and assayed for prolactin (cosecreted by many GH-secreting tumors), IGF-1 (increased to over five times normal in most acromegalics), glucose (diabetes is common in acromegaly), liver enzymes and BUN, serum inorganic phosphorus (frequently elevated), serum free thyroxine, and TSH (secondary hypothyroidism is common in acromegaly; primary hypothyroidism may increase prolactin, and hyperthyroidism may occur as a result of excess TSH). Serum calcium is determined to screen for hyperparathyroidism.

Glucose syrup (75 g) is then administered orally, and serum GH is measured 60 minutes afterward; acromegaly is excluded if the serum GH is less than 1 ug/L (IRMA or chemiluminescent assays) or less than 2 ug/L (older radioimmunoassays) after glucose syrup, and if the IGF-1 is normal.

C. Imaging

MRI shows a pituitary tumor in 90% of acromegalics. MRI is generally superior to CT scanning, especially in the postoperative setting. X-rays of the skull may show an enlarged sella and thickened skull. X-rays may also show tufting of the terminal phalanges of the fingers and toes. A lateral view of the foot shows increased thickness of the heel pad.

Differential Diagnosis

Active acromegaly must be distinguished from familial coarse features, large hands and feet, and isolated prognathism and from inactive ("burned-out") acromegaly in which there has been a spontaneous remission due to infarction of the pituitary adenoma. GH-induced gigantism must be differentiated from familial tall stature and from aromatase deficiency. (See Osteoporosis.)

Misleadingly high serum GH levels can be caused by exercise or eating just prior to the test, acute illness or agitation, hepatic or renal failure, malnourishment, diabetes mellitus, or concurrent treatment with estrogens, beta-blockers, or clonidine.

Complications

Complications include hypopituitarism, hypertension, glucose intolerance or frank diabetes mellitus, cardiac enlargement, and cardiac failure. Carpal tunnel syndrome may cause thumb weakness and thenar atrophy. Arthritis of hips, knees, and spine can be troublesome. Cord compression may be seen. Visual field defects may be severe and progressive. Acute loss of vision or cranial nerve palsy may occur if the tumor undergoes spontaneous hemorrhage and necrosis (pituitary apoplexy).

Treatment

Endoscopic transnasal, transsphenoidal pituitary microsurgery removes the adenoma while preserving anterior pituitary function in most patients. Surgical remission is achieved in about 70% of patients followed over 3 years. Growth hormone levels fall immediately; diaphoresis and carpal tunnel syndrome often improve within a day after surgery. Transsphenoidal surgery is usually well tolerated, but complications occur in about 10%, including infection, cerebrospinal fluid leak, and hypopituitarism. Hyponatremia can occur 4-13 days postoperatively and is manifested by nausea, vomiting, headache, malaise, or seizure. Dietary salt supplements for 2 weeks postoperatively may prevent this complication.

Patients who fail to have a clinical or biochemical remission after surgery are treated with a dopamine agonist. This treatment is most successful for tumors that secrete both PRL and GH. About one-third of such tumors shrink by more than 50% with cabergoline given in dosages of 1-1.75 mg/wk orally.

Somatostatin analogs may be used to treat patients who have persistent acromegaly despite pituitary surgery. Octreotide and lanreotide are somatostatin analogs that are given by subcutaneous injection. Short-acting octreotide acetate in doses of 50 ug is injected subcutaneously three times daily. Responders who tolerate the drug are switched to long-acting octreotide acetate injectable suspension in a dosage of 20 mg intragluteally per month. The dosage may be adjusted—up to a maximum of 40 mL monthly—to maintain the serum GH between 1 and 2.5 ng/mL, keeping IGF-1 levels normal. Lanreotide SR (not available in United States) is given by subcutaneous injection at a dosage of 30 mg every 7-14 days. Lanreotide Autogel (not available in United States) is a newer formulation that is administered by deep subcutaneous injection in doses of 60-120 mg every 28 days; this preparation is better-tolerated than lanreotide SR. All somatostatin analogs are expensive and must be continued indefinitely or until other treatment has been effective. Octreotide long-acting release preparations (Sandostatin LAR depot) are superior to shorter-acting octreotide, ultimately achieving serum GH levels under 2 ug/L in 79% and normal serum IGF-I levels in 53%. Headaches often improve, and tumor shrinkage of about 30% may be expected. Acromegalic patients with pretreatment serum GH levels exceeding 20 ug/L are less likely to respond to octreotide therapy. Side effects are experienced by about one-third of patients and include injection site pain, loose acholic stools, abdominal discomfort, or cholelithiasis.

Pegvisomant (not available in United States) is a GH receptor antagonist. A series of 160 acromegalic patients were treated with pegvisomant 20 mg subcutaneously daily for 6-18 months. Serum IGF-1 levels fell to normal in over 90% of patients. Pegvisomant was well tolerated. GH levels rose, but only two patients were noted to have progressive growth of their pituitary tumors.

Pituitary irradiation is suggested for patients who are not cured by surgical and medical therapy. Stereotactic radiosurgery is the preferred modality.

Prognosis

Patients with acromegaly who are treated and have a glucose-suppressed serum GH level under 2.5 ug/L (radioimmunoassay) or under 1 ug/L (immunofluorometric assay) have reduced morbidity and mortality. Patients with untreated or persistent acromegaly tend to have premature cardiovascular disease and progressive acromegalic symptoms. Transsphenoidal pituitary surgery is successful in 80-90% of patients with tumors less than 2 cm in diameter and GH levels less than 50 ng/mL. Postoperatively, normal pituitary function is usually preserved. Soft tissue swelling regresses but bone enlargement is permanent. Hypertension frequently persists despite successful surgery. Conventional radiation therapy (alone) produces a remission in about 40% by 2 years and 75% by 5 years after treatment. Gamma knife radiation reduces GH levels an average of 77%, with 20% having a full remission after 12 months. Heavy particle pituitary radiation produces a remission in about 70% by 2 years and 80% by 5 years. Radiation therapy eventually produces some degree of hypopituitarism in most patients. Conventional radiation therapy may cause some degree of organic brain syndrome and predisposes to small strokes. Growth hormone levels over 5 ng/mL and rising usually indicate a recurrent tumor.

HYPERPROLACTINEMIA

Essentials of Diagnosis

- Women: Menstrual cycle disturbances (oligomenorrhea, amenorrhea); galactorrhea; infertility.
- Men: Hypogonadism; decreased libido and erectile dysfunction; infertility.
- Elevated serum prolactin.
- CT scan or MRI often demonstrates pituitary adenoma.

Normal Physiology

Prolactin's main role is to induce lactation. Serum prolactin levels increase during pregnancy from a normal (follicular phase) level of less than 20 ng/mL to as high as 600 ng/mL by the time of delivery. Under the combined effect of prolactin, increased estrogen, and progesterone, breast development takes place, with eventual formation of milk in the acini. Estrogens inhibit the actual secretion of milk. After parturition, the sudden withdrawal of estrogen caused by expulsion of the placenta results in the onset of lactation. During the puerperal period, suckling constitutes a powerful stimulus for the continued production of prolactin as well as oxytocin. Lactation will cease if prolactin secretion is interrupted by prolactin-lowering drugs or by pituitary destruction. Prolactin is an unusual hormone in terms of control of secretion in that it is under mainly inhibitory control. Thus, section of the pituitary stalk will result in marked increases in prolactin secretion. Prolactin inhibitory factor (PIF) is dopamine.

Prolactin circulates in different forms. Normally, the predominant form is "little prolactin" (molecular mass 23 kDa), with lesser amounts of "big prolactin" (50-60 kDa) and even lesser amounts of "macroprolactin" (150-170 kDa). Macroprolactin is relatively inactive but has a long serum half-life. Some individuals have normal pituitaries that preferentially secrete more macroprolactin; they account for about 10% of patients determined to have hyperprolactinemia. Elevated serum prolactin can be caused by numerous conditions ([Table 26-4](#)).

General Considerations

Prolactin-secreting pituitary tumors are more common in women than in men and are usually sporadic but may rarely be familial as part of multiple endocrine neoplasia (MEN 1). Most are microadenomas (< 1 cm in diameter) which do not grow even with pregnancy or oral contraceptives. However, some giant prolactinomas can spread into the cavernous sinuses and suprasellar areas; rarely, they may erode the floor of the sella to invade the sinuses.

Clinical Findings

A. Symptoms and Signs

Hyperprolactinemia due to any cause may result in hypogonadotropic hypogonadism. Men usually have erectile dysfunction and diminished libido; gynecomastia sometimes occurs, but never with galactorrhea. Women may note oligomenorrhea or amenorrhea, though some women continue to menstruate normally; galactorrhea is common. Of women with secondary amenorrhea and galactorrhea, about 70% have hyperprolactinemia. Untreated hypogonadism ultimately increases the risk for developing osteoporosis.

Pituitary prolactinomas may cosecrete growth hormone and cause acromegaly (see above). Large tumors may cause headaches, visual symptoms, and pituitary insufficiency.

B. Laboratory Findings

Patients found to have hyperprolactinemia are evaluated for conditions known to cause it, particularly pregnancy (serum hCG), hypothyroidism (serum free thyroxine and TSH), renal failure (BUN and serum creatinine), and cirrhosis (clinical evaluation and serum bilirubin and liver enzymes). A serum calcium is obtained to screen for hyperparathyroidism. Patients are assessed for hypogonadism. An assay for macroprolactinemia should be considered for patients with hyperprolactinemia who are relatively asymptomatic and have no apparent cause for hyperprolactinemia. Screening for macroprolactinemia may be done with gel filtration chromatography or polyethylene glycol gel precipitation. Patients having pituitary macroadenomas (> 3 cm in diameter) should have prolactin measured on serial dilutions of serum, since IRMA assays may otherwise report falsely low titers, the "high-dose hook effect."

C. Imaging

When hyperprolactinemia persists without obvious cause, MRI of the pituitary and hypothalamus is indicated. Small prolactinomas may thus be demonstrated, but clear differentiation from normal variants is not always possible.

Differential Diagnosis

The differential diagnosis of prolactinoma should include acromegaly, since pituitary tumors often cosecrete prolactin and growth hormone. However, the most common causes of hyperprolactinemia are pregnancy and suckling. High prolactin levels are also commonly seen in conditions such as hypothyroidism, cirrhosis, renal failure, systemic lupus erythematosus, and hypothalamic disease. Chronic nipple stimulation, nipple piercing, augmentation mammoplasty, and mastectomy may stimulate prolactin secretion. Hyperprolactinemia may also be idiopathic. About 10% of hyperprolactinemic patients are found to be secreting macroprolactin, a relatively inactive "big prolactin"; pituitary MRI is normal in 78% of cases. Many drugs cause hyperprolactinemia, particularly psychotropic agents, cimetidine, tricyclic antidepressants, and oral contraceptives. (See [Table 26-4](#).) Increased pituitary size is a normal variant in young women.

Treatment

Medications known to increase prolactin should be stopped if possible. Hyperprolactinemia due to hypothyroidism is corrected by thyroxine. Patients with hyperprolactinemia not induced by drugs, hypothyroidism, or pregnancy should be examined by pituitary MRI. Women with microprolactinomas who have amenorrhea or are desirous of contraception may safely take oral contraceptives or estrogen replacement—there is minimal risk of stimulating enlargement of the adenoma. Since estrogens or testosterone treatment can stimulate the growth of macroprolactinomas, they should not be used by patients with large pituitary adenomas unless in full remission with dopamine agonist medication or surgery.

A. Dopamine Agonists

Dopamine agonists are the initial treatment of choice for patients with giant prolactinomas and those with hyperprolactinemia desiring restoration of normal sexual function and fertility. Of the ergot-derived dopamine agonists, cabergoline is usually the best-tolerated and is prescribed beginning with a dosage of 0.25 mg orally once weekly for 1 week, then 0.25 mg twice weekly for the next week, then 0.5 mg twice weekly. Further dosage increases may be required monthly, based upon serum prolactin levels, up to a maximum of 1.5 mg twice weekly. Alternative drugs include bromocriptine (1.25-20 mg/d orally) and pergolide (0.125-2 mg/d orally). Women who experience nausea with oral preparations may find relief with deep vaginal insertion of cabergoline or bromocriptine tablets; vaginal irritation sometimes occurs. Quinagolide (Norprolac; not available in United States) is a non-ergot-derived dopamine agonist for patients intolerant or resistant to ergot-derived medications; the starting dosage is 0.075 mg/d orally, increasing as needed and tolerated to a maximum of 0.6 mg/d.

Dopamine agonists are given at bedtime to minimize side effects of fatigue, nausea, dizziness, and orthostatic hypotension. These symptoms usually improve with dosage reduction and continued use. Erythromelalgia is rare. A variety of psychiatric side effects may be seen which are not dose-related and may take weeks to resolve once the dopamine agonist is discontinued.

With dopamine agonist treatment, 90% of patients with prolactinomas experience a fall in serum prolactin to 10% or less of pretreatment levels; about 80% of treated

patients achieve a normal serum prolactin level. Shrinkage of a pituitary adenoma occurs early, but maximum effect may take up to a year. Nearly half—even massive tumors—shrink more than 50%. Such shrinkage of giant prolactinomas can result in spinal fluid rhinorrhea. Discontinuing therapy after months or years usually results in reappearance of hyperprolactinemia and galactorrhea-amenorrhea, but a few patients with microadenomas remain in remission. Since fertility is usually promptly restored with dopamine agonists, many pregnancies have resulted, with no evidence of teratogenicity. Women with microadenomas may have treatment safely withdrawn during pregnancy. Macroadenomas may enlarge significantly during pregnancy; if therapy is withdrawn, patients must be followed clinically and with computer-assisted visual field perimetry.

B. Surgical Treatment

For most patients with prolactinomas, therapy with dopamine agonists is overwhelmingly preferable to surgery, particularly for giant prolactinomas that distort surgical fields. Transsphenoidal pituitary surgery may be urgently required for large tumors undergoing apoplexy or those severely compromising visual fields. It is also used electively for patients who do not tolerate or respond to dopamine agonists. Craniotomy is rarely indicated, since even large tumors can usually be decompressed via the transsphenoidal approach.

C. Radiation Therapy

Radiation therapy is reserved for patients with macroadenomas that are growing despite treatment with dopamine agonists. Conventional radiation therapy is most commonly used, but it must be given over 5 weeks and carries a high risk of eventual hypopituitarism. Other possible side effects include some degree of memory impairment and an increased long-term risk of second tumors and small vessel ischemic strokes. After radiation therapy, patients are advised to take low-dose aspirin to reduce their stroke risk. A single gamma knife treatment may be preferable for certain patients whose optic chiasm is clear of tumor, since it is generally safer and more convenient.

■ DISEASES OF THE THYROID GLAND

An adult's thyroid gland normally weighs about 15-20 g. Embryologic defects may result in a rare lingual thyroid, retrosternal thyroid, or agenesis of one or both lobes.

Thyroid-stimulating hormone (TSH, thyrotropin) is secreted by the pituitary and stimulates several steps of thyroid hormone production: trapping of iodine, peroxidase linking of iodine to tyrosine, coupling of monoiodotyrosine or diiodotyrosine to form T₃ (triiodothyronine) or T₄ (thyroxine), and release of T₃ and T₄. The thyroid secretes mostly T₄ and very little T₃. About 90% of circulating T₃, the most active thyroid hormone, is derived from peripheral deiodination of T₄. Circulating thyroid hormones have a direct feedback inhibition effect upon the pituitary thyrotroph cells, desensitizing them from the stimulatory effect of hypothalamic thyrotropin-releasing hormone (TRH).

Over 99% of circulating thyroid hormones are bound to serum proteins, mostly thyroid-binding globulin (TBG). Only free hormone enters cells, binding to nuclear hormone receptors, which regulate DNA control of oxidative processes throughout the body.

The thyroid tests discussed in the following section are ordinarily very helpful in the evaluation of thyroid disorders. However, many conditions and drugs alter serum thyroxine levels without affecting clinical status ([Table 26-5](#)). Furthermore, a serum thyroxine determination is not sufficiently sensitive to detect mild degrees of hypo- or hyperthyroidism. Therefore, other tests may be used, but all are imperfect.

TESTS OF THYROID FUNCTION (TABLE 26-6)

The tests most widely used in clinical practice are serum immunoassays for TSH and "free" thyroxine (FT₄). Assays for FT₄ have largely supplanted measurements of total thyroxine (T₄), resin T₃ uptake (RT₃U), and free thyroxine index (FT₄I).

1. Serum Thyroid Tests

Thyroid-Stimulating Hormone (TSH) Immunoassay

TSH levels as low as 0.01 mU/L can be detected by ultrasensitive "third-generation" assays. In order to diagnose hyperthyroidism, an assay sensitive to at least 0.1 mU/L (sensitive "second-generation" assay) should be employed. Owing to discrepancies between different TSH assay methods, it is prudent to recheck unexpected results with a different assay.

TSH levels are **decreased** in patients with primary hyperthyroidism (eg, Graves' disease, toxic multinodular goiter, toxic nodule, subacute thyroiditis, or release of stored hormone in Hashimoto's thyroiditis). TSH levels may also be suppressed in some clinically euthyroid individuals with autonomous thyroid secretion (eg, euthyroid Graves' ophthalmopathy). TSH can also be suppressed by thyroid hormone administration in either excessive or adequate replacement amounts. TSH is also frequently low during severe nonthyroidal illness; distinction from hypopituitarism can usually be made clinically.

Dopamine and dopamine agonists (levodopa, bromocriptine) can cause suppression of TSH and may cause true secondary hypothyroidism during prolonged administration. Other conditions associated with decreased TSH include pregnancy (especially with morning sickness), hCG-secreting trophoblastic tumors, acute psychiatric illness (1% incidence), and acute administration of glucocorticoids. Certain drugs cause mild suppression of TSH without clinical hyperthyroidism; these include nonsteroidal anti-inflammatory agents, amphetamine, octreotide, opioids, and certain calcium channel blockers (especially nifedipine; also verapamil, but not diltiazem).

In clinically euthyroid persons age 60 or older, the TSH is very low (= 0.1 mU/L) in 3% and mildly low (0.1-0.4 mU/L) in 9%. The chance of developing atrial fibrillation is higher with very low TSH (2.8% yearly) than with normal TSH (1.1% yearly). Asymptomatic patients with very low TSH are followed closely but not treated unless they develop atrial fibrillation or other manifestations of hyperthyroidism.

TSH levels are **elevated** in primary hypothyroidism, either clinical or subclinical. TSH may also be elevated or inappropriately normal in the very rare cases of hyperthyroidism due to pituitary neoplastic or nonneoplastic inappropriate secretion of thyrotropin. Autoimmune disease may also falsely elevate serum TSH levels by interfering with the assay. TSH may be transiently elevated during recovery from nonthyroidal illness and in about 14% of patients with acute psychiatric admissions; the TSH returns to normal in the great majority of these patients. TSH may be increased by dopamine antagonists (eg, metoclopramide), phenothiazines, and atypical antipsychotics. TSH may be mildly elevated in some individuals, especially elderly women (10% incidence). Such patients with normal T₄ levels must be carefully evaluated for subtle signs of hypothyroidism (eg, fatigue, depression, hyperlipidemia). About 18% later become definitely hypothyroid.

Free Thyroxine Immunoassay (FT₄)

FT₄ is a direct measurement of the serum concentration of free (unbound) thyroxine. FT₄ represents only about 0.025% of the serum concentration of the total T₄. It is the only metabolically active fraction of T₄ that freely enters cells to produce its effects.

When performed properly, this assay is superior to the total T₄ assay and free thyroxine index, since it is not affected by variations in protein binding. It is the procedure of choice for following the thyroid's changing secretion of T₄ during treatment for hyperthyroidism. Serum FT₄ levels may be suppressed in patients with severe nonthyroid illness. In patients receiving heparin, measured levels of FT₄ may be falsely high, particularly when a dialysis assay is used. Serum FT₄ levels rise transiently in acute nonthyroidal illness, when thyroid-binding protein frequently falls.

T₄ Immunoassay

This test measures the total serum concentration of thyroxine (bound and free). An increased serum T₄ confirms a clinical diagnosis of hyperthyroidism, while a decreased serum T₄ confirms a clinical diagnosis of hypothyroidism. It is affected by altered states of thyroxine binding (see [Table 26-5](#)). Therefore, this test is usually run with a resin T₃ uptake to provide a free thyroxine index (see below).

Resin T₃ (or T₄) Uptake

This is an indirect inverse test of serum thyroid-binding proteins (TBP)—ie, it is high when thyroid-binding proteins are low. The assay involves adding labeled T_3 or T_4 to the serum sample; it competes with the patient's thyroxine for binding to TBP. This mixture is then added to a thyroid hormone-binding resin. The resin is then assayed for its uptake of the label. A high resin uptake indicates that the patient's serum contains relatively low amounts of TBP or high levels of thyroxine.

This test corrects a total serum thyroxine measurement for the effect of increased or decreased binding, creating a free thyroxine index (see below). A low resin uptake (high TBP) is seen with estrogen therapy, pregnancy, acute hepatitis, genetic TBP increase, and hypothyroidism. A low resin uptake with low TBP may be seen in severe illness. A high resin uptake (low TBP) is seen with hyperthyroidism and with chronic liver disease, nephrotic syndrome, anabolic steroid administration, and high-dose glucocorticoid administration.

Free Thyroxine Index (FTI)

The product of T_4 and resin T_3 uptake ($T_4 \times T_3$ uptake) helps correct for abnormalities of thyroxine binding. A good free T_4 assay is more accurate.

The FTI, when calculated using the RT_3U , may be elevated in euthyroid patients with familial dysalbuminemic hyperthyroxinemia. This is a benign autosomal dominant trait in which an abnormal albumin molecule binds T_4 with much greater affinity than T_3 . The RT_3U is not decreased (failing to compensate for the increased binding, as it would for TBG excess), because the T_3 used in the RT_3U assay is not significantly affected. Serum levels of free thyroxine and TSH are normal.

T_3

This test is of value in the diagnosis of thyrotoxicosis with normal T_4 values (T_3 thyrotoxicosis). It is not useful for the diagnosis of hypothyroidism.

Free T_3

This test measures the very tiny amount of T_3 that circulates unbound. It is useful in looking for hyperthyroidism in women who are pregnant or taking oral estrogen.

2. Thyroid Radioactive Iodine Uptake & Scan

Radioiodine (^{123}I or ^{131}I) Uptake of Thyroid Gland

A. Elevated

Graves' disease, dietary iodine deficiency, toxic nodular goiter, pregnancy, early Hashimoto's thyroiditis, some thyroid enzyme deficiencies, nephrotic syndrome, recovery from subacute thyroiditis, and recovery from thyroid hormone suppression.

B. Low

Administration of iodides or iodine in any form (drugs, radiology contrast dyes, etc), antithyroid drugs, subacute thyroiditis, thyroid hormone administration, thyroid gland damage (from thyroiditis, surgery, or radioiodine), hypopituitarism, ectopic functioning thyroid tissue, azotemia, severe (high-turnover) Graves' disease, heart failure, and some thyroid enzyme abnormalities.

Radioiodine (RAI) Scans

A rectilinear scan over the neck may be obtained after radioiodine administration, thereby obtaining a life-sized picture of thyroid uptake. RAI scans are useful also for detecting metastatic thyroid cancer. (See Thyroid Cancer.) Following administration of a treatment dose of ^{131}I for thyroid cancer, a whole body scan is useful for detecting metastases.

3. Other Thyroid Tests

Thyroid Antibodies

Antibodies against several thyroid constituents (thyroglobulin and thyroperoxidase) are most commonly found in Hashimoto's thyroiditis and Graves' disease. Antithyroid antibodies are found in about 5-10% of normal subjects. There is an increasing incidence with age. About 20% of hospitalized patients have detectable antithyroid antibodies. In the latter, the titers tend to be low, and they increase with age. TSH receptor antibody (TSH-R Ab [stim]) titers are elevated in approximately 80% of patients with Graves' disease. These titers—and those of antithyroglobulin and antithyroperoxidase antibodies—often decrease during pregnancy and during treatment of Graves' disease with antithyroid drugs. TSH-R Ab [stim] titers have been used with variable results to predict the rate of relapse of Graves' disease after chronic thiourea therapy.

Serum Thyroglobulin

The level of serum thyroglobulin rises in autoimmune thyroid disease, thyroid injury or inflammation, and thyroid cancer. Levels are of little value in diagnosing or distinguishing among these conditions, but they provide a useful marker in thyroid cancer to indicate recurrence of disease and the need for further studies and therapy. Serum thyroglobulin is to be distinguished from serum thyroid-binding globulin (see above).

Calcitonin Assay

This test is elevated in medullary thyroid carcinoma, azotemia, hypercalcemia, pernicious anemia, thyroiditis, and pregnancy. High levels are also seen in many other malignancies such as carcinomas of the lung (45%), pancreas, breast (38%), and colon (24%).

Ultrasound

Ultrasound may be used to guide fine-needle aspiration biopsy of clinically suspicious thyroid nodules and nodes. In patients with established thyroid malignancy, ultrasound of the neck is useful for surveillance, localization, and quantitation of residual or recurrent tumor. Small nonpalpable nodules are detected in half of "normal" thyroids and are rarely malignant.

Fine-Needle Thyroid Biopsy

Aspiration of thyroid tissue with a fine needle (25-gauge) is helpful in the diagnosis of thyroid disorders, especially nodular lesions. This technique has become the preferred approach to the diagnosis of thyroid masses. (See Nodular Thyroid.)

4. Effect of Nonthyroidal Illness & Drugs on Thyroid Function Tests

Many factors affect thyroid function tests, causing misleading laboratory evidence of hypothyroidism or hyperthyroidism in patients who are clinically euthyroid. (See [Table 26-5](#).)

Serum thyroxine is frequently low in patients with severe illness, caloric deprivation, or major surgery who have accelerated peripheral metabolism of serum T_4 to reverse T_3 (rT_3). Furthermore, in most patients who are critically ill, there is a circulating inhibitor of thyroid hormone binding to serum thyroid-binding proteins. This causes the resin uptake of thyroid hormone (RT_3U) to be misleadingly low, causing the computed free thyroxine index to be very low. The presence of a very low serum T_4 in severe nonthyroidal illness indicates a poor prognosis.

Direct assays of free thyroxine often show low levels of FT_4 in severe illness. Since studies of giving replacement thyroxine to such patients have shown no improvement in survival, they are considered "euthyroid." Serum TSH tends to be suppressed in severe nonthyroidal illness, making the diagnosis of concurrent primary hypothyroidism quite difficult, although the presence of a goiter suggests the diagnosis.

The clinician must decide whether such severely ill patients (with a low serum T_4 but nonelevated TSH) might have hypothyroidism due to pituitary insufficiency. Patients without symptoms of prior brain lesion or hypopituitarism are very unlikely to suddenly develop hypopituitarism during an unrelated illness. Patients with diabetes insipidus, hypopituitarism, or other signs of a central nervous system lesion may have thyroxine given empirically. Patients receiving prolonged dopamine infusions may develop true secondary hypothyroidism due to direct dopamine suppression of TSH-secreting cells.

Certain antiseizure medications cause low serum free T₄ levels by accelerating hepatic conversion of T₄ to T₃; serum TSH levels are normal.

THYROID NODULES & MULTINODULAR GOITER

Essentials of Diagnosis

- Single or multiple thyroid nodules are commonly found with careful thyroid examinations.
- Thyroid function tests mandatory.
- Thyroid biopsy for single or dominant nodules or for a history of prior head-neck radiation.
- Ultrasound examination sometimes useful for biopsy and follow-up.
- Clinical follow-up required.

General Considerations

Palpable enlargement of the thyroid (goiter) may be diffuse or nodular and is detectable in 4% of North American adults. The incidence of goiter is higher in iodine-deficient geographic areas (see Endemic Goiter, below). The presence of a goiter warrants further testing and follow-up. Most patients with goiter are euthyroid, but there is a high incidence of hypothyroidism or hyperthyroidism. Diffuse and multinodular goiters are ordinarily benign and may be caused by numerous conditions, eg, benign multinodular goiter, iodine deficiency, pregnancy (in areas of iodine deficiency), Graves' disease, Hashimoto's thyroiditis, subacute thyroiditis, or infections. A solitary thyroid nodule is most often a benign adenoma, colloid nodule, or cyst but may sometimes be a primary thyroid malignancy or (less frequently) a metastatic neoplasm. The risk of a palpable nodule being malignant is higher among patients with a history of head-neck radiation, a family history of thyroid cancer, or a personal history of another malignancy. The risk of malignancy is higher if a thyroid nodule is large, adherent to the trachea or strap muscles, or associated with lymphadenopathy.

The thyroid is best examined in a well-lighted room. The seated patient is given water to drink and the anterior neck is observed during swallowing. The thyroid moves upward during swallowing and may be visible in a thin neck; enlargement or asymmetry of the thyroid may be noted. Palpation of the thyroid is best done from behind a seated patient using the second and third fingers of both hands. As the patient swallows water, thyroid nodules may be perceived moving beneath the fingers. The location of any nodules should be noted, along with their size, firmness, and tenderness. The neck should be examined for lymphadenopathy. Enlarged thyroids should be auscultated for bruits.

Clinical Evaluation (Table 26-7)

A. Symptoms and Signs

Most small thyroid nodules are asymptomatic and are discovered incidentally on routine neck inspection or palpation; some are discovered as an incidental finding during radiological imaging of the neck. Graves' disease, toxic multinodular goiter, hyperfunctioning nodules, and subacute thyroiditis can cause hyperthyroidism. Hashimoto's thyroiditis may cause goiter and hypothyroidism.

A thyroid nodule or multinodular goiter can grow to become visible and of concern to the patient. Particularly large nodular goiters can become a cosmetic embarrassment. Nodules can grow large enough to cause discomfort, hoarseness, or dysphagia. Retrosternal large multinodular goiters can cause dyspnea due to tracheal compression. Large substernal goiters may cause superior vena cava syndrome, manifested by facial erythema and jugular vein distention that progress to cyanosis and facial edema when both arms are kept raised over the head (Pemberton's sign).

B. Laboratory Findings

Thyroid nodules are an indication for thyroid function testing. Serum determinations for TSH (sensitive assay) and free thyroxine (FT₄) are preferred. Tests for antithyroperoxidase antibodies and antithyroglobulin antibodies may also be helpful. Very high antibody levels are found in Hashimoto's thyroiditis. However, thyroiditis frequently coexists with malignancy, so a suspicious nodule should be biopsied.

Fine-needle aspiration (FNA) biopsy is the best way to assess a nodule for malignancy. A 25-gauge needle is used to biopsy suspicious nodules. The needle is attached to a syringe and special syringe holder. The biopsy is done without local anesthesia. The success rate of FNA biopsy is increased by ultrasound guidance. Care must be taken to avoid bloody dilution of the specimens. Material obtained is placed on a slide; a thin smear is obtained by laying a second slide over the material and then drawing the slides apart. One slide is air-dried while the other is preserved in 95% alcohol. Two or more biopsies may be obtained. Reading by an experienced cytopathologist is mandatory.

In one review of thyroid biopsies, about 70% were benign, 10% follicular neoplasm (suspicious), 5% malignant, and 15% nondiagnostic. About 20-40% of patients with "suspicious" cytology harbor a malignancy, with the risk being higher in young patients and those with nodules that are fixed or over 3 cm in diameter. Most such patients undergo thyroid surgery. However, a subgroup of elderly patients with "suspicious" cytology (nodules < 4 cm in diameter) have a malignancy rate of just 5%; such patients may elect to be followed every 6 months with palpation and ultrasound.

Cystic nodules yielding serous fluid are usually benign, but fluid should be submitted for cytology. Cystic nodules yielding bloody fluid have a higher chance of being malignant. Repeat FNA biopsy is done if the cytology is nondiagnostic (eg, diluted with blood or hypocellular) and the lesion remains palpable.

C. Imaging Studies

Neck ultrasound should be performed on most patients with thyroid nodules, since it frequently adds important information. Ultrasound is more accurate than palpation in measuring the size of a nodule and can help determine whether a palpable nodule is part of a multinodular goiter, thus having less chance of being malignant. Ultrasound is also helpful in following thyroid nodules. The following ultrasound characteristics of thyroid nodules increase the likelihood of malignancy: irregular margins, intranodular vascular spots, or microcalcifications. FNA biopsy is performed on such nodules—even if they are nonpalpable—if they are over 8 mm in diameter. Ultrasound-guided fine-needle aspiration biopsy is helpful in obtaining representative and adequate specimens, especially from complex thyroid nodules. Ultrasonography is generally preferred over CT and MRI because of its accuracy, ease of use, and lower cost.

Radioactive iodine (RAI; ¹²³I or ¹³¹I) scans have limited utility in the evaluation of thyroid nodules. Hypofunctioning (cold) nodules have a somewhat increased risk of being malignant, but most are benign. Hyperfunctioning (hot) nodules are ordinarily benign but may sometimes be malignant. RAI scanning and uptake are helpful if a patient is found to have evidence of hyperthyroidism. (See Hyperthyroidism, below.)

Treatment

All thyroid nodules, including those with benign cytology, need to be followed by regular periodic palpation and rebiopsied if growth occurs. Patients with elevated levels of serum TSH are treated with thyroxine replacement. Otherwise, for small nodules, thyroxine is not required. For larger nodules (> 2 cm), if TSH levels are elevated or normal, "suppression" with levothyroxine sodium (0.05-0.1 mg daily) can be considered. Levothyroxine should not be administered if the baseline TSH is low, since that is an indication of autonomous thyroid secretion, such that levothyroxine treatment will be ineffective and liable to cause clinical thyrotoxicosis. Long-term levothyroxine suppression of TSH tends to keep nodules from enlarging, but only a few will actually shrink. Additional nodules develop in fewer treated patients. Suppressive levothyroxine therapy is most suitable for younger patients. All patients require regular careful clinical evaluation and thyroid palpation or ultrasound examinations. Levothyroxine suppression therapy should usually not be given to patients with certain cardiovascular problems since it may increase the risk for angina and arrhythmia. Levothyroxine suppression causes a small loss of bone density in many postmenopausal women biophosphonate or other therapy for osteoporosis may be indicated. Patients at risk for osteoporosis are advised to have periodic bone density testing.

A. Solitary Thyroid Nodules

Palpable solitary thyroid nodules call for fine-needle aspiration biopsy (see above). A solitary thyroid nodule in a patient with a remote history of radiation therapy to the head or neck (or exposure to nuclear fallout) is considered at high risk of malignancy and the nodule is resected. Cystic nodules can be managed by removal of fluid for cytologic examination, which may deflate the cyst. However, cysts tend to recur, requiring repeated aspirations. Solitary nodules in a patient with hyperthyroidism are an indication for radioactive iodine scan, which generally distinguishes toxic adenoma from Graves' disease. However, Graves' disease may occasionally be unilateral owing to agenesis of the contralateral lobe, so additional studies with antithyroid antibodies may be helpful. A "hot" nodule is usually benign but is resected to cure the hyperthyroidism.

B. Multinodular Goiters

A thyroid containing multiple nodules is likely to be a benign multinodular goiter. Nevertheless, fine-needle aspiration biopsy is performed on any nodule that is growing or is particularly dominant or hard. Large retrosternal goiters rarely harbor a malignancy but can be followed by CT scan or MRI. Continued growth or compressive symptoms are reasons for surgical excision. Patients found to be hyperthyroid may have a radioactive iodine scan and uptake for additional evaluation, especially if ^{131}I is a therapeutic consideration.

C. Nonpalpable Thyroid Nodules

Nonpalpable small thyroid nodules are detected in about 50% of scans of the neck (MRI, CT, ultrasound) done for other reasons. In one series, only 2% of such thyroids were found to have significant malignancy after surgical resection. Therefore, ultrasound-guided FNA biopsy is considered only for patients with nonpalpable nodules over 1.5 cm in diameter and for those with a history of head-neck irradiation. For incidentally discovered thyroid nodules of borderline concern, follow-up thyroid ultrasound in 3 months may be helpful; growing lesions may be biopsied or resected.

Microscopic "micropapillary" carcinoma is a variant of normal, being found in 24% of thyroidectomies performed for benign thyroid disease when 2-mm sections were carefully examined. It thus appears that the overwhelming majority of these microscopic foci never become clinically significant. The surgical pathology report of such a tiny papillary carcinoma that is otherwise benign does not justify aggressive follow-up or treatment because a cancer diagnosis is unwarranted and harmful. All that may be required is yearly follow-up with palpation of the neck and mild TSH suppression by thyroxine.

Prognosis

The great majority of thyroid nodules are benign. Benign thyroid nodules tend to persist or grow slowly, but they may involute. Only about 1% of benign nodules increase in diameter with follow-up. Conversion to a malignant nodule is rare. The prognosis for patients with thyroid nodules that prove to be malignant is determined by the histologic type and other factors (see below). Overall, differentiated thyroid carcinoma has an excellent prognosis, but metastases do occur. Multinodular goiters tend to persist or grow slowly, even in iodine-deficient areas where iodine repletion usually does not shrink established goiters. Patients with small incidentally discovered nonpalpable thyroid nodules are at very low risk for malignancy, and even those that are malignant have a minor effect on morbidity and mortality.

THYROID CANCER (TABLE 26-8)

Essentials of Diagnosis

- Painless swelling in region of thyroid.
- Thyroid function tests usually normal.
- Past history of irradiation to head and neck region may be present.
- Positive thyroid needle aspiration.

General Considerations

The incidence of papillary and follicular (differentiated) thyroid carcinomas increases with age. The female:male ratio is 3:1. About 13% of persons in the United States are found to have microscopic thyroid cancer at autopsy. However, thyroid cancer is diagnosed in only about 40 per million population. Clearly, most thyroid cancers remain microscopic and indolent. Those cancers that do become aggressive often have mutations in the *P53* tumor suppressor gene or the *ras* and *gsp* oncogenes.

Papillary carcinoma is the most common thyroid malignancy. Pure papillary or mixed papillary-follicular carcinoma represents about 76% of all thyroid cancers. It usually presents as a single nodule, but it can arise out of a multinodular goiter. Patients who have had external x-ray treatments to the neck or head during childhood have an increased lifelong risk. Similarly, childhood exposure to radioactive isotopes of iodine in nuclear fallout (eg, after the Chernobyl accident) carries a high risk for later development of papillary thyroid cancer. It may also be familial (3%) or associated with Cowden's disease (multiple hamartomas of the skin and mucous membranes with a high incidence of breast cancer) or adenomatous polyposis coli.

Generally speaking, papillary carcinoma is the least aggressive thyroid malignancy. However, the tumor spreads via lymphatics within the thyroid, becoming multifocal in 60% and involving both lobes in 30%. About 80% of patients have microscopic metastases to cervical lymph nodes; palpable lymph node involvement is present in 15% of adults and 60% of youths. Unlike other forms of cancer, patients with papillary thyroid cancer who have palpable lymph node metastases do not have a particularly increased mortality rate; however, their risk of local recurrence is increased.

Occult metastases to the lung occur in 10-15% of differentiated thyroid cancer; such lung metastases may be first noted on the whole-body scan following ^{131}I therapy. About 70% of small lung metastases resolve following ^{131}I therapy; however, larger pulmonary metastases have only a 10% remission rate.

Chronic low-grade papillary carcinoma can sometimes undergo a late anaplastic transformation into an aggressive carcinoma.

Follicular carcinoma accounts for about 16% of thyroid malignancies and is generally more aggressive than papillary carcinoma. Rarely, some follicular carcinomas secrete enough thyroxine to cause thyrotoxicosis if the tumor load becomes significant. Metastases commonly are found in neck nodes, bone, and lungs. Most follicular thyroid carcinomas avidly absorb iodine, making possible diagnostic scanning and treatment with ^{131}I after total thyroidectomy. Certain follicular histopathologic features are associated with a high risk of metastasis and recurrence: poorly differentiated and Hurthle cell (oncocytic) variants. The latter variants do not take up radioiodine.

Medullary thyroid carcinoma represents about 4% of thyroid cancers. About one-third are sporadic; one-third are familial; and one-third are associated with multiple endocrine neoplasia (MEN) type 2. Therefore, discovery of a medullary thyroid carcinoma makes family surveillance advisable. It arises from parafollicular thyroid cells that can secrete calcitonin, prostaglandins, serotonin, ACTH, corticotropin-releasing hormone (CRH), and other peptides. These peptides can cause symptoms and can be used as tumor markers. Early local metastases are usually present, usually to adjacent muscle and trachea as well as to local and mediastinal lymph nodes. Eventually, late metastases may appear in the bones, lungs, adrenals, or liver. This tumor does not concentrate iodine.

Anaplastic thyroid carcinoma represents about 1% of thyroid cancers. It usually presents in an older patient as a rapidly enlarging mass in a multinodular goiter. It is the most aggressive thyroid carcinoma and metastasizes early to surrounding nodes and distant sites. Local pressure symptoms include dysphagia or vocal cord paralysis. This tumor does not concentrate iodine.

Other thyroid malignancies together represent about 3% of thyroid cancers. **Lymphoma of the thyroid** is more common in older women. It usually presents as a rapidly enlarging, painful mass arising out of a multinodular or diffuse goiter affected by autoimmune thyroiditis, with which it may be confused microscopically. About 20% of cases have concomitant hypothyroidism. Thyroid lymphomas are most commonly B cell lymphomas (50%) or mucosa-associated lymphoid tissue (MALT; 23%); other types include follicular, small lymphocytic, and Burkitt's lymphoma and Hodgkin's disease. Thyroidectomy is rarely required. **Metastatic cancers** may sometimes involve the thyroid, particularly bronchogenic, breast, and renal carcinomas and malignant melanoma.

Clinical Findings

A. Symptoms and Signs

Thyroid carcinoma usually presents as a palpable, firm, nontender nodule in the thyroid. About 3% of thyroid malignancies present with a metastasis, usually to local lymph nodes but sometimes to distant sites such as bone or lung. Metastatic functioning differentiated thyroid carcinoma can sometimes secrete enough thyroid hormone to produce thyrotoxicosis.

Medullary thyroid carcinoma frequently causes flushing and diarrhea (30%), fatigue, and other symptoms; about 5% develop Cushing's syndrome from secretion of ACTH or CRH. Signs of pressure or invasion of surrounding tissues are present in anaplastic or long-standing tumors with recurrent laryngeal nerve palsy or fixation of nodule to neighboring structures.

B. Laboratory Findings

(Fine-needle aspiration is discussed above in the section on nodular thyroid.) Thyroid function tests are generally normal unless there is concomitant thyroiditis. Follicular carcinoma may secrete enough thyroxine to suppress TSH and cause clinical hyperthyroidism.

Serum thyroglobulin is high in most metastatic papillary and follicular tumors, making this a useful marker for recurrent or metastatic disease. Caution must be exercised for the following reasons: (1) Circulating antithyroglobulin antibodies can cause erroneous thyroglobulin determinations. (2) Thyroglobulin levels may be misleadingly elevated in thyroiditis, which often coexists with carcinoma. (3) Certain thyroglobulin assays falsely report the continued presence of thyroglobulin after total thyroidectomy and tumor resection, causing undue concern about possible metastases. Therefore, unexpected thyroglobulin levels should prompt a repeat assay in another reference laboratory.

A promising development is the use of reverse transcriptase polymerase chain reaction (RT-PCR) assay for the detection of thyroglobulin messenger RNA in peripheral blood. In patients who have had a thyroidectomy for differentiated thyroid cancer, analysis of peripheral blood by RT-PCR for thyroglobulin mRNA is very sensitive for the presence of residual normal thyroid or metastatic disease even in patients taking TSH-suppressive doses of thyroxine replacement.

Serum calcitonin levels are frequently elevated in medullary thyroid carcinoma, making this a marker for metastatic disease. However, serum calcitonin may be elevated in many other conditions such as thyroiditis, pregnancy, azotemia, hypercalcemia, and other malignancies, including pheochromocytomas, carcinoid tumors, and carcinomas of the lung, pancreas, breast, and colon.

Serum carcinoembryonic antigen (CEA) levels are usually elevated with medullary carcinoma, making this a useful second marker; however, it is not specific for this carcinoma.

Serum determinations for calcitonin and CEA should be obtained before surgery for medullary carcinoma, then periodically in postoperative follow-up. Calcitonin levels remain elevated in patients with persistent tumor but also in some patients with apparent cure. Therefore, rising levels of calcitonin or CEA are the best indication for recurrence.

Since up to two-thirds of medullary thyroid carcinoma cases are familial or MEN 2 (both autosomal dominant), siblings and children of patients with medullary carcinoma are advised to have genetic testing to detect *RET* proto-oncogene mutations. Mutation analysis of exons 10, 11, 13, and 14 detects 95% of the mutations causing MEN 2a and 90% of the mutations causing familial medullary thyroid carcinoma. (See Multiple Endocrine Neoplasia, below.)

C. Imaging

Radioiodine (^{131}I or ^{123}I) whole-body scanning is typically performed about 2-4 months following surgery for differentiated thyroid carcinoma. Thyroid cancer tissue is generally not as avid for radioiodine as is normal thyroid tissue, which competes for radioiodine. About 65% of metastases are detectable by radioiodine scanning, but only after optimal preparation: Patients should ideally have had total or near-total thyroidectomy. Intravenous iodinated contrast must be avoided for at least 2 months before scanning. Patients must follow a low-iodine diet for at least 2 weeks before scanning. Patients are allowed to become hypothyroid; high levels of endogenous TSH are required to stimulate the uptake of radioiodine into metastases. Prior to scanning, serum TSH is assayed to confirm that it is elevated; serum hCG is assayed to screen for pregnancy in all women of reproductive age; and serum thyroglobulin and antithyroglobulin antibody titers are also determined.

The radioisotope ^{131}I is generally available and most commonly used for scanning. However, ^{131}I given in scanning doses of 3 mCi (111 MBq) appears to reduce the effectiveness of radioiodine therapy by impairing the ability of the remnant tissue to take up subsequent therapeutic doses of ^{131}I (the "stunning" phenomenon). Lower scanning doses of 1 mCi (37 MBq) of ^{131}I are less likely to interfere with radioiodine therapy. The radioisotope ^{123}I has the advantage of a shorter half-life, allowing quicker dissipation of background radiation and next-day scanning. The lower-energy gamma radiation of ^{123}I also allows for single photon emission computed tomography (SPECT) to better localize metastases; the lack of beta emission from ^{123}I scanning avoids "stunning" the tumor, which might otherwise reduce the effectiveness of subsequent ^{131}I therapy.

Thyrotropin-stimulated Tg and radioiodine scanning may be useful for some patients who have no anti-Tg antibodies and a very low risk of metastatic thyroid cancer or who refuse thyroid hormone withdrawal because of the discomforts of hypothyroidism.

Thyrotropin alfa injections can stimulate uptake of ^{131}I by thyroid cancer or residual thyroid. The dosage is 0.9 mg intragluteally (not intravenously) every 24 hours for two doses or every 72 hours for three doses. Radioiodine is administered 24 hours after the final thyrotropin injection; 72 hours after the final injection, a whole-body scan is obtained and blood is drawn for serum thyroglobulin determination. Side effects of thyrotropin injections include nausea (11%) and headache (7%). Hyperthyroidism can occur in patients with significant metastases or residual normal thyroid. Thyrotropin has caused neurologic deterioration in 7% of patients with central nervous system metastases. The combination of thyrotropin-stimulated scan and thyroglobulin (Tg) level detects a thyroid remnant or cancer with a sensitivity of 94% (three injections) or 84% (two injections). The presence of anti-Tg antibodies renders the serum Tg determination uninterpretable. Thyrotropin injections do not stimulate radioiodine uptake sufficiently to allow ^{131}I ablative therapy of thyroid cancer.

Ultrasound of the neck is useful in determining the size and location of the malignancy as well as neck metastases. Bone and soft tissue metastases that take up radioiodine may be demonstrable on radioisotope scans. Chest x-ray or CT may demonstrate metastases. However, iodinated contrast greatly reduces the effectiveness of radioiodine scanning and therapy. Medullary carcinoma in the thyroid, nodes, and liver may calcify, but lung metastases rarely do so. Metastases may be detected with positron emission tomography (PET) scanning and MRI.

Differential Diagnosis

Lymphocytic thyroiditis, multinodular goiter, and colloid nodules can be distinguished from malignancies by FNA biopsy. However, FNA cannot distinguish benign follicular adenoma from follicular carcinoma. Overall, in such "suspicious" cases, the risk of malignancy is about 20% higher in fixed lesions over 4 cm in diameter. The risk of malignancy is 5% for nodules in elderly patients with lesions under 4 cm in diameter having "suspicious" cytology.

Neuroendocrine carcinomas may metastasize to the thyroid and be confused with medullary thyroid carcinoma.

False-positive ^{131}I scans are common with normal residual thyroid tissue and have been reported with Zenker's diverticulum, struma ovarii, pleuropericardial cyst, gastric pull-up, and ^{131}I -contaminated bodily secretions. False-negative ^{131}I scans are common in early metastatic differentiated thyroid carcinoma but occur also in more advanced disease, including 14% of bone metastases.

Complications

The complications vary with the type of carcinoma. Differentiated thyroid carcinomas may have local or distant metastases. One-third of medullary carcinomas may secrete serotonin and prostaglandins, producing flushing and diarrhea, and may be complicated by the coexistence of pheochromocytomas or hyperparathyroidism. The complications of radical neck surgery often include permanent hypoparathyroidism and, less commonly, vocal cord palsy; permanent hypothyroidism is expected and should always be treated adequately.

Treatment of Differentiated Thyroid Carcinoma

A. Surgical Treatment

Surgical removal is the treatment of choice for thyroid carcinomas. Neck ultrasound is useful both preoperatively and in follow-up. For differentiated papillary and follicular carcinoma, thyroidectomy with limited removal of cervical lymph nodes is adequate. However, for patients with Hurthle cell carcinoma who have metastases to lymph nodes, modified radical neck dissection is recommended. Highly skilled surgeons can perform near-total thyroidectomies with a less than 1% rate of serious complications (hypoparathyroidism or recurrent laryngeal nerve damage). Other series have reported up to an 11% incidence of permanent hypoparathyroidism after total thyroidectomy.

Following thyroidectomy, patients should be hospitalized as inpatients until it is determined that they have safely recovered from surgery. This requires at least an overnight hospital admission, since late bleeding, airway problems, and tetany can occur. Ambulatory thyroidectomy is potentially dangerous and should not be done.

The incidence of hypoparathyroidism may be reduced if accidentally resected parathyroids are immediately autotransplanted into the neck muscles. The advantage of near-total thyroidectomy for differentiated thyroid carcinoma is that multicentric foci of carcinoma are more apt to be resected and there is then less normal thyroid tissue to compete with cancer for ^{131}I administered later for scans or treatment. Subtotal thyroidectomy is acceptable for adults under age 45 who have a single small tumor (= 1 cm in diameter). Neck muscle dissections are usually avoided for differentiated thyroid carcinoma. Thyroxine is prescribed in doses of 0.05-0.1 mg/d immediately postoperatively. The dosage is adjusted to keep the serum TSH slightly suppressed during long-term follow-up of differentiated thyroid carcinoma.

About 2-4 months after surgery, a whole-body ^{131}I scan is performed. Thyroxine is stopped for 6 weeks prior to the scan, thereby causing hypothyroidism; TSH then rises and stimulates iodide uptake and thyroglobulin release from residual tumor or normal thyroid. Iodine-containing foods and contrast media are avoided.

Metastases to the brain are best treated surgically, since treatment with radiation or radioactive iodide is ineffective. Patients with bulky recurrent tumor in the neck region also benefit from surgery.

B. Medical Treatment

Patients who have had a thyroidectomy for differentiated thyroid cancer must take thyroid hormone replacement for life. Patients need to be followed regularly for recurrent or metastatic disease. Serum TSH levels must be monitored. Patients with differentiated thyroid carcinoma, including Hurthle cell carcinoma, should be given thyroxine in doses that suppress serum TSH without causing thyrotoxicosis.

C. Radioiodine

Patients must be prepared for ^{131}I therapy by stopping thyroid hormone replacement for 2-3 weeks, thereby inducing hypothyroidism and increasing TSH, which then stimulates tumor cells to take up iodine. Patients must follow a low-iodine diet for 2 weeks before ^{131}I therapy. Just before therapy, serum is obtained for measurement of TSH (to make certain it is elevated), thyroglobulin, and hCG (in all reproductive-age women). Pregnant women may not receive radioiodine therapy; women are advised to avoid pregnancy for at least 4 months following ^{131}I therapy.

Sodium iodide I 131, 30-50 mCi, is administered orally to patients with an original papillary or follicular carcinoma = 1.5 cm in diameter and also to patients having persistent radioiodine uptake in the thyroid bed following near-total thyroidectomy. Patients with extrathyroidal uptake from metastatic disease are given larger doses of about 150 mCi orally in the hospital. Another whole-body scan several days after ^{131}I treatment will sometimes detect metastases not visible on pretreatment scans.

About 35% of patients with metastatic differentiated thyroid carcinoma have poor uptake of radioiodine into metastases. Lithium inhibits the release of ^{131}I from differentiated thyroid cancer, while ^{131}I uptake is unaffected. Lithium thereby increases the absorbed radiation dose by augmenting the accumulation and retention of ^{131}I by metastases. Lithium is potentially useful for improving the efficacy of ^{131}I for treating metastases with relatively poor radioiodine uptake. Lithium carbonate, 300 mg orally once to three times daily (10 mg/kg daily) is taken beginning 7 days before ^{131}I therapy and continued for 5-7 days after. Serum lithium levels are measured every 1 or 2 days to achieve a therapeutic serum lithium concentration.

^{131}I ablation in doses over 100 mCi can cause gastritis, temporary oligospermia, sialadenitis, and xerostomia. Sialadenitis and xerostomia may be prevented by treatment with amifostine, 500 mg/m² intravenously before high-dose radioiodine. Cumulative doses of ^{131}I over 500 mCi can cause infertility, pancytopenia (4%), and leukemia (0.3%). The kidneys excrete radioiodine. In order to reduce the risk of radiation-induced side effects, patients receiving dialysis for renal failure require a dosage reduction to only 20% of the usual dose of ^{131}I .

D. External Radiation Therapy

External radiation may be delivered to bone metastases. Brain metastases do not usually respond to ^{131}I and are best resected or treated with gamma knife radiation therapy.

E. Surveillance

Patients with differentiated thyroid carcinoma are followed clinically with neck palpation, physical examination, and chest x-ray and observed for thyrotoxicosis that might indicate functioning metastases. About 6-12 months after their postoperative scan, patients usually receive another ^{131}I whole-body scan and serum thyroglobulin measurement while hypothyroid (see above); these have a combined sensitivity of 95% for metastases. Serum thyroglobulin in a patient receiving thyroxine has a lower sensitivity of 62%. Regular neck ultrasound is advisable as an adjunct to the physical examination since neck palpation often does not detect local metastases. Patients who need particularly close surveillance include those with prior known metastases and those who have persistent elevation in serum thyroglobulin or who have detectable levels of antithyroglobulin antibodies.

Thallium-201 (^{201}Tl) scans may be useful for detecting metastatic differentiated thyroid carcinoma when ^{131}I scan is normal but serum thyroglobulin is elevated. MRI or ultrasound is useful in distinguishing recurrent thyroid tumor from postoperative changes.

Positron emission tomography whole-body scanning using ^{18}F -deoxyglucose (FDG-PET) is a sensitive method for detecting thyroid cancer metastases—particularly those that are not revealed on radioiodine scanning.

Patients with papillary carcinoma should have at least two consecutively negative scans before they are considered in remission. Patients with radioiodine uptake restricted to the thyroid bed need not have repeated ^{131}I therapies. Further scans may be required for patients with more aggressive follicular carcinomas, prior metastases, rising serum thyroglobulin, or other evidence of metastases.

Treatment of Other Thyroid Malignancies

Patients with anaplastic thyroid carcinoma are treated with local resection and radiation. Thyroid lymphomas are best treated with external radiation therapy; chemotherapy is added for extensive lymphoma.

Medullary thyroid carcinoma is treated surgically; repeated neck dissections are often required over time. Patients found to have *RET* proto-oncogene mutations are advised to have a prophylactic total thyroidectomy, ideally at age 6 years. This cancer does not take up ^{131}I .

Anaplastic thyroid carcinoma is also treated surgically. It does not take up ^{131}I .

Patients with MALT lymphomas have a low risk of recurrence after simple thyroidectomy. Patients with other types of systemic lymphomas involving the thyroid are usually treated with chemotherapy.

Prognosis

The prognosis for differentiated (papillary and follicular) thyroid carcinoma is generally excellent, particularly for adults under age 45 years. The following characteristics imply a worse prognosis: older age, male sex, bone or brain metastases, large pulmonary metastases, and lack of ^{131}I uptake into metastases. Certain papillary histologic types are associated with a higher risk of recurrence: tall cell, columnar cell, and diffuse sclerosing types. Staging and survival rates are presented in [Table 26-9](#). Brain metastases are detected in 1%; they reduce median survival to 12 months, but their prognosis is improved by surgical resection. Patients with follicular carcinoma have a cancer mortality rate that is 3.4 times higher than patients with papillary carcinoma. The Hurthle cell variant of follicular carcinoma is more aggressive. Patients with primary tumors over 1 cm in diameter who undergo limited thyroid surgery (subtotal thyroidectomy or lobectomy) have a 2.2-fold increased mortality over those having total or near-total thyroidectomies. Patients who have not received ^{131}I ablation have mortality rates that are increased twofold by 10 years and threefold by 25 years (over those who have received ablation). The risk of cancer recurrence is twofold higher in men than in women and 1.7-fold higher in multifocal than in unifocal tumors.

Medullary thyroid carcinoma has a variable prognosis. Patients with sporadic disease usually have lymph node involvement at the time of diagnosis, whereas distal metastases may not be noted for years; the 5-year survival is 82% and the 10-year survival rate is 69%. Familial cases or those associated with MEN 2a tend to be less aggressive; the 10-year survival rate is higher, in part due to earlier detection. Women with medullary thyroid carcinoma who are under age 40 also have a better prognosis. A better prognosis is also obtained in patients undergoing total thyroidectomy and neck dissection; radiation therapy reduces recurrence in patients with metastases to neck nodes. The mortality rate is increased 4.5-fold when primary or metastatic tumor tissue stains heavily for myelomonocytic antigen M-1. Conversely, tumors with heavy immunoperoxidase staining for calcitonin are associated with prolonged survival even in the presence of significant metastases.

Anaplastic thyroid carcinoma has a 1-year survival rate of about 10%, and a 5-year survival rate of about 5%. Patients with fully localized tumors on MRI have a better prognosis.

Patients with localized lymphoma have nearly 100% 5-year survival. Those with disease outside the thyroid have a 63% 5-year survival. However, the prognosis is better for those with the mucosa-associated lymphoid tissue (MALT) type. Patients presenting with stridor, pain, laryngeal nerve palsy, or mediastinal extension tend to fare worse.

ENDEMIC GOITER

Essentials of Diagnosis

- Common in regions of the world with low-iodine diets.
- High rate of congenital hypothyroidism and cretinism.
- Goiters may become multinodular and grow to great size.
- Most adults with endemic goiter are found to be euthyroid; however, some are hypothyroid or hyperthyroid.
- Impaired cognition and hearing may be subtle or severe in congenital hypothyroidism.

General Considerations

Approximately 5% of the world's population have goiters. Of these, about 75% are in persons dwelling in areas of iodine deficiency. Such areas are found in 115 countries, mostly in developing areas but also in Europe.

In Pescopagano, Italy, 60% of adults have goiters. Hyperthyroidism (present or past) occurred in 2.9%; hypothyroidism was overt in 0.2% and subclinical in 3.8%. The incidence of thyroid cancer was less than 0.1%. Up to 0.5% of iodine-deficient populations have full-blown cretinism, with less severe manifestations of congenital hypothyroidism being even more common (eg, isolated deafness, short stature, or impaired mentation). Intelligence quotients in iodine-deficient adults are an average of 13 points lower than expected. Although iodine deficiency is the most common cause of endemic goiter, certain foods (eg, sorghum, millet, maize, cassava), mineral deficiencies (selenium, iron), and water pollutants can themselves cause goiter or aggravate a goiter proclivity caused by iodine deficiency. Pregnancy is associated with an increase in size of thyroid nodules and the emergence of new nodules. Some individuals are particularly susceptible to goiter owing to congenital partial defects in thyroid enzyme activity.

Clinical Findings

A. Symptoms and Signs

Endemic goiters may become multinodular and very large. Growth often occurs during pregnancy and may cause compressive symptoms.

Substernal goiters are usually asymptomatic but can cause tracheal compression, respiratory distress and failure, dysphagia, superior vena cava syndrome, gastrointestinal bleeding from esophageal varices, palsies of the phrenic or recurrent laryngeal nerves, or Horner's syndrome. Cerebral ischemia and stroke can result from arterial compression or thyrocervical steal syndrome. Substernal goiters can rarely cause pleural or pericardial effusions. The incidence of significant malignancy is less than 1%.

Some patients with endemic goiter may become hypothyroid. Others may become thyrotoxic as the goiter grows and becomes more autonomous, especially if iodine is added to the diet.

B. Laboratory Findings

The serum thyroxine is usually normal. Serum TSH is generally normal. TSH falls in the presence of hyperthyroidism if a multinodular goiter has become autonomous in the presence of sufficient amounts of iodine for thyroid hormone synthesis. TSH rises with hypothyroidism. Thyroid radioactive iodine uptake is usually elevated, but it may be normal if iodine intake has improved. Serum levels of antithyroid antibodies are usually either undetectable or in low titers. Serum thyroglobulin is often elevated.

Differential Diagnosis

Endemic goiter must be distinguished from all other forms of nodular goiter that may coexist in an endemic region (see above).

Prevention

Iodine supplementation was started in Switzerland in 1922, initially by adding 5 mg of potassium iodide per kilogram of salt, with later increases to the current level of 20 mg/kg salt. Iodized salt has greatly reduced the incidence of endemic goiter. Unfortunately, many iodine-deficient countries have inadequate programs for iodine supplementation. The minimum dietary requirement for iodine is about 50 ug daily, with optimal iodine intake being 150-300 ug daily. Iodine sufficiency is assessed by measurement of urinary iodide excretion, the target being more than 10 ug/dL.

Initiating iodine supplementation in a geographic area causes an increased frequency of hyperthyroidism in the first year, followed by greatly reduced rates of toxic nodular goiter and Graves' disease thereafter.

Treatment

The addition of potassium iodide to table salt greatly reduces the prevalence of endemic goiter and cretinism but is less effective in shrinking established goiter. Dietary iodine supplementation increases the risk of autoimmune thyroid dysfunction which may result in hypothyroidism or thyrotoxicosis. Excessive iodine intake may increase the risk of goiter. Thyroxine supplementation can shrink goiters and reduce the risk of further goiter growth, but such treatment likewise carries a risk of inducing hyperthyroidism in individuals with autonomous multinodular goiters; therefore, thyroxine suppression should not be started in patients with suppressed TSH levels.

Adults with large multinodular goiter may require thyroidectomy for cosmesis, compressive symptoms, or thyrotoxicosis. Following partial thyroidectomy in iodine-deficient geographic areas, there is a high goiter recurrence rate, so total thyroidectomy is preferred when surgery is indicated. Certain patients may be treated with ¹³¹I for large compressive goiters. Such patients may rarely develop Graves' disease 3-10 months after treatment.

HYPOTHYROIDISM & MYXEDEMA

Essentials of Diagnosis

- Weakness, fatigue, cold intolerance, constipation, weight change, depression, menorrhagia, hoarseness.
- Dry skin, bradycardia, delayed return of deep tendon reflexes.
- Anemia, hyponatremia.
- T₄ and radioiodine uptake usually low.
- TSH elevated in primary hypothyroidism.

General Considerations

Thyroid hormone deficiency may affect virtually all body functions. The degree of severity ranges from mild and unrecognized hypothyroid states to striking myxedema. The fluid retention seen in myxedema is caused by the interstitial accumulation of hydrophilic mucopolysaccharides, which leads to lymphedema. Hyponatremia is due to impaired renal tubular sodium reabsorption due to reductions in Na⁺-K⁺ ATPase. Cellular proteins are also affected in myxedema.

Hypothyroidism may be due to primary disease of the thyroid gland itself or lack of pituitary TSH. Florid hypothyroidism, ie, myxedema and cretinism, is readily recognized on clinical grounds alone, but mild hypothyroidism often escapes detection without screening (ie, serum TSH). Maternal hypothyroidism during pregnancy results in offspring with IQ scores that are an average 7 points lower than those of euthyroid mothers.

Goiter is frequently noted when hypothyroidism is due to Hashimoto's thyroiditis, iodide deficiency, genetic thyroid enzyme defects, drug goitrogens (lithium, iodide, propylthiouracil or methimazole, phenylbutazone, sulfonamides, amiodarone, interferon-alfa, interleukin-2), food goitrogens in iodide-deficient areas (eg, turnips, cassavas), or, rarely, peripheral resistance to thyroid hormone or infiltrating diseases (eg, cancer, sarcoidosis). A hypothyroid phase occurs in subacute (de Quervain's) viral thyroiditis following initial hyperthyroidism.

Goiter is usually absent when hypothyroidism is due to deficient pituitary TSH secretion, or destruction of the gland by surgery, external radiation, or ¹³¹I. Patients who have received central nervous system radiation for leukemia have a 15% chance of developing hypothyroidism years later. Patients with primary pulmonary hypertension have a 22% incidence of hypothyroidism.

Amiodarone, because of its high iodine content, causes clinically significant hypothyroidism in about 8% of patients. The T₄ level is normal or low, and the TSH is elevated, usually over 20 ng/dL. Another 17% of patients develop milder elevations of TSH and are asymptomatic. Low-dose amiodarone is less likely to cause hypothyroidism. Cardiac patients with amiodarone-induced symptomatic hypothyroidism are treated with just enough thyroxine to relieve symptoms. Patients with a high iodine intake from other sources may also develop hypothyroidism, especially if they have underlying lymphocytic thyroiditis.

Interferon-alfa treatment induces thyroid dysfunction (usually hypothyroidism, sometimes hyperthyroidism) in 6%. Spontaneous resolution occurs in over half of cases once interferon-alfa is discontinued.

Clinical Findings

These may vary from the rather rare full-blown myxedema to mild states of hypothyroidism, which are far more common.

A. Symptoms and Signs

1. Early—Frequent symptoms are fatigue, lethargy, weakness, arthralgias or myalgias, muscle cramps, cold intolerance, constipation, dry skin, headache, and menorrhagia. Physical findings may be few or absent. Features may include thin, brittle nails, thinning of hair, and pallor, with poor turgor of the mucosa. Delayed return of deep tendon reflexes is often noted.

2. Late—The symptoms are variable but may include slow speech, absence of sweating, constipation, peripheral edema, pallor, hoarseness, decreased sense of taste and smell, muscle cramps, aches and pains, dyspnea, weight changes (usually gain, but weight loss is not rare), and diminished auditory acuity. Some women have amenorrhea; others have menorrhagia. Galactorrhea may also be present. Physical findings may include goiter, puffiness of the face and eyelids, typical carotenemic skin color, thinning of the outer halves of the eyebrows, thickening of the tongue, hard pitting edema, and effusions into the pleural, peritoneal, and pericardial cavities, as well as into joints. Cardiac enlargement ("myxedema heart") is often due to pericardial effusion. The heart rate is slow; the blood pressure is more often normal than low, and reversible diastolic hypertension may be found. Hypothermia may be present. Pituitary enlargement due to hyperplasia of TSH-secreting cells, which is reversible following thyroid therapy, may be seen in long-standing hypothyroidism. Hypothyroidism rarely causes true obesity.

B. Laboratory Findings

The FT₄ may be low or low normal. TSH is increased with primary hypothyroidism but is low or normal with pituitary insufficiency. Other laboratory abnormalities may often be seen: increased serum cholesterol, liver enzymes, and creatine kinase; increased serum prolactin; and hyponatremia, hypoglycemia, and anemia (with normal or increased mean corpuscular volume). Titers of antibodies against thyroperoxidase and thyroglobulin are high in patients with Hashimoto's thyroiditis. Serum T₃ is not a good test for hypothyroidism.

Differential Diagnosis

Hypothyroidism must be considered in states of asthenia, unexplained menstrual disorders, myalgias, constipation, weight change, hyperlipidemia, and anemia. Myxedema enters into the differential diagnosis of unexplained heart failure that does not respond to digitalis or diuretics, and unexplained ascites. The protein content of myxedematous effusions is high. The thick tongue may be confused with that seen in primary amyloidosis. Pernicious anemia may be suggested by the pallor and the macrocytic anemia sometimes seen in myxedema; the two disorders may even coexist. Some cases of depression, primary psychosis and structural diseases of the brain have been confused with myxedema. The pituitary is often quite enlarged in primary hypothyroidism due to reversible hyperplasia of TSH-secreting cells; the concomitant hyperprolactinemia seen in hypothyroidism can lead to the mistaken diagnosis of a pituitary adenoma.

A number of factors can lower serum T₄ levels without causing true hypothyroidism ([Table 26-5](#)).

Complications

Complications are mostly cardiac in nature, occurring as a result of advanced coronary artery disease and congestive failure, which may be precipitated by too vigorous thyroid therapy. There is an increased susceptibility to infection. Megacolon has been described in long-standing hypothyroidism. Organic psychoses with paranoid delusions may occur ("myxedema madness"). Rarely, adrenal crisis may be precipitated by thyroid therapy. Hypothyroidism is a rare cause of infertility, which may respond to thyroid medication. Pregnancy in a woman with untreated hypothyroidism often results in miscarriage. On the other hand, if the hypothyroidism is due to autoimmune disease, it may improve during pregnancy. Sellar enlargement and even well-defined TSH-secreting tumors may develop in untreated cases. These tumors decrease in size after replacement therapy is instituted.

A rare complication of severe hypothyroidism is deep stupor, at times progressing to **myxedema coma**, with severe hypothermia, hypoventilation, hyponatremia, hypoxia, hypercapnia, and hypotension. Convulsions and abnormal central nervous system signs may occur. Myxedema coma is often induced by an underlying infection; cardiac, respiratory, or central nervous system illness; cold exposure; or drug use. It is most often seen in elderly women. The mortality rate is high. Myxedematous patients are unusually sensitive to opioids and may die from average doses.

Refractory hyponatremia is often seen in severe myxedema. Inappropriate secretion of antidiuretic hormone has been observed in some patients, but a defect in distal

tubular reabsorption of sodium and water has been demonstrated in many others.

Treatment

Levothyroxine (thyroxine; T_4) is the treatment of choice. It is partially converted in the body to T_3 , the more active thyroid hormone. In patients taking a certain daily dose of levothyroxine, significant increases in serum T_4 levels are seen within 1-2 weeks, and near-maximum levels are seen within 3-4 weeks. It is best taken in the morning with water, avoiding concomitant intake of foods and drugs that may interfere with its absorption (see below). Brand preparations of levothyroxine in the United States appear to be bioequivalent to each other and certain generics. Before therapy with thyroid hormone is commenced, the hypothyroid patient requires at least a clinical assessment for adrenal insufficiency, which would require concurrent treatment.

A. Routine Initiation of Treatment

Patients without coronary insufficiency who are under age 60 years may receive starting doses of levothyroxine, 50-100 ug daily orally. Women who are pregnant and significantly hypothyroid may begin therapy with levothyroxine at doses of 100-150 ug orally daily. Patients with coronary disease or those who are over age 60 are treated with smaller initial doses of levothyroxine, 25-50 ug daily. The dose can be increased by 25 ug every 1-3 weeks until the patient is euthyroid.

B. Myxedema

Patients with severe hypothyroidism require larger initial doses of levothyroxine, particularly since myxedema itself can interfere with the intestinal absorption of thyroxine.

Myxedema coma is a medical emergency with a high mortality rate. It is caused by hypothyroidism but usually precipitated by an acute illness or trauma. Patients have the manifestations of hypothyroidism as well as impaired mentation. Hyponatremia and hypoglycemia are often present. Levothyroxine sodium 400 ug is given intravenously as a loading dose, followed by 100 ug intravenously daily. The hypothermic patient is warmed only with blankets, since faster warming can precipitate cardiovascular collapse. Patients with hypercapnia require intubation and assisted mechanical ventilation. Infections must be detected and treated aggressively. Patients suspected of having concomitant adrenal insufficiency are treated with hydrocortisone, 100 mg intravenously, followed by 25-50 mg every 8 hours.

C. Maintenance

It is important to stress to the patient that levothyroxine therapy must be continued for life and that regular periodic dosage reassessments will be required. Most patients ultimately require 100-250 ug daily. Women with hypothyroidism require increased doses of thyroxine during therapy with estrogen. There is no standardized optimal dose of levothyroxine, so each patient's dose must be based upon careful clinical assessment. Although serum TSH levels can be helpful in determining optimal dosing, it is important not to rely entirely on this test.

During pregnancy, thyroxine dosage requirements increase substantially due to estrogen-induced increases in thyroid-binding globulin. Also, placental deiodinase promotes the turnover of thyroxine. The fetal thyroid begins secreting thyroid hormone at about 18 weeks of gestation, but thyroid development is not complete until term. Maternal thyroxine crosses the placenta, and the fetus is at least partially dependent upon maternal thyroxine for neuron development—particularly beginning in the second trimester. Maternal hypothyroidism after the first trimester appears to cause some developmental delay in offspring. It is therefore important to carefully follow women with hypothyroidism during their pregnancies with frequent serum TSH and free thyroxine determinations and to increase thyroxine replacement progressively as required.

Elevated serum TSH levels usually indicate underreplacement with levothyroxine. However, before increasing the T_4 dosage, it is wise to question the patient about compliance and the presence of angina and to consider the following: A high TSH in a patient receiving standard replacement doses of T_4 may indicate malabsorption of levothyroxine due to concurrent administration with binding substances, particularly iron preparations, sucralfate, aluminum hydroxide antacids, calcium supplements, or soy milk. Bile acid-binding resins such as cholestyramine can bind T_4 and impair its absorption even when administered 5 hours before the thyroxine. Malabsorption of T_4 can also occur in short bowel syndrome; therapy with medium chain triglyceride oil may improve absorption. Impaired absorption of T_4 can also be caused by diarrhea of any cause or malabsorption due to sprue, regional enteritis, liver disease, or pancreatic exocrine insufficiency. Serum TSH may be elevated transiently in acute psychiatric illness and during recovery from nonthyroidal illness. Autoimmune disease can cause false elevations of TSH by interfering with the assay. A high TSH can also be caused by thyrotropin-secreting pituitary tumors.

Suppressed serum TSH levels < 0.1 mU/L (using a sensitive assay) may indicate overreplacement with levothyroxine; if such a patient has manifestations of hyperthyroidism, the dosage is reduced. However, patients with suppressed serum TSH levels may exhibit no symptoms of hyperthyroidism. For such patients, it is important to determine whether hypopituitarism or severe nonthyroidal illness is present, which can result in low serum TSH levels without hyperthyroidism. TSH can also be suppressed by certain medications, such as nonsteroidal anti-inflammatory agents, opioids, nifedipine, verapamil, and acute administration of glucocorticoids. Absent such conditions, a clinically euthyroid patient with a low serum TSH should be given a lower dosage of levothyroxine unless symptoms of hypothyroidism develop.

Some hypothyroid patients treated with levothyroxine complain of hypothyroid-type symptoms despite having normal or suppressed levels of TSH and normal levels of free T_4 . Such patients require careful assessment for other concurrent illnesses such as adrenal insufficiency, hypogonadism, anemia, or depression. If such conditions are ruled out or treated and hypothyroid-type symptoms persist despite normal or low TSH levels, a serum T_3 level (free T_3 in women receiving oral estrogens) may help make the difficult decision about whether to increase the levothyroxine dose. If the T_3 level is low or low normal, such a patient may benefit from a careful increase in thyroxine dosage; if a definite clinical benefit is achieved, the higher dose is continued. However, long-term surveillance for atrial arrhythmias and for osteoporosis is recommended for such patients, though such complications are uncommon in those who are clinically euthyroid. The malaise felt by some hypothyroid patients despite apparent optimal replacement therapy with T_4 may be due to an abnormally low ratio of T_3/T_4 levels in certain tissues. In one small study, the addition of triiodothyronine, 12.5 ug daily, to the levothyroxine regimen caused an improvement in cognition, mood, and physical symptoms in some patients.

Prognosis

With early treatment, striking transformations take place both in appearance and mental function. Return to a normal state is usually the rule, but relapses will occur if treatment is interrupted. The patient may rarely die from the complications of myxedema coma. On the whole, response to thyroid treatment is most satisfactory. Hypothyroidism caused by interferon-alfa resolves within 17 months of stopping the drug in 50% of patients. Chronic maintenance therapy with unduly large doses of thyroid hormone may lead to subtle but important side effects (eg, bone demineralization) and is to be avoided.

HYPERTHYROIDISM (THYROTOXICOSIS)

Essentials of Diagnosis

- Sweating, weight loss or gain, anxiety, loose stools, heat intolerance, irritability, fatigue, weakness, menstrual irregularity.
- Tachycardia; warm, moist skin; stare; tremor.
- In Graves' disease: goiter (often with bruit); ophthalmopathy.

- Suppressed TSH in primary hyperthyroidism; increased T_{4C} , free T_{4C} , and free T_4 index.

General Considerations

The term "thyrotoxicosis" refers to the clinical manifestations associated with serum levels of thyroxine or triiodothyronine that are excessive for the individual. The causes are many and diverse, as described below.

A. Graves' Disease

Graves' disease (known as Basedow's disease in Europe) is the most common cause of thyrotoxicosis. It is an autoimmune disorder affecting the thyroid gland, characterized by an increase in synthesis and release of thyroid hormones; the thyroid gland is typically enlarged. Graves' disease is much more common in women than in men (8:1), and its onset is usually between the ages of 20 and 40. It may be accompanied by infiltrative ophthalmopathy (Graves' exophthalmos) and, less commonly, by infiltrative dermopathy (pretibial myxedema). The thymus gland is typically hyperplastic and enlarged. Graves' disease may also be associated with other systemic autoimmune disorders such as pernicious anemia, myasthenia gravis, and diabetes mellitus. It has a familial tendency, and histocompatibility studies have shown an association with group HLA-B8 and HLA-DR3. The pathogenesis of the hyperthyroidism of Graves' disease involves the formation of autoantibodies that bind to the TSH receptor in thyroid cell membranes and stimulate the gland to hyperfunction. TSH receptor antibodies (TSH-R Ab [stim]) are demonstrable in the plasma of about 80% of patients with Graves' disease. Other antibodies such as ANA are generated in Graves' disease, with antithyroperoxidase or antithyroglobulin antibodies being increased in most patients. Patients with Graves' disease have an increased risk for developing Addison's disease, alopecia areata, celiac disease, diabetes mellitus type 1, myasthenia gravis, cardiomyopathy, and hypokalemic periodic paralysis.

B. Toxic Adenomas

Autonomous toxic adenomas of the thyroid may be single (Plummer's disease) or multiple (toxic multinodular goiter). These adenomas are not accompanied by infiltrative ophthalmopathy or dermopathy. Antithyroid antibodies are usually not present in the plasma, and tests for TSH-R Ab [stim] are negative.

C. Subacute Thyroiditis

Subacute thyroiditis (thought to be due to viral infection) is characterized by a moderately enlarged, tender thyroid. If the gland is nontender, the disorder is called "silent thyroiditis." Hyperthyroidism is followed by hypothyroidism. During thyrotoxicosis, thyroid radioiodine uptake is low. A similar problem is seen with interleukin-2 therapy and after neck surgery for hyperparathyroidism. Patients taking lithium may rarely experience thyrotoxicosis due to silent thyroiditis. Symptoms mimic a manic episode such that the diagnosis is often missed.

D. Jodbasedow Disease

Jodbasedow disease, or iodine-induced hyperthyroidism, may occur in patients with multinodular goiters after intake of large amounts of iodine in the diet or in the form of radiographic contrast materials or drugs, especially amiodarone.

E. Thyrotoxicosis Factitia

Thyrotoxicosis factitia is due to ingestion of excessive amounts of exogenous thyroid hormone. Isolated epidemics of thyrotoxicosis have been caused by consumption of ground beef contaminated with bovine thyroid gland.

F. Struma Ovarii

Thyroid tissue is contained in about 3% of ovarian dermoid tumors and teratomas. This thyroid tissue may autonomously secrete thyroid hormone due to a toxic nodule or in concert with the woman's thyroid gland in Graves' disease or toxic multinodular goiter.

G. Pituitary Tumor

TSH hypersecretion by the pituitary may be caused by a tumor and is a rare cause of hyperthyroidism. Serum TSH is elevated or normal (determined by a sensitive TSH assay) in the presence of true thyrotoxicosis. No ophthalmopathy is present. Antithyroid antibodies and TSH-R Ab [stim] are usually normal. TSH hypersecretion may be caused by a pituitary adenoma, in which case it is known as "neoplastic inappropriate secretion of thyrotropin." The tumor may present as a mass lesion following treatment of hyperthyroidism. The pituitary adenoma is usually removed by transsphenoidal surgery. Larger tumors may require radiation therapy; treatment with a somatostatin analog (octreotide, lanreotide) is also usually effective.

Hyperthyroidism is treated symptomatically with propranolol. This condition may also be due to pituitary hyperplasia, in which case it is known as "nonneoplastic inappropriate secretion of thyrotropin." Pituitary hyperplasia may be detected on MRI scan as pituitary enlargement without a discrete adenoma being visible. This condition appears to be due to a diminished feedback effect of T_4 upon the pituitary. It may be familial, but it can also be caused by prolonged untreated hypothyroidism, especially in youth. Hyperthyroid symptoms are treated with propranolol. Definitive treatment is with radioactive iodine or thyroid surgery.

H. Hashimoto's Thyroiditis

Hashimoto's thyroiditis may cause transient hyperthyroidism during the initial destructive phase. This is also seen in some patients receiving interferon-alfa, interferon-beta, and interleukin-2.

I. Pregnancy and Trophoblastic Tumors

Postpartum thyroiditis is common, occurring in 5-9% of women in the first 6 months after delivery. Transient hyperthyroidism results from the release of stored thyroid hormone following damage to the thyroid by thyroperoxidase antibodies whose IgG subclasses activate the complement cascade. The damaged thyroid is then unable to produce thyroid hormone, and hypothyroidism ensues. Most of these women eventually return to a euthyroid state, but a third of them remain hypothyroid. Therapy is with propranolol during the hyperthyroid phase, followed by thyroxine during hypothyroidism. Women with postpartum thyroiditis may experience depression. About 75% of women experience recurrence after a subsequent pregnancy.

Although hCG generally has a low affinity for the thyroid's TSH receptors, very high serum levels of hCG may cause sufficient receptor activation to cause thyrotoxicosis. Mild gestational hyperthyroidism may occur during the first 4 months of pregnancy, when hCG levels are very high. Pregnant women are more likely to have thyrotoxicosis and hyperemesis gravidarum if they have high serum levels of asialo-hCG, a subfraction of hCG with greater affinity for TSH receptors.

Thyrotoxicosis may also be caused by the high serum levels of hCG seen in molar pregnancy, choriocarcinoma, and testicular malignancies.

J. Thyroid Carcinoma

Metastatic functioning thyroid carcinoma is a rare cause of thyrotoxicosis.

K. Amiodarone-Induced Thyrotoxicosis

Amiodarone is used to treat cardiac arrhythmias. The drug is concentrated in thyroid, adipose tissue, heart, and skeletal muscle and is 38% iodine by weight; its elimination half-life can be as long as 100 days. Amiodarone causes symptomatic hyperthyroidism in about 3% of patients in the United States; the incidence is higher in Europe and in iodine-deficient geographic areas. Hyperthyroidism can occur 4 months to 3 years after initiation of amiodarone and may develop many months after amiodarone has been discontinued. Thyrotoxicosis may cause angina or a relapse of the cardiac arrhythmia. Since high levels of T_4 and free T_4 are normally seen in patients taking amiodarone, suppressed TSH (sensitive assay) must be present along with a greatly elevated T_4 (> 20 ug/dL) or T_3 (> 200 ng/dL). (**Note:** Hypothyroidism occurs in an additional 6% of patients receiving amiodarone after 2-39 weeks of therapy.) Amiodarone-induced thyrotoxicosis can occur by various mechanisms.

Type I amiodarone-induced thyrotoxicosis is caused by active elaboration of excessive thyroid hormone and may occur by either of two mechanisms: (a) Free iodine may cause toxic multinodular goiter in iodine-deficient patients with preexisting autonomous thyroid nodules (jodbasedow phenomenon). This is infrequently encountered in iodine-sufficient countries such as the United States. Thyroid radioiodine uptake ranges from low to high. (b) Excessive free iodine can trigger an immunologic attack on the thyroid; this may cause Graves' disease, commonly with diffuse thyroid enlargement and antithyroid peroxidase antibodies (70%). The presence of proptosis, TSH receptor antibody (TSH-R Ab [stim]), or thyrotropin-binding inhibitory immunoglobulin (TBII) is diagnostic. Thyroid radioiodine uptake is almost always negligible in the United States; however, up to 80% of such patients in Europe have detectable or normal radioiodine uptake.

Treatment of type I amiodarone-induced thyrotoxicosis usually requires a prolonged course of methimazole. After two doses of methimazole, iopanoic acid or sodium ipodate may be added to the regimen to further block conversion of T_4 to T_3 ; the recommended dosage for each is 500 mg orally twice daily for 3 days, followed by 500 mg once daily until thyrotoxicosis is resolved. Beta-blockers may be required. Withdrawal of amiodarone does not have a significant therapeutic effect for several months. Therapy with ^{131}I may be successful in some patients with adequate radioiodine uptake. Thyroidectomy is reserved for resistant cases.

Type II amiodarone-induced thyrotoxicosis is caused by destructive thyroiditis, which releases stored thyroid hormone from damaged cells; hyperthyroidism can last 1-3 months and may be followed by hypothyroidism. Thyroid radioiodine uptake is very low. Serum levels of interleukin 6 (IL-6) are usually quite elevated. Treatment consists of prednisone plus either iopanoic acid or ipodate sodium (see above). Beta-blockers may be required. Withdrawal of amiodarone is not usually necessary. Since the condition is transient, thyroidectomy is rarely required.

Patients are likely to have type I amiodarone-induced thyrotoxicosis if they have a pretreatment history of multinodular goiter or autoimmune thyroid disease, if they have proptosis, or if they have elevated serum levels of antithyroperoxidase or antithyroglobulin antibodies or TSH-R Ab [stim]. A thyroid radioiodine uptake is not usually obtained in the United States but may be useful elsewhere. It may be necessary to obtain a thyroid ultrasound with color flow Doppler sonography. Ultrasound can usually detect thyroid nodularity characteristic of toxic multinodular goiter. In Graves' disease blood flow is normal or increased, whereas in destructive thyroiditis blood flow is decreased. In practice, the accuracy of this test may depend upon the proficiency of the ultrasonographer.

Patients in atrial fibrillation usually require anticoagulation with warfarin; close monitoring of the INR is required, since both methimazole and hyperthyroidism potentiate the hypoprothrombinemia of anticoagulants. Hyperthyroidism increases the catabolism of vitamin K-dependent clotting factors, and methimazole potentiates anti-vitamin K activity. Changing thyroid levels also modify the coagulation profile.

Clinical Findings

A. Symptoms and Signs

Thyrotoxicosis due to any cause produces many different manifestations of variable intensity among different individuals. Patients may complain of nervousness, restlessness, heat intolerance, increased sweating, fatigue, weakness, muscle cramps, frequent bowel movements, or weight change (usually loss). There may be palpitations or angina pectoris. Women frequently report menstrual irregularities.

Hypokalemic periodic paralysis occurs in about 15% of Asian or Native American men with thyrotoxicosis. It usually presents abruptly with paralysis (and few thyrotoxic symptoms), often after intravenous dextrose, oral carbohydrate, or vigorous exercise. Attacks last 7-72 hours.

Signs of thyrotoxicosis may include stare and lid lag, tachycardia or atrial fibrillation, fine resting finger tremors, moist warm skin, hyperreflexia, fine hair, onycholysis, and (rarely) heart failure. Chronic thyrotoxicosis may cause osteoporosis. At times there may be clubbing and swelling of the fingers (acropachy). Graves' disease usually presents with additional findings of goiter (often with a bruit).

Ophthalmopathy is clinically apparent in 20-40% of patients with Graves' disease and usually consists of chemosis, conjunctivitis, and mild proptosis. More severe lymphocytic infiltration of the eye muscles occurs in 5-10% and may produce exophthalmos and sometimes diplopia due to extraocular muscle entrapment. The optic nerve may be compressed in severe cases. Corneal drying may occur with inadequate lid closure. Eye changes may sometimes be asymmetric or unilateral. The severity of the eye disease is not closely correlated with the severity of the thyrotoxicosis. Some patients with Graves' ophthalmopathy are clinically euthyroid.

Diplopia can also be caused by coexistent ocular **myasthenia gravis**, which is more common in Graves' disease and is usually mild, often with selective eye involvement. Acetylcholinesterase receptor antibody (AChRAB) levels are elevated in only 36% of such patients, and a thymoma is present in 9%.

Graves' dermopathy (myxedema) occurs in about 3% of patients with Graves' disease, usually in the pretibial region. Glycosaminoglycan accumulation and lymphoid infiltration occur in affected skin, which becomes erythematous with a thickened, rough texture.

B. Laboratory Diagnosis

Serum T₃, T₄, thyroid resin uptake, and free thyroxine are usually all increased. Sometimes the T₄ level may be normal but the serum T₃ is elevated. A reliable sensitive TSH assay is the best test for thyrotoxicosis; it is suppressed except in the very rare cases of pituitary inappropriate secretion of thyrotropin. Other laboratory abnormalities may include hypercalcemia, increased alkaline phosphatase, anemia, and decreased granulocytes.

TSH receptor antibody (TSH-R Ab [stim]) levels are usually high (80%). Second-generation TSH-R Ab assays using human recombinant TSH-R are about 99% sensitive for Graves' disease. Antithyroglobulin or antithyroperoxidase antibodies are usually elevated in Graves' disease. Serum ANA and anti-double-stranded DNA antibodies are also usually elevated without any evidence of lupus erythematosus or other collagen-vascular disease.

Patients with subacute thyroiditis often have an increased erythrocyte sedimentation rate.

Thyroid radioactive iodine uptake and scan is usually performed on patients with an established diagnosis of thyrotoxicosis. A high radioactive iodine uptake is seen in Graves' disease and toxic nodular goiter but can be seen in other conditions as well. A low radioactive iodine uptake is characteristic of subacute thyroiditis but can also be seen in other conditions. (For conditions affecting radioactive iodine uptake, see section on tests of thyroid function.)

C. Imaging

MRI of the orbits is the imaging method of choice to visualize Graves' ophthalmopathy affecting the extraocular muscles. CT scanning and ultrasound can also be used. Imaging is required only in severe cases or in euthyroid exophthalmos that must be distinguished from orbital tumors or other disorders.

Differential Diagnosis

True thyrotoxicosis must be distinguished from those conditions elevating serum thyroxine without affecting clinical status ([Table 26-5](#)).

Hyperthyroidism may be confused with anxiety neurosis or mania, but in the latter the thyroid is not enlarged and thyroid function tests are usually normal. Problems of diagnosis occur in patients with acute psychiatric disorders, about 30% of whom have hyperthyroxinemia without thyrotoxicosis. The TSH is not suppressed, distinguishing psychiatric disorder from true hyperthyroidism. T₄ levels return to normal gradually.

Exogenous thyroid administration will present the same laboratory features as thyroiditis. A rare pituitary tumor may produce the picture of thyrotoxicosis with high levels of TSH.

Some states of hypermetabolism without thyrotoxicosis—notably severe anemia, leukemia, polycythemia, and cancer—rarely cause confusion. Pheochromocytoma is often associated with hypermetabolism, tachycardia, weight loss, and profuse sweating. Acromegaly may also produce tachycardia, sweating, and thyroid enlargement. Appropriate laboratory tests will easily distinguish these entities.

Cardiac disease (eg, atrial fibrillation, angina) refractory to treatment suggests the possibility of underlying ("apathetic") hyperthyroidism. Other causes of ophthalmoplegia (eg, myasthenia gravis) and exophthalmos (eg, orbital tumor, pseudotumor) must be considered. Thyrotoxicosis must also be considered in the differential diagnosis of muscle weakness and osteoporosis. Diabetes mellitus and Addison's disease may coexist with thyrotoxicosis.

Complications

Cardiac complications of thyrotoxicosis include atrial fibrillation with a ventricular response that is difficult to control. Episodes of periodic paralysis induced by exercise or heavy carbohydrate ingestion and accompanied by hypokalemia may complicate thyrotoxicosis in Asian or Native American men. Hypercalcemia, osteoporosis, and nephrocalcinosis may occur. Decreased libido, impotence, decreased sperm count, and gynecomastia may be noted in men with hyperthyroidism.

Patients who have "subclinical hyperthyroidism" (suppressed TSH but normal free T₄ and clinically euthyroid) generally do well without treatment. No accelerated bone loss has been noted.

Treatment

The methods used to treat thyrotoxicosis will vary according to the cause and severity of the hyperthyroidism, the patient's age, the clinical situation, and the desires of the patient.

A. Graves' Disease

The treatment of Graves' disease involves a choice of methods rather than a method of choice.

1. Propranolol—Propranolol is generally used for symptomatic relief until the hyperthyroidism is resolved. It effectively relieves the tachycardia, tremor, diaphoresis, and anxiety that occur with hyperthyroidism due to any cause. It is the initial treatment of choice for thyroid storm. The periodic paralysis seen in association with thyrotoxicosis is also effectively treated with beta blockade. It has no effect on thyroid hormone secretion. Treatment is usually begun with 10 mg orally and increased progressively until an adequate response is achieved, usually 20 mg four times daily. Doses as high as 80 mg four times daily are occasionally required. Propranolol is available in a long-acting formulation that provides more consistent relief.

2. Thiourea drugs—Methimazole or propylthiouracil is generally used for young adults or patients with mild thyrotoxicosis, small goiters, or fear of isotopes. Aged patients usually respond particularly well. These drugs are also useful for preparing hyperthyroid patients for surgery and elderly patients for radioactive iodide

treatment. The drugs do not permanently damage the thyroid and are associated with a lower chance of posttreatment hypothyroidism (compared with radioactive iodide or surgery). Unfortunately, there is a high rate of recurrent hyperthyroidism (about 50%) after a year or more of therapy. A greater likelihood of long-term remission is seen in patients with small goiters or mild hyperthyroidism. Patients whose thyroperoxidase and thyroglobulin antibodies remain high after 2 years of therapy have been reported to have only a 10% rate of relapse.

Agranulocytosis is an uncommon but serious complication of thiourea therapy, being reported in about 0.1% of patients taking methimazole and about 0.4% of patients taking propylthiouracil. Patients are warned that if they develop a sore throat or febrile illness, they should stop the drug while a white blood count is rechecked. The agranulocytosis is generally reversible; recovery is not improved by filgrastim (G-CSF). Periodic surveillance of the white blood count during treatment has been advocated by some clinicians, but onset is generally abrupt.

Other side effects common to thiourea drugs include pruritus, allergic dermatitis, nausea, and dyspepsia. Antihistamines may control mild pruritus without discontinuation of the drug. Since the two thiourea drugs are similar, patients who have had a major allergic reaction from one should not be given the other.

Primary hypothyroidism may occur. The patient may become clinically hypothyroid for 2 weeks or more before TSH levels rise, having been suppressed by the preceding hyperthyroidism. Therefore, the patient's changing thyroid status is best followed clinically and with serum levels of free thyroxine. Rapid growth of the goiter usually occurs if the patient is allowed to develop prolonged hypothyroidism; the goiter may sometimes become massive but usually regresses rapidly with thyroid hormone replacement.

a. Methimazole—Methimazole has the advantage of requiring less frequent dosing and fewer pills than propylthiouracil, making treatment more convenient. Patients treated with methimazole (compared with those taking propylthiouracil) have a lower risk of developing fulminant hepatic necrosis; methimazole therapy is also less likely to cause ¹³¹I treatment failure. Rare complications peculiar to methimazole include serum sickness, cholestatic jaundice, loss of taste, alopecia, nephrotic syndrome, and hypoglycemia. Methimazole is given orally in initial doses of 30-60 mg once daily. The dosage is usually reduced as manifestations of hyperthyroidism resolve and as the free thyroxine level becomes normal.

b. Propylthiouracil—Propylthiouracil has been considered the drug of choice during breast feeding or pregnancy, possibly causing fewer problems in the newborn. Rare complications peculiar to propylthiouracil include arthritis, lupus erythematosus, aplastic anemia, thrombocytopenia, and hypoprothrombinemia. Acute hepatitis occurs rarely and is treated with prednisone but may progress to liver failure. Propylthiouracil is given orally in initial doses of 300-600 mg daily in four divided doses. The dosage and frequency of administration are generally reduced as symptoms of hyperthyroidism resolve and the free thyroxine level becomes normal. During pregnancy, the dose is kept below 200 mg/d in order to avoid goitrous hypothyroidism in the infant.

3. Iodinated contrast agents—These agents provide effective temporary treatment for thyrotoxicosis of any cause. Iopanoic acid (Telepaque) or ipodate sodium (Bilivist, Oragrafin) is given orally in a dosage of 500 mg twice daily for 3 days, then 500 mg once daily. These agents inhibit peripheral 5'-monodeiodination of thyroxine, thereby blocking its conversion to active triiodothyronine (T₃). Within 24 hours, serum T₃ levels fall an average of 62%. For patients with Graves' disease, methimazole is begun first in order to block iodine organification; the next day, ipodate sodium or iopanoic acid may be added. The iodinated contrast agents are particularly useful for patients who are very symptomatically thyrotoxic (see Thyroid Storm, below). They offer a therapeutic option for patients with thyroxine overdosage, subacute thyroiditis, and amiodarone-induced thyrotoxicosis and for those intolerant to thioureas and for newborns with thyrotoxicosis (due to maternal Graves' disease). Treatment periods of 8 months or more are possible, but efficacy tends to wane with time. In Graves' disease, thyroid radioiodine uptake may be suppressed during treatment but returns to pretreatment uptake by 7 days after discontinuation of the drug, allowing ¹³¹I treatment.

4. Radioactive iodine (¹³¹I)—The administration of radioiodine is an excellent method of destroying overactive thyroid tissue (either diffuse or toxic nodular goiter). The radioiodine damages the cells that concentrate it. Patients have no apparent risk of subsequent thyroid cancer, leukemia, or other malignancies. Children born to parents previously treated with ¹³¹I show normal rates of congenital abnormalities.

Since fetal radiation is harmful, *radioactive iodine should not be given to pregnant women*. It is prudent to obtain a sensitive pregnancy test (serum β-hCG) on all women of reproductive age prior to ¹³¹I therapy.

Most patients may receive ¹³¹I while being symptomatically treated with just propranolol, which is then reduced in dosage as hyperthyroxinemia resolves. However, some patients (those with coronary diseases, the elderly, or those with severe hyperthyroidism) are usually rendered euthyroid with a thiouracil drug (see above) while the dosage of propranolol is reduced. Treatment with methimazole is discontinued for about 1 week prior to ¹³¹I therapy. A higher rate of ¹³¹I treatment failure has been reported in patients with Graves' disease who have been receiving methimazole or propylthiouracil. However, therapy with ¹³¹I will usually be effective if the methimazole is discontinued about 6 days before radioiodine therapy and if the therapeutic dosage of ¹³¹I is adjusted (upward) according to ¹²³I uptake on the pretherapy scan.

Following ¹³¹I treatment for hyperthyroidism, Graves' ophthalmopathy appears or worsens in 15% and improves in none, whereas during treatment with methimazole, ophthalmopathy worsens in 3% and improves in 2%. Among patients receiving 3 months of prednisone following ¹³¹I treatment, preexistent ophthalmopathy worsens in none and improves in 67%.

Smoking increases the risk of having a flare in ophthalmopathy following ¹³¹I treatment and also reduces the effectiveness of prednisone treatment. Therefore, patients who smoke are strongly encouraged to quit prior to ¹³¹I treatment.

Free T₄ levels may sometimes drop within 2 months after ¹³¹I treatment, but then rise again to thyrotoxic levels, at which time thyroid radioiodine uptake is low. This phenomenon is caused by a release of stored thyroid hormone from injured thyroid cells and does not indicate a treatment failure. In fact, serum free T₄ then falls abruptly to hypothyroid levels.

There is a high incidence of hypothyroidism several years after ¹³¹I even when small doses are given. However, hypothyroidism also occurs quite frequently years after surgical or medical treatment of Graves' disease, and eventual hypothyroidism may be part of the natural history of this condition. Lifelong clinical follow-up is mandatory, with measurements of free T₄ and TSH when indicated.

5. Thyroid surgery—Thyroid surgery for Graves' disease and toxic nodular goiter has been performed less frequently as radioiodine treatment has become more widely accepted. Surgery is usually preferred for pregnant women whose thyrotoxicosis is not controlled with low doses of thioureas, for patients with particularly large goiters, and whenever there is a significant chance of malignancy.

Patients are ordinarily rendered euthyroid with a thiourea drug or ipodate preoperatively. Propranolol is given until the T₃ is normal preoperatively. Thyroid vascularity is reduced by preoperative treatment with either ipodate sodium or iopanoic acid (500 mg twice daily for 3 days) or iodine (eg, Lugol's solution, 2 or 3 drops orally daily for several days). If a patient undergoes surgery while thyrotoxic, larger doses of propranolol are given perioperatively to reduce the likelihood of thyroid crisis.

Morbidity includes possible damage to the recurrent laryngeal nerve, with resultant vocal cord paralysis. Hypoparathyroidism also occurs, which means that calcium levels must be checked postoperatively. These complications are unusual (< 1%) when the surgery is performed by a competent, experienced neck surgeon. Thyroid surgery should be performed as an inpatient, with at least an overnight observational period.

B. Toxic Solitary Thyroid Nodules

Hyperthyroidism caused by a single hyperfunctioning thyroid nodule may be treated symptomatically with propranolol as in Graves' disease. Definitive treatment is with surgery or radioactive iodine. For patients under age 40, surgery is usually recommended; patients are made euthyroid with a thiourea preoperatively and given several days of iodine, ipodate sodium, or iopanoic acid before surgery as in Graves' disease (see above). Transient postoperative hypothyroidism resolves spontaneously. Permanent hypothyroidism occurs in about 14% of patients by 6 years after surgery. Patients over age 40 with a toxic solitary nodule are offered radioactive iodine. Permanent hypothyroidism occurs in about one-third of patients by 8 years after radioactive iodine. The nodule remains palpable in half and may grow in 10% of patients after radioactive iodine.

C. Toxic Multinodular Goiter

Hyperthyroidism caused by a toxic multinodular goiter may also be treated symptomatically with propranolol as in Graves' disease. This disorder usually affects older individuals, so radioactive iodine is ordinarily selected over surgery as definitive treatment. Thioureas do reverse hyperthyroidism, but there is a 95% recurrence rate after they are stopped. Older patients who are quite thyrotoxic are rendered nearly euthyroid with methimazole, which is stopped at least 3 days before radioactive iodine treatment. Meanwhile, the patient follows a low-iodine diet; this is done to enhance the thyroid gland's uptake of radioactive iodine, which may be relatively low in this condition (compared to Graves' disease). Relatively high doses of radioactive iodine are usually required; recurrent thyrotoxicosis and hypothyroidism are common, so patients must be followed closely. Surgery is generally reserved for pressure symptoms or cosmetic indications. Patients are prepared for surgery as in Graves' disease (see above).

D. Subacute Thyroiditis

Patients with hyperthyroidism due to subacute thyroiditis are treated symptomatically with propranolol. Ipodate sodium or iopanoic acid, 500 mg orally daily, promptly corrects elevated T₃ levels and is continued for 15-60 days until the serum FT₄ level normalizes. The condition subsides spontaneously within weeks to months.

Thioureas are ineffective, since thyroid hormone production is actually low in this condition. Radioactive iodine is ineffective, since the thyroid's iodine uptake is low. Since periods of hypothyroidism may occur following the initial inflammatory episode, patients should have close clinical follow-up, with serum free thyroxine measurement when necessary. Prompt treatment of the transient hypothyroidism may reduce the incidence of recurrent thyroiditis. Pain can usually be managed with aspirin or other nonsteroidal anti-inflammatory agents.

E. Hashimoto's Thyroiditis

Rarely, patients develop hyperthyroidism as a result of release of stored thyroid hormone during severe Hashimoto's thyroiditis. The thyroperoxidase or thyroglobulin antibodies are usually high, but radioiodine uptake is low, thus distinguishing it from Graves' disease. This is especially common in postpartum women, in whom it may be transient. Treatment is with propranolol. Patients are followed carefully for the development of hypothyroidism and treated according to their thyroid status.

F. Treatment of Complications

1. Graves' ophthalmopathy—The risk of having a "flare" of ophthalmopathy following ¹³¹I treatment for hyperthyroidism is about 6% for nonsmokers and 23% for smokers. For progressive exophthalmos, prednisone must be given promptly in doses of 40-60 mg/d, with dosage reduction over several weeks. Higher initial prednisone doses of 80-120 mg/d are used when there is optic nerve compression. Prednisone alleviates eye symptoms in 64% of nonsmokers, but only 14% of smokers respond well. Thiazolidinediones (pioglitazone, rosiglitazone) may aggravate ophthalmopathy and should be avoided.

Progressive exophthalmos may be treated with radiation therapy using a supervoltage linear accelerator (4-6 MeV) to deliver 20 Gy over 2 weeks to the extraocular muscles, avoiding the cornea and lens. Prednisone in high doses is given concurrently. Patients who are apt to respond well to orbital radiation include those with signs of acute inflammation, recent exophthalmos, or optic nerve compression. Patients with chronic proptosis and orbital muscle restriction respond less well.

For severe cases, orbital decompression surgery may save vision, though diplopia often persists postoperatively. General eye protective measures include wearing glasses to protect the protruding eye and taping the lids shut during sleep if corneal drying is a problem. Methylcellulose drops and gels ("artificial tears") may also help. Tarsorrhaphy or canthoplasty can frequently help protect the cornea and provide improved appearance. Hypothyroidism and hyperthyroidism must be treated promptly.

2. Cardiac complications—

a. Sinus tachycardia or heart pounding is usually present in thyrotoxicosis. Treatment consists of treating the thyrotoxicosis. A beta-blocker (as described above) such as propranolol is used in the interim unless there is an associated cardiomyopathy.

b. Atrial fibrillation is commonly seen in thyrotoxicosis and may be the presenting manifestation. Electrical cardioversion is unlikely to convert atrial fibrillation to normal sinus rhythm while the patient is thyrotoxic. Spontaneous conversion to normal sinus rhythm tends to occur with achievement of euthyroidism, but that likelihood decreases with age. Hyperthyroidism must be treated (see above). Other drugs may be required:

(1) Digoxin is used to slow a fast ventricular response to thyrotoxic atrial fibrillation; it must be used in larger than normal doses because of increased clearance and an increased number of cardiac cellular sodium pumps requiring inhibition. Digoxin doses are reduced as hyperthyroidism is corrected.

(2) Beta-blockers may also reduce the ventricular rate, but they must be used with caution—particularly in patients with cardiomegaly or signs of heart failure—since their negative inotropic effect may precipitate congestive heart failure. Therefore, an initial trial of a short-duration beta-blocker should be considered, such as esmolol intravenously. If a beta-blocker is used, doses of digoxin must be reduced.

(3) Anticoagulation is indicated to prevent arterial thromboembolism in thyrotoxicosis-induced atrial fibrillation in the following situations: left atrial enlargement on echocardiogram, global left ventricular dysfunction, recent congestive heart failure, hypertension, recurrent atrial fibrillation, or a history of previous thromboembolism. The doses of warfarin required in thyrotoxicosis are smaller than normal because of an accelerated plasma clearance of vitamin K-dependent clotting factors. Higher warfarin doses are usually required as hyperthyroidism subsides.

c. Heart failure due to thyrotoxicosis may be caused by extreme tachycardia, cardiomyopathy, or both. Very aggressive treatment of the hyperthyroidism is required in either case (see Thyroid Crisis, below). The tachycardia from atrial fibrillation is treated with digoxin as above. Intravenous furosemide is typically required. If tachycardia appears to be the main cause of the failure, beta-blockers are administered cautiously as described above.

Congestive heart failure may occur as a result of low-output dilated cardiomyopathy in the setting of hyperthyroidism. It is uncommon and may be caused by an idiosyncratic severe toxic effect of hyperthyroidism upon certain hearts. Cardiomyopathy may occur at any age and without preexisting cardiac disease. Beta-blockers and calcium channel blockers are avoided. Emergency treatment may include afterload reduction, diuretics, digoxin, and other inotropic agents while the patient is being rendered euthyroid. Heart failure usually persists despite correction of hyperthyroidism.

d. Apathetic hyperthyroidism may present with angina pectoris. Treatment is directed at reversing the hyperthyroidism as well as providing standard antianginal therapy. Coronary angioplasty or bypass grafting can often be avoided by prompt diagnosis and treatment.

3. Thyroid crisis or "storm"—This disorder, rarely seen today, is an extreme form of thyrotoxicosis that may occur with stressful illness, thyroid surgery, or radioactive iodine administration and is manifested by marked delirium, severe tachycardia, vomiting, diarrhea, dehydration, and, in many cases, very high fever. The mortality rate is high.

A thiourea drug is given (eg, propylthiouracil, 150-250 mg every 6 hours, or methimazole, 15-25 mg every 6 hours). Iodide is given 1 hour later as Lugol's solution (10 drops three times daily orally) or as sodium iodide (1 g intravenously slowly). Ipodate sodium (500 mg/d orally) can be helpful if begun 1 hour after the first dose of thiourea. Propranolol is given (cautiously in the presence of heart failure; see above) in a dosage of 0.5-2 mg intravenously every 4 hours or 20-120 mg orally every 6 hours. Hydrocortisone is usually given in doses of 50 mg every 6 hours, with rapid dosage reduction as the clinical situation improves. Aspirin is avoided since it displaces T₄ from thyroid-binding globulin, raising free T₄ serum levels. Definitive treatment with ¹³¹I or surgery is delayed until the patient is euthyroid.

4. Hyperthyroidism and pregnancy—The prevalence of hyperthyroidism in pregnancy—most commonly due to Graves' disease—is about 0.2%. Struma ovarii is rare. Diagnosis may be difficult, since normal pregnancy may be accompanied by tachycardia, warm skin, heat intolerance, increased sweating, and a palpable thyroid. Laboratory tests are helpful: The free T₄ is clearly elevated, while the TSH is suppressed. However, apparent lack of full TSH suppression can be seen due to misidentification of hCG as TSH in certain assays. Although the total T₄ is elevated in most pregnant women, values over 20 ug/dL are encountered only in hyperthyroidism. The T₃ resin uptake, which is low in normal pregnancy because of high TBG concentration, is normal or high in thyrotoxic subjects. Pregnancy can have a beneficial effect upon the thyrotoxicosis of Graves' disease, with decreasing antibody titers and decreasing free T₄ levels as the pregnancy advances. However, there is an increased risk of thyroid storm, preeclampsia-eclampsia, congestive heart failure, premature delivery, and abruptio placentae. Newborns have an increased risk of intrauterine growth retardation, prematurity, and transient thyrotoxicosis from transplacental transfer of TSH-R Ab [stim]. Pregnant women with hyperthyroidism are treated with methimazole or propylthiouracil in the smallest dose possible, permitting mild hyperthyroidism to occur since it is usually well tolerated. The drug does cross the placenta and rarely may induce TSH hypersecretion and fetal goiter. Thyroid hormone administration to the mother does not prevent hypothyroidism in the fetus, since T₄ and T₃ do not freely cross the placenta. Fetal hypothyroidism is rare if the mother's hyperthyroidism is controlled with small daily doses of propylthiouracil (50-150 mg/d) or methimazole (5-15 mg/d). Thyroidectomy is reserved for women who are allergic or resistant to antithyroid drugs (usually due to noncompliance) or who have very large goiters.

During lactation, women treated with propylthiouracil secrete very little of it into breast milk. Methimazole is secreted in higher concentrations in breast milk. However, the use of either propylthiouracil or methimazole during breast feeding does not significantly affect the infant's thyroid hormone levels. No adverse reactions to these drugs (eg, rash, hepatic dysfunction, leukopenia) have been reported in breast-fed infants. Recommended doses are 20 mg or less daily for methimazole and 450 mg or less daily for propylthiouracil. It is recommended that the medication be taken just after breast feeding.

5. Graves' dermopathy—An uncommon complication of Graves' disease, dermopathy is an abnormal thickening of the skin due to deposition of glycosaminoglycans. It is known as "pretibial myxedema" since it usually occurs in the anterior lower leg, sometimes also including the dorsum of the foot. Treatment involves application of a topical glucocorticoid (eg, fluocinolone) with nocturnal plastic occlusive dressings.

6. Thyrotoxic hypokalemic periodic paralysis—Asian or Native American men presenting with sudden symmetric flaccid paralysis, hypokalemia, and hypophosphatemia must always be suspected of having thyrotoxicosis, especially since classic signs of thyrotoxicosis may be lacking. Therapy with oral propranolol, 3 mg/kg, normalizes the serum potassium and phosphate levels and reverses the paralysis within 2-3 hours. No intravenous potassium or phosphate is ordinarily required. Intravenous dextrose and oral carbohydrate aggravate the condition and are to be avoided. Therapy is continued with propranolol, 60-80 mg every 8 hours (or

sustained-action propranolol daily at equivalent daily dosage), along with a thiourea drug such as methimazole to treat the hyperthyroidism.

Prognosis

Graves' disease may rarely subside spontaneously and may even result in spontaneous hypothyroidism. However, it usually progresses. The ocular, cardiac, and psychologic complications often are more serious than the chronic wasting of tissues and may become irreversible even after treatment. Permanent hypoparathyroidism and vocal cord palsy are risks of surgical thyroidectomy. Recurrences are common following thiourea therapy but also occur after low-dose ¹³¹I therapy or subtotal thyroidectomy. With adequate treatment and long-term follow-up, the results are usually good. However, despite treatment for their hyperthyroidism, women experience an increased long-term risk of death from thyroid disease, cardiovascular disease, stroke, and fracture of the femur. Posttreatment hypothyroidism is common. It may occur within a few months or up to several years after radioactive iodine therapy or subtotal thyroidectomy. Malignant exophthalmos has a poor prognosis unless treated aggressively.

THYROIDITIS

Essentials of Diagnosis

- Swelling of thyroid gland, often causing pressure symptoms in acute and subacute forms; painless enlargement in chronic form.
- Thyroid function tests variable.
- Serum antithyroid antibody tests often positive.

General Considerations

Thyroiditis may be classified as follows: (1) chronic lymphocytic ("Hashimoto's") thyroiditis due to autoimmunity, (2) subacute thyroiditis, (3) suppurative thyroiditis, and (4) Riedel's thyroiditis.

Clinical Findings

A. Symptoms and Signs

1. Hashimoto's thyroiditis—Hashimoto's thyroiditis—also called chronic lymphocytic thyroiditis—is the most common form of thyroiditis and probably the most common thyroid disorder in the United States. It tends to be familial and is six times more common in women than in men. Its frequency is increased by dietary iodine supplementation. Certain drugs (amiodarone, alpha-interferon, interleukin-2, granulocyte-colony stimulating factor) frequently induce thyroid autoantibodies.

The thyroid gland is usually diffusely enlarged, firm, and finely nodular. One thyroid lobe may be asymmetrically enlarged, raising concerns about neoplasm. Although patients may complain of neck tightness, pain and tenderness are not usually present. About 10% of cases are atrophic, the gland being fibrotic, particularly in elderly women.

Thyroiditis often progresses to hypothyroidism, which is usually permanent, remitting in fewer than 5% of cases. Uncommonly, thyroiditis causes acute destruction of thyroid tissue and release of stored thyroid hormone, causing thyrotoxicosis. Rarely, a hypofunctioning gland may become hyperfunctioning with the onset of coexistent Graves' disease.

Systemic manifestations of Hashimoto's thyroiditis are mostly related to ambient levels of thyroid hormone. However, depression and chronic fatigue are more common in such patients, even after correction of hypothyroidism. About one-third of patients with Hashimoto's thyroiditis have mild dry mouth (xerostomia) or dry eyes (keratoconjunctivitis sicca) of an autoimmune nature related to Sjogren's syndrome. It may be associated with myasthenia gravis, which is usually of mild severity, mainly affecting the extraocular muscles and having a relatively low incidence of detectable acetylcholinesterase receptor antibodies or thymic disease.

Hashimoto's thyroiditis is sometimes associated with adrenal insufficiency (Schmidt's syndrome) and other endocrine deficiencies as part of polyglandular autoimmunity. Thyroiditis is also more common in patients with other autoimmune conditions, such as inflammatory bowel disease, or celiac disease (10%). Women with gonadal dysgenesis (Turner's syndrome) have a 15% incidence of significant thyroid dysfunction by age 40 years. Thyroiditis is also commonly seen in patients with hepatitis C.

Patients with clinically evident disease usually have increased circulating levels of antithyroid peroxidase (95%) or antithyroglobulin (60%) antibodies.

Subclinical thyroiditis is very common, and in autopsy series about 40% of women and 20% of men exhibit focal thyroiditis. Mildly elevated serum titers of antithyroid antibodies are found in 13% of women and 3% of men. However, only 1% of the population has antibody titers greater than 1:6400.

Postpartum thyroiditis is a form of autoimmune thyroiditis occurring soon after parturition and accompanied by transient hyperthyroidism followed by hypothyroidism; recovery of normal function occurs in most cases.

2. Subacute thyroiditis—This fairly common disorder—also called de Quervain's thyroiditis, granulomatous thyroiditis, and giant cell thyroiditis—is an acute, usually painful enlargement of the thyroid gland, with dysphagia. The pain may radiate to the ears. If there is no pain, it is called "silent thyroiditis." The manifestations may persist for weeks or months and may be associated with signs of thyrotoxicosis and malaise. Young and middle-aged women are most commonly affected. Viral infection has been suggested as the cause. The erythrocyte sedimentation rate is markedly elevated, and antithyroid antibodies are low, which helps differentiate this form of thyroiditis from others. Radioactive iodine uptake is low, distinguishing this disorder from Graves' disease. Aspiration biopsy is usually not required but shows characteristic giant multinucleated cells.

3. Suppurative thyroiditis—Suppurative thyroiditis is a rare disorder causing severe pain, tenderness, redness, and fluctuation in the region of the thyroid gland. It is caused by pyogenic organisms, usually in the course of systemic infection.

4. Riedel's thyroiditis—Riedel's thyroiditis is also called invasive fibrous thyroiditis, Riedel's struma, woody thyroiditis, ligneous thyroiditis, and invasive thyroiditis. It usually causes hypothyroidism and may cause hypoparathyroidism as well. It is the rarest form of thyroiditis and is found most frequently in middle-aged or elderly women. Enlargement is often asymmetric; the gland is stony hard and adherent to the neck structures, causing signs of compression and invasion, including dysphagia, dyspnea, pain, and hoarseness. It is usually a manifestation of a multifocal systemic fibrosis syndrome, with anterior neck symptoms predominating. Related conditions include retroperitoneal fibrosis, fibrosing mediastinitis, sclerosing cervicitis, subretinal fibrosis, and biliary tract sclerosis. It responds to therapy with tamoxifen (see Treatment, below).

B. Laboratory Findings

The T₄ and T₃ resin uptakes are usually markedly elevated in acute and subacute thyroiditis and normal or low in the chronic forms. Radioiodine uptake is characteristically very low in the initial, hyperthyroid phase of subacute thyroiditis; it may be high with an uneven scan in chronic thyroiditis, with enlargement of the gland, and low in Riedel's struma. Thyroid autoantibodies are most commonly demonstrable in Hashimoto's thyroiditis but are also found in the other types. The serum TSH level is elevated if thyroid hormone is not elaborated in adequate amounts by the thyroid gland.

Complications

In the suppurative forms of thyroiditis, any of the complications of infection may occur; the subacute and chronic forms of the disease are complicated by the effects of pressure on the neck structures: dyspnea and, in Riedel's struma, vocal cord palsy. Hashimoto's thyroiditis may lead to hypothyroidism or transient thyrotoxicosis. Perimenopausal women with high serum levels of antithyroperoxidase antibodies have a higher relative risk of depression independently of ambient thyroid hormone levels. Graves' disease may sometimes develop. Carcinoma or lymphoma may be associated with chronic thyroiditis and must be considered in the diagnosis of uneven painless enlargements that continue in spite of treatment. Hashimoto's thyroiditis may be associated with Addison's disease, hypoparathyroidism, diabetes, pernicious anemia, biliary cirrhosis, vitiligo, and other autoimmune conditions.

Differential Diagnosis

Thyroiditis must be considered in the differential diagnosis of all types of goiters, especially if enlargement is rapid. The very low radioiodine uptake in subacute thyroiditis with elevated T₄ and T₃ is helpful. Chronic thyroiditis, especially if the enlargement is uneven and if there is pressure on surrounding structures, may resemble carcinoma, and both disorders may be present in the same gland. The subacute and suppurative forms of thyroiditis may resemble any infectious process in or near the neck structures. Thyroid autoantibody tests have been of help in the diagnosis of chronic lymphocytic (Hashimoto's) thyroiditis, but the tests are not specific and may also be positive in patients with goiters, carcinoma, and thyrotoxicosis—though the titers are usually higher in Hashimoto's thyroiditis. Biopsy may be required for diagnosis.

Treatment

A. Suppurative Thyroiditis

Treatment is with antibiotics and with surgical drainage when fluctuation is marked.

B. Subacute Thyroiditis

All treatment is empirical and must be continued for several weeks. Recurrence is common. The drug of choice is aspirin, which relieves pain and inflammation. Thyrotoxic symptoms are treated with propranolol, 10-40 mg every 6 hours. Iodinated contrast agents cause a prompt fall in serum T₃ levels and a dramatic improvement in thyrotoxic symptoms. Sodium ipodate (Oragrafin, Bilivist) or iopanoic acid (Telepaque) is given orally in doses of 500 mg daily until serum free T₄ levels return to normal. Transient hypothyroidism is treated with thyroxine (0.05-0.1 mg/d) if symptomatic.

C. Hashimoto's Thyroiditis

Levothyroxine should be given in the usual doses (0.05-0.2 mg daily) if hypothyroidism or large goiter is present. In one study, selenium selenite (200 ug daily orally for 3 months) reduced the serum levels of antithyroperoxidase antibodies by 49% versus a 10% reduction in the placebo arm. If the thyroid gland is only minimally enlarged and the patient is euthyroid (with normal TSH levels), regular observation is in order, since hypothyroidism may develop subsequently—often years later. (See Hypothyroidism section.)

D. Riedel's Struma

The treatment of choice for invasive fibrous thyroiditis, like that of its related conditions, is tamoxifen, 10 mg orally twice daily. Tamoxifen can induce partial to complete remissions in most patients within 3-6 months. Tamoxifen treatment must be continued for years. Its mode of action appears to be unrelated to its antiestrogen activity. Short-term glucocorticoid treatment may be added for partial alleviation of pain and compression symptoms. Surgical decompression usually fails to permanently alleviate compression symptoms; such surgery is difficult due to dense fibrous adhesions, making surgical complications more likely.

Prognosis

The course of this group of diseases is quite variable. Spontaneous remissions and exacerbations are common in the subacute form, and therapy is nonspecific. The disease process may smolder for months. Hashimoto's thyroiditis is occasionally associated with other autoimmune disorders (diabetes mellitus, Addison's disease, pernicious anemia, etc). In general, however, patients with Hashimoto's thyroiditis have an excellent prognosis, since the condition either remains stable for years or progresses slowly to hypothyroidism, which is easily treated. Women with postpartum thyroiditis usually regain normal thyroid function.

INTRODUCTION

•

■ THE PARATHYROIDS

The main physiologic effects of parathyroid hormone are as follows: (1) It increases the osteoclastic activity in bone, with increased delivery of calcium and phosphorus to the circulation; (2) it increases the renal tubular reabsorption of calcium in the glomerular filtrate; (3) it inhibits the net absorption of phosphate and bicarbonate by the renal tubule; and (4) it stimulates the synthesis of 1,25-dihydroxycholecalciferol by the kidney. All of these steps result in a net increase in the amount of serum ionized calcium. Serum calcium is largely bound to albumin. Therefore, ionized calcium should be determined, or the serum calcium level should be corrected for serum albumin level as follows:

"Corrected" serum Ca^{2+} = Serum Ca^{2+} mg/dL + (0.8 × [4.0 - Albumin g/dL])

HYPOPARATHYROIDISM & PSEUDOHYPOPARATHYROIDISM

Essentials of Diagnosis

- Tetany, carpopedal spasms, tingling of lips and hands, muscle and abdominal cramps, psychologic changes.
- Positive Chvostek's sign and Trousseau's phenomenon; defective nails and teeth; cataracts.
- Serum calcium low; serum phosphate high; alkaline phosphatase normal; urine calcium excretion reduced.
- Serum magnesium may be low.

General Considerations

Hypoparathyroidism is most commonly seen following thyroidectomy, when it is usually transient but may be permanent. It may also occur after surgical removal of a parathyroid adenoma for primary hyperparathyroidism due to suppression of the remaining normal parathyroids and accelerated remineralization of the skeleton (hungry bone syndrome).

Hypoparathyroidism may also be seen in DiGeorge's syndrome, along with congenital cardiac and facial anomalies; hypocalcemia usually presents with tetany in infancy, but some cases are not detected until adulthood. Parathyroid deficiency may also be the result of damage from heavy metals such as copper (Wilson's disease) or iron (hemochromatosis, transfusion hemosiderosis), granulomas, sporadic autoimmunity, Riedel's thyroiditis, tumors, or infection.

Functional hypoparathyroidism may also occur as a result of magnesium deficiency (malabsorption, chronic alcoholism), which prevents the secretion of PTH. Correction of hypomagnesemia results in rapid disappearance of the condition. Hypoparathyroidism may rarely occur after neck irradiation.

Polyglandular autoimmunity type I (PGA-1) is also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED). PGA-1 presents in childhood with at least two of the following manifestations: candidiasis, hypoparathyroidism, or Addison's disease. Patients may also develop cataracts, uveitis, alopecia, vitiligo, or autoimmune thyroid disease.

Fat malabsorption occurs in 20% of patients with PGA-1 and may present as weight loss, diarrhea, or malabsorption of vitamin D, a fat-soluble vitamin used to treat the hypoparathyroidism. The fat malabsorption may be due to a deficiency in the jejunal enteroendocrine cells that produce cholecystokinin, causing a reduction in bile acid secretion.

Pseudohypoparathyroidism is a group of diseases characterized by hypocalcemia due to renal resistance to parathyroid hormone. There are several subtypes caused by different mutations involving the parathyroid hormone receptor or its G protein or adenyl cyclase. PTH levels are high and the PTH receptors in bone are typically not involved, such that bony changes of hyperparathyroidism may be evident. Various phenotypic abnormalities may be associated—classically, short stature, round face, obesity, short fourth metacarpals, ectopic bone formation, and mental retardation. Patients without hypocalcemia but sharing the phenotypic abnormalities are said to have "pseudopseudohypoparathyroidism."

Clinical Findings

A. Symptoms and Signs

Acute hypoparathyroidism causes tetany, with muscle cramps, irritability, carpopedal spasm, and convulsions; tingling of the circumoral area, hands, and feet is almost always present. Symptoms of the chronic disease are lethargy, personality changes, anxiety state, blurring of vision due to cataracts, parkinsonism, and mental retardation.

Chvostek's sign (facial muscle contraction on tapping the facial nerve in front of the ear) is positive, and Trousseau's phenomenon (carpal spasm after application of a cuff) is present. Cataracts may occur; the nails may be thin and brittle; the skin is dry and scaly, at times with fungus infection (candidiasis), and there may be loss of hair (eyebrows); and deep tendon reflexes may be hyperactive. Papilledema and elevated cerebrospinal fluid pressure are occasionally seen. Teeth may be defective if the onset of the disease occurs in childhood.

B. Laboratory Findings

Serum calcium is low, serum phosphate high, urinary calcium low, and alkaline phosphatase normal. Parathyroid hormone levels are low. Serum magnesium should be determined since hypomagnesemia frequently accompanies hypocalcemia and may exacerbate symptoms and decrease parathyroid function.

C. Imaging

Radiographs or CT scans of the skull may show basal ganglia calcifications; the bones may be denser than normal. Cutaneous calcification may occur.

D. Other Examinations

Slit-lamp examination may show early posterior lenticular cataract formation. The ECG shows prolonged QT intervals and T wave abnormalities.

Complications

Acute tetany with stridor, especially if associated with vocal cord palsy, may lead to respiratory obstruction requiring tracheostomy. The complications of chronic hypoparathyroidism depend largely upon the duration of the disease. There may be associated autoimmunity causing sprue syndrome, pernicious anemia, or Addison's disease. In long-standing cases, cataract formation and calcification of the basal ganglia are seen. Occasionally, parkinsonian symptoms or choreoathetosis develops. Ossification of the paravertebral ligaments may occur with nerve root compression; surgical decompression may be required. Seizures are common in untreated patients. Overtreatment with vitamin D and calcium may produce nephrocalcinosis and impairment of renal function.

Differential Diagnosis

The symptoms of hypocalcemic tetany may be confused with paresthesias, muscle cramps, or tetany due to respiratory alkalosis, in which the serum calcium is normal. In fact, hyperventilation tends to accentuate hypocalcemic symptoms. Chronic hypocalcemia can cause heart failure and be confused with myocardial infarction and ischemic cardiomyopathy.

At times hypoparathyroidism is misdiagnosed as idiopathic epilepsy, choreoathetosis, or brain tumor (on the basis of brain calcifications, convulsions, choked disks) or, more rarely, as "asthma" (on the basis of stridor and dyspnea). Hypocalcemia is frequently seen in patients with hypoalbuminemia; serum levels of ionized calcium are normal.

Hypocalcemia may also be due to malabsorption of calcium, magnesium, or vitamin D; patients do not always have diarrhea. It may also be caused by certain drugs such as loop diuretics, plicamycin, phenytoin, alendronate, and foscarnet. In addition, hypocalcemia may be seen in cases of rapid intravascular volume expansion or due to chelation from transfusions of large volumes of citrated blood. Hypocalcemia is also frequently seen following parathyroidectomy for hyperparathyroidism. It is also observed in patients with acute pancreatitis. Some patients with certain osteoblastic metastatic carcinomas (especially breast, prostate) may develop hypocalcemia instead of the expected hypercalcemia. Hypocalcemia with hyperphosphatemia (simulating hypoparathyroidism) is seen in azotemia but may also be caused by large doses of intravenous, oral, or rectal phosphate preparations and by chemotherapy of responsive lymphomas or leukemias.

Hypocalcemia with hypercalciuria may be due to a familial syndrome involving a mutation in the calcium-sensing receptor; such patients have levels of serum PTH that are in the normal range, distinguishing it from hypoparathyroidism. It is transmitted as an autosomal dominant. Such patients are hypercalciuric; treatment with calcium and vitamin D may cause nephrocalcinosis.

Treatment

A. Emergency Treatment for Acute Attack (Hypoparathyroid Tetany)

This usually occurs after surgery and requires immediate treatment.

1. Be sure an adequate airway is present.

2. Intravenous calcium gluconate—Calcium gluconate, 10-20 mL of 10% solution intravenously, may be given *slowly* until tetany ceases. Ten to 50 mL of 10% calcium gluconate may be added to 1 L of 5% glucose in water or saline and administered by slow intravenous drip. The rate should be so adjusted that the serum calcium is maintained between 8 and 9 mg/dL.

3. Oral calcium—Calcium salts should be given orally as soon as possible to supply 1-2 g of calcium daily. Liquid calcium carbonate (Titalac Plus), 500 mg/5 mL, may be especially useful. The dosage is 1-3 g calcium daily. Calcium citrate contains 21% calcium, but a higher proportion is absorbed with less gastrointestinal intolerance.

4. Vitamin D preparations—(Table 26-10.) Therapy should be started as soon as oral calcium is begun. The treatment of choice for chronic hypoparathyroidism is vitamin D₂ (ergocalciferol). The usual dose ranges from 25,000 to 150,000 units/d. It is a slow-acting preparation, and if toxicity develops, hypercalcemia—treatable with hydration and prednisone—may persist for weeks after it is discontinued. Ergocalciferol usually gives a more stable serum calcium level than do the shorter-acting preparations.

The active metabolite of vitamin D, 1,25-dihydroxycholecalciferol (calcitriol), has a very rapid onset of action, and if toxicity develops it is not long-lasting. It is of great use in the treatment of acute hypocalcemia in doses ranging from 0.25 to 4 ug/d. Despite its high cost, calcitriol is being used with increasing frequency for the treatment of chronic hypocalcemia. Therapy is commenced at a dosage of 0.25 ug orally each morning with upward dosage titration to near-normocalcemia. Ultimately, doses of 0.5-2 ug/d are usually required.

Calcifediol (25-hydroxyvitamin D₃) is another option for treatment which has an intermediate onset and duration of action; the usual starting dose is 20 ug/d orally.

Dihydrotachysterol is faster in onset of action and is three times more potent than ergocalciferol. The usual daily maintenance dose is 0.125-1 mg/d. It is more expensive than vitamin D₂.

5. Magnesium—If hypomagnesemia is present (chronic alcoholism, malnutrition, renal loss, drugs such as cisplatin, etc), it must be corrected in order to treat the resulting hypocalcemia. Acutely, MgSO₄ is given intravenously, 1-2 g every 6 hours. Chronic magnesium replacement may be given as magnesium oxide tablets (600 mg), one or two per day, or as a combined magnesium and calcium preparation (Dolomite, others).

6. Transplantation of cryopreserved parathyroid tissue removed during prior surgery—Transplantation restores normocalcemia in about 23%.

B. Maintenance Treatment

The goal should be to maintain the serum calcium in a slightly low but asymptomatic range (8-8.6 mg/dL). This will minimize the hypercalciuria that would otherwise occur and provides a margin of safety against overdosage and hypercalcemia, which may produce permanent damage to renal function. Calcium supplementation (1-2 g/d) is continued, and a vitamin D preparation (see above) is given. Monitoring of serum calcium at regular intervals (at least every 3 months) is mandatory. One should also monitor urine calcium with "spot" urine determinations and keep the level below 30 mg/dL if possible. Hypercalciuria may respond to oral hydrochlorothiazide, usually given with a potassium supplement.

Caution: Phenothiazine drugs should be administered with caution to hypocalcemic patients, since they may precipitate extrapyramidal symptoms. Furosemide should be avoided, since it may worsen hypocalcemia.

Prognosis

The outlook is good if the diagnosis is made promptly and treatment instituted. Any dental changes, cataracts, and brain calcifications are permanent. Periodic blood chemical evaluation is required, since changes in calcium levels may call for modification of the treatment schedule. Hypercalcemia that develops in patients with seemingly stable, treated hypoparathyroidism may be a presenting sign of Addison's disease.

HYPERPARATHYROIDISM

Essentials of Diagnosis

- Patients frequently asymptomatic, detected by screening.
- Renal stones, polyuria, hypertension, constipation, fatigue, mental changes.
- Bone pain; rarely, cystic lesions and pathologic fractures.
- Serum and urine calcium elevated; urine phosphate high with low to normal serum phosphate; alkaline phosphatase normal to elevated.
- Elevated parathyroid hormone.

General Considerations

Primary hyperparathyroidism is an increasingly recognized disorder, present in up to 0.1% of adult patients examined. It can be seen at any age but is more frequent in persons over the age of 50 and is three times more common in women than in men.

The disease is caused by hypersecretion of parathyroid hormone, usually by a parathyroid adenoma, and less commonly by hyperplasia or carcinoma (rare). However, when hyperparathyroidism presents before age 30, there is a higher incidence of multiglandular disease (36%) and carcinoma (5%). The size of the parathyroid adenoma correlates with the serum parathyroid hormone level.

Parathyroid adenomas or hyperplasia can be familial (about 5%) and may be part of multiple endocrine neoplasia types 1, 2a, and 2b. (See Table 26-16.)

Hyperparathyroidism causes excessive excretion of calcium and phosphate by the kidneys. Parathyroid hormone stimulates renal tubular reabsorption of calcium; however, hyperparathyroidism causes hypercalcemia and an increase in calcium in the glomerular filtrate that overwhelms tubular reabsorption capacity, resulting in hypercalciuria. At least 5% of renal stones are associated with this disease. Diffuse parenchymal calcification (nephrocalcinosis) is seen less commonly. Chronic bone resorption induced by excessive PTH in the circulation may produce diffuse demineralization, pathologic fractures, or cystic bone lesions throughout the skeleton ("osteitis fibrosa cystica").

In chronic renal failure, hyperphosphatemia and decreased renal production of 1,25(OH)₂D₃ initially produce a decrease in ionized calcium. The parathyroid glands are stimulated (secondary hyperparathyroidism) and may enlarge, becoming autonomous (tertiary hyperparathyroidism). The bone disease seen in this setting is known as "renal osteodystrophy." Diabetics seem somewhat less prone to develop this syndrome. Hypercalcemia often occurs after renal transplant but usually subsides spontaneously.

Parathyroid carcinoma is a rare cause of hyperparathyroidism but is more common in patients with severe hypercalcemia.

Clinical Findings

A. Symptoms and Signs

Hypercalcemia is frequently discovered accidentally by routine chemistry panels. Most patients are asymptomatic. Parathyroid adenomas are usually so small and deeply located in the neck that they are almost never palpable; when a mass is palpated, it usually turns out to be an incidental thyroid nodule.

Although many patients with mild hypercalcemia offer no complaints, symptomatic patients are said to have problems with "bones, stones, abdominal groans, psychic moans, with fatigue overtones." The manifestations are more formally categorized as follows:

1. Skeletal manifestations—Hyperparathyroidism causes a loss of cortical bone and a gain of trabecular bone. Bone mineral concentration tends to be decreased in the distal radius and in the midshaft of the femur but not in the femoral neck. Similarly, bone mineral is decreased in vertebral posterior processes but increased in the vertebral bodies. Significant bone demineralization is uncommon in mild hyperparathyroidism, but osteitis fibrosa cystica may present as pathologic fractures or as "brown tumors" or cysts of the jaw. More commonly, patients have bone pain and arthralgias.

2. Urinary tract manifestations—Polyuria and polydipsia may be present and are due to hypercalcemia-induced nephrogenic diabetes insipidus. Calcium-containing kidney stones are reported in about 18% of those with newly discovered primary hyperparathyroidism. Nephrocalcinosis and renal failure can occur.

3. Manifestations of hypercalcemia—Mild hypercalcemia is often asymptomatic. In more severe cases, thirst, anorexia, nausea, and vomiting are present. Constipation, fatigue, anemia, weight loss, and hypertension are commonly found. Pancreatitis occurs in 3%. Some patients present primarily with neuromuscular disorders such as muscle weakness, easy fatigability, or paresthesias. Depression, intellectual weariness, and increased sleep requirement are common. Pruritus and psychosis or even coma may accompany severe hypercalcemia. Calcium may precipitate in the corneas ("band keratopathy") or soft tissue (calciophylaxis). Pancreatitis can occur.

B. Laboratory Findings

The hallmark of primary hyperparathyroidism is hypercalcemia (serum calcium > 10.5 mg/dL when corrected for serum albumin; see above). In hyperproteinemic states, the total serum calcium may be elevated but the ionized fraction is normal, whereas in primary hyperparathyroidism the ionized calcium is almost always elevated. The serum phosphate is often low (< 2.5 mg/dL). The urine calcium excretion may be high or normal (averaging 250 mg/g creatinine) but it is usually low for the degree of hypercalcemia. There is an excessive loss of phosphate in the urine in the presence of low (25% of cases) to low normal serum phosphate. (In secondary hyperparathyroidism due to renal failure, the serum phosphate is high.) The alkaline phosphatase is elevated only if bone disease is present. The plasma chloride and uric acid levels may be elevated. Elevated levels of parathyroid hormone confirm the diagnosis. The best immunoassay recognizes the intact molecule at two different sites—the amino terminal and the carboxyl terminal ends—with two different antibodies. This assay, known as immunoradiometric assay (IRMA), is specific and sensitive, making it easier to distinguish primary hyperparathyroidism from other causes of hypercalcemia.

C. Imaging

Localizing preoperative imaging may allow a limited surgery and is especially important for patients with prior neck surgery. Performing two different types of studies reduces the chance of false positives. Since the gland or glands affected are rarely larger than 1.5 cm in diameter (and usually *much* smaller), preoperative imaging techniques are often unsuccessful. Imaging techniques include ultrasonography, CT, MRI, and Tc-99m MIBI studies. The accuracy of a given technique depends upon the available equipment and technical personnel. It is advisable to attempt preoperative localization with Tc-99m sestamibi/Tc-pertechnetate subtraction scintigraphy; this scan's sensitivity is 87%. Neck ultrasound may also be performed with a sensitivity of 80%. The sensitivity of combining both tests is 94%—but only about 55% in patients with multiglandular disease. Three-dimensional scintigraphic imaging techniques can help localize ectopic glands. Tc-99m MIBI specificity is over 95%, but false-positive scans can occur. Incidental small benign thyroid nodules are discovered incidentally in nearly half of patients with hyperparathyroidism who have imaging with ultrasound or MRI.

Bone x-rays are usually normal and not required to make the diagnosis of hyperparathyroidism. There may be demineralization, subperiosteal resorption of bone (especially in the radial aspects of the fingers), or loss of the lamina dura of the teeth. There may be cysts throughout the skeleton, mottling of the skull ("salt-and-pepper appearance"), or pathologic fractures. Articular cartilage calcification (chondrocalcinosis) is sometimes found.

Patients with renal osteodystrophy may have ectopic calcifications around joints or in soft tissue. Such patients may exhibit x-ray changes of osteopenia, osteitis fibrosa, or osteosclerosis, alone or in combination. Osteosclerosis of the vertebral bodies is known as "rugger jersey spine."

Complications

Pathologic fractures are more common in patients with hyperparathyroidism than in the general population. Urinary tract infection due to stone and obstruction may lead to renal failure and uremia. If the serum calcium level rises rapidly, clouding of sensorium, renal failure, and rapid precipitation of calcium throughout the soft tissues may occur. Peptic ulcer and pancreatitis may be intractable before surgery. Insulinomas or gastrinomas may be associated, as well as pituitary tumors (multiple endocrine neoplasia type 1). Pseudogout may complicate hyperparathyroidism both before and after surgical removal of tumors. Hypercalcemia during gestation produces neonatal hypocalcemia.

In secondary hyperparathyroidism due to renal failure, high serum calcium and phosphate levels may cause disseminated calcification in the skin, soft tissues, and arteries (calciophylaxis); this can result in painful ischemic necrosis of skin and gangrene, cardiac arrhythmias, and respiratory failure. The actual serum levels of calcium and phosphate have not correlated well with calciophylaxis, but a calcium (mg/dL) × phosphate (mg/dL) product over 70 is usually present.

Differential Diagnosis

A. Artifact

A report of hypercalcemia may be due to laboratory error or excess tourniquet time and should always be repeated. Hypercalcemia may be due to high serum protein concentrations; serum calcium should be corrected for albumin (see above). It may also be seen with dehydration.

B. Hypercalcemia of Malignancy

Many malignant tumors (breast, lung, pancreas, uterus, hypernephroma, etc) can produce hypercalcemia. In some cases (breast carcinoma especially), bony metastases are present. In others, no metastases to bone can be demonstrated. Most of these tumors secrete parathyroid hormone-related protein (PTHrP), which has tertiary structural homologies to PTH and causes bone resorption and hypercalcemia similar to those of parathyroid hormone. The clinical features of the hypercalcemia of cancer can closely simulate hyperparathyroidism. Serum phosphate is often low, but the plasma level of PTH by IRMA is *low*. Serum PTHrP may be elevated.

Multiple myeloma is a common cause of hypercalcemia in the older population. Many other hematologic cancers such as monocytic leukemia, T cell leukemia and lymphoma, Burkitt's lymphoma, etc, have also been associated with hypercalcemia. Multiple myeloma causes renal dysfunction; resultant increased levels of carboxyl terminal PTH may cause it to be confused with hyperparathyroidism if a carboxyl terminal PTH assay is used. Serum protein and urine electrophoresis and bone marrow biopsy establish the diagnosis.

C. Sarcoidosis and Other Granulomatous Disorders

Macrophages and perhaps other cells present in granulomatous tissue have the ability to synthesize 1,25-dihydroxycholecalciferol. Hypercalcemia has been reported in patients with tuberculosis, sarcoidosis, berylliosis, histoplasmosis, coccidioidomycosis, leprosy, and even foreign-body granuloma. Increased intestinal calcium absorption and hypercalciuria are more common than hypercalcemia. Serum levels of 1,25-dihydroxycholecalciferol are elevated. Therapy with ketoconazole improves the hypercalcemia while treatment is directed at the underlying disorder.

D. Calcium or Vitamin D Ingestion

Ingestion of large amounts of calcium (usually as an antacid) or vitamin D can cause hypercalcemia, which is reversible following its cessation. If it persists, the possibility of associated hyperparathyroidism should be strongly considered.

In vitamin D intoxication, patients may take large amounts of vitamin D for unclear reasons, so a check of all medications is important. Hypercalcemia may persist for several weeks. Serum levels of 25-hydroxycholecalciferol are helpful to confirm the diagnosis. A brief course of glucocorticoid therapy may be necessary if hypercalcemia is severe.

E. Familial Hypocalciuric Hypercalcemia

This benign condition can be easily mistaken for mild hyperparathyroidism. It is an autosomal dominant inherited disorder characterized by hypocalciuria (usually < 50 mg/24 h), variable hypermagnesemia, and normal or minimally elevated levels of PTH. These patients do not normalize their hypercalcemia after subtotal parathyroid removal and should not be subjected to surgery. The condition has an excellent prognosis and is easily diagnosed with family history and urinary calcium clearance determination.

F. Adrenal Insufficiency

Hypercalcemia is common in untreated Addison's disease. This is partly due to disinhibition of calcium uptake by the renal tubule and gut. Additionally, Addison's disease can cause dehydration and hyperproteinemia, resulting in higher levels of nonionized calcium.

G. Hyperthyroidism

Increased bone turnover is a feature of thyrotoxicosis. Mild hypercalcemia may also be present.

H. Other Causes

Other causes of hypercalcemia are shown in [Table 21-9](#). Modest hypercalcemia is also occasionally seen in patients taking thiazide diuretics or lithium; such patients may have an inappropriately nonsuppressed PTH level in the face of hypercalcemia. Prolonged immobilization at bed rest may also cause hypercalcemia, especially in adolescents and patients with extensive Paget's disease of bone. Hypercalcemia is noted in up to one-third of acutely ill patients being treated in intensive care units, particularly patients with acute renal failure. Serum PTH levels are usually slightly elevated, consistent with mild hyperparathyroidism.

Treatment

A. Surgical Measures

Parathyroidectomy is recommended for patients with symptomatic hyperparathyroidism, kidney stones, or bone disease. Seemingly asymptomatic patients may be surgical candidates for other reasons such as (1) serum calcium 1 mg/dL above the upper limit of normal with urine calcium excretion > 50 mg/24 h, (2) urine calcium excretion over 400 mg/24 h, (3) cortical bone density = 2 SD below normal, (4) relative youth (under age 50-60 years), (5) difficulty ensuring medical follow-up, or (6) pregnancy. Removal of a parathyroid adenoma usually results in cure. During pregnancy, parathyroidectomy is performed in the second trimester. If a parathyroid adenoma is identified preoperatively, limited neck exploration is usually sufficient to find and excise it. Without preoperative localization, bilateral neck exploration is usually advisable. Parathyroid glands are not uncommonly supernumerary (five or more) or ectopic (eg, intrathyroidal, carotid sheath, mediastinum). An intraoperative "quick" serum PTH determination is advisable to document the removal of the correct gland.

Parathyroid hyperplasia, commonly seen with chronic renal failure, is best treated with subtotal parathyroidectomy; three and one-half glands are usually removed, and a metal clip is left to mark the location of residual parathyroid tissue.

Parathyroid carcinoma can cause severe hypercalcemia associated with very high serum levels of PTH. Preoperative localizing studies usually detect a large invasive tumor. Therapy consists of en-bloc resection of the tumor and the ipsilateral thyroid lobe. Metastases to local and to distant sites occur in about 50% of patients. Reoperation for neck recurrence is usually necessary. Adjuvant treatment includes radiation therapy. Intravenous bisphosphonate (zoledronate) and calcimimetic agents (NPS R-568) are used for treatment of hypercalcemia.

Complications: Serum PTH levels fall below normal in 70% of patients within hours after successful surgery, commonly causing hypocalcemic paresthesias or even tetany. Hypocalcemia tends to occur the evening after surgery or on the next day. Therefore, frequent postoperative monitoring of serum ionized calcium (or serum calcium plus albumin) is advisable beginning the evening after surgery. Once hypercalcemia has resolved, liquid or chewable calcium carbonate is given orally to reduce the likelihood of hypocalcemia. Symptomatic hypocalcemia is treated with larger doses of calcium; calcitriol (0.25-1 ug daily orally) may be added, with the dosage depending upon symptom severity. Magnesium salts are sometimes required postoperatively, since adequate magnesium is required for functional recovery of the remaining suppressed parathyroid glands.

In about 12% of patients having successful parathyroid surgery, PTH levels rise above normal (while serum calcium is normal or low) by 1 week postoperatively. This secondary hyperparathyroidism is probably due to "hungry bones" and is treated with calcium and vitamin D preparations. Such therapy is usually needed only for 3-6 months but is required chronically by some patients.

Hyperthyroidism commonly occurs immediately following parathyroid surgery. It is caused by release of stored thyroid hormone during surgical manipulation of the thyroid. Short-term treatment with propranolol may be required for several days.

B. Medical Measures

Hypercalcemia is treated with a large fluid intake unless contraindicated. Severe hypercalcemia requires hospitalization and intensive hydration with intravenous saline. (See [Chapter 21](#).)

Bisphosphonates are potent inhibitors of bone resorption and can temporarily treat the hypercalcemia of hyperparathyroidism, malignancy, or immobilization. They may relieve bone pain as with patients with metastatic breast or prostate cancer. Pamidronate in doses of 30-90 mg (in 0.9% saline) is administered intravenously over 2-4 hours. Zoledronate 2-4 mg is administered intravenously over 15 minutes; it is quite effective but also quite expensive. These drugs cause a gradual decline in serum calcium over several days that may last for weeks to months. Other bisphosphonates such as alendronate may be effective orally, but their long-term use for chronic hyperparathyroidism has not been studied. Such bisphosphonates are used generally for patients with severe hyperparathyroidism in preparation for surgery.

Patients with parathyroid carcinoma are treated with surgical resections. Severe hypercalcemia may respond to the above measures and also to mithramycin. A calcium receptor agonist (R-568, calcimimetic) may also be effective.

Patients with mild, asymptomatic hyperparathyroidism are often followed closely medically. Such patients are advised to keep active, avoid immobilization, and drink adequate fluids. They need to avoid thiazide diuretics, large doses of vitamins D and A, and calcium-containing antacids or supplements. Serum calcium and albumin are checked about twice yearly, renal function and urine calcium once yearly, and bone density (of the distal radius) every 2 years.

Estrogen replacement is given to postmenopausal women. Digitalis preparations are avoided, since patients with hypercalcemia are sensitive to its toxic effects. Propranolol may be useful for preventing the adverse cardiac effects of hypercalcemia. Glucocorticoid therapy is ineffective for treating hypercalcemia in hyperparathyroidism.

Renal osteodystrophy is caused by secondary hyperthyroidism during renal failure; it may be prevented by avoiding hyperphosphatemia. Calcium acetate is given with meals to bind phosphate. Calcitriol, given orally or intravenously after dialysis, suppresses parathyroid hyperplasia of renal failure. Vitamin D analogs (eg, paricalcitol) suppress parathyroid hormone secretion but cause less hypercalcemia compared with calcitriol (see [Chapter 22](#)). Calcimimetic agents such as AMG 073 (Cinacalcet) are in clinical trials for the treatment of uncontrolled secondary hyperparathyroidism associated with end-stage renal disease.

Prognosis

Completely asymptomatic patients with mild hypercalcemia may be followed and treated medically without compromising survival. There can be unexplained exacerbations and partial remissions. Surgical removal of sporadic parathyroid adenomas generally results in a permanent cure. Patients with MEN 1 undergoing subtotal parathyroidectomy may experience long remissions, but hyperparathyroidism usually recurs.

Spontaneous cure due to necrosis of the tumor has been reported but is exceedingly rare. The bones, in spite of severe cyst formation, deformity, and fracture, will heal if a parathyroid tumor is successfully removed. The presence of pancreatitis increases the mortality rate. Acute pancreatitis usually resolves with correction of hypercalcemia, whereas subacute or chronic pancreatitis tends to persist. Significant renal damage may progress even after removal of an adenoma. Parathyroid carcinoma tends to invade local structures and may sometimes metastasize; repeat surgical resections and radiation therapy can prolong life. Aggressive surgical and medical management of parathyroid carcinoma can result in an 85% 5-year survival rate and a 57% 10-year survival rate.

■ METABOLIC BONE DISEASE

The term "metabolic bone disease" denotes those conditions producing diffusely decreased bone density (osteopenia) and diminished bone strength. It is categorized by histologic appearance: osteoporosis (common; bone matrix and mineral both decreased) and osteomalacia (unusual; bone matrix intact, mineral decreased).

OSTEOPOROSIS

Essentials of Diagnosis

- Asymptomatic to severe backache from vertebral fractures.
- Spontaneous fractures often discovered incidentally on radiography; loss of height.
- Serum parathyroid hormone, 25(OH)D₂, calcium, phosphorus, and alkaline phosphatase usually normal.
- Demineralization, especially of spine, hip, and pelvis.

General Considerations

Osteoporosis is the most common metabolic bone disease and is estimated to cause 1.5 million fractures annually in the United States—mainly of the spine. The morbidity and indirect mortality rates are very high. Since the usual form of the disease is clinically evident in middle life and beyond and since women are more frequently affected than men, it is often referred to as "postmenopausal" osteoporosis. It is characterized by a decrease in the amount of bone present to a level below which it is capable of maintaining the structural integrity of the skeleton. The rate of bone formation is often normal, whereas the rate of bone resorption is increased. There is a greater loss of trabecular bone than compact bone, accounting for the primary features of the disease, ie, crush fractures of vertebrae, fractures of the neck of the femur, and fractures of the distal end of the radius. Whatever bone is present is normally mineralized.

Osteogenesis imperfecta (see [Chapter 20](#)) is caused by a major mutation in the gene encoding for type I collagen, the major collagen constituent of bone. This causes severe osteoporosis. Spontaneous fractures occur in utero or during childhood. Less severe mutations in the type I collagen gene are common, resulting in collagen disarray and predisposing to hypogonadal (eg, menopausal) or idiopathic osteoporosis.

Etiology

The causes of osteoporosis are listed in [Table 26-11](#).

Clinical Findings

A. Symptoms and Signs

Osteoporosis is usually asymptomatic until fractures occur. It may present as backache of varying degrees of severity or as a spontaneous fracture or collapse of a vertebra. Loss of height is common. Once osteoporosis is identified, a carefully directed history and physical examination must be performed to determine its cause (see [Table 26-11](#)).

B. Laboratory Findings

Serum calcium, phosphate, and PTH are normal. The alkaline phosphatase is usually normal but may be slightly elevated, especially following a fracture. Once osteoporosis is identified, further testing for thyrotoxicosis, hypogonadism, and vitamin D deficiency may be required.

C. Imaging

The principal areas of demineralization are the spine and pelvis, especially in the femoral neck and head; demineralization is less marked in the skull and extremities. Compression of vertebrae is common. Bone densitometry permits screening for osteopenia in high-risk individuals and allows assessment of response to therapy. CT densitometry of vertebrae is highly accurate and reproducible. Dual energy x-ray absorptiometry (DEXA) can determine the density of any bone, is quite accurate, and delivers negligible radiation.

Differential Diagnosis

Osteoporosis has many causes ([Table 26-11](#)). Additionally, osteopenia and fractures can be caused by osteomalacia (see below) and bone marrow neoplasia such as myeloma or metastatic bone disease. These conditions coexist in many patients.

Treatment

A. Specific Measures

Several treatment options are available, so a regimen is tailored to each patient.

1. Sex hormones—Women with hypogonadism should be considered for replacement estrogen (see Hormone Replacement Therapy) or raloxifene (see below). Men with hypogonadism are treated with testosterone (see Male Hypogonadism).

2. Bisphosphonates—These agents work similarly, inhibiting osteoclast-induced bone resorption. To ensure intestinal absorption, bisphosphonates must be taken in the morning with at least 8 oz of plain water at least 30 minutes before consumption of anything else. The patient must remain upright after taking alendronate to reduce the risk of esophagitis. Alendronate is excreted in the urine. However, no dosage adjustments are required for patients with creatinine clearances above 35 mL/min. There has been little experience giving alendronate to patients with severe renal insufficiency; if given, the dose would need to be greatly reduced and serum phosphate levels monitored.

Alendronate, 10 mg/d orally, has proved effective for increasing bone density and reducing fracture risk; esophagitis can occur, especially in patients with hiatal hernia. Gastritis, anorexia, and weight loss are common side effects. Alendronate, 70 mg orally once weekly, appears to be as effective as daily dosing and is more convenient and possibly better tolerated. An alternative oral bisphosphonate is risedronate, 5 mg orally daily. It must also be taken in the morning at least 30 minutes before eating, but it is associated with a lower incidence of gastrointestinal side effects than daily alendronate. All patients should receive some supplementation with oral calcium (given with the evening meal) and vitamin D. Pamidronate is a parenteral bisphosphonate that can be given in doses of 60 mg by slow intravenous infusion in normal saline solution every 3 months for patients with osteoporosis who cannot tolerate the oral bisphosphonate preparations. Zoledronate is a third-generation bisphosphonate and a potent osteoclast inhibitor. It can be given every 6-12 months in doses of 2-4 mg intravenously over 15 minutes. Zoledronate is particularly useful for patients who cannot tolerate oral bisphosphonates. Transient postinfusion myalgia and fever occur commonly.

Bisphosphonates have been effective in preventing corticosteroid-induced osteoporosis.

3. Selective estrogen receptor modulators (SERMs)—Raloxifene, 60 mg/d orally, can be used by postmenopausal women in place of estrogen for prevention of osteoporosis. Bone density increases about 1% over 2 years in postmenopausal women versus 2% increases with estrogen replacement. Raloxifene produces a reduction in LDL cholesterol but not the rise in HDL cholesterol seen with estrogen. It has no direct effect on coronary plaque. Unlike estrogen, raloxifene does not reduce hot flashes; in fact, it often intensifies them. It does not relieve vaginal dryness. Unlike estrogen, raloxifene does not cause endometrial hyperplasia, uterine bleeding, or cancer, nor does it cause breast soreness. The risk of breast cancer is reduced 76% in women taking raloxifene for 3 years. Since it is a potential teratogen, it is contraindicated in premenopausal women.

Raloxifene increases the risk for thromboembolism and should not be used by women with such a history. Leg cramps can also occur.

4. Calcitonin—A nasal spray of calcitonin-salmon (Miacalcin) is available that contains 2200 units/mL in 2-mL metered-dose bottles. The usual dose is one puff (0.09 mL, 200 IU) once daily, alternating nostrils. Nasal administration causes significantly less nausea and flushing than the parenteral route. However, nasal symptoms such as rhinitis and epistaxis occur commonly; other less common adverse reactions include flu-like symptoms, allergy, arthralgias, back pain, and headache. Five years of therapy increases bone 2-3% and reduces the number of new vertebral fractures. Both nasal and parenteral calcitonin have analgesic effects on bone pain;

reduction of pain may be noted within 2-4 weeks after commencing therapy.

5. Calcium and vitamin D—Adequate oral intakes of calcium and vitamin D are required throughout life in order to maintain peak bone mass and reduce the risk of subsequent osteoporosis and osteomalacia. Supplements are recommended for patients at high risk for osteoporosis (see above) and for those with established osteoporosis. Other possible benefits are that the risk of breast cancer is reduced by vitamin D and that calcium supplements may reduce the risk of colon cancer. Calcium supplementation may be given as calcium citrate (0.4-0.7 g elemental calcium per day) or calcium carbonate (1-1.5 g elemental calcium per day). Vitamin D₂ is given in doses of 400-1000 IU daily.

6. Teriparatide—Teriparatide (Forteo, Parathar) is an analog of parathyroid hormone. When administered to patients with osteoporosis in doses of 20 mg/d subcutaneously, it dramatically improves bone density in practically all bones except the distal radius. The recommended dose should not be exceeded, since teriparatide has caused osteosarcoma in rats when administered in very high doses. The drug should not be used by patients with Paget's disease of bone or by those with open epiphyses or hypercalcemia. Side effects may include dizziness and leg cramps. Teriparatide is approved only for a 2-year course of treatment.

Precautions: Patients who are taking glucocorticoids and thiazide diuretics may develop hypercalcemia when given oral calcium supplements. Calcium salts are given with meals in order to reduce the risk of calcium oxalate nephrolithiasis. Patients with renal failure who take calcium carbonate supplements experience a higher risk of calciphylaxis.

B. General Measures

For prevention and treatment of osteoporosis, the diet should be adequate in protein, total calories, calcium, and vitamin D. Pharmacologic glucocorticoid doses should be reduced or discontinued if possible. Thiazides may be useful if hypercalciuria is present. High-impact physical activity (eg, jogging) significantly increases bone density in men and women. Stair- climbing increases bone density in women. Patients who cannot exercise vigorously should be encouraged to engage in other exercise regularly, thereby increasing strength and reducing the risk of falling. Weight training is also helpful to increase muscle strength as well as bone density. Measures should be taken to avoid falls at home (eg, adequate lighting, handrails on stairs, handholds in bathrooms). Patients who have weakness or balance problems must use a cane or a walker; rolling walkers should have a brake mechanism. Balance exercises (eg, tai chi) can reduce the risk of falls. Patients should be kept active; bedridden patients should be given active or passive exercises. The spine may be adequately supported (though braces or corsets are usually not well tolerated), but rigid or excessive immobilization must be avoided. Alcohol and smoking should be avoided.

Prognosis

The prognosis is good for preventing postmenopausal osteoporosis if estrogen therapy or raloxifene is started early and maintained for years. Bisphosphonates can reverse osteoporosis and decrease fracture risk.

OSTEOMALACIA

Essentials of Diagnosis

- Painful proximal muscle weakness (especially pelvic girdle); bone pain and tenderness.
- Decreased bone density from diminished mineralization of osteoid.
- Laboratory abnormalities may include increases in alkaline phosphatase, decreased 25-hydroxyvitamin D, or hypocalcemia, hypocalciuria, hypophosphatemia, secondary hyperparathyroidism.
- Classic radiologic features may be present.

General Considerations

Defective mineralization of the growing skeleton in childhood causes permanent bone deformities (rickets). Defective skeletal mineralization in adults is known as osteomalacia.

Osteomalacia is commonly caused by a deficiency in vitamin D, which is a hormone with a complex set of actions and mechanism of synthesis. Ergocalciferol (vitamin D₂) is derived from plants and is used in most pharmaceutical preparations of vitamin D. Cholecalciferol (vitamin D₃) is synthesized in the skin, under the influence of ultraviolet radiation, from 7-dehydrocholesterol. Both vitamin D₂ and vitamin D₃ are used to fortify foods and have equivalent potency. Two sequential hydroxylations are necessary for full biologic activity: The first one takes place in the liver—to 25-hydroxycholecalciferol (25[OH]D₃)—and the second one in the kidney, resulting in the formation of the most potent biologic metabolite of vitamin D, 1,25-dihydroxycholecalciferol (1,25[OH]₂D₃). The main action of vitamin D is to increase the absorption of calcium and phosphate from the intestine. However, vitamin D appears to have other systemic effects, since 1,25(OH)₂D receptors are also found in other tissues, including the parathyroids, bones, kidneys, skin, brain, pituitary, activated lymphocytes, and various tumors.

Etiology (Table 26-12)

Osteomalacia is a common disorder and is caused by any condition that results in inadequate calcium or phosphate mineralization of bone osteoid.

A. Vitamin D Deficiency and Resistance

Vitamin D deficiency impairs the intestinal absorption of calcium and is the most common cause of osteomalacia. Borderline vitamin D deficiency (serum 25[OH]D < 50 nmol/L or < 20 ng/mL) was found in 24.3% of postmenopausal women from 25 countries in the MORE study. The incidence varied: < 1% in Southeast Asia, 29.3% in the United States, and 36% in Italy. Severe vitamin D deficiency (serum 25[OH]D < 25 nmol/L or < 10 ng/mL) was found in 4.1% of these women; 3.5% in the United States, and 12.5% in Italy. Vitamin D deficiency is particularly common in the institutionalized elderly, with the incidence exceeding 60% in some groups not receiving vitamin D supplementation. Deficiency of vitamin D may arise from insufficient sun exposure, malnutrition, or malabsorption (due to pancreatic insufficiency, cholestatic liver disease, sprue, inflammatory bowel disease, jejunioileal bypass, Billroth type II gastrectomy, etc). Cholestyramine binds bile acids necessary for vitamin D absorption. Patients with severe nephrotic syndrome lose large amounts of vitamin D-binding protein in the urine and may also develop osteomalacia.

Vitamin D-dependent rickets type I is caused by a rare autosomal recessive defect in renal synthesis of 1,25(OH)₂D. It presents in childhood with rickets; adults develop osteomalacia unless treated with oral calcitriol in doses of 0.5-1 ug daily. Vitamin D-dependent rickets type II (now better known as hereditary 1,25[OH]₂D-resistant rickets) is caused by a genetic defect in the 1,25(OH)₂D receptor. It presents in childhood with rickets and alopecia. Adults respond variably to oral calcitriol in very large doses (2-6 ug daily).

Anticonvulsants (eg, phenytoin, carbamazepine, valproate, phenobarbital) inhibit the hepatic production of 25(OH)D and sometimes cause osteomalacia. Phenytoin can also directly inhibit bone mineralization. Serum levels of 1,25(OH)₂D are usually normal.

B. Deficient Calcium Intake

Rickets and osteomalacia continue to be common problems in many tropical countries despite adequate exposure to sunlight. A nutritional deficiency of calcium can occur in any severely malnourished patient. Some degree of calcium deficiency is common in the elderly, since intestinal calcium absorption declines with age. Ingestion of excessive wheat bran also causes calcium malabsorption.

C. Phosphate Deficiency

Phosphatonin is a circulating peptide that inhibits sodium-dependent phosphate transport in the renal tubule; high levels of this peptide cause excessive phosphaturia, resulting in hypophosphatemia. X-linked hypophosphatemic rickets is associated with high levels of phosphatonin, probably caused by familial or sporadic mutations in PHEX endopeptidase, which fails to cleave phosphatonin. Oncogenic osteomalacia is caused by excessive production of phosphatonin by a wide variety of soft tissue tumors (87% benign). The condition is characterized by hypophosphatemia, excessive phosphaturia, reduced serum 1,25(OH)₂D concentrations, and osteomalacia. Excessive renal phosphate losses are also seen in proximal renal tubular acidosis and Fanconi's syndrome. Some cases of hyperphosphaturia are idiopathic.

Other causes of hypophosphatemic osteomalacia include poor nutrition, alcoholism, or chelation of phosphate in the gut by aluminum hydroxide antacids, calcium acetate (Phos-Lo), or sevelamer hydrochloride (Renagel).

D. Aluminum Toxicity

Bone mineralization is inhibited by aluminum. Osteomalacia may occur in patients receiving chronic renal hemodialysis with tap water dialysate or from aluminum-containing antacids used to reduce phosphate levels. Patients being maintained on long-term total parenteral nutrition may develop osteomalacia if the casein hydrolysate used for amino acids contains high levels of aluminum.

E. Hypophosphatasia

Osteomalacia results from an autosomal recessive deficiency of bone alkaline phosphatase, which usually inactivates pyrophosphate; pyrophosphate inhibits bone mineralization. It may present in childhood as rickets or in adulthood as a propensity to fracture—due to osteomalacia. Patients have low serum levels of alkaline phosphatase and high urinary excretion of phosphoethanolamine.

F. Fibrogenesis Imperfecta Ossium

This rare condition sporadically affects middle-aged patients, who present with progressive bone pain and pathologic fractures. Bones have a dense "fishnet" appearance on x-ray. MRI of unfractured bone shows low signal intensity on both T1- and T2-weighted imaging. Serum alkaline phosphatase levels are elevated. Some patients have a monoclonal gammopathy, indicating a possible plasma cell dyscrasia causing an impairment in osteoblast function and collagen disarray. Remission has been reported after repeated courses of melphalan, corticosteroids, and vitamin D analog over 3 years.

Clinical Findings

The clinical manifestations of defective bone mineralization depend on the age at onset and the severity. In adults, osteomalacia is typically asymptomatic at first. Eventually, bone pain occurs, along with muscle weakness due to calcium deficiency. Fractures may occur with little or no trauma.

Diagnostic Tests

Serum is obtained for calcium, albumin, phosphate, alkaline phosphatase, parathyroid hormone, and 25-hydroxyvitamin D (25[OH]D₃) determinations. Bone densitometry helps document the degree of osteopenia. X-rays may show diagnostic features.

In one series of biopsy-proved osteomalacia, alkaline phosphatase was elevated in 94%; the calcium or phosphorus was low in 47%; 25(OH)D₃ was low in 29%; pseudofractures were seen in 18%; and urinary calcium was low in 18%. 1,25(OH)₂D₃ may be low even when 25(OH)D₂ levels are normal.

Bone biopsy is not usually necessary but is diagnostic of osteomalacia if there is significant unmineralized osteoid.

Differential Diagnosis

Osteomalacia usually can be distinguished from osteoporosis by the relative absence of biochemical abnormalities in the latter. Phosphate deficiency must be distinguished from hypophosphatemia seen in hyperparathyroidism.

Prevention & Treatment

Prevention of vitamin D deficiency may be achieved with adequate sunlight exposure and vitamin D supplements. In the United States, the current recommended daily allowance (RDA) of vitamin D is at least 10 ug (400 IU) daily. However, in sunlight-deprived individuals (eg, veiled women, confined patients, or residents of higher latitudes during winter), the RDA should be 1000 IU daily. Patients receiving chronic phenytoin therapy may be treated prophylactically with vitamin D, 50,000 IU orally every 2-4 weeks.

Vitamin D deficiency is treated with ergocalciferol (D₂), 50,000 IU orally once or twice weekly for 6-12 months, followed by at least 1000 IU daily. Ergocalciferol has a long duration of action and may also be given orally every 2 months in doses of 50,000 IU. In patients with intestinal malabsorption, oral doses of 25,000-100,000 IU of vitamin D₂ daily may be required. Some patients with steatorrhea respond better to oral 25(OH)D₃ (calcifediol), 50-100 ug daily. All patients receive supplemental oral calcium salts (eg, calcium citrate or calcium carbonate), which are given with meals. Recommended doses of calcium are as follows: calcium citrate (eg, Citracal), 0.4-0.6 g elemental calcium per day, or calcium carbonate (eg, OsCal, Tums), 1-1.5 g elemental calcium per day.

In hypophosphatemic osteomalacia, nutritional deficiencies are corrected, aluminum-containing antacids are discontinued, and patients with renal tubular acidosis are given bicarbonate therapy. In patients with sporadic adult-onset hypophosphatemia, hyperphosphaturia, and low serum 1,25(OH)₂D levels, a search is conducted for occult tumors that may be resected; whole-body MRI scanning may be required.

For those with X-linked or idiopathic hypophosphatemia and hyperphosphaturia, oral phosphate supplements must be given chronically; calcitriol, 0.25-0.5 ug/d, is given also to improve the impaired calcium absorption caused by the oral phosphate. Human recombinant growth hormone reduces phosphaturia and may be added to the above regimen.

PAGET'S DISEASE OF BONE (OSTEITIS DEFORMANS)

Essentials of Diagnosis

- Often asymptomatic.

- Bone pain may be the first symptom.
- Kyphosis, bowed tibias, large head, deafness, and frequent fractures that vary with location of process.
- Serum calcium and phosphate normal; alkaline phosphatase elevated; urinary hydroxyproline elevated.
- Dense, expanded bones on x-ray.

General Considerations

Paget's disease of bone is a common condition manifested by one or more bony lesions having high bone turnover and disorganized osteoid formation. Involved bones become vascular, weak, and deformed. Paget's disease is present in 1-2% of the population of the United States, with a higher prevalence in the elderly and in the Northeast. It is usually discovered incidentally during radiology imaging or due to incidentally discovered elevations in serum alkaline phosphatase. Only 27% of affected individuals are symptomatic at the time of diagnosis. Familial Paget's disease is unusual but is generally more severe than sporadic cases. A rare form occurs in young people.

Clinical Findings

A. Symptoms and Signs

Paget's disease is usually diagnosed in patients over 40 years of age and often mild and asymptomatic. It can involve just one bone (monostotic) or multiple bones (polyostotic), particularly the skull, femur, tibia, pelvis, and humerus. Pain is the usual first symptom. The bones become soft, leading to bowed tibias, kyphosis, and frequent fractures with slight trauma. If the skull is involved, the patient may report headaches and an increased hat size. Deafness may occur. Increased vascularity over the involved bones causes increased warmth.

B. Laboratory Findings

Serum calcium and phosphorus are normal, but serum alkaline phosphatase is markedly elevated. Urinary hydroxyproline is also elevated in active disease. Serum calcium may be elevated, particularly if the patient is at bed rest.

C. Imaging

On radiographs the involved bones are expanded and denser than normal. Multiple fissure fractures may be seen in the long bones. The initial lesion may be destructive and radiolucent, especially in the skull ("osteoporosis circumscripta"). Technetium pyrophosphate bone scans are helpful in delineating activity of bone lesions even before any radiologic changes are apparent.

Differential Diagnosis

Paget's disease must be differentiated from primary bone lesions such as osteogenic sarcoma, multiple myeloma, and fibrous dysplasia and from secondary bone lesions such as metastatic carcinoma and osteitis fibrosa cystica. Fibrogenesis imperfecta ossium is a rare symmetric disorder that can mimic the features of Paget's disease; alkaline phosphate is likewise elevated. If serum calcium is elevated, hyperparathyroidism may be present in some patients as well.

Complications

Fractures are frequent and occur with minimal trauma. If immobilization takes place and there is an excessive calcium intake, hypercalcemia and kidney stones may develop. Vertebral collapse may lead to spinal cord compression. Osteosarcoma may develop in long-standing lesions. Sarcomatous change is suggested by marked increase in bone pain, sudden rise in alkaline phosphatase, and appearance of a new lytic lesion. The increased vascularity may give rise to high-output cardiac failure. Arthritis frequently develops in joints adjacent to involved bone.

Extensive skull involvement may cause cranial nerve palsies from impingement of the neural foramina. Ischemic neurologic events may occur as a result of a vascular "steal" phenomenon. Involvement of the auditory region frequently causes hearing loss (mixed sensorineural and conductive) and occasionally tinnitus or vertigo.

Treatment

Asymptomatic patients require no treatment except for those with extensive skull involvement, in whom prophylactic treatment may prevent deafness and stroke.

A. Bisphosphonates

Bisphosphonates have become the treatment of choice for Paget's disease. The oral compounds should all be taken with 8 oz of plain water only. Bisphosphonates are usually given cyclically. Therapy is given until a therapeutic response occurs, as evidenced by normalization of the serum alkaline phosphatase. Patients are then given a break from therapy for about 3 months or until the serum alkaline phosphatase becomes elevated again; another cycle is then commenced.

Tiludronate, 400 mg orally daily for 3 months, is very effective in reducing the activity of bone lesions. It should not be taken within 2 hours of meals, aspirin, indomethacin, calcium, magnesium, or aluminum-containing antacids. Esophagitis is uncommon, so recumbency after dosing is not restricted, and the drug may be taken in the evening as well as during the day. The most common side effects have been gastrointestinal, including abdominal pain in 13% and nausea in 9%.

Alendronate, 20-40 mg orally daily (or 70 mg orally once weekly) for 3-month cycles, is also effective. It must be taken in the morning, at least 1/2-1 hour before breakfast. Its main side effect is esophagitis, so recumbency after dosing is prohibited, and the drug is contraindicated in patients with a history of esophagitis, esophageal stricture, dysphagia, hiatal hernia, or achalasia.

Risedronate, 30 mg orally daily for 3-month cycles, has been effective in normalizing alkaline phosphatase and eliminating bone pain in the majority of patients. It has been generally well tolerated, but arthralgias and gastrointestinal side effects do occur.

Etidronate disodium is given in doses of 5 mg/kg orally daily for 90-180 days. In severe disease, 10 mg/kg daily may be used for 90 days, with a rest period before another course is given. Etidronate can aggravate bone pain, particularly in the femur. It is much less effective than the other bisphosphonates.

Pamidronate, 60-120 mg intravenously over 2-4 hours, may produce improvements lasting several months. Alkaline phosphatase may continue to drop for 6 months after treatment. (See Treatment of Hypercalcemia.)

B. Nasal Calcitonin-Salmon

Miacalcin, 200 IU/unit dose spray, is administered as one spray daily, alternating nostrils. It is just as effective as the parenteral preparation and is associated with fewer side effects. Nasal irritation may occur, as may occasional epistaxis. Calcitonin has been used for many years to treat Paget's disease. However, its use has declined dramatically with the introduction of more potent bisphosphonates.

Prognosis

The prognosis in general is good, but sarcomatous changes (in 1-3%) can alter the prognosis unfavorably. In general, the prognosis is worse the earlier in life the disease starts. Fractures usually heal well. In the severe forms, marked deformity, intractable pain, and cardiac failure are found. These complications should become rare with prompt bisphosphonate treatment.

■ DISEASES OF THE ADRENAL CORTEX

ADRENAL CORTEX PHYSIOLOGY

Aldosterone is the major mineralocorticoid secreted by the zona glomerulosa, the outer layer of the adrenal cortex. It stimulates the renal tubule to reabsorb sodium and excrete potassium, thereby protecting against hypovolemia and hyperkalemia.

Aldosterone secretion is stimulated by hypovolemia in an indirect way. Hypovolemia causes the renal juxtaglomerular cells to secrete renin; renin stimulates the

peripheral conversion of angiotensin I to angiotensin II; and angiotensin II then causes aldosterone secretion. Hyperkalemia directly stimulates aldosterone secretion. Secretion is inhibited by atrial natriuretic factor and by dopamine.

Cortisol is the major glucocorticoid secreted by the middle zona fasciculata and the inner zona reticularis of the adrenal cortex.

Cortisol counters insulin effects, tending to cause hyperglycemia by inhibiting insulin secretion and by increasing hepatic gluconeogenesis, substrate being provided by the increased amino acids made available by cortisol's inhibition of protein synthesis in muscles.

Cortisol is secreted in a diurnal pattern, being highest upon awakening and lowest at bedtime. Cortisol production normally increases during exercise, making more glucose and fatty acids available for energy. Cortisol is also secreted in response to acute trauma, infection, and other stresses; it dampens defense mechanisms, helping prevent their dangerous overactivity. It inhibits the production or action of many mediators of inflammation and immunity such as interleukin-6 (IL-6), lymphokines, prostaglandins, and histamine. Cortisol is required for production of angiotensin II, thereby helping maintain adequate vascular tone.

Glucocorticoids increase renal free water clearance. They lower serum calcium by inhibiting calcium uptake by the renal tubule and gut and by redistributing calcium intracellularly.

Androgens are produced in the adrenal cortex, mostly by the inner zona fasciculata. The adrenal cortex's fetal zone atrophies after birth, but the adrenal continues to make large amounts of dehydroepiandrosterone sulfate (DHEAS) and dehydroepiandrosterone (DHEA), which have no known significance during adult life, having minimal androgenic activity; but they continue to be the adrenals' most abundantly secreted steroids. DHEAS secretion declines steadily with age. There are individual differences in secretion, and—for unknown reasons—there is a positive correlation between DHEAS levels and longevity.

Testosterone and androstenedione are the major functional androgens secreted by the adrenal. Their secretion causes adrenarche, which precedes gonadal androgen secretion and stimulates the first sexual hair of puberty.

ACUTE ADRENOCORTICAL INSUFFICIENCY (ADRENAL CRISIS)

Essentials of Diagnosis

- Weakness, abdominal pain, fever, confusion, nausea, vomiting, and diarrhea.
- Low blood pressure, dehydration; skin pigmentation may be increased.
- Serum potassium high, sodium low, blood urea nitrogen high.
- Cosyntropin (ACTH₁₋₂₄) unable to stimulate a normal increase in serum cortisol.

General Considerations

Acute adrenal insufficiency is an emergency caused by insufficient cortisol. Crisis may occur in the course of chronic treated insufficiency, or it may be the presenting manifestation of adrenal insufficiency. Acute adrenal crisis is more commonly seen in primary adrenal insufficiency (Addison's disease) than in disorders of the pituitary gland causing secondary adrenocortical hypofunction.

Adrenal crisis may occur in the following situations: (1) Following stress, eg, trauma, surgery, infection, or prolonged fasting in a patient with latent insufficiency. (2) Following sudden withdrawal of adrenocortical hormone in a patient with chronic insufficiency or in a patient with temporary insufficiency due to suppression by exogenous glucocorticoids or megestrol. (3) Following bilateral adrenalectomy or removal of a functioning adrenal tumor that had suppressed the other adrenal. (4) Following sudden destruction of the pituitary gland (pituitary necrosis), or when thyroid is given to a patient with hypoadrenalism. (5) Following injury to both adrenals by trauma, hemorrhage, anticoagulant therapy, thrombosis, infection, or, rarely, metastatic carcinoma.

Clinical Findings

A. Symptoms and Signs

The patient complains of headache, lassitude, nausea and vomiting, abdominal pain, and often diarrhea. Confusion or coma may be present. Fever may be 40.6°C or more. The blood pressure is low. Patients with preexisting type 1 diabetes may present with recurrent hypoglycemia and reduced insulin requirements. Other signs may include cyanosis, dehydration, skin hyperpigmentation, and sparse axillary hair (if hypogonadism is also present). Meningococcemia may be associated with purpura and adrenal insufficiency secondary to adrenal infarction (Waterhouse-Friderichsen syndrome).

B. Laboratory Findings

The eosinophil count may be high. Hyponatremia or hyperkalemia (or both) are usually present. Hypoglycemia is frequent. Hypercalcemia may be present. Blood, sputum, or urine culture may be positive if bacterial infection is the precipitating cause of the crisis.

The diagnosis is made by a simplified cosyntropin stimulation test, which is performed as follows: (1) Synthetic ACTH₁₋₂₄ (cosyntropin), 0.25 mg, is given parenterally. (2) Serum is obtained for cortisol between 30 and 60 minutes after cosyntropin is administered. Normally, serum cortisol rises to at least 20 ug/dL. For patients receiving glucocorticoid treatment, hydrocortisone must not be given for at least 8 hours before the test. Other glucocorticoids (eg, prednisone, dexamethasone) do not interfere with specific assays for cortisol.

Plasma ACTH is markedly elevated if the patient has primary adrenal disease (generally > 200 pg/mL).

Differential Diagnosis

Acute adrenal insufficiency must be distinguished from other causes of shock (eg, septic, hemorrhagic, cardiogenic). Hyperkalemia is also seen with gastrointestinal bleeding, rhabdomyolysis, hyperkalemic paralysis, and certain drugs (eg, ACE inhibitors, spironolactone). Hyponatremia is seen in many other conditions (eg, hypothyroidism, diuretic use, heart failure, cirrhosis, vomiting, diarrhea, severe illness, or major surgery). It must also be distinguished from an acute abdomen where neutrophilia is the rule, whereas eosinophilia and lymphocytosis are characteristic of adrenal insufficiency.

Treatment

A. Acute Phase

If the diagnosis is suspected, draw a blood sample for cortisol determination and treat with hydrocortisone, 100-300 mg intravenously, and saline *immediately*, without waiting for the results. Thereafter, give hydrocortisone phosphate or hydrocortisone sodium succinate, 100 mg intravenously immediately, and continue intravenous infusions of 50-100 mg every 6 hours for the first day. Give the same amount every 8 hours on the second day and then adjust the dosage in view of the clinical picture.

Since bacterial infection frequently precipitates acute adrenal crisis, broad-spectrum antibiotics should be administered empirically while waiting for the results of initial cultures. Hypoglycemia should be vigorously treated while serum electrolytes, blood urea nitrogen, and creatinine are monitored.

B. Convalescent Phase

When the patient is able to take food by mouth, give oral hydrocortisone, 10-20 mg every 6 hours, and reduce dosage to maintenance levels as needed. Most patients ultimately require hydrocortisone twice daily (AM, 10-20 mg; PM, 5-10 mg). Mineralocorticoid therapy is not needed when large amounts of hydrocortisone are being given, but as the dose is reduced it is usually necessary to add fludrocortisone acetate, 0.05-0.2 mg daily. Some patients never require fludrocortisone or become edematous at doses of more than 0.05 mg once or twice weekly. Once the crisis has passed, the patient must be investigated to assess the degree of permanent adrenal insufficiency and to establish the cause if possible.

Prognosis

Rapid treatment will usually be life-saving. However, acute adrenal insufficiency is frequently unrecognized and untreated since its manifestations mimic more common conditions; lack of treatment leads to shock that is unresponsive to volume replacement and vasopressors, resulting in death.

CHRONIC ADRENOCORTICAL INSUFFICIENCY (ADDISON'S DISEASE)

Essentials of Diagnosis

- Weakness, easy fatigability, anorexia, weight loss; nausea and vomiting, diarrhea; abdominal pain, muscle and joint pains; amenorrhea.
- Sparse axillary hair; increased skin pigmentation, especially of creases, pressure areas, and nipples.
- Hypotension, small heart.
- Serum sodium may be low; potassium, calcium, and urea nitrogen may be elevated; neutropenia, mild anemia, eosinophilia, and relative lymphocytosis may be present.
- Plasma cortisol levels are low or fail to rise after administration of corticotropin.
- Plasma ACTH level elevated.

General Considerations

Addison's disease is an uncommon disorder caused by destruction or dysfunction of the adrenal cortices. It is characterized by chronic deficiency of cortisol, aldosterone, and adrenal androgens and causes skin pigmentation that can be subtle or strikingly dark. Volume and sodium depletion and potassium excess eventually occur in primary adrenal failure. In contrast, if chronic adrenal insufficiency is secondary to pituitary failure (atrophy, necrosis, tumor), mineralocorticoid production (controlled by the renin-angiotensin system) persists and hyperkalemia is not present. Furthermore, if ACTH is not elevated, skin pigmentary changes are not encountered.

Etiology

Autoimmune destruction of the adrenals is the most common cause of Addison's disease in the United States (accounting for about 80% of spontaneous cases). It may occur alone or as part of a polyglandular autoimmune (PGA) syndrome. Type 1 PGA is also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APCED) syndrome and is caused by a defect in T cell-mediated immunity inherited as an autosomal recessive trait. It usually presents in early childhood with mucocutaneous candidiasis, followed by hypoparathyroidism and dystrophy of the teeth and nails; Addison's disease usually appears by age 15 years. Partial or late expression of the syndrome is common. A varied spectrum of associated diseases may be seen in adulthood, including hypogonadism, hypothyroidism, pernicious anemia, alopecia, vitiligo, hepatitis, malabsorption, and Sjogren's syndrome.

Type 2 PGA usually presents in adulthood with autoimmune adrenal insufficiency (no hypoparathyroidism) that is HLA-related. It is associated with autoimmune thyroid disease (usually hypothyroidism, sometimes hyperthyroidism), vitiligo, type 1 diabetes, alopecia areata, or celiac sprue. Autoimmune Addison's disease can also be associated with primary ovarian failure (40% of women before age 50), testicular failure (5%), and pernicious anemia (4%). The combination of Addison's disease and hypothyroidism is known as Schmidt's syndrome.

Tuberculosis was formerly a leading cause of Addison's disease. The association is now relatively rare in the United States but common where tuberculosis is more prevalent.

Bilateral adrenal hemorrhage may occur during sepsis, heparin-associated thrombocytopenia or anticoagulation, or with antiphospholipid antibody syndrome. It may occur in association with major surgery or trauma, presenting about 1 week later with pain, fever, and shock. It may also occur spontaneously.

Adrenoleukodystrophy is an X-linked peroxisomal disorder causing accumulation of very long chain fatty acids in the adrenal cortex, testes, brain, and spinal cord. It may present at any age and accounts for one-third of cases of Addison's disease in boys. Aldosterone deficiency occurs in 9%. Hypogonadism is common. Psychiatric symptoms often include mania, psychosis, or cognitive impairment. Neurologic deterioration may be severe or mild (particularly in heterozygote women), mimics symptoms of multiple sclerosis, and can occur years after the onset of adrenal insufficiency.

Rare causes of adrenal insufficiency include lymphoma, metastatic carcinoma, coccidioidomycosis, histoplasmosis, cytomegalovirus infection (more frequent in patients with AIDS), syphilitic gummas, scleroderma, amyloid disease, and hemochromatosis.

Familial glucocorticoid deficiency is caused by a mutation in the gene encoding the adrenal ACTH receptor. Triple A (Allgrove's) syndrome is characterized by variable expression of the following: adrenal ACTH resistance with cortisol deficiency, achalasia, alacrima, nasal voice, and neuromuscular disease of varying severity (hyperreflexia to spastic paraplegia). Cortisol deficiency usually presents in infancy but may not occur until the third decade of life. Congenital adrenal hypoplasia causes adrenal insufficiency due to absence of the adrenal cortex; patients may also have hypogonadotropic hypogonadism, myopathy, and high-frequency hearing loss. Patients with hereditary defects in adrenal enzymes for cortisol synthesis develop **congenital adrenal hyperplasia** due to ACTH stimulation. The most common enzyme defect is P450c21 (21-hydroxylase). Patients with severely defective P450c21 enzymes manifest deficiency of mineralocorticoids (salt wasting) in addition to deficient cortisol and excessive androgens. Women with milder enzyme defects have adequate cortisol but develop hirsutism in adolescence or adulthood and are said to have "late-onset" congenital adrenal hyperplasia. (See Hirsutism section.)

Isolated hypoaldosteronism can be caused by various conditions. Hyporeninemic hypoaldosteronism can be caused by renal tubular acidosis type IV and is commonly seen with diabetic nephropathy, hypertensive nephrosclerosis, tubulointerstitial diseases, and AIDS; patients present with hyperkalemia, hyperchloremia, and metabolic acidosis (see [Chapter 21](#)). Hyperreninemic hypoaldosteronism can be seen in patients with myotonic dystrophy, aldosterone synthase deficiency, and congenital adrenal hyperplasia. Some patients with congenital adrenal hyperplasia (CYP17 deficiency) may present in adulthood with hyperkalemia, hypertension, and hypogonadism; cortisol deficiency is also usually present but may not be clinically evident.

Clinical Findings

A. Symptoms and Signs

The symptoms may include weakness and fatigability, weight loss, myalgias, arthralgias, fever, anorexia, nausea and vomiting, anxiety, and mental irritability. Some of these symptoms may be due to high serum levels of IL-6. Pigmentary changes consist of diffuse tanning over nonexposed as well as exposed parts or multiple freckles; hyperpigmentation is especially prominent over the knuckles, elbows, knees, and posterior neck and in palmar creases and nail beds. Nipples and areolas tend to darken. The skin in pressure areas such as the belt or brassiere lines and the buttocks also darkens. New scars are pigmented. Some patients have associated vitiligo (10%). Emotional changes are common. Hypoglycemia, when present, may worsen the patient's weakness and mental functioning, rarely leading to coma. Manifestations of other autoimmune disease (see above) may be present. Patients tend to be hypotensive and orthostatic; about 90% have systolic blood pressures under 110 mm Hg; blood pressure over 130 mm Hg is rare. Other findings may include a small heart, hyperplasia of lymphoid tissues, and scant axillary and pubic hair (especially in women).

Patients with adult-onset adrenoleukodystrophy may present with neuropsychiatric symptoms, sometimes without adrenal insufficiency.

B. Laboratory Findings

The white count usually shows moderate neutropenia, lymphocytosis, and a total eosinophil count over 300/uL. Among patients with *chronic* Addison's disease, the serum sodium is usually low (90%) while the potassium is elevated (65%). Patients with diarrhea may not be hyperkalemic. Fasting blood glucose may be low. Hypercalcemia may be present. Young men with idiopathic Addison's disease are screened for adrenoleukodystrophy by determining plasma very long chain fatty acid levels; affected patients have high levels.

Low plasma cortisol (< 3 ug/dL) at 8 AM is diagnostic, especially if accompanied by simultaneous elevation of the plasma ACTH level (usually > 200 pg/ mL). The cosyntropin stimulation test is performed as described above. Serum DHEA levels are under 1000 ng/mL in 100% of patients with Addison's disease. About 15% of the general population have such low DHEA levels, particularly children and elderly individuals. Antiadrenal antibodies are found in the serum in about 50% of cases of autoimmune Addison's disease. Antibodies to thyroid (45%) and other tissues may be present.

Elevated plasma renin activity indicates the presence of depleted intravascular volume and the need for higher doses of fludrocortisone replacement.

C. Imaging

When Addison's disease is not clearly autoimmune, a chest x-ray is obtained to look for tuberculosis, fungal infection, or cancer as possible causes. CT scan of the abdomen will show small noncalcified adrenals in autoimmune Addison's disease. The adrenals are enlarged in about 85% of cases due to metastatic or granulomatous disease. Calcification is noted in about 50% of cases of tuberculous Addison's disease but is also seen with hemorrhage, fungal infection, pheochromocytoma, and melanoma.

Differential Diagnosis

Addison's disease should be considered in any patient with hypotension or hyperkalemia. Unexplained weight loss, weakness, and anorexia may be mistaken for occult cancer. Nausea, vomiting, diarrhea, and abdominal pain may be misdiagnosed as intrinsic gastrointestinal disease. The hyperpigmentation may be confused with that

due to ethnic or racial factors. Weight loss may simulate anorexia nervosa. The neurologic manifestations of Allgrove's syndrome and adrenoleukodystrophy (especially in women) often mimic multiple sclerosis. Hemochromatosis also enters the differential diagnosis of skin hyperpigmentation, but it should be remembered that it may truly be a cause of Addison's disease as well as diabetes mellitus and hypoparathyroidism. Serum ferritin is increased in most cases of hemochromatosis and is a useful screening test. About 17% of patients with AIDS have symptoms of cortisol resistance. AIDS can also cause frank adrenal insufficiency.

Complications

Any of the complications of the underlying disease (eg, tuberculosis) are more likely to occur, and the patient is susceptible to intercurrent infections that may precipitate crisis. Associated autoimmune diseases are common (see above).

Treatment

A. Specific Therapy

Replacement therapy should include a combination of glucocorticoids and mineralocorticoids. In mild cases, hydrocortisone alone may be adequate.

Hydrocortisone is the drug of choice. Most addisonian patients are well maintained on 15-25 mg of hydrocortisone orally daily in two divided doses, two-thirds in the morning and one-third in the late afternoon or early evening. Some patients respond better to prednisone in a dosage of about 2-3 mg in the morning and 1-2 mg in the evening. Adjustments in dosage are made according to the clinical response. A proper dose usually results in a normal differential white count. Many patients, however, do not obtain sufficient salt-retaining effect and require fludrocortisone supplementation or extra dietary salt.

Fludrocortisone acetate has a potent sodium-retaining effect. The dosage is 0.05-0.3 mg orally daily or every other day. In the presence of postural hypotension, hyponatremia, or hyperkalemia, the dosage is increased. Similarly, in patients with fatigue, elevated plasma renin activity indicates the need for a higher replacement dose of fludrocortisone. If edema, hypokalemia, or hypertension ensues, the dose is decreased.

Dehydroepiandrosterone (DHEA) is given to some women with adrenal insufficiency. Women taking DHEA 50 mg orally each morning have experienced an improvement in their overall sense of well-being, mood, and sexuality. Since over-the-counter preparations of DHEA have variable potencies, it is best to have the pharmacy formulate this with pharmaceutical-grade DHEA.

B. General Measures

Treat all infections immediately and vigorously, and raise the dose of hydrocortisone appropriately. The dose of glucocorticoid should also be raised in case of trauma, surgery, stressful diagnostic procedures, or other forms of stress. The maximum hydrocortisone dose for severe stress is 50 mg intravenously or intramuscularly every 6 hours. Lower doses, oral or parenteral, are used for lesser stress. The dose is reduced back to normal as the stress subsides. Patients are advised to wear a medical alert bracelet or medal reading, "Adrenal insufficiency—takes hydrocortisone."

For patients with adrenoleukodystrophy, therapy with "Lorenzo's oil" normalizes serum very long chain fatty acid concentrations but is ineffective clinically. Neurologic manifestations may improve following hematopoietic stem cell transplantation from normal donors.

Prognosis

Patients with Addison's disease can expect a normal life expectancy if their adrenal insufficiency is diagnosed and treated with appropriate replacement doses of glucocorticoids and (if required) mineralocorticoids. However, associated conditions can pose additional health risks. For example, patients with adrenoleukodystrophy or Allgrove syndrome may suffer from neurologic disease. Patients with adrenal tuberculosis may have a serious systemic infection that requires treatment. Adrenal crisis can occur in patients who stop their medication or who experience stress such as infection, trauma, or surgery without appropriately higher doses of glucocorticoids. Patients who take excessive doses of glucocorticoid replacement can develop Cushing's syndrome, which imposes its own risks. Many patients with treated Addison's disease complain of chronic low-grade fatigue. Such fatigue may be due to epinephrine deficiency, which can result from adrenal destruction. Fatigue may also be an indication of suboptimal dosing of medication, electrolyte imbalance, or concurrent problems such as hypothyroidism or diabetes mellitus. However, most patients with Addison's disease are able to live fully active lives.

CUSHING'S SYNDROME (HYPERCORTISOLISM)

Essentials of Diagnosis

- Central obesity, muscle wasting, thin skin, easy bruisability, psychologic changes, hirsutism, purple striae.
- Osteoporosis, hypertension, poor wound healing.
- Hyperglycemia, glycosuria, leukocytosis, lymphocytopenia, hypokalemia.
- Elevated serum cortisol and urinary free cortisol. Lack of normal suppression by dexamethasone.

General Considerations

The term Cushing's "syndrome" refers to the manifestations of excessive corticosteroids, commonly due to supraphysiologic doses of glucocorticoid drugs and rarely due to spontaneous production of excessive corticosteroids by the adrenal cortex. Cases of spontaneous Cushing's syndrome are rare (2.6 new cases yearly per million population) and have several possible causes.

About 43% of cases are due to Cushing's "disease," by which is meant the manifestations of hypercortisolism due to ACTH hypersecretion by the pituitary. Cushing's disease is caused by a benign pituitary adenoma that is typically very small (< 5 mm). It is at least three times more frequent in women than men.

About 10% are due to nonpituitary neoplasms (eg, small cell lung carcinoma), which produce excessive amounts of ectopic ACTH. Hypokalemia and hyperpigmentation are commonly found in this group.

About 15% are due to ACTH from a source that cannot be initially located.

About 32% are due to excessive autonomous secretion of cortisol by the adrenals—independently of ACTH, serum levels of which are usually low. Most such cases are due to a unilateral adrenal tumor: Benign adrenal adenomas are generally small and produce mostly cortisol; adrenal carcinomas are usually large when discovered and can produce excessive cortisol as well as androgens, with resultant hirsutism and virilization. ACTH-independent macronodular adrenal hyperplasia can also produce hypercortisolism due to the adrenal cortex cells' abnormal stimulation by hormones such as catecholamines, arginine vasopressin, serotonin, hCG/LH, or gastric inhibitory polypeptide; in the latter case, hypercortisolism may be intermittent and food-dependent and serum ACTH may not be completely suppressed. Pigmented bilateral macronodular adrenal hyperplasia is a rare cause of Cushing's syndrome in children and young adults; it may be an isolated condition or part of the Carney complex.

Clinical Findings

A. Symptoms and Signs

Patients with Cushing's syndrome usually have central obesity with a plethoric "moon face," "buffalo hump," supraclavicular fat pads, protuberant abdomen, and thin extremities; oligomenorrhea or amenorrhea (or impotence in the male); weakness, backache, and headache; hypertension; osteoporosis; avascular bone necrosis; and acne and superficial skin infections. Patients may have thirst and polyuria (with or without glycosuria), renal calculi, glaucoma, purple striae (especially around the thighs, breasts, and abdomen), and easy bruisability. Wound healing is impaired. Mental symptoms may range from diminished ability to concentrate to increased lability of mood to frank psychosis. Patients are susceptible to opportunistic infections.

B. Laboratory Findings

Glucose tolerance is impaired as a result of insulin resistance. Polyuria is present as a result of increased free water clearance; diabetes mellitus with glycosuria may worsen it. Patients with Cushing's syndrome often have leukocytosis with relative granulocytosis and lymphopenia. Hypokalemia (but not hypernatremia) may be present, particularly in cases of ectopic ACTH secretion.

Tests for Hypercortisolism

The easiest screening test for hypercortisolism involves giving dexamethasone, 1 mg orally, at 11 PM and collecting serum for cortisol determination at about 8 AM the next morning; a cortisol level under 5 ug/dL (fluorometric assay) or under 2 ug/dL (HPLC assay) excludes Cushing's syndrome with 98% certainty. Other patients require further investigation, which includes a 24-hour urine collection for free cortisol and creatinine. An abnormally high 24-hour urine free cortisol (or free cortisol to creatinine ratio of > 95 ug cortisol/g creatinine) helps confirm hypercortisolism. A misleadingly high urine free cortisol excretion occurs with high fluid intake.

In cases of blatant Cushing's syndrome, no further confirmation of hypercortisolism is necessary. In less certain cases, a suppression test can also be done by giving dexamethasone, 0.5 mg orally every 6 hours for 48 hours. Urine is collected on the second day. Urine free cortisol over 20 ug/d or urine 17-hydroxycorticosteroid over 4.5 mg/d also helps confirm hypercortisolism.

A midnight serum cortisol level > 7.5 ug/dL is indicative of Cushing's syndrome and distinguishes it from other conditions associated with a high urine free cortisol (pseudo-Cushing states; see Differential Diagnosis, below). Requirements for this test include being in the same time zone for at least 3 days, being without food for at least 3 hours, and having an indwelling intravenous line established in advance for the blood draw.

Saliva may be collected for cortisol measurement but must be sent to a laboratory with demonstrated expertise in the test procedure. A midnight salivary cortisol level greater than 550 ng/dL (15.2 nmol/L) identifies 93% of patients with Cushing's syndrome and excludes most others.

Certain drugs such as phenytoin, phenobarbital, and primidone accelerate the metabolism of dexamethasone, in that way causing a "false-positive" dexamethasone suppression test. Estrogens—during pregnancy or as oral contraceptives or estrogen replacement therapy—may also cause lack of dexamethasone suppressibility. In pregnancy, urine free cortisol is increased, while 17-hydroxycorticosteroids remain normal and diurnal variability of serum cortisol is normal.

Finding the Cause of Hypercortisolism

Once hypercortisolism is confirmed, a baseline plasma ACTH is obtained. It must be collected properly on ice and processed quickly by a laboratory with a reliable, sensitive assay. A level of ACTH below the normal range (about 20 pg/mL) indicates a probable adrenal tumor, whereas higher levels are produced by pituitary or ectopic tumors.

Localizing Techniques

In ACTH-dependent Cushing's syndrome, MRI of the pituitary can demonstrate a pituitary adenoma in about 50% of cases. Premature cerebral atrophy is often noted. When the pituitary MRI is normal or shows a tiny irregularity that may be incidental, selective inferior petrosal venous sampling for ACTH is performed (with CRH stimulation) where available to confirm a pituitary ACTH source, distinguishing it from an occult nonpituitary tumor secreting ACTH.

Two tests that are not useful for distinguishing the source of ACTH in Cushing's syndrome are the high-dose dexamethasone suppression test and the corticotropin-releasing hormone (CRH) test.

Location of ectopic sources of ACTH is done with CT scan of the chest and abdomen, with special attention to the lungs (for carcinoid or small cell carcinomas), the thymus, the pancreas, and the adrenals. Chest masses are frequently due to opportunistic infections, so biopsy is done to confirm the pathologic diagnosis prior to resection.

In non-ACTH-dependent Cushing's syndrome, a CT scan of the adrenals can localize the adrenal tumor in most cases.

Differential Diagnosis

Alcoholic patients can have hypercortisolism and many clinical manifestations of Cushing's syndrome. Depressed patients also have hypercortisolism that can be nearly impossible to distinguish biochemically from Cushing's syndrome but without clinical signs of Cushing's syndrome. Some adolescents develop violaceous striae on the abdomen, back, and breasts; these are known as "striae distensae" and are not indicative of Cushing's syndrome. Cushing's syndrome can be misdiagnosed as anorexia nervosa (and vice versa) owing to the muscle wasting and extraordinarily high urine free cortisol levels found in anorexia. Patients with severe obesity frequently have an abnormal dexamethasone suppression test, but the urine free cortisol is usually normal, as is diurnal variation of serum cortisol. Patients with familial cortisol resistance have hyperandrogenism, hypertension, and hypercortisolism without actual Cushing's syndrome. Patients with familial partial lipodystrophy type I develop central obesity and a moon facies, along with thin extremities due to atrophy of subcutaneous fat. However, their muscles are strong and may be hypertrophic, distinguishing this condition from Cushing's syndrome. Patients receiving antiretroviral therapy for HIV-1 infection frequently develop partial lipodystrophy with thin extremities and central obesity with a dorsocervical fat pad ("buffalo hump") that may mimic Cushing's syndrome.

Complications

Cushing's syndrome, if untreated, produces serious morbidity and even death. The patient may suffer from any of the complications of hypertension or of diabetes. Susceptibility to infections is increased. Compression fractures of the osteoporotic spine and aseptic necrosis of the femoral head may cause marked disability. Nephrolithiasis and psychosis may occur. Following bilateral adrenalectomy for Cushing's disease, a pituitary adenoma may enlarge progressively, causing local destruction (eg, visual field impairment) and hyperpigmentation; this complication is known as Nelson's syndrome.

Treatment

Cushing's disease is best treated by selective transsphenoidal resection of the pituitary adenoma, after which the rest of the pituitary usually returns to normal function; however, the normal corticotrophs are suppressed and require 6-36 months to recover normal function. Hydrocortisone replacement therapy is necessary in the meantime. Patients who fail to have a remission (or who have a recurrence) can be treated by bilateral laparoscopic adrenalectomy. Alternatively, stereotactic pituitary radiosurgery (gamma knife) induces normalization of urine free cortisol in two-thirds of patients within 12 months. Conventional radiation therapy results in a 23% cure rate. Patients who are not surgical candidates may be given a trial of ketoconazole in doses of about 200 mg every 6 hours; liver enzymes must be monitored for progressive elevation.

Adrenal neoplasms secreting cortisol are resected laparoscopically. The contralateral adrenal is suppressed, so postoperative hydrocortisone replacement is required until recovery occurs. Metastatic adrenal carcinomas may be treated with mitotane; ketoconazole or metyrapone can help suppress hypercortisolism in unresectable adrenal carcinoma.

Ectopic ACTH-secreting tumors should be surgically resected. If that cannot be done, medical treatment with ketoconazole or metyrapone (or both) may at least suppress the hypercortisolism; however, metyrapone may exacerbate female virilization. The somatostatin analog octreotide, given parenterally, suppresses ACTH secretion in about one-third of such cases.

Prognosis

Patients with Cushing's syndrome from a benign adrenal adenoma experience a 5-year survival of 95% and a 10-year survival of 90%, following a successful adrenalectomy. Patients with Cushing's disease from a pituitary adenoma experience a similar survival if their pituitary surgery is successful. However, transsphenoidal surgery incurs a failure rate of about 10-20%, often due to the adenoma's ectopic position or invasion of the cavernous sinus. Those patients who have a complete remission after transsphenoidal surgery have about a 15-20% chance of recurrence over the next 10 years. Patients with failed pituitary surgery may require pituitary radiation therapy, which has its own morbidity. Bilateral adrenalectomy is often complicated by infection; recurrence of hypercortisolism may occur as a result of growth of an adrenal remnant stimulated by high levels of ACTH. The prognosis for patients with ectopic ACTH-producing tumors is dependent upon the aggressiveness and stage of the particular tumor. Patients with ACTH of unknown source have a 5-year survival rate of 65% and a 10-year survival rate of 55%. Patients with adrenal carcinoma have a median survival of 7 months.

HIRSUTISM & VIRILIZATION

Essentials of Diagnosis

- Menstrual disorders, hirsutism, acne.
- Virilization may occur: increased muscularity, androgenic alopecia, deepening of the voice, enlargement of the clitoris.
- Occasionally a palpable pelvic tumor.
- Urinary 17-ketosteroids and serum DHEAS and androstenedione elevated in adrenal disorders, variable in others.
- Serum testosterone often elevated.

General Considerations

Major androgens include testosterone, androstenedione, and dehydroepiandrosterone sulfate (DHEAS). In women, circulating testosterone is derived from direct ovarian secretion (60%) and from peripheral conversion from androstenedione (40%). Androstenedione is secreted in about equal amounts by the adrenals and ovaries. DHEAS is secreted exclusively by the adrenals.

Testosterone is the most potent androgen, but 98% circulates in a bound state: About 65% is strongly bound to sex hormone-binding globulin (SHBG), while 33% is weakly bound to albumin. Only free testosterone and a portion of the weakly bound testosterone can enter target cells to exert androgenic effect. Assays have therefore been devised to measure "total," "free," or "free and weakly bound" testosterone.

Testosterone is converted in the skin to dihydrotestosterone, which actually stimulates the hair follicle. Dihydrotestosterone is metabolized to androstenediol glucuronide, which can be measured and is elevated in most cases of hirsutism.

Etiology

Hirsutism may be caused by the following disorders.

A. Idiopathic or Familial

Most women with hirsutism or androgenic alopecia have no detectable hyperandrogenism. Patients often have a strong familial predisposition to hirsutism that may be considered normal in the context of their genetic background. Such patients may have elevated serum levels of androstenediol glucuronide, a metabolite of dihydrotestosterone that is produced by skin in cosmetically unacceptable amounts.

B. Polycystic Ovary Syndrome (Hyperthecosis, Stein-Leventhal Syndrome)

This is a common functional disorder of the ovaries which accounts for at least half the cases of clinical hirsutism. Patients frequently have amenorrhea or oligomenorrhea with anovulation and obesity. The serum LH:FSH ratio is often greater than 2.0. Both adrenal and ovarian androgen hypersecretion are commonly present. Insulin resistance and obesity are common; fasting insulin levels are elevated in 70%. Diabetes mellitus is present in about 13%. Women frequently regain normal menstrual cycles with aging.

C. Steroidogenic Enzyme Defects

Baby girls with "classic" 21-hydroxylase deficiency have ambiguous genitalia and may become virilized unless treated with corticosteroid replacement; about half of such patients have clinically evident mineralocorticoid deficiency (salt-wasting) as well.

About 2% of patients with adult-onset hirsutism have been found to have a partial defect in adrenal 21-hydroxylase, whose phenotypic expression is delayed until adolescence or adulthood; such patients do not have salt-wasting. These women are more likely to develop polycystic ovaries and adrenal adenomas.

Some rare patients with hyperandrogenism and hypertension have 11-hydroxylase deficiency. This is distinguished from cortisol resistance by high cortisol serum levels in the latter and by high serum 11-deoxycortisol levels in the former.

Patients with an XY karyotype and a deficiency in 17 β -hydroxysteroid dehydrogenase-3 or a deficiency in 5 α -reductase-2 may present as phenotypic girls who develop virilization at puberty.

D. Neoplastic Disorders

Ovarian tumors are very uncommon causes of hirsutism (0.8%) and include arrhenoblastomas, Sertoli-Leydig cell tumors, dysgerminomas, and hilar cell tumors. Adrenal carcinoma is a rare cause of hyperandrogenism that can be quite virilizing.

E. Other Rare Causes

Other rare causes of hirsutism include acromegaly and ACTH-induced Cushing's syndrome. Maternal virilization during pregnancy may occur as a result of a luteoma of pregnancy, hyperreactio luteinalis, or polycystic ovaries. In postmenopausal women, diffuse stromal Leydig cell hyperplasia is a rare cause of hyperandrogenism. Pharmacologic causes include minoxidil, cyclosporine, phenytoin, anabolic steroids, diazoxide, and certain progestins.

Clinical Findings

A. Symptoms and Signs

Modest androgen excess from any source increases sexual hair (chin, upper lip, abdomen, and chest) and increases sebaceous gland activity, producing acne. Menstrual irregularities, anovulation, and amenorrhea are common. If androgen excess is pronounced, defeminization (decrease in breast size, loss of feminine adipose tissue), and virilization (frontal balding, muscularity, clitoromegaly, and deepening of the voice) occur. Virilization implicates the presence of an androgen-producing neoplasm.

Hypertension may be seen in rare patients with Cushing's syndrome, adrenal 11-hydroxylase deficiency, or cortisol resistance syndrome.

A pelvic examination may disclose clitoromegaly or ovarian enlargement that may be cystic or neoplastic.

B. Laboratory Testing and Imaging

Serum androgen testing is mainly useful to screen for rare occult adrenal or ovarian neoplasms. Some general guidelines are presented here, though exceptions are common.

Serum is assayed for total testosterone and free testosterone. Certain assays for free testosterone are not reliable, including the free androgen index, the analog free testosterone assay, and the electrochemical luminescence assay. It is best to specify the assay desired, eg, free testosterone by equilibrium dialysis, calculated free testosterone, or non-sex-hormone-bound testosterone assay.

A serum testosterone level greater than 200 ng/dL or free testosterone greater than 40 ng/dL indicates the need for pelvic examination and ultrasound. If that is negative, an adrenal CT scan is performed.

A serum androstenedione greater than 1000 ng/dL also implicates an ovarian or adrenal neoplasm.

Patients with milder elevations of serum testosterone or androstenedione usually are treated with an oral contraceptive.

Patients with very elevated serum DHEAS (> 700 ug/dL) have an adrenal source of androgen. This usually is due to adrenal hyperplasia and rarely to adrenal carcinoma. An adrenal CT scan is performed.

No firm guidelines exist as to which patients (if any) with hyperandrogenism should be screened for "late-onset" 21-hydroxylase deficiency. The evaluation requires levels of serum 17-hydroxyprogesterone to be drawn at baseline and at 30-60 minutes after the intramuscular injection of 0.25 mg of cosyntropin (ACTH₁₋₂₄). This test should ideally be done during the follicular phase of a woman's menstrual cycle. Patients with congenital adrenal hyperplasia will usually have a baseline 17-hydroxyprogesterone over 300 ng/dL or a stimulated level over 1000 ng/dL. The diagnosis, once made, is interesting academically but not helpful to the patient since glucocorticoid treatment is not particularly more effective in this condition than are other treatment modalities (see below).

Patients with any clinical signs of Cushing's syndrome should receive a screening test. (See Cushing's Syndrome.)

Serum levels of FSH and LH are elevated if amenorrhea is due to ovarian failure. An LH:FSH ratio greater than 2.0 is common in patients with polycystic ovary syndrome. On abdominal ultrasound, about 33% of normal young women have polycystic ovaries, so the appearance of ovarian cysts on ultrasound is not helpful diagnostically.

Virilizing tumors of the ovary can usually be detected by pelvic ultrasound or MRI. However, small virilizing ovarian tumors may not be detectable on imaging studies; selective venous sampling for testosterone may be employed for diagnosis in such patients.

Treatment

Any underlying cause of hyperandrogenism must be detected and treated if possible. Postmenopausal women with severe hyperandrogenism should undergo laparoscopic bilateral oophorectomy (if CT scan of the adrenals and ovaries is normal), since small hilar cell tumors of the ovary may not be visible on scans. Girls with hyperandrogenism due to classic salt-wasting congenital adrenal hyperplasia may be treated with laparoscopic bilateral adrenalectomy. Any drugs causing hirsutism are stopped. Treatment options for other cases are summarized in the following paragraphs.

Spironolactone may be taken in doses of 50-100 mg twice daily on days 5-25 of the menstrual cycle or daily if used concomitantly with an oral contraceptive. Hyperkalemia or hyponatremia is uncommon.

Cyproterone acetate is a potent antiandrogen with progestational activity. A dose of 2 mg is effective. An oral contraceptive is usually prescribed also. Cyproterone is not available in the United States. It is available elsewhere as the progestin element in an oral contraceptive (Diane-35: ethinyl estradiol 35 ug with cyproterone acetate 2 mg). Side effects may include fatigue, nausea, or depression.

Finasteride inhibits 5 α -reductase, the enzyme that converts testosterone to active dihydrotestosterone in the skin. Given as 2.5-mg doses orally daily, it provides modest reduction in hirsutism over 6 months—comparable to results achieved with spironolactone. Finasteride is ineffective for androgenic alopecia in women. Side effects are rare.

Flutamide inhibits androgen reception uptake and also suppresses serum androgen. It is given orally in a dosage of 250 mg/d for the first year and then 125 mg/d for maintenance. Used with an oral contraceptive, it appears to be more effective than spironolactone in improving hirsutism, acne, and male pattern baldness. Hepatotoxicity has been reported but is rare.

Oral contraceptives stimulate menses (if that is desired) but are less effective for hirsutism. Contraceptives with low-androgenic progestins (desogestrel, gestodene) may be tried.

Metformin, 500-1000 mg twice daily, in women with polycystic ovary syndrome and amenorrhea tends to restore normal menses and reduce hirsutism. It is contraindicated in renal disease. Gastrointestinal side effects are usually tolerable. Metformin can be taken by nondiabetics without causing hypoglycemia.

Local treatment by shaving or depilatories, waxing, electrolysis, or bleaching should be encouraged. Laser therapy is an effective treatment for facial hirsutism, particularly for women with dark hair and light skin; complications include skin hypopigmentation (rare) and hyperpigmentation, which occurs in 20% but usually resolves.

Women with androgenic alopecia may be effectively treated with topical minoxidil 2% solution applied chronically twice daily to a dry scalp. Hypertrichosis is an unwanted side effect of topical minoxidil, occurring in 3-5% of treated women; it may affect the forehead, cheeks, upper lip, or chin. Hypertrichosis resolves within 1-6 months after the drug is stopped.

Note: Antiandrogen treatments must be given only to nonpregnant women. Women must be counseled to take oral contraceptives, when indicated, and avoid pregnancy, since use during pregnancy causes malformations and pseudohermaphroditism in male infants.

PRIMARY HYPERALDOSTERONISM

Essentials of Diagnosis

- Hypertension, polyuria, polydipsia, muscular weakness.
- Hypokalemia, alkalosis.
- Elevated plasma and urine aldosterone levels and low plasma renin level.

General Considerations

Classic hyperaldosteronism (with hypokalemia) accounts for about 0.7% of cases of hypertension; milder hyperaldosteronism is more frequent. The disorder is more common in women. Primary hyperaldosteronism may be due to unilateral adrenocortical adenoma (Conn's syndrome, 73%) or bilateral cortical hyperplasia (27%), which may be glucocorticoid-suppressible due to an autosomal dominant genetic defect allowing ACTH stimulation of aldosterone production.

Clinical Findings

A. Symptoms and Signs

Hypertension, muscular weakness (at times with paralysis simulating periodic paralysis), paresthesias with frank tetany, headache, polyuria, and polydipsia are the main complaints. Hypertension is typically moderate. Some patients have only diastolic hypertension, without other symptoms and signs. Malignant hypertension is rare. Edema is rarely seen in primary hyperaldosteronism.

B. Laboratory Findings

For a patient to be properly tested for hyperaldosteronism, all antihypertensive medications must be discontinued. Calcium channel blockers can normalize aldosterone secretion, thus interfering with the diagnosis. The patient must have a high sodium intake (> 120 meq/d) during the entire evaluation period; serum potassium is low. A 24-hour urine collection is assayed for aldosterone, free cortisol, and creatinine. A low plasma renin activity (< 5 ug/dL) with 24-hour urine aldosterone over 20 ug indicates hyperaldosteronism. A urine aldosterone of less than 20 ug/24 h is seen with rare adrenal or gonadal enzyme defects in the activity of 17 α -hydroxylase (associated with ambiguous genitalia or primary amenorrhea) or 11 β -hydroxylase (associated with virilization).

The ratio of plasma aldosterone concentration to plasma renin activity has been used to screen for hyperaldosteronism. Unfortunately, this test lacks sensitivity and specificity.

Once hyperaldosteronism is diagnosed, plasma is assayed for 18-hydroxycorticosterone; a level over 85 ug/dL is seen with adrenal neoplasms, whereas levels under 85 ug/dL are nondiagnostic. Additionally, plasma can be assayed for aldosterone at 8 AM while the patient is supine after overnight recumbency and again after 4 hours upright. Patients with an adrenal adenoma usually have a baseline plasma aldosterone greater than 20 ug/dL which does not rise. Patients with hyperplasia typically have a baseline plasma aldosterone less than 20 ug/dL which rises during upright posture. Exceptions occur.

C. Imaging

If biochemical testing implicates an adrenal aldosterone-secreting adenoma, a thin-section CT scan of the adrenals is obtained. A discrete adrenal adenoma (> 1 cm in diameter with normal contralateral adrenal) is found in 60-80% of such patients. However, about 20% of such "adenomas" are found to be hyperplasia at surgery. A dexamethasone-suppressed ¹³¹I-labeled 6 β -iodomethyl-19-norcholesterol scan (adrenal scintigraphy) can identify an aldosteronoma but may yield misleading results. Therefore, it is often prudent to supplement CT localization with adrenal vein catheterization for aldosterone.

Differential Diagnosis

The differential diagnosis of hyperaldosteronism includes other causes of hypokalemia (see [Chapter 21](#)) in patients with essential hypertension. For example, many hypertensive patients taking diuretics develop hypokalemia even while taking potassium-sparing diuretics or potassium supplements. Chronic depletion of intravascular volume stimulates renin secretion and secondary hyperaldosteronism. Thus, it is important to discontinue diuretics and ensure adequate hydration and sodium intake when assessing a patient for primary hyperaldosteronism (see above).

Excessive ingestion of real licorice (black and derived from anise) may produce hypertension and hypokalemia caused by a derivative of its glycyrrhizinic acid inhibiting 11 β -hydroxysteroid dehydrogenase, thereby enhancing cortisol's mineralocorticoid effect. Oral contraceptives may increase aldosterone secretion in some patients. Renal vascular disease can cause severe hypertension with hypokalemia; plasma renin activity is high, distinguishing it from primary hyperaldosteronism.

Excessive adrenal secretion of other corticosteroids (besides aldosterone) may also cause hypertension with hypokalemia. This occurs with certain congenital adrenal enzyme disorders such as P450c11 deficiency (increased deoxycorticosterone with virilization and deficient cortisol) or P450c17 deficiency (increased deoxycorticosterone, corticosterone, and progesterone but deficient estradiol and testosterone). Primary cortisol resistance can cause hypertension and hypokalemia; renin and aldosterone are suppressed, while plasma levels of cortisol, ACTH, and deoxycorticosterone are high. Liddle's syndrome is an autosomal dominant cause of hypertension and hypokalemia resulting from excessive sodium absorption from the renal tubule; renin and aldosterone levels are low. Thyrotoxicosis and familial periodic paralysis may also present with hypokalemia. Hyperaldosteronism may rarely be due to a malignant ovarian tumor.

Treatment

Conn's syndrome (unilateral adrenal adenoma secreting aldosterone) is treated by laparoscopic adrenalectomy, though lifelong spironolactone therapy is an option. Bilateral adrenal hyperplasia is best treated with spironolactone; bilateral adrenalectomy corrects the hypokalemia but not the hypertension and should *not* be performed. Antihypertensive agents may also be necessary. Hyperplasia sometimes responds well to dexamethasone suppression.

Complications

All of the complications of chronic hypertension are encountered in primary hyperaldosteronism. Progressive renal damage is less reversible than hypertension. Following unilateral adrenalectomy for Conn's syndrome, suppression of the contralateral adrenal may result in temporary postoperative hypoaldosteronism, characterized by hyperkalemia and hypotension.

Prognosis

The hypertension is reversible in about two-thirds of cases but persists or returns in spite of surgery in the remainder. The prognosis is much improved by early diagnosis and treatment. Only 2% of aldosterone-secreting adrenal tumors are malignant.

The low renin levels found in this condition (and in about 25% of cases of essential hypertension) also imply a relatively good prognosis.

■ DISEASES OF THE ADRENAL MEDULLA

PHEOCHROMOCYTOMA

Essentials of Diagnosis

- "Attacks" of headache, perspiration, palpitations.
- Hypertension, frequently sustained but often paroxysmal, especially during surgery or delivery.
- Attacks of nausea, abdominal pain, chest pain, weakness, dyspnea, tremor, visual disturbance.
- Anxiety, tremor, weight loss, or heat intolerance.
- Elevated urinary catecholamines or their metabolites. Normal serum T₄ and TSH.

General Considerations

Pheochromocytomas are rare, being found in less than 0.3% of hypertensive individuals. The incidence is higher in patients with moderate to severe hypertension. About two new cases per million population are diagnosed annually. However, in autopsy cases, the incidence of pheochromocytoma is 250-1300 cases per million, indicating that most cases are not detected during life. The hypertension is caused by excessive plasma levels of norepinephrine or neuropeptide Y. Patients have disease characterized by paroxysmal or sustained hypertension due to a tumor located in either or both adrenals or anywhere along the sympathetic nervous chain, and rarely in such aberrant locations as the thorax, bladder, or brain. Primary extra-adrenal pheochromocytomas are known as "paragangliomas." Pheochromocytomas are characterized by a rough "rule of tens": About 10% of cases are not associated with hypertension; 10% are extra-adrenal, and of those about 10% are extra-abdominal (paraganglioma); 10% occur in children; most tumors are sporadic, with only 10-15% familial; in about 10%, the tumor involves both adrenal glands

(bilateral adrenal tumors tend to occur more frequently in familial cases); and about 10% have metastatic disease noted around the time of diagnosis. Initially occult metastases are later discovered in another 5%.

Familial pheochromocytomas are usually bilateral (70%) and may be associated with the following: calcitonin-secreting medullary thyroid carcinoma and hyperparathyroidism (multiple endocrine neoplasia type 2), medullary thyroid carcinoma and the syndrome of multiple mucosal neuromas (multiple endocrine neoplasia type 2b), neurofibromatosis (Recklinghausen's disease, and islet cell tumors (rare).

Pheochromocytomas develop in about 20% of patients with von Hippel-Lindau disease (hemangiomas of the retina, cerebellum, brainstem, and spinal cord; pancreatic cysts; renal cysts, adenomas and carcinomas); inheritance is autosomal dominant.

Clinical Findings

A. Symptoms and Signs

Pheochromocytomas are usually lethal unless they are diagnosed and treated appropriately. They typically cause attacks of severe headache (80%), perspiration (70%), and palpitations (60%); other symptoms may include anxiety (50%), a sense of impending doom, or tremor (40%). Vasomotor changes during an attack cause mottled cyanosis and facial pallor; as the attack subsides, facial flushing may occur as a result of reflex vasodilation. Other findings may include tachycardia, precordial or abdominal pain, vomiting, increasing nervousness and irritability, increased appetite, and loss of weight. Anginal attacks may occur. Physical findings usually include hypertension (90%), which may be sustained (20%), sustained with paroxysms (50%), or paroxysmal only (25%). There may be cardiac enlargement, postural tachycardia (change of more than 20 beats/min) and postural hypotension, and mild elevation of basal body temperature. Retinal hemorrhage or cerebrovascular hemorrhage occurs occasionally.

The manifestations of pheochromocytoma are quite varied and mimic other conditions. Some patients are normotensive and asymptomatic. Besides the above symptoms, some patients can present with psychosis or confusion, seizures, hyperglycemia, bradycardia, hypotension, constipation, paresthesias, or Raynaud's phenomenon. Other patients may have pulmonary edema and heart failure due to cardiomyopathy. Epinephrine secretion may cause episodic tachyarrhythmias, hypotension, or syncope. Other patients may be entirely asymptomatic despite high serum levels of catecholamines. Some patients present with abdominal discomfort due to a pheochromocytoma presenting as a large abdominal mass.

Besides catecholamines and their metabolites, pheochromocytomas secrete a wide range of other peptides that can sometimes cause Cushing's syndrome (ACTH), erythrocytosis (erythropoietin), or hypercalcemia (parathyroid-related peptide; PTHrP). Serum chromogranin A is elevated in 90% and can serve as a tumor marker.

B. Laboratory Findings

Hypermetabolism is present; thyroid function tests are normal, including serum T₄, free T₄, T₃, and TSH. Hyperglycemia is present in about 35% but is usually mild. Leukocytosis is common. The erythrocyte sedimentation rate is sometimes elevated. Plasma renin activity may be increased by catecholamines.

C. Special Tests

Assay of urinary catecholamines (total and fractionated), metanephrines, and creatinine detects most pheochromocytomas, especially when samples are obtained during or immediately following an episodic attack. A 24-hour urine specimen is usually obtained, although an overnight or shorter collection may be used; patients with pheochromocytomas generally have more than 2.2 ug of total metanephrine per milligram of creatinine, and more than 135 ug total catecholamines per gram creatinine. Urinary assay for total metanephrines is about 97% sensitive for detecting functioning pheochromocytomas. Urinary assay for vanillylmandelic acid (VMA) is about 89% sensitive and is not usually required.

Testing for catecholamines and metanephrines should be done using high-performance liquid chromatography with electrochemical detection (HPLC-ECD); this minimizes false test results. Nevertheless, some drugs and foods can interfere with certain assays, and stresses can also cause misleading elevations in catecholamine excretion ([Table 26-13](#)). About 10% of hypertensive patients have a misleadingly elevated level of one or more tests.

Direct assay of epinephrine and norepinephrine in blood and urine during or following an attack is a sensitive test for pheochromocytoma associated with paroxysmal hypertension. Plasma free metanephrine concentrations may also be used. Proper, quiet collection of plasma specimens is essential.

Imaging should not replace biochemical testing since incidental adrenal adenomas are common (2-4% of scans) and can be misleading. CT scanning of the abdomen is performed using thin sections through the adrenals. Glucagon should not be used during scanning, since it can provoke hypertensive crisis; similarly, intravenous contrast can precipitate hypertensive crisis, particularly in patients whose hypertension is uncontrolled. MRI scanning has the advantage of not requiring intravenous contrast dye; its lack of radiation makes it the imaging of choice during pregnancy. On T2-weighted MRI, adrenal tumors that are hyperintense relative to liver have an increased likelihood of being pheochromocytomas. Both CT and MRI scanning have a sensitivity of about 90% for adrenal pheochromocytoma and a sensitivity of 95% for adrenal tumors over 0.5 cm in diameter. However, scanning is less sensitive for detecting recurrent tumors, metastases, and extra-adrenal paragangliomas. If no adrenal tumor is found, the scan is extended to include the entire abdomen, pelvis, and chest. A whole-body ¹²³I mIBG scan can localize tumors with a sensitivity of 85% and a specificity of 99%. It is less sensitive for MEN 2a- or MEN 2b-related pheochromocytomas. Somatostatin receptor imaging using ¹¹¹In-octreotide is quite sensitive for head and neck paragangliomas and metastatic pheochromocytomas; it is less useful (25% sensitivity) for detecting primary pheochromocytomas. Positron emission tomography (PET) scanning may also detect tumors using ¹⁸F-deoxyglucose or ¹⁸F-dopamine.

Pharmacologic provocative and suppressive tests that evaluate the rise or fall in blood pressure are usually not required or recommended.

Patients or relatives suspected of having von Hippel-Lindau disease may have DNA analysis of the *VHL* gene performed (83% sensitivity). Patients or relatives suspected of having MEN 2a or 2b may have genetic testing for mutation of the *RET* proto-oncogene.

Differential Diagnosis

Tachycardia, tremor, palpitation, and hypermetabolism may give rise to confusion with thyrotoxicosis. Pheochromocytoma may also be misdiagnosed as essential hypertension, myocarditis, glomerulonephritis or other renal lesions, toxemia of pregnancy, eclampsia, and psychoneurosis (anxiety attack). It can sometimes be mistaken for an acute abdomen.

Other conditions that have manifestations similar to those of pheochromocytoma include acute intermittent porphyria, hypogonadal vascular instability (hot flushes), cocaine or amphetamine use, clonidine withdrawal, hypertensive crisis caused by foods containing tyramine (eg, cheeses) in patients taking MAO inhibitor antidepressants, labile hypertension, and unstable angina. Patients with erythromelalgia can have hypertensive crises; their episodic painful flushing and leg swelling is relieved by cold, distinguishing this condition from pheochromocytoma. Pheochromocytomas can cause chest pain and electrocardiographic changes that mimic acute cardiac ischemia. Renal artery stenosis can cause severe hypertension and may coexist with pheochromocytoma.

False-positive testing for catecholamines and metabolites occurs in about 10% of hypertensives, but levels are usually less than 50% above normal and typically normalize with repeat testing.

Complications

All of the complications of severe hypertension may be encountered. Additionally, a catecholamine-induced cardiomyopathy may develop. Sudden death may occur due to cardiac arrhythmia. Hypertensive crises with sudden blindness or cerebrovascular accidents are not uncommon. Paroxysms may be precipitated by sudden movement, by manipulation during or after pregnancy, by emotional stress or trauma, or during surgical removal of the tumor. Decongestant medications, fluoxetine, and other SSRIs may induce hypertensive paroxysms. Cardiomyopathy may develop. Occasionally, the initial manifestation of pheochromocytoma may be hypotension or even shock.

After removal of the tumor, a state of severe hypotension and shock (resistant to epinephrine and norepinephrine) may ensue with precipitation of renal failure or myocardial infarction. Hypotension and shock may occur from spontaneous infarction or hemorrhage of the tumor.

On rare occasions, a patient dies as a result of the complications of diagnostic tests or during surgery. During surgery, pheochromocytoma cells may be seeded within the peritoneum, resulting in multifocal recurrent tumors.

Treatment

Laparoscopic removal of the tumor or tumors is the treatment of choice. Very large and invasive tumors are treated with open laparotomy. Patients with small familial or bilateral pheochromocytomas may undergo selective resection of the tumors, sparing the adrenal cortex; however, there is a recurrence rate of 10% over 10 years. Preoperative administration of α -adrenergic blocking drugs has made pheochromocytoma surgery a great deal safer in recent years. Phenoxybenzamine is given initially in a dosage of 10 mg orally every 12 hours, increasing gradually—about every 3 days—until hypertension is controlled. The usual maintenance dose is 40-120

mg daily. Optimal alpha blockade is achieved when supine arterial pressure is below 160/90 mm Hg and standing arterial pressure is above 80/45 mm Hg. Calcium channel blockers can also be effective and are better tolerated than alpha-blockers.

After appropriate antihypertensive therapy, the beta-blocker propranolol (10-40 mg four times daily) can be employed to control tachycardia and other arrhythmias. Maintain blood pressure control for a minimum of 4-7 days or until optimal cardiac status is established. Monitor the ECG until it becomes stable. (It may take a week or even months to correct electrocardiographic changes in patients with catecholamine myocarditis, and it may be prudent to defer surgery until then in such cases.) Patients must be very closely monitored during surgery in order to promptly detect sudden changes in blood pressure or cardiac arrhythmias.

Hypertensive crisis can be managed initially with sublingual administration of nifedipine 10 mg (pierced capsule). Intraoperative severe hypertension is managed with continuous intravenous nicardipine (a short-acting calcium channel blocker), 2-6 ug/ kg/ min, or nitroprusside, 0.5-10 ug/kg/min. Prolonged nitroprusside administration can cause cyanide toxicity. Tachyarrhythmia is treated with intravenous atenolol (1 mg boluses), esmolol, or lidocaine.

Autotransfusion of 1-2 units of blood at 12 hours preoperatively plus generous intraoperative volume replacement reduces the risk of postresection hypotension caused by desensitization of the vascular α_1 receptors. Shock may therefore occur following removal of the pheochromocytoma. It is treated with intravenous saline or colloid and high doses of intravenous norepinephrine. Intravenous 5% dextrose is infused postoperatively to prevent hypoglycemia.

Since there may be multiple or metastatic tumors, it is essential to recheck urinary catecholamine levels postoperatively (1-2 weeks after surgery). Thereafter, blood pressure and symptoms must be rechecked regularly; urinary catecholamines and metanephrines are rechecked postoperatively and if hypertension or symptoms recur or if metastases are evident.

For inoperable or metastatic tumors, metyrosine may be added to reduce catecholamine synthesis. Metyrosine is a competitive blocker in the synthesis of catecholamines that is also useful; the initial dosage is 250 mg four times daily, increased daily by increments of 250-500 mg to a maximum of 4 g/d. Metyrosine causes central nervous system side effects and crystalluria; hydration must be ensured. Metastatic pheochromocytomas may be treated with combination chemotherapy (eg, cyclophosphamide, vincristine, and dacarbazine) or with high doses of ^{131}I MIBG.

Prognosis

The prognosis depends upon how early the diagnosis is made. The malignancy of a pheochromocytoma cannot be determined by histologic examination. A tumor is considered malignant if metastases are present; this may take many years to become clinically evident. Therefore, lifetime surveillance is required. If the tumor is successfully removed before irreparable damage to the cardiovascular system has occurred, a complete cure is usually achieved. Complete cure (or improvement) may follow removal of a tumor that has been present for many years. In about 25%, hypertension persists or returns in spite of successful surgery. Although this may be essential hypertension, biochemical reevaluation is then required, looking for a second or metastatic pheochromocytoma.

Before the advent of blocking agents, the surgical mortality rate was as high as 30%, but this has rapidly decreased. A team approach—endocrinologist, anesthesiologist, and surgeon—is critically important. With optimal management, the surgical mortality rate is less than 3%.

Patients with metastatic pheochromocytoma have a 50% 5-year survival rate; however, prolonged survival does occur.

■ PANCREATIC & DUODENAL NEUROENDOCRINE TUMORS*

*Diabetes mellitus and hyperglycemia are discussed in [Chapter 27](#).

ISLET CELL TUMORS

Essentials of Diagnosis

- Half the tumors are nonsecretory, and patients present with weight loss, abdominal pain, or jaundice.
- Secretory tumors cause a variety of manifestations depending upon the hormones secreted.

General Considerations

The pancreatic islets are composed of several types of cells, each with distinct chemical and microscopic features: the A cells (20%) secrete glucagon, the B cells (70%) secrete insulin, and the D cells (5%) secrete somatostatin or gastrin. F cells secrete "pancreatic polypeptide." Each type of cell may give rise to benign or malignant neoplasms that may be multiple and usually present with a clinical syndrome related to hypersecretion of a native or ectopic hormonal product. The endocrine diagnosis of a particular pancreatic islet neoplasm depends upon first suspecting it from its clinical manifestations. Many tumors secrete two or more different hormones.

Insulinomas are usually (about 82%) benign and secrete excessive amounts of insulin (as well as proinsulin and C-peptide), which causes hypoglycemia. The tumors may be multiple, especially in familial MEN 1—about 12% of cases (see [Chapter 27](#)).

Gastrinomas secrete excessive quantities of the hormone gastrin (as well as "big" gastrin), which stimulates the stomach to hypersecrete acid, thereby causing hyperplastic gastric rugae and peptic ulceration (Zollinger-Ellison syndrome). Most gastrinomas are benign, but a minority are malignant and metastasize to the liver. Gastrinomas are typically found in the duodenum (49%), pancreas (24%), or lymph nodes (11%). Patients may present with abdominal pain (75%), diarrhea (73%), heartburn (44%), bleeding (25%), or weight loss (17%). Endoscopy usually discovers prominent gastric folds (94%). Sporadic Zollinger-Ellison syndrome is rarely suspected at the onset of symptoms; typically, there is a 5-year delay in diagnosis. About 22% of patients have multiple endocrine neoplasia type 1 (MEN 1). Patients with MEN 1 usually present at a younger age; hyperparathyroidism may occur from 14 years preceding the Zollinger-Ellison diagnosis to 38 years afterward. (See Multiple Endocrine Neoplasia, below.) Therapy with high doses of proton pump inhibitors is usually effective. Surgery is not usually employed because of the low cure rates, particularly in patients with MEN 1. Note that serum gastrin levels tend to be high in any patient who is taking a proton pump inhibitor; hypercalcemia also stimulates gastrin release.

The 5-, 10-, and 20-year survival rates with MEN 1 are 94%, 75%, and 58%, respectively, while the survival rates for sporadic Zollinger-Ellison syndrome are 62%, 50%, and 31%, respectively. (See [Chapter 14](#).)

Glucagonomas are usually malignant; weight loss and liver metastases are ordinarily present by the time of diagnosis. They usually secrete other hormones besides glucagon, often gastrin. Other initial symptoms often include diarrhea, nausea, peptic ulcer, or necrolytic migratory erythema. About 35% of patients ultimately develop diabetes. The median survival is 2.8 years after diagnosis.

Somatostatinomas are very rare and are associated with weight loss, diabetes mellitus, malabsorption, and hypochlorhydria.

Other rare tumors secrete excessive amounts of **vasoactive intestinal polypeptide (VIP)**, a substance that causes profuse watery diarrhea (Verner-Morrison

syndrome). Treatment with octreotide improves the symptoms but does not halt tumor growth. Symptomatic improvement with calcitonin treatment has also been reported.

Islet cell tumors can secrete ectopic hormones in addition to native hormones, often in combinations producing a variety of clinical syndromes. They may secrete ACTH, producing Cushing's syndrome. Secretion of serotonin can produce an atypical carcinoid syndrome manifested by pain, diarrhea, and weight loss; skin flushing occurs in only 39%. Pancreatic carcinoid tumors grow slowly but usually metastasize to local and distant sites, particularly to other endocrine organs.

Islet cell tumors may be part of the syndrome of multiple endocrine adenomatosis type I (with pituitary and parathyroid adenomas).

Localization of noninsulinoma pancreatic islet cell tumors and their metastases is best done with somatostatin receptor scintigraphy (SRS); SRS detects about 75% of noninsulinomas. CT and MRI are also useful. Insulinomas can usually be located preoperatively by endoscopic ultrasonography. For insulinomas, preoperative localization studies are less successful and have the following sensitivities: ultrasonography 25%, computed tomography 25%, endoscopic ultrasonography 27%, transhepatic portal vein sampling 40%, arteriography 45%, intraoperative palpation 55%, and intraoperative pancreatic ultrasound 75%. Nearly all insulinomas can be successfully located at surgery by intraoperative palpation and ultrasound. An abdominal CT scan is usually obtained, but extensive preoperative localization procedures, especially with invasive methods, are not required. Tumors may be located in the pancreatic head or neck (57%), body (15%), or tail (19%) or in the duodenum (9%).

Direct resection of the tumor (or tumors), which often spreads locally, is the primary form of therapy for all types of islet cell neoplasm except Zollinger-Ellison syndrome, where use of high doses of a proton pump inhibitor is the therapy of choice. Insulinomas are resected. However, in MEN 1, insulinomas are rarely cured, so surgery is reserved for dominant masses in such cases. Palliation of functioning malignant disease often requires both antihormonal and anticancer chemotherapy. The use of streptozocin, doxorubicin, and asparaginase, especially for malignant insulinoma, has produced some encouraging results, though these drugs are quite toxic. The hypoglycemia of insulinoma may be counteracted by verapamil or diazoxide. Octreotide long-acting release (LAR) is useful in the therapy of islet cell tumors with the exception of insulinoma; monthly subcutaneous injections of 20-30 mg are required.

The prognosis in these neoplasms is variable. The surgical complication rate is about 40%, with patients commonly developing fistulas and infections. Extensive pancreatic resection may cause diabetes mellitus. The overall 5-year survival is higher with functional tumors (77%) than with nonfunctional ones (55%) and higher with benign tumors (91%) than with malignant ones (55%).

■ DISEASES OF THE TESTES

MALE HYPOGONADISM

Essentials of Diagnosis

- Diminished libido and erections.
- Decreased growth of body hair.
- Testes may be small or normal in size. Serum testosterone is usually decreased.
- Serum gonadotropins (LH and FSH) are decreased in hypogonadotropic hypogonadism; they are increased in testicular failure (hypergonadotropic hypogonadism).

General Considerations

Male hypogonadism is caused by deficient testosterone secretion by the testes. It may be classified according to whether it is due to (1) insufficient gonadotropin secretion by the pituitary (hypogonadotropic) or (2) pathology in the testes themselves (hypergonadotropic) (see [Table 26-14](#)). The evaluation for hypogonadism begins with a serum testosterone or free testosterone measurement. A low serum testosterone is evaluated with serum LH and FSH levels. Patients with low gonadotropins are further evaluated for other pituitary abnormalities, including hyperprolactinemia.

Etiology BR>

A. Hypogonadotropic Hypogonadism

A deficiency in FSH and LH may be isolated or associated with other pituitary hormonal abnormalities. (See Hypopituitarism.) Patients must be evaluated for signs of Cushing's syndrome or adrenal insufficiency, growth hormone excess or deficiency, and thyroid hormone excess or deficiency.

Acquired hypogonadotropic hypogonadism may be due to pituitary or hypothalamic factors but may be idiopathic. Hyperprolactinemia ([Table 26-4](#)) may also induce hypogonadism.

Men receiving GnRH agonist therapy for prostate cancer develop hypogonadotropic hypogonadism that can persist following cessation of therapy.

B. Hypergonadotropic Hypogonadism

A failure in testicular secretion of testosterone causes a rise in LH. If testicular Sertoli cell function is deficient, FSH will be elevated. Conditions that can cause testicular failure include viral infection (eg, mumps), irradiation, cancer chemotherapy, autoimmunity, myotonic dystrophy, uremia, XY gonadal dysgenesis, partial 17-ketosteroid reductase deficiency, Klinefelter's syndrome, and male climacteric.

Klinefelter's syndrome (seminiferous tubule dysgenesis) is a common cause of male hypogonadism that is due to the expression of an abnormal karyotype, classically 47,XXY. Other forms are common, eg, 46,XY/47,XXY mosaicism, 48,XXYY, 48,XXXYY, or 46,XX males.

The manifestations of Klinefelter's syndrome are variable. Testes feel normal during childhood, but during adolescence they usually become firm, fibrotic, small, and nontender to palpation. Although puberty occurs at the normal time, the degree of virilization is variable. About 85% have some gynecomastia at puberty.

Other common findings include tall stature and abnormal body proportions that are unusual for hypogonadal men (height greater than arm span; crown-pubis length greater than pubis-floor). Patients with multiple X or Y chromosomes are more apt to have mental deficiency and other abnormalities such as clinodactyly or synostosis. They may also exhibit problems with coordination and social skills. Other problems include a higher incidence of breast cancer, chronic pulmonary disease, varicosities of the legs, and diabetes mellitus (8%); impaired glucose tolerance occurs in an additional 19%.

Most men (about 95%) have azoospermia, but men with 46,XY/47,XXY mosaicism may be fertile. The diagnosis is confirmed by karyotyping or by determining the presence of RNA for X-inactive-specific transcriptase (XIST) in peripheral blood leukocytes by PCR.

The serum testosterone is low, and FSH and LH are elevated. Sometimes the serum testosterone is normal, but serum free testosterone is usually low.

All causes of gynecomastia ([Table 26-1](#)) must be differentiated from Klinefelter's syndrome.

C. Androgen Insensitivity

Partial resistance to testosterone is a rare condition in which phenotypic males have variable degrees of apparent hypogonadism, hypospadias, cryptorchism, and gynecomastia. Serum testosterone levels are normal.

Clinical Findings

A. Symptoms and Signs

Hypogonadism that is congenital or acquired during childhood presents as delayed puberty. Men with acquired hypogonadism have variable manifestations. Most men experience decreased libido. Others complain of erectile dysfunction, hot sweats, fatigue, or depression. Their presenting complaint may also be infertility, gynecomastia, headache, fracture, or other symptoms related to the cause or result of the hypogonadism. The patient's history often gives a clue to the cause ([Table 26-14](#)).

Physical signs associated with hypogonadism may include decreased body, axillary, beard, or pubic hair; such diminished sexual hair growth is not reliably present except after years of severe hypogonadism. Men who develop hypogonadism tend to lose muscle mass and gain weight due to an increase in subcutaneous fat. Examination should include measurements of arm span and height. Testicular size should be assessed with an orchidometer (normal volume is about 10-25 mL; normal length is usually over 6 cm). Testicular size may decrease but usually remains within the normal range in men with postpubertal hypogonadotropic hypogonadism, but it may be diminished with testicular injury or Klinefelter's syndrome. The testes must also be carefully palpated for masses, since Leydig cell tumors may secrete estrogen and present with hypogonadism. The testicles must be carefully examined for evidence of trauma, infiltrative lesions (eg, lymphoma), or ongoing infection (eg, leprosy, tuberculosis).

B. Laboratory Findings

The hemoglobin and hematocrit may be slightly below the male range due to hypogonadism.

To evaluate a man for hypogonadism, the morning serum total testosterone concentration is determined. Normal ranges for serum testosterone have been derived from nonfasting morning blood specimens, which tend to be the highest of the day. Later in the day, serum testosterone levels can be 25-50% lower. Therefore, a serum testosterone drawn fasting or late in the day may be misleadingly below the "normal range." Serum testosterone levels in men are highest at age 20-30 years and slightly lower at age 30-40 years; testosterone falls gradually but progressively after age 40 years. Elderly men have higher levels of SHBG, with consequently lower levels of free testosterone. The electrochemical luminescence assay for measuring serum total testosterone suffers interference in hyperlipidemic patients.

Serum free testosterone levels are low in hypogonadism. Different assay methodologies for free testosterone are in use. Assays employing equilibrium dialysis, calculated free testosterone, and non-SHBG-bound testosterone are reasonably accurate. However, the free androgen index, direct radioimmunoassay, and analog free testosterone assays are inaccurate.

In patients with low or borderline-low serum testosterone levels, serum LH and FSH should be measured. LH and FSH tend to be high in patients with hypergonadotropic hypogonadism but low or inappropriately normal in men with hypogonadotropic hypogonadism. Bone densitometry may be reduced in long-standing male hypogonadism.

1. Hypogonadotropic hypogonadism—Men with hypogonadotropic hypogonadism have low serum testosterone levels without a compensatory increase in gonadotropins. A serum prolactin determination is obtained but may be elevated for many reasons ([Table 26-4](#)). Men with gynecomastia may be screened for partial 17-ketosteroid reductase deficiency with serum determinations for androstenedione and estrone, which are elevated in this condition. X-linked congenital adrenal hypoplasia is a rare condition in which a *DAX-1* gene mutation causes hypogonadotropic hypogonadism and azoospermia, which usually present in adolescence; the associated primary adrenal insufficiency usually presents in childhood, but it may remain undiagnosed into adulthood. The serum estradiol level may be elevated in patients with cirrhosis and in rare cases of estrogen-secreting tumors (testicular Leydig cell tumor or adrenal carcinoma). Men with no discernible definite cause for hypogonadotropic hypogonadism should be screened for hemochromatosis and have an MRI of the pituitary and hypothalamic region to look for a tumor or other lesion. (See Hypopituitarism.)

2. Hypergonadotropic hypogonadism—Men with hypergonadotropic hypogonadism have low serum testosterone levels with a compensatory increase in gonadotropins. Klinefelter's syndrome can be confirmed by karyotyping or by measurement of leukocyte X-inactive-specific transcriptase (XIST). Testicular biopsy is usually reserved for younger patients in whom the reason for primary hypogonadism is unclear.

Treatment

Testosterone replacement is ordinarily commenced once the diagnosis of hypogonadism is confirmed and the cause determined. It is prudent to screen older men for prostate cancer before testosterone therapy is begun. Testosterone helps reverse sexual dysfunction and muscle atrophy. Men with Klinefelter's syndrome have a reduced risk of developing verbal fluency problems if testosterone therapy is begun at the time of normal puberty. Hypogonadism is usually treated with parenteral testosterone (enanthate or cypionate). The usual dose is about 300 mg intramuscularly every 3 weeks or 200 mg every 2 weeks. The preparation is oil-based and is usually given in the gluteal area. The dose is adjusted according to the patient's response. Oral androgen preparations include methyltestosterone and fluoxymesterone. These oral preparations have rarely caused liver tumors or peliosis hepatis with long-term use. Cholestatic jaundice occurs in 1-2% but usually remits after the medication is discontinued. The oral androgens are not as effective as parenteral testosterone.

Testosterone transdermal systems (skin patches) are available in two formulations for application to nongenital skin. The testosterone may be mixed with the adhesive (eg, Testoderm II, 5 mg/d) with a new patch applied daily to a different site; this system leaves a sticky residue but causes little skin irritation. A different patch uses testosterone in a reservoir system applied to skin (eg, Androderm); this system adheres more tightly to the skin but may cause more skin irritation. Both produce reliable serum levels of testosterone which are somewhat lower than those achieved with injections. The patch systems also suffer from being rather inconvenient and expensive.

Topical 1% testosterone gel is commercially available as Androgel (2.5-g and 5-g packets). The starting dose is 5 g (50 mg testosterone) applied once daily to clean, dry skin of the shoulders, upper arms, or abdomen. The skin serves as a reservoir that slowly releases about 10% of the testosterone into the blood; serum testosterone levels reach a steady state in 1-3 days. The gel should not be applied to the genitals. The entire contents of a packet are squeezed onto the palm and then immediately applied. The hands should be washed and the application site allowed to dry for 3-5 minutes before dressing. A shirt must be worn during contact with women or children to prevent transfer of testosterone to them. The serum testosterone level should be determined about 14 days after starting therapy; if the level remains below normal or the clinical response is inadequate, the dose may be increased to 7.5 g or 10 g.

Side effects of any testosterone therapy may include acne, gynecomastia, aggravation of sleep apnea, and reduced HDL levels.

Men with hypogonadism due to endocrine therapy for prostate cancer usually develop severe hot flashes. Symptomatic relief can be obtained with the progestational agent megestrol acetate, 20 mg orally twice daily; the dose can be progressively reduced in some men. Megestrol has some glucocorticoid-like activity and tends to increase appetite and cause weight gain. Hyperglycemia and hypertriglyceridemia may occur, so the dosage should be kept minimal.

Men with mosaic Klinefelter's syndrome (eg, 46,XY/47,XXY) may be fertile. However men with nonmosaic Klinefelter's syndrome (eg, 47,XXY) are usually azoospermic; fertility may be achieved by testicular sperm retrieval and in vitro intracytoplasmic sperm injection (ICSI) into an ovum.

Men with hypogonadotropic hypogonadism must receive further evaluation and specific treatment (see Hypopituitarism).

Prognosis of Hypogonadism

If hypogonadism is due to a pituitary lesion, the prognosis is that of the primary disease (eg, tumor, necrosis). The prognosis for restoration of virility is good if testosterone is given.

TESTICULAR TUMORS IN ADULTS (SEE ALSO [CHAPTER 23.](#))

About 95% of testicular tumors are germ cell tumors (seminomas or nonseminomas). They may produce (as serum markers) hCG and alpha-fetoprotein. Seminomas do not produce alpha-fetoprotein, but about 5-10% produce some hCG; nonseminomas, on the other hand, produce increased serum levels of one or both of these markers in about 90% of cases. Men with liver disease may have misleadingly high levels of alpha-fetoprotein. Most germ cell tumors are sensitive to cisplatin-based chemotherapy. Sperm banking is advised.

About 5% of testicular tumors are Leydig or Sertoli cell tumors. Leydig cell tumors tend to produce estrogen (75%) and cause gynecomastia and impotence on that basis; they may sometimes produce androgens that can cause pseudoprecocious puberty in boys. Sertoli cell tumors may also produce estrogen (30%) with feminization; gynecomastia may be due to hCG secretion (25%).

Some testicular tumors may be small and nonpalpable yet may secrete sufficient amounts of hCG or estrogen to cause gynecomastia or impotence. Testicular ultrasound may help reveal small tumors.

After unilateral orchiectomy for testicular cancer, an elevated FSH level prior to further treatment indicates a patient at higher risk for cancer in the remaining testis.

■ AMENORRHEA & MENOPAUSE (SEE ALSO [CHAPTER 17.](#))

PRIMARY AMENORRHEA

Menarche ordinarily occurs between ages 11 and 15 years (average in the United States: 12.7 years). The failure of any menses to appear is termed primary amenorrhea, and evaluation is commenced (1) at age 14 if neither menarche nor breast development has occurred or if height is in the lowest 3%, or (2) at age 16 if menarche has not occurred.

Etiology

The causes of primary amenorrhea include the following.

A. Hypothalamic-Pituitary Causes (with Low-Normal FSH)

A genetic deficiency of GnRH and gonadotropins may be isolated or associated with other pituitary deficiencies or diminished olfaction (Kallmann's syndrome). Hypothalamic lesions, particularly craniopharyngioma, may be present. Pituitary tumors may be nonsecreting or may secrete prolactin or growth hormone. Cushing's syndrome may be caused by glucocorticoid treatment, a cortisol-secreting adrenal tumor, or an ACTH-secreting pituitary tumor. Hypothyroidism can delay adolescence. Head trauma or encephalitis can cause gonadotropin deficiency. Primary amenorrhea may also be caused by constitutional delay of adolescence, organic illness, vigorous exercise (eg, ballet dancing, running), stressful life events, dieting, or anorexia nervosa; however, these conditions should not be assumed to account for amenorrhea without a full physical and endocrinologic evaluation. (See section on Hypopituitarism.)

B. Hyperandrogenism (with Low-Normal FSH)

Excess testosterone may be secreted by adrenal tumors or by adrenal hyperplasia caused by steroidogenic enzyme defects such as P450c21 deficiency (salt-wasting) or P450c11 deficiency (hypertension). Ovarian tumors or polycystic ovaries may also secrete excess testosterone. Androgenic steroids may also cause this syndrome.

C. Ovarian Causes (with High FSH)

Gonadal dysgenesis (Turner's syndrome and variants; see below) is a frequent cause of primary amenorrhea. Ovarian failure due to autoimmunity is a common cause. Rare deficiencies in certain ovarian steroidogenic enzymes are causes of primary hypogonadism without virilization: 3β-hydroxysteroid dehydrogenase deficiency (adrenal insufficiency with low serum 17-hydroxyprogesterone) and P450c17 deficiency (hypertension and hypokalemia with high serum 17-hydroxyprogesterone). A whole-body deficiency in P450 aromatase (P450arom) activity produces female hypogonadism associated with polycystic ovaries, tall stature, osteoporosis, and virilization.

D. Pseudohermaphroditism (with High LH)

An enzymatic defect in testosterone synthesis may present as a sexually immature phenotypic girl with primary amenorrhea. Complete androgen resistance (testicular feminization) presents as a phenotypic young woman without sexual hair but with normal breast development and primary amenorrhea. In both cases, the uterus is absent and testes are intra-abdominal or cryptorchid. Intra-abdominal testes are surgically resected. Such patients are treated as normal but infertile, hypogonadal women.

E. Uterine Causes (with Normal FSH)

Congenital absence or malformation of the uterus may be responsible for primary amenorrhea, as may an unresponsive or atrophic endometrium. An imperforate hymen is occasionally the reason for the absence of visible menses.

F. Pregnancy (with High hCG)

Pregnancy may be the cause of primary amenorrhea even when the patient denies ever having had sexual intercourse.

Clinical Findings

A. Symptoms and Signs

Patients with primary amenorrhea require a thorough history and physical examination to look for signs of the conditions noted above. Headaches or visual field abnormalities implicate a hypothalamic or pituitary tumor. Signs of pregnancy may be present. Blood pressure abnormalities, acne, and hirsutism should be noted. Short stature may be seen with an associated growth hormone or thyroid hormone deficiency. Short stature with manifestations of gonadal dysgenesis indicates Turner's syndrome (see below). Olfaction testing screens for Kallmann's syndrome. Obesity and short stature may be signs of Cushing's syndrome. Tall stature may be due to eunuchoidism or gigantism. Hirsutism or virilization suggests excessive testosterone.

An external pelvic examination plus a rectal examination should be performed to assess hymenal patency and the presence of a uterus.

B. Laboratory Findings

The initial endocrine evaluation should include serum determinations of FSH, LH, PRL, testosterone, TSH, free T₄, and hCG (pregnancy test). Patients who are virilized or hypertensive require serum electrolyte determinations and further hormonal evaluation. Girls with low-normal FSH and LH—especially those with high PRL levels—are evaluated by MRI of the hypothalamus and pituitary. Girls who have a normal uterus and high FSH without the classic features of Turner's syndrome may require a karyotype to diagnose X chromosome mosaicism.

Treatment

Treatment of primary amenorrhea is directed at the underlying cause. Girls with permanent hypogonadism are treated with estrogen replacement therapy (see below).

SECONDARY AMENORRHEA & MENOPAUSE

Secondary amenorrhea is defined as absence of menses for 3 consecutive months in women who have passed menarche. Menopause is defined as the terminal episode of naturally occurring menses; it is a retrospective diagnosis, usually made after 6 months of amenorrhea.

Etiology

The causes of secondary amenorrhea include the following.

A. Pregnancy (High hCG)

Pregnancy is the most common cause for secondary amenorrhea in women of childbearing age. The differential diagnosis includes rare ectopic secretion of hCG by a choriocarcinoma or bronchogenic carcinoma.

B. Hypothalamic-Pituitary Causes (with Low-Normal FSH)

The hypothalamus must release gonadotropin-releasing hormone (GnRH) in a pulsatile manner in order for the pituitary to secrete gonadotropins. GnRH pulses occurring more than once per hour favor LH secretion, while less frequent pulses favor FSH secretion. In normal ovulatory cycles, GnRH pulses in the follicular phase are rapid and favor LH synthesis and ovulation; ovarian luteal progesterone is then secreted that slows GnRH pulses, causing FSH secretion during the luteal phase. Most women with hypothalamic amenorrhea have a persistently low frequency of GnRH pulses.

Secondary "hypothalamic" amenorrhea may be caused by stressful life events such as school examinations or leaving home. Such women usually have a history of normal sexual development and irregular menses since menarche. Amenorrhea may also be the result of strict dieting, vigorous exercise, organic illness, or anorexia nervosa. Intrathecal infusion of opioids causes amenorrhea in most women. These conditions should not be assumed to account for amenorrhea without a full physical and endocrinologic evaluation. Young women in whom the results of evaluation and progestin withdrawal test are normal have noncyclic secretion of gonadotropins resulting in anovulation. Such women typically recover spontaneously but should have regular evaluations and a progestin withdrawal test about every 3 months to detect loss of estrogen effect.

Prolactin elevation due to any cause (see section on hyperprolactinemia) may cause amenorrhea. Pituitary tumors or other lesions may cause hypopituitarism. Glucocorticoid excess of any cause suppresses gonadotropins.

C. Hyperandrogenism (With Low-Normal FSH)

Elevated serum levels of testosterone can cause hirsutism, virilization, and amenorrhea. In polycystic ovarian syndrome, GnRH pulses are persistently rapid, favoring LH synthesis with excessive androgen secretion; reduced FSH secretion impairs follicular maturation. Progesterone administration can slow the GnRH pulses, thus favoring FSH secretion that induces follicular maturation. Rare causes include adrenal P450c21 deficiency, ovarian or adrenal malignancies, ectopic ACTH secretion by a malignancy, and Cushing's disease. Anabolic steroids also cause amenorrhea.

D. Uterine Causes (With Normal FSH)

Infection of the uterus commonly occurs following delivery or D&C but may occur spontaneously. Endometritis due to tuberculosis or schistosomiasis should be suspected in endemic areas. Endometrial scarring may result, causing amenorrhea (Asherman's syndrome). Such women typically continue to have monthly premenstrual symptoms. The vaginal estrogen effect is normal. Diagnosis and treatment are best done by direct hysteroscopic inspection of the endometrium and lysis of adhesions. A small Foley catheter is left in the uterus for 1 week while antibiotics are given. The catheter is then replaced by an IUD for about 2 months. Cyclic estrogen and progestin are given to build up the endometrial lining. After such treatment, menses usually resume and fertility is possible, but spontaneous abortions and other pregnancy complications occur commonly.

E. Premature Ovarian Failure (With High FSH)

This refers to primary hypogonadism that occurs before age 40. This affects about 1% of women. About 30% of such cases are due to autoimmunity against the ovary. About 8% of cases are due to X chromosome mosaicism. Other causes include surgical bilateral oophorectomy, radiation therapy for pelvic malignancy, and chemotherapy. Women who have undergone hysterectomy are prone to premature ovarian failure even though the ovaries were left intact. Myotonic dystrophy, galactosemia, and mumps oophoritis are additional causes. Other cases may be familial or idiopathic. Ovarian failure is usually irreversible. Treatment consists of estrogen replacement therapy plus a progestin if the uterus is present.

F. Menopause (With High FSH)

"Climacteric" is defined as the period of natural physiologic decline in ovarian function, generally occurring over about 10 years. By about age 40, the remaining ovarian follicles are those that are the least sensitive to gonadotropins. Increasing titers of FSH are required to stimulate estradiol secretion. Estradiol levels may actually rise during early climacteric. Frequent anovulation tends to cause menometrorrhagia (dysfunctional uterine bleeding). Fertility declines progressively. Psychologic symptoms may include depression and irritability. Women may experience fatigue, insomnia, headache, diminished libido, or rheumatologic symptoms. Vasomotor instability (hot flushes) is experienced by 80% of women, lasting seconds to many minutes. Hot flushes may be most severe at night or may be triggered by emotional stress; they must be distinguished from panic attacks. Some women continue to menstruate for many months despite symptoms of estrogen deficiency. Estrogen supplementation provides symptomatic relief.

The normal age for menopause in the United States ranges between 48 and 55 years, with an average of about 51.5 years. Serum estradiol levels fall and the remaining estrogen after menopause is estrone, derived mainly from peripheral aromatization of adrenal androstenedione. Such peripheral production of estrone is enhanced by obesity and liver disease. Individual differences in estrone levels partly explain why the symptoms noted above may be minimal in some women but severe in others. The acute symptoms of estrogen deficiency noted above tend to decline in severity within several years after menopause. However, about 35% of women have symptoms for more than 5 years. The late manifestations of estrogen deficiency include urogenital atrophy with vaginal dryness and dyspareunia; dysuria, frequency, and incontinence may occur. Increased bone osteoclastic activity increases the risk for osteoporosis and fractures. The skin becomes more wrinkled. Increases in the LDL:HDL cholesterol ratio cause an increased risk for arteriosclerosis.

Clinical Findings

A. Symptoms and Signs

All women with amenorrhea require a complete history and physical examination. Nausea and breast engorgement are typical signs of early pregnancy. Hot flushes are common in ovarian failure. Headache or visual field abnormalities are seen with pituitary or hypothalamic tumors. Complaints of thirst and polyuria require evaluation; diabetes insipidus implicates a hypothalamic lesion. Goiter may be due to hyperthyroidism. Weight loss, diarrhea, or skin darkening may indicate adrenal insufficiency. Weight loss with a distorted body image implicates anorexia nervosa. The breasts are examined carefully for galactorrhea, a common sign of hyperprolactinemia. Hirsutism or virilization may be a sign of hyperandrogenism. Manifestations of hypercortisolism (eg, weakness, psychiatric changes, hypertension, central obesity, hirsutism, thin skin, ecchymoses) may indicate alcoholism or Cushing's syndrome. Signs of acromegaly or gigantism may also indicate a pituitary tumor. Signs of systemic illness (eg, cirrhosis, renal failure) should be appreciated. Various drugs may elevate prolactin and cause amenorrhea (see section on Hyperprolactinemia). Needle tracks may indicate heroin or amphetamine abuse.

A careful pelvic examination is always required to check for uterine or adnexal enlargement and to obtain a Papanicolaou smear and a vaginal smear for assessment of estrogen effect. Various life stresses, vigorous exercise, and "crash" dieting all predispose to amenorrhea; however, such factors should not be assumed to account for amenorrhea without a complete workup to screen for other causes.

B. Laboratory Findings

Since pregnancy is the most common cause of amenorrhea, women of childbearing age are immediately screened with a serum or urine hCG (pregnancy test). An elevated hCG overwhelmingly indicates pregnancy; false-positive testing may occur very rarely with ectopic hCG secretion (eg, choriocarcinoma or bronchogenic carcinoma). Women without an elevated hCG receive further laboratory evaluation including serum PRL, FSH, LH, TSH, and plasma potassium. Hyperprolactinemia or hypopituitarism (without obvious cause; see section on Hypopituitarism) should prompt an MRI study of the pituitary region. Routine testing for renal and hepatic function (eg, BUN, serum creatinine, bilirubin, alkaline phosphatase, and ALT) is also performed. A serum testosterone level is obtained in hirsute or virilized women. Patients with manifestations of hypercortisolism receive a 1-mg overnight dexamethasone suppression test for initial screening (see section on Cushing's syndrome). Nonpregnant women without any laboratory abnormality may receive a 10-day course of a progestin (eg, medroxyprogesterone acetate, 10 mg/d); absence of withdrawal menses typically indicates a lack of estrogen or a uterine abnormality.

Treatment

Treatment of secondary amenorrhea is directed at the cause. Therapy of hypogonadism generally consists of hormone replacement therapy (see below). The doses of estrogen required for symptomatic relief from vasomotor symptoms are sometimes higher than typical physiologic replacement doses. If estrogen replacement therapy is declined or contraindicated, partial symptomatic relief from hot flushes may sometimes be afforded by progestins or phytoestrogens. Slow, deep breathing can also ameliorate hot flushes. Tamoxifen and raloxifene offer bone protection but aggravate hot flushes. Treatment or prevention of postmenopausal osteoporosis with bisphosphonates such as alendronate (see section on Osteoporosis) is another therapeutic option.

Estrogen Replacement Therapy

The goals of estrogen replacement therapy are several: (1) to replace adequate estrogen to prevent osteoporosis; (2) to restore menses when the patient wants this for psychologic reasons; (3) to reduce manifestations of estrogen deficiency such as hot flushes, mood changes, vaginal dryness, urinary incontinence, and skin wrinkling; and (4) to improve the serum lipid profile, reducing the risk of cardiovascular disease.

Estrogen replacement therapy should begin with the onset of hypogonadism. However, it is not necessary to treat all cases, especially temporary amenorrhea or irregular menses. Patients who have normal menses after a short course of medroxyprogesterone acetate (see above) may have menses induced every 1-3 months in this manner.

Oral estrogen preparations include conjugated equine estrogens (0.3, 0.625, 0.9, 1.25, and 2.5 mg), ethinyl estradiol (20 and 50 ug), estradiol (0.5, 1, 1.5, and 2 mg), estropipate (0.625, 1.25, and 2.5 mg), a plant-derived estrogen (eg, Estratab, 0.3, 0.625, and 2.5 mg); and synthetic estrogens (eg, Cenestin, 0.625, 0.9 mg).

Oral estrogen plus progestin preparations: Conjugated estrogens with medroxyprogesterone acetate (Prempro 0.625/2.5 or 0.625/5), and estradiol with norgestimate (Ortho-Prefest, sequences of 1 mg estradiol daily for 3 days followed by a single tablet containing 1 mg estradiol combined with 0.09 mg norgestimate daily for 3 days. The 3-day sequences are repeated continuously during treatment.)

Estradiol transdermal systems (skin patches): Estradiol can be delivered systemically with different transdermal systems:

(1) Transdermal systems with estradiol mixed with adhesive: These systems tend to cause minimal skin irritation. Available preparations include the following: Climara (0.05 mg/d or 0.1 mg/d), replaced weekly; Fempatch (0.025 mg/d), replaced weekly; Alora (0.05 mg/d, 0.075 mg/d, or 0.1 mg/d), replaced twice weekly; and Vivelle-Dot (0.0375 mg/d, 0.05 mg/d, 0.075 mg/d, or 0.1 mg/d), replaced twice weekly.

(2) Transdermal systems with estradiol in a drug reservoir: These systems cause significant skin irritation in some women. Available preparations include Estraderm (0.05 mg/d or 0.1 mg/d), replaced twice weekly.

(3) Transdermal systems with estradiol (E) and norethindrone acetate (NA) mixed with adhesive: Available preparations include Combipatch (0.05 mg/d E and 0.14 mg/d NA, or 0.05 mg/d E and 0.25 mg/d NA), replaced twice weekly. The addition of a progestin increases the likelihood of side effects compared with therapy with estrogen alone.

Intramuscular estrogen preparations include estradiol cypionate in oil (5 mg/mL; 1-5 mL every 3-4 weeks) and estradiol valerate (10, 20, and 40 mg/mL; 10-20 mg every 3-4 weeks). These preparations are rarely required.

Progestins: For a woman with an intact uterus, a progestin may be added to estrogen replacement in order to transform proliferative into secretory endometrium and to reduce the risk of endometrial carcinoma, which is otherwise increased by prolonged exposure to unopposed estrogen. Progestins also counter the increased risk of ovarian cancer caused by unopposed estrogen replacement. Progestins given on a daily or monthly cycled regimen appear to increase the risk of breast cancer more than estrogens alone. Progestins commonly increase the density of breast tissue, reducing the sensitivity of screening mammograms. Theoretically, less frequent administration of progestins (eg, for 10-14 days every 3-4 months) should reduce the adverse effects while causing the endometrium to slough any cells that might be undergoing early malignant transformation. Progestins may cause moodiness, particularly in women with a history of premenstrual dysphoric disorder. Cycled progestins may trigger migraines in certain women. Many other adverse reactions have been reported, including breast tenderness, alopecia, and fluid retention. Contraindications to the use of progestins include thromboembolic disorders, liver disease, breast cancer, and pregnancy. The type of progestin preparation, its dosage, and the timing of administration may be tailored to the given situation.

Micronized progesterone (Prometrium, 100-mg capsules) is an oral formulation of natural progesterone. Preliminary studies indicate that it may be associated with fewer adverse effects on quality of life than other progestins. It also appears to have a less deleterious effect on plasma lipids than other progestins. Micronized progesterone 100 mg/d may be administered with estrogen. Alternatively, estrogen may be given daily, with micronized progesterone (100-200 mg) added for 10-12 days of the month. If the estrogen is being cycled, micronized progesterone 200 mg/d may be given for the last 10 days of the estrogen cycle. It may cause drowsiness, in which case it is taken in the evening.

Medroxyprogesterone acetate (Provera, Cytrin; 2.5-, 5-, and 10-mg scored tablets) is the progestin that is in widest use. A dosage of 2.5-5 mg/d may be administered along with estrogen. If the estrogen is being cycled, medroxyprogesterone acetate 5 mg/d is given for the last 10 days of the estrogen cycle. Alternatively, estrogen may be given daily, with medroxyprogesterone acetate 5 mg/d added for 10-12 days of the month.

Topical progesterone (20-50 mg/d) may reduce hot flushes in women who are intolerant to oral hormone replacement therapy. It may be applied to the upper arms, thighs, or inner wrists daily. It may be compounded as micronized progesterone 250 mg/mL in a transdermal gel. Its effects upon the breast and endometrium are unknown.

Potential benefits of hormone replacement therapy: Women receiving long-term estrogen replacement therapy experience a significant reduction in overall mortality, mainly due to fewer cardiovascular deaths. A "healthy user" effect accounts for much of this observation. However, estrogen replacement does improve lipoprotein parameters in most women. Serum levels of atherogenic lipoprotein(a) are reduced by estrogen replacement with or without daily or cycled progestins. Improvement in serum HDL cholesterol is greatest with unopposed estrogen but is also seen with the addition of a progestin. However, in the HERS study, women with established coronary disease who received conjugated estrogens plus progestin were not protected from further coronary events. Similarly, women with cerebrovascular events were not protected from stroke by estrogen replacement.

Estrogen replacement improves or eliminates postmenopausal hot flushes and diaphoretic episodes. Vaginal moisture is improved. Libido is enhanced in some women. Perimenopause-related depression is improved by unopposed estrogen replacement; the addition of a progestin may negate this effect. Estrogen therapy may enhance verbal memory but does not protect against Alzheimer's disease. Estrogen replacement reduces bone loss and the risk of osteoporotic fractures. Women receiving estrogen replacement therapy experience a lower mortality rate from lung and colon cancers. In women with type 2 diabetes, unopposed estrogen replacement improves glycemic control. Estrogen replacement does not prevent facial skin wrinkling; however, it may improve facial skin moisture and thickness, reducing seborrhea and atrophy.

Potential risks of hormone replacement therapy: Women with an intact uterus who receive unopposed estrogens have a high risk of experiencing dysfunctional uterine bleeding. Continued abnormal bleeding necessitates a pelvic examination; endometrial biopsy may be required. Women receiving unopposed estrogen (conjugated estrogens, 0.625 mg/d or more) have a risk of endometrial carcinoma that is ten times greater than the risk in untreated patients. However, unopposed estrogen replacement at lower doses (eg, conjugated estrogens, 0.3 mg/d) does not appear to cause such an increased risk. Progestins, when added to estrogen replacement in either a continuous or cycled mode, greatly reduce the risk of endometrial cancer—but may have their own adverse effects (see below).

Long-term estrogen replacement therapy appears to increase the risk of breast cancer. The relative risk of breast cancer for women taking estrogen is 1.2, and the relative risk for women taking estrogen-progestin is 1.4. This increased risk for breast cancer appears to be confined to relatively thin women with a BMI < 24.4. Ironically, women receiving estrogen replacement experience a reduced mortality from breast cancer, possibly due to earlier detection. The Iowa Women's Health Study reported an increase in breast cancer with estrogen replacement only in women consuming more than 1 oz of alcohol weekly. No accelerated risk of breast cancer has been seen in users of estrogen replacement therapy who have benign breast disease or a family history of breast cancer.

Women receiving long-term unopposed estrogen appear to experience an increase in mortality from ovarian cancer. The annual age-adjusted ovarian cancer death rates for women who had taken estrogen replacement for = 10 years were 64:100,000 for baseline users, 38:100,000 for former users, and 26:100,000 for women who had never taken estrogen. Women taking combined estrogen-progestin replacement do not experience this risk of ovarian cancer.

Women receiving combined estrogen-progestin replacement experience an increased risk of developing asthma. Elderly women experience an increased risk of urinary incontinence. Some women complain of estrogen-induced edema or mastalgia. Estrogen replacement has been reported to lower the seizure threshold in some women with epilepsy. Untreated large pituitary prolactinomas may enlarge if exposed to estrogen.

There is an increased risk of venous thrombosis with oral estrogens. Oral estrogen therapy may cause hypertriglyceridemia, particularly in women with preexistent hyperlipidemia, which may rarely result in pancreatitis. Oral estrogens also reduce the effectiveness of growth hormone replacement. Using transdermal estrogen rather than oral estrogen replacement may avert the latter problems.

Androgen replacement: Women who have undergone a bilateral oophorectomy almost invariably have low serum androgens. Women with panhypopituitarism tend to have particularly low androgen levels. However, after natural menopause, the ovaries and adrenals continue to secrete testosterone, such that postmenopausal women are not always androgen-deficient. Androgen deficiency contributes to hot flushes, loss of libido and sexual hair, muscle atrophy, and osteoporosis. Selected women may be treated with low-dose methyltestosterone, which is available in combination with conjugated estrogens (eg, Estratest). Tablets contain either 1.25 mg conjugated estrogens with 2.5 mg methyltestosterone or 0.625 mg conjugated estrogens with 1.25 mg methyltestosterone. Estratest is usually started at the lowest strength every 2 days, alternating days with standard estrogen replacement (see above). It should be given cyclically at the lowest dose that controls symptoms. At small doses, side effects of androgens are usually minimal but may include nausea, polycythemia, emotional changes, paresthesias, electrolyte disturbances, and potentiation of anticoagulant therapy. Reduction in HDL cholesterol may negate the beneficial effect on cardiovascular mortality conferred by estrogen replacement therapy. Cholestatic jaundice and elevation of liver enzymes occur rarely. Hepatocellular neoplasms and peliosis hepatis, rare complications of oral androgens at higher doses, have not been reported with lower doses. Side effects of excess androgen treatment include hirsutism and virilization. Androgens should not be given to women with liver disease or during pregnancy or breast feeding.

Selective estrogen receptor modulators (SERMs) (eg, raloxifene; Evista) are an alternative to estrogen replacement for hypogonadal women at risk for osteoporosis who prefer not to take estrogens because of their contraindications (eg, breast or uterine cancer) or side effects. Raloxifene does not reduce hot flushes, vaginal dryness, skin wrinkling, or breast atrophy; it does not improve cognition. However, in doses of 60 mg/d orally, it inhibits bone loss without stimulating effects upon the breasts or endometrium. Since raloxifene may slightly increase the risk of venous thromboembolism, it should not be used by women at prolonged bed rest or by those prone to thrombosis. In contrast with the use of estrogen replacement therapy, concomitant progesterone therapy is not needed, and raloxifene does not increase the

risk of development of breast cancer. Tibolone (Livial) is an SERM whose metabolites have mixed estrogenic, progestogenic, and weak androgenic activity. It is comparable to hormone replacement therapy for the treatment of climacteric-related complaints. It does not appear to significantly stimulate proliferation of breast or endometrial tissue. It depresses both serum triglycerides and HDL cholesterol. Long-term studies are lacking. It is not available in the United States.

Phytoestrogens are substances found in plants (legumes) which bind to estrogen receptors. Isoflavones are phytoestrogens which bind weakly to estrogen receptor β . Soy and red clover isoflavones are selective estrogen receptor modulators, which act as estrogen on bone, brain, and vasculature but have no stimulatory effects upon the uterus or breast. Daily intake of 60 g of isolated soy protein reduces hot flushing by about 45% within 12 weeks. Isoflavones also improve the plasma lipid profile and inhibit the development of coronary atherosclerosis in male monkeys. In a study of female oophorectomized monkeys, soy phytoestrogens significantly inhibited carotid atherosclerosis, but the effect on coronary atherosclerosis was not statistically significant. In climacteric premenopausal women, soy supplementation does not appear to affect the menstrual cycle. Genistein, a flavone found in soy, has been proposed to account for the low incidence of breast cancer in Asian women. Genistein has a pronounced antiproliferative effect upon breast cancer cells in nude mice.

TURNER'S SYNDROME (GONADAL DYSGENESIS)

Turner's syndrome is a chromosomal disorder associated with primary hypogonadism, short stature, and other phenotypic anomalies. It is a common cause of primary amenorrhea and early ovarian failure. Patients with the classic syndrome lack one of the two X chromosomes and have a 45,XO karyotype.

Typical Turner's Syndrome (45,XO Gonadal Dysgenesis)

Features of Turner's syndrome ([Table 26-15](#)) are variable and may be subtle in girls with mosaicism. Typical manifestations in adulthood include short stature, hypogonadism, webbed neck, high-arched palate, wide-spaced nipples, hypertension, and renal abnormalities. 45,XO is the most common major chromosomal abnormality in humans. Less than 3% of these zygotes survive to term, with the incidence of Turner's syndrome being about 1:10,000 female newborns.

Girls with Turner's syndrome may be diagnosed at birth, since they tend to be small and may exhibit severe lymphedema. Evaluation for childhood short stature often leads to the diagnosis. Growth hormone and somatomedin levels are normal. Hypogonadism presents as "delayed adolescence" (80%) or early ovarian failure (20%); FSH and LH are high, making a diagnosis of primary hypogonadism. A blood karyotype showing 45,XO (or X chromosome abnormalities or mosaicism) establishes the diagnosis.

Treatment of short stature with daily injections of growth hormone (0.1 unit/kg/d) plus an androgen (eg, oxandrolone) for at least 4 years before epiphysial fusion increases final height by a mean of about 10.3 cm over the mean predicted height of 144.2 cm. Such growth hormone treatment rarely causes pseudotumor cerebri. After age 12, estrogen therapy is begun with low doses of conjugated estrogens (0.3 mg) or ethinyl estradiol (5 ug) given on days 1-21 per month. When growth stops, hormone replacement therapy is begun with estrogen and progestin (see below).

Women with Turner's syndrome have a reduced life expectancy due in part to their increased risk for diabetes mellitus (types 1 and 2), hypertension, dyslipidemia, and osteoporosis. Diagnostic vigilance and aggressive treatment of these conditions reduces the risk of ischemic heart disease, stroke, and fracture. Patients are prone to keloid formation after surgery or ear piercing. Yearly ocular examinations and periodic thyroid evaluations are recommended. It is advisable to evaluate patients for cardiac, aortic, and renal abnormalities.

Turner's Syndrome Variants

A. 46,X (Abnormal X) Karyotype

An abnormality or deletion of certain genes on the short arm of the X chromosome causes short stature and other signs of Turner's syndrome; some gonadal function and even fertility is possible. Transmission of Turner's syndrome from mother to daughter can occur. There may be an increased risk of trisomy 21 in the conceptuses of women with Turner's syndrome. Abnormalities or deletions of other genes located on both the long and short arms of the X chromosome can produce gonadal dysgenesis with few other somatic features.

B. 45,XO/46,XX Mosaicism

This karyotype results in a modified form of Turner's syndrome. Such girls tend to be taller and may have more gonadal function and fewer other manifestations of Turner's syndrome.

C. Other Variants

45,XO/46,XY mosaicism can produce some manifestations of Turner's syndrome. Patients may have ambiguous genitalia or male infertility with an otherwise normal phenotype.

■ MULTIPLE ENDOCRINE NEOPLASIA

Several syndromes with multiple gland involvement have been described (Table 26-16).

MEN 1 (Wermer's Syndrome)

The most common multiglandular syndrome is multiple endocrine neoplasia type 1 (MEN 1). Biochemical testing identifies affected individuals by age 14-18 years, but the syndrome usually becomes clinically manifest in the fourth decade. **Hyperparathyroidism** occurs in over 80% of patients; it presents with hypercalcemia and usually involves hyperplasia or adenomas of several parathyroid glands. **Pancreatic islet cell tumors** occur in about 75% of patients; gastrinomas are the most common tumor and can result in gastric hyperacidity (Zollinger-Ellison syndrome) with peptic ulcer disease or diarrhea. Islet cell tumors may also secrete insulin, somatostatin, or glucagon. **Pituitary adenomas** occur in about 60% and may secrete prolactin, growth hormone, or ACTH but are usually nonfunctional; such tumors may produce local pressure effects and hypopituitarism. About 37% of these patients have adrenal cortical adenomas or hyperplasia—bilateral in about half. They are generally benign and nonfunctional. In one series, one out of 12 such patients developed a feminizing adrenal carcinoma. These adrenal lesions are pituitary-independent.

Tumors of the pituitary gland, the parathyroid gland, and the pancreatic islets may occur in the same patient, though not necessarily at the same time. Some individuals in the same family express the abnormality as children, whereas in others the clinical manifestations may not appear until late in adult life. The clinical manifestations of MEN 1 are extremely variable, since the glandular tumors may secrete a variety of different hormones.

The kindreds expressing MEN 1 have been shown to harbor a gene mutation on the long arm of chromosome 11 (11q13), which causes phenotypic expression as a dominant trait. Germline mutations may be detected by analyzing the ten exons of the MEN 1 gene using single-strand confirmational analysis (SSCA), followed by autosequencing of abnormal SSCA shifts. Genetic linkage analysis can also be used to determine which other family members will express this syndrome. This permits informed genetic counseling and avoids unnecessary testing for unaffected individuals.

The differential diagnosis of MEN 1 includes sporadic or familial tumors of the pituitary, parathyroids, or pancreatic islets. Hypercalcemia (from any cause) may cause gastrointestinal symptoms and increased gastrin levels, simulating a gastrinoma. Treatment of gastrointestinal symptoms with H₂ blockers or metoclopramide causes hyperprolactinemia, simulating a pituitary prolactinoma.

Surgical treatment of hyperparathyroidism in MEN 1 can induce prolonged remissions, but relapse is typical. Aggressive parathyroid resection can cause permanent hypoparathyroidism. Medical treatment of hyperparathyroidism with bisphosphonates (eg, zoledronate) is thus an important option.

MEN 2a (Sipple's Syndrome)

A separate disorder of multiglandular hypersecretion of hormones is multiple endocrine neoplasia type 2a. It also is inherited as an autosomal dominant trait. In MEN 2a, patients may have **medullary thyroid carcinoma** (> 90%); hyperparathyroidism (20-50%), due to hyperplasia or multiple adenomas in over 70% of cases; **pheochromocytomas** (20-35%), which are often bilateral; or **Hirschsprung's disease**. The medullary thyroid carcinoma is of mild to moderate aggressiveness and generally occurs in the third or fourth decade in the familial syndrome and in the sixth decade in sporadic cases.

Siblings or children of patients with MEN 2a should have genetic testing to determine if they have a mutation of the *RET* proto-oncogene on chromosome 10cen-10q11.2; this identifies about 95% of affected individuals. Each kindred has a certain *RET* codon mutation that correlates with the particular variation in the MEN 2 syndrome, such as the age of onset and aggressiveness of medullary thyroid cancer. The specific mutation as well as case histories of family members should guide the timing for prophylactic thyroidectomy. Before any surgical procedure, MEN 2 carriers should be screened for pheochromocytoma. There is incomplete penetrance, and about 30% of those with such mutations never manifest endocrine tumors.

Patients may be screened with a serum calcitonin drawn after 3 days of omeprazole, 20 mg orally twice daily; calcitonin levels rise in the presence of medullary thyroid carcinoma to levels above 80 pg/mL in women or above 190 pg/mL in men.

MEN 2b

Patients with MEN 2b have a syndrome characterized by mucosal neuromas (> 90% with bumpy lips, enlarged tongue, Marfan-like habitus), pheochromocytomas (60%), and medullary thyroid carcinoma (80%). Patients also have intestinal abnormalities (75%), skeletal abnormalities (87%), and delayed puberty (43%). The medullary thyroid carcinoma is aggressive and tends to present in the third to fourth decades. Prophylactic thyroidectomy is advisable for patients with mucosal neuromas and family members with the syndrome or *RET* proto-oncogene mutations after screening for pheochromocytoma.

■ CLINICAL USE OF GLUCOCORTICOIDS

Mechanisms of Action

Cortisol is a steroid hormone that is normally secreted by the adrenal cortex in response to ACTH. It exerts its action by binding to nuclear receptors which then act upon chromatin to regulate gene expression, producing effects throughout the body.

Relative Potencies

Hydrocortisone and cortisone acetate, like cortisol, have mineralocorticoid effects that become excessive at higher doses. Other synthetic glucocorticoids such as prednisone, dexamethasone, and deflazacort (an oxazoline derivative of prednisolone) have minimal mineralocorticoid activity. The relative potencies relative to hydrocortisone are listed in Table 26-17. Anticonvulsant drugs (eg, phenytoin, carbamazepine, phenobarbital) accelerate the metabolism of glucocorticoids other than hydrocortisone, making them significantly less potent. Megestrol, a synthetic progestin, has slight glucocorticoid activity that becomes significant when administered in high doses for appetite stimulation.

Adverse Effects

Prolonged treatment with systemic glucocorticoids causes a variety of adverse effects that can be life-threatening. Patients should be thoroughly informed of the major possible side effects of treatment such as insomnia, personality change, weight gain, muscle weakness, polyuria, kidney stones, diabetes mellitus, sex hormone suppression, occasional amenorrhea in women, candidiasis and opportunistic infections, osteoporosis with fractures, or aseptic necrosis of bones, particularly of the hips, which may become manifest many months after even brief treatment (see section on Cushing's syndrome). Alendronate, 5-10 mg orally daily, prevents the development of osteoporosis among patients receiving prolonged courses of glucocorticoids. For convenience, alendronate, 70 mg orally, may be taken once weekly. For patients who are unable to tolerate oral bisphosphonates (due to esophagitis, hiatal hernia, or gastritis), periodic intravenous infusions of pamidronate, 60-90 mg, or

zoledronate, 2-4 mg, should also be effective. It is wise to follow an organized treatment plan such as the one outlined in [Table 26-18](#).

Androgen resistance syndromes	Ethionamide
Aromatase excess syndrome (sporadic or familial)	Finasteride
Hyperprolactinemia	Flutamide
Hyperthyroidism	Goserelin (Zoladex)
Klinefelter's syndrome	Haloperidol
Male hypogonadism	Hydroxyzine
Partial 17-ketosteroid reductase deficiency	Isoniazid
	Ketoconazole
Systemic diseases	Leuprolide
Chronic liver disease	Marijuana
Chronic renal disease	Meprobamate
Refeeding after starvation	Methadone
Spinal cord injury	Methyldopa
	Metoclopramide
Neoplasms	Molindone
Adrenal tumors	Nilutamide
Bronchogenic carcinoma	Omeprazole
Carcinoma of the breast	Opioids
Testicular tumors	Penicillamine
Hepatocellular carcinoma (rare)	Phenothiazines
Drugs (partial list)	Progestins
Alcohol	Protease inhibitors
Alkylating agents	Reserpine
Amiodarone	Somatropin (growth hormone)
Androgens	Spirololactone
Bicalutamide	Testosterone
	Thioidazine
	Tricyclic antidepressants

Table 26-3. Pituitary hormones.

Anterior pituitary

- Growth hormone (GH)¹
- Prolactin (PRL)
- Adrenocorticotrophic hormone (ACTH)
- Thyroid-stimulating hormone (TSH)
- Luteinizing hormone (LH)²
- Follicle-stimulating hormone (FSH)

Posterior pituitary

- Arginine vasopressin (AVP)³
- Oxytocin

¹GH closely resembles human placental lactogen (hPL).
²LH closely resembles human chorionic gonadotropin (hCG).
³AVP is identical with antidiuretic hormone (ADH).

Table 26-5. Factors falsely altering serum thyroxine measurements without affecting clinical status.^{1,2}

Factors Increasing T ₄	Factors Decreasing T ₄
Laboratory error	Laboratory error
AIDS (increased thyroid-binding globulin)	Severe illness (eg, chronic renal failure, major surgery, caloric deprivation)
Autoimmunity	Acute psychiatric problems
Acute illness (eg, viral hepatitis, chronic active hepatitis; primary biliary cirrhosis; acute intermittent porphyria; AIDS)	Cirrhosis
High-estrogen states (may also increase total T ₃)	Nephrotic syndrome
Oral estrogen-containing contraceptives	Hereditary TBG deficiency
Pregnancy	Drugs
Estrogen replacement therapy	Androgens
Tamoxifen	Asparaginase
Acute psychiatric problems	Carbamazepine
Hyperemesis gravidarum and morning sickness (may also increase T ₃)	Chloral hydrate
Familial thyroid-binding abnormalities	Fenclofenac
Generalized resistance to thyroid hormone	Fluorouracil
Drugs	Glucocorticoids
Amiodarone	Halofenate (lowers triglycerides and uric acid; not marketed in USA)
Amphetamines	Mitotane
Clofibrate	Nicotinic acid
Heparin (dialysis method)	Phenobarbital
Heroin	Phenylbutazone
Levothyroxine (T ₄) replacement therapy	Phenytoin (T ₄ may be as low as 2 µg/dL)
Methadone (may also increase T ₃)	Salicylates (large doses)
Perphenazine	Sertraline
	Triiodothyronine (T ₃) therapy

Table 26-6. Appropriate use of thyroid tests.

Purpose	Test	Comment
Screening	Serum TSH (sensitive assay)	Most sensitive test for primary hypothyroidism and hyperthyroidism
	Free T ₄	Excellent test
For hypothyroidism	Serum TSH	High in primary and low in secondary hypothyroidism
	Elevated in Hashimoto's thyroiditis	
For hyperthyroidism	Serum TSH (sensitive assay)	Suppressed except in TSH-secreting pituitary tumor or hyperplasia (rare)
	T ₃ (RIA)	Elevated
	¹²³ I uptake and scan	Increased diffuse versus "hot" areas
	Antithyroglobulin and antimicrosomal antibodies	Elevated in Graves' disease
For nodules	TSH receptor antibody (TSH-R Ab [stim])	Usually positive in Graves' disease
	Fine-needle aspiration (FNA)	Best diagnostic method for thyroid cancer
	¹²³ I uptake and scan	Cancer is usually "cold." Less reliable than FNA.
	^{99m} Tc scan	Vascular versus avascular
	Ultrasonography	Solid versus cystic. Pure cysts are usually not malignant.

-

Table 26-18. Management of patients receiving systemic glucocorticoids.¹

- Do not administer glucocorticoids unless absolutely indicated or more conservative measures have failed.
- Keep dosage and duration of administration to the minimum required for adequate treatment.
- Screen for tuberculosis before treatment with a PPD test or chest x-ray.
- Screen for diabetes mellitus before treatment and at each physician visit. Train the patient to test urine weekly for glucose.
- Screen for hypertension before treatment and at each physician visit.
- Screen for glaucoma and cataracts before treatment, 3 months into treatment, and then at least yearly.
- Prepare the patient and family for possible adverse effects on mood, memory, and cognitive function. Inform them about other possible side effects, particularly weight gain, osteoporosis, and aseptic necrosis of bone.
- Institute a vigorous physical exercise and isometric regimen tailored to each patient's disabilities.
- Administer calcium (1 g elemental calcium) and vitamin D₃, 400-800 IU orally daily. Check spot morning urines, and alter dosage to keep urine calcium concentration below 30 mg/dL. If the patient is receiving thiazide diuretics, check for hypercalcemia, and administer only 500 mg elemental calcium daily. Consider a bisphosphonate such as alendronate (5-10 mg orally daily or 70 mg orally weekly) or periodic intravenous infusions of pamidronate or zoledronate.
- Avoid prolonged bed rest that will accelerate muscle weakness and bone mineral loss. Ambulate early after fractures.
- Treat hypogonadism in women or men.
- Avoid elective surgery, if possible. Vitamin A in a daily dose of 20,000 units orally for 1 week may improve wound healing, but it is not prescribed in pregnancy.
- Avoid activities that could cause falls or other trauma.
- Watch for fungal or yeast infections of skin, nails, mouth, vagina, and rectum, and treat appropriately.
- Ulcer prophylaxis: Administer oral glucocorticoids with meals. If administered with nonsteroidals, consider prophylaxis with omeprazole, 20-40 mg/d. Glucocorticoids alone do not need prophylaxis with H₂ blockers or omeprazole. Avoid large doses of antacids containing aluminum hydroxide (many popular brands); aluminum hydroxide binds phosphate and may cause a hypophosphatemic osteomalacia that can compound glucocorticoid osteoporosis.
- Treat infections aggressively. Consider unusual pathogens.
- Weigh daily. Use dietary measures to avoid obesity and optimize nutrition.
- Measure height frequently. This serves to document the degree of axial spine demineralization and compression.
- Treat edema as indicated.
- Monitor plasma potassium for hypokalemia. Treat as indicated.
- Obtain bone densitometry before treatment and then periodically. Treat osteoporosis.
- Council to avoid smoking and excessive ethanol consumption.
- With dosage reduction, watch for signs of adrenal insufficiency or glucocorticoid withdrawal syndrome.

■ DIABETES MELLITUS

Essentials of Diagnosis

Type 1 diabetes:

- Polyuria, polydipsia, and weight loss associated with random plasma glucose = 200 mg/dL.
- Plasma glucose of 126 mg/dL or higher after an overnight fast, documented on more than one occasion.
- Ketonemia, ketonuria, or both.

Type 2 diabetes:

- Most patients are over 40 years of age and obese.
- Polyuria and polydipsia. Ketonuria and weight loss generally are uncommon at time of diagnosis. Candidal vaginitis in women may be an initial manifestation. Many patients have few or no symptoms.
- Plasma glucose of 126 mg/dL or higher after an overnight fast on more than one occasion. After 75 g oral glucose, diagnostic values are 200 mg/dL or more 2 hours after the oral glucose.
- Hypertension, dyslipidemia, and atherosclerosis are often associated.

Classification & Pathogenesis (Table 27-1)

Diabetes mellitus is a syndrome with disordered metabolism and inappropriate hyperglycemia due to either a deficiency of insulin secretion or to a combination of insulin resistance and inadequate insulin secretion to compensate. An international committee of experts in the field has recommended use of the terms "type 1 and type 2 diabetes," with arabic numerals being used rather than roman numerals, since the numeral II can be confused with the number 11. Type 1 diabetes is due to pancreatic islet B cell destruction predominantly by an autoimmune process, and these patients are prone to ketoacidosis. Type 2 diabetes is the more prevalent form and results from insulin resistance with a defect in compensatory insulin secretion.

A. Type 1 Diabetes Mellitus

This form of diabetes is immune-mediated in over 90% of cases and idiopathic in less than 10%. The rate of pancreatic B cell destruction is quite variable, being rapid in some individuals and slow in others. Type 1 diabetes is usually associated with ketosis in its untreated state. It occurs most commonly in juveniles, with the highest incidence worldwide among the 10- to 14-year-old group, but occasionally occurs in adults, especially the nonobese and those who are elderly when hyperglycemia first appears. It is a catabolic disorder in which circulating insulin is virtually absent, plasma glucagon is elevated, and the pancreatic B cells fail to respond to all insulinogenic stimuli. Exogenous insulin is therefore required to reverse the catabolic state, prevent ketosis, reduce the hyperglucagonemia, and reduce blood glucose.

The highest incidence of immune-mediated type 1 diabetes is in Scandinavia and northern Europe, where the yearly incidence per 100,000 youngsters 14 years of age or less is as high as 37 in Finland, 27 in Sweden, 22 in Norway, and 19 in the United Kingdom. The incidence of type 1 diabetes generally decreases across the rest of Europe to 10 in Greece and 8 in France. Surprisingly, the island of Sardinia has as high an incidence as Finland (37) even though in the rest of Italy, including the island of Sicily, it is only 10 per 100,000 per year. The United States averages 15 per 100,000, with higher incidences in states more densely populated with persons of Scandinavian descent such as Minnesota. The lowest incidence of type 1 diabetes worldwide was found to be less than 1 per 100,000 per year in China and parts of South America.

Certain human leukocyte antigens (HLA) are strongly associated with the development of type 1 diabetes. About 95% of type 1 patients possess either HLA-DR3 or HLA-DR4, compared with 45-50% of Caucasian controls. HLA-DQ genes are even more specific markers of type 1 susceptibility, since a particular variety (*HLA-DQB1*0302*) is found in the DR4 patients with type 1, while a "protective" gene (*HLA-DQB1*0602*) is often present in the DR4 controls. In addition, circulating islet cell antibodies have been detected in as many as 85% of patients tested in the first few weeks of their diabetes, and when sensitive immunoassays are used, the majority of these patients also have detectable anti-insulin antibodies prior to receiving insulin therapy. Most islet cell antibodies are directed against glutamic acid decarboxylase, an enzyme localized within pancreatic B cells. Immunoassays for this marker of type 1 diabetes facilitate screening of siblings of affected children as well as adults with atypical features of type 2 for an autoimmune cause of their diabetes.

Certain unrecognized patients with a milder expression of type 1 diabetes initially retain enough B cell function to avoid ketosis but later in life develop increasing dependency on insulin therapy as their B cell mass diminishes. Islet cell antibody surveys among northern Europeans indicate that up to 15% of "type 2" patients may actually have this mild form of type 1 diabetes (latent autoimmune diabetes of adulthood; LADA).

1. Immune-mediated type 1 diabetes mellitus—Immune-mediated type 1 diabetes is felt to result from an infectious or toxic insult to persons whose immune system is genetically predisposed to develop a vigorous autoimmune response either against altered pancreatic B cell antigens or against molecules of the B cell resembling the viral protein (molecular mimicry). Extrinsic factors that affect B cell function include damage caused by viruses such as mumps or coxsackie B4 virus, by toxic chemical agents, or by destructive cytotoxins and antibodies released from sensitized immunocytes. Specific HLA immune response genes are believed to predispose patients to a destructive autoimmune response against their own islet cells (autoaggression) which is mediated primarily by cytotoxic T cells. Amelioration of hyperglycemia in patients given an immunosuppressive agent (eg, cyclosporine) shortly after onset of type 1 diabetes lends further support to the pathogenetic role of autoimmunity.

2. Idiopathic type 1 diabetes mellitus—Fewer than 10% of subjects have no evidence of pancreatic B cell autoimmunity to explain their insulinopenia and ketoacidosis. This subgroup has been classified as "idiopathic type 1 diabetes" and designated as "type 1B." Although only a minority of patients with type 1 diabetes fall into this group, most of these are of Asian or African origin.

B. Type 2 Diabetes

This represents a heterogeneous group comprising milder forms of diabetes that occur predominantly in adults but occasionally in juveniles. More than 90% of all diabetics in the United States are included under this classification. Circulating endogenous insulin is sufficient to prevent ketoacidosis but is inadequate to prevent hyperglycemia in the face of increased needs owing to tissue insensitivity. In most cases of this type of diabetes, the cause is unknown.

Tissue insensitivity to insulin has been noted in most type 2 patients irrespective of weight and has been attributed to several interrelated factors. These include a putative (and as yet undefined) genetic factor, which is aggravated in time by additional enhancers of insulin resistance such as aging, a sedentary lifestyle, and abdominal-visceral obesity. In addition, there is an accompanying deficiency in the response of pancreatic B cells to glucose. Both the tissue resistance to insulin and the impaired B cell response to glucose appear to be further aggravated by increased hyperglycemia (glucose toxicity), and both defects are ameliorated by treatment that reduces the hyperglycemia toward normal. Most epidemiologic data indicate strong genetic influences, since in monozygotic twins over 40 years of age, concordance develops in over 70% of cases within a year whenever one twin develops type 2 diabetes. Attempts to identify genetic markers for type 2 have as yet been unsuccessful, though linkage to a gene on chromosome 2 encoding a cysteine protease, *calpain-10*, has been reported in a Mexican-American population. However, its association with other ethnic populations and any role it plays in the pathogenesis of type 2 diabetes remain to be clarified.

Two subgroups of patients are currently distinguished by the absence or presence of obesity. The degree and prevalence of obesity varies among different racial groups. While obesity is apparent in no more than 30% of Chinese and Japanese patients with type 2, it is found in 60-70% of North Americans, Europeans, or Africans with type 2 and approaches 100% of patients with type 2 among Pima Indians or Pacific Islanders from Nauru or Samoa.

Nonobese type 2 patients generally show an absent or blunted early phase of insulin release in response to glucose; however, it can be elicited in response to other insulinogenic stimuli such as acute intravenous administration of sulfonyleureas, glucagon, or arginine.

Although insulin resistance may be detected with special tests, it does not seem to be clinically relevant to the treatment of most nonobese type 2 patients, who generally respond to appropriate therapeutic supplements of insulin in the absence of rare associated conditions such as lipodystrophy or acanthosis nigricans.

Among this heterogeneous subgroup of patients with nonobese type 2 diabetes, the majority are idiopathic. However, with increasing frequency, a variety of etiologic genetic abnormalities have been documented in a subset of these patients who have recently been reclassified within a group designated "other specific types." (See [Table 27-2](#).)

C. Other Specific Types of Diabetes Mellitus

1. Maturity-onset diabetes of the young (MODY)—This subgroup is a relatively rare monogenic disorder characterized by non-insulin-dependent diabetes with autosomal dominant inheritance and an age at onset of 25 years or younger. Patients are nonobese, and their hyperglycemia is due to impaired glucose-induced secretion of insulin. Six types of MODY have been described. Except for MODY 2, in which a glucokinase gene is defective, all other types involve mutations of a nuclear transcription factor that regulates islet gene expression.

MODY 2 is quite mild, associated with only slight fasting hyperglycemia and few if any microvascular diabetic complications. It generally responds well to hygienic measures or low doses of oral hypoglycemic agents. MODY 3—the most common form—accounts for two-thirds of all MODY cases. The clinical course is similar to that of idiopathic type 2 diabetes in terms of microangiopathy and failure to respond to oral agents with time.

2. Diabetes due to mutant insulins—This is a very rare subtype of nonobese type 2 diabetes, with no more than ten families having been described. Since affected individuals were heterozygous and possessed one normal insulin gene, diabetes was mild, did not appear until middle age, and showed autosomal dominant genetic transmission. There is generally no evidence of clinical insulin resistance and these patients respond well to standard therapy.

3. Diabetes due to mutant insulin receptors—Defects in one of their insulin receptor gene have been found in more than 40 people with diabetes, and most have extreme insulin resistance associated with acanthosis nigricans. In very rare instances when both insulin receptor genes are abnormal, newborns present with a leprechaun-like phenotype and seldom live through infancy.

4. Diabetes mellitus associated with a mutation of mitochondrial DNA—Since sperm do not contain mitochondria, only the mother transmits mitochondrial genes to her offspring. Diabetes due to a mutation of mitochondrial DNA that impairs the transfer of leucine or lysine into mitochondrial proteins has been described. Most patients have a mild form of diabetes that responds to oral hypoglycemic agents, some a nonimmune form of type 1 diabetes. Two-thirds of patients with this subtype of diabetes have a hearing loss, and a smaller proportion (15%) had a syndrome of myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (MELAS).

5. Obese type 2 patients—Patients with this most common form of diabetes have an insensitivity to endogenous insulin. When an associated defect of insulin production prevents adequate compensation for this insulin resistance, nonketotic mild diabetes occurs. Hyperplasia of pancreatic B cells is often present and probably accounts for the fasting hyperinsulinism and exaggerated insulin and proinsulin responses to glucose and other stimuli seen early in the disease. After several years' duration of diabetes, chronic deposition of amyloid in the islets may combine with inherited genetic defects to progressively impair B cell function.

The mechanisms underlying the insulin resistance of type 2 diabetes are poorly understood. Obesity is generally associated with abdominal distribution of fat, producing an abnormally high waist-to-hip ratio. This "visceral" obesity, due to accumulation of fat in the omental and mesenteric regions, correlates with insulin resistance; subcutaneous abdominal fat seems to have less of an association with insulin insensitivity. Exercise may affect the deposition of visceral fat as suggested by CT scans of Japanese wrestlers, whose extreme obesity is predominantly subcutaneous. Their daily vigorous exercise program prevents accumulation of visceral fat, and they have normal serum lipids and euglycemia despite daily intakes of 5000-7000 kcal and development of massive subcutaneous obesity. Several **adipokines**, secreted by fat cells, can affect insulin action in obesity. Two of these, **leptin** and **adiponectin**, seem to increase sensitivity to insulin, presumably by increasing hepatic responsiveness. Two others—**tumor necrosis factor- α** , which inactivates insulin receptors, and the newly discovered peptide **resistin**—interfere with insulin action on glucose metabolism and have been reported to be elevated in obese animal models. Mutations or abnormal levels of these adipokines may contribute to the development of insulin resistance in human obesity.

Hyperglycemia per se can impair insulin action by causing accumulation of hexosamines in muscle and fat tissue and inhibits glucose transport (acquired glucose toxicity). Correction of hyperglycemia reverses this acquired insulin resistance.

Epidemiologic Considerations

An estimated 16 million people in the United States are known to have diabetes, of which 1.4 million have type 1 diabetes and approximately 14.5 million have type 2 diabetes. The remainder, numbered only in the thousands, comprise a third group that was designated as "other specific types" by the American Diabetes Association ([Table 27-2](#)). These other types include disorders for which causes are known. Among these are the rare monogenic defects of either B cell function or of insulin action, primary diseases of the exocrine pancreas, endocrinopathies, and drug-induced diabetes.

Insulin Resistance Syndrome (Syndrome X; Metabolic Syndrome)

Twenty-five percent of the general nonobese nondiabetic population have insulin resistance of a magnitude similar to that seen in type 2 diabetes. These insulin-resistant nondiabetic individuals are at much higher risk of developing type 2 diabetes than insulin-sensitive subjects. In addition to diabetes, these individuals have increased risk for elevated plasma triglycerides, lower high-density lipoproteins, and higher blood pressure—a cluster of abnormalities termed syndrome X. These associations have now been expanded to include small, dense, low-density lipoprotein, hyperuricemia, abdominal obesity, prothrombotic state with increased levels of plasminogen activator inhibitor type 1 (PAI-1), and proinflammatory state. These clusters of abnormalities significantly increase the risk of atherosclerotic disease.

It has been postulated that hyperinsulinemia and insulin resistance play a direct role in these metabolic abnormalities, but supportive evidence is inconclusive. Although hyperinsulinism and hypertension often coexist in Caucasians, that is not the case in blacks or Pima Indians. Moreover, patients with hyperinsulinism due to insulinoma are not hypertensive, and there is no fall in blood pressure after surgical removal of the insulinoma restores normal insulin levels. The main value of grouping these disorders as a syndrome, however, is to remind clinicians that the therapeutic goals are not only to correct hyperglycemia but also to manage the elevated blood pressure and dyslipidemia that result in increased cerebrovascular and cardiac morbidity and mortality in these patients. Clinicians aware of this syndrome are more cautious in prescribing therapies that correct hypertension but may raise lipids (diuretics, beta-blockers) or that correct hyperlipidemia but increase insulin resistance, with aggravation of diabetes (niacin). Finally, the use of long-acting insulins and sulfonylureas that promote sustained hyperinsulinism may have to be moderated, with insulin-sparing drugs such as metformin or a thiazolidinedione being preferable, if the hypothesis behind the insulin resistance syndrome is ever substantiated.

Clinical Findings

The principal clinical features of the two major types of diabetes mellitus are listed for comparison in [Table 27-3](#).

Patients with type 1 diabetes present with a characteristic symptom complex. An absolute deficiency of insulin results in accumulation of circulating glucose and fatty acids, with consequent hyperosmolality and hyperketonemia.

Patients with type 2 diabetes may or may not present with characteristic features. The presence of obesity or a strongly positive family history for mild diabetes suggests a high risk for the development of type 2 diabetes.

A. Symptoms and Signs

1. Type 1 diabetes—Increased urination is a consequence of osmotic diuresis secondary to sustained hyperglycemia. This results in a loss of glucose as well as free water and electrolytes in the urine. Thirst is a consequence of the hyperosmolar state, as is blurred vision, which often develops as the lenses are exposed to hyperosmolar fluids.

Weight loss despite normal or increased appetite is a common feature of type 1 when it develops subacutely. The weight loss is initially due to depletion of water, glycogen, and triglycerides; thereafter, reduced muscle mass occurs as amino acids are diverted to form glucose and ketone bodies.

Lowered plasma volume produces symptoms of postural hypotension. Total body potassium loss and the general catabolism of muscle protein contribute to the weakness.

Paresthesias may be present at the time of diagnosis, particularly when the onset is subacute. They reflect a temporary dysfunction of peripheral sensory nerves, which clears as insulin replacement restores glycemic levels closer to normal, suggesting neurotoxicity from sustained hyperglycemia.

When absolute insulin deficiency is of acute onset, the above symptoms develop abruptly. Ketoacidosis exacerbates the dehydration and hyperosmolality by producing anorexia and nausea and vomiting, interfering with oral fluid replacement.

The patient's level of consciousness can vary depending on the degree of hyperosmolality. When insulin deficiency develops relatively slowly and sufficient water intake is maintained, patients remain relatively alert and physical findings may be minimal. When vomiting occurs in response to worsening ketoacidosis, dehydration progresses and compensatory mechanisms become inadequate to keep serum osmolality below 320-330 mosm/L. Under these circumstances, stupor or even coma may occur. The fruity breath odor of acetone further suggests the diagnosis of diabetic ketoacidosis.

Hypotension in the recumbent position is a serious prognostic sign. Loss of subcutaneous fat and muscle wasting are features of more slowly developing insulin deficiency. In occasional patients with slow, insidious onset of insulin deficiency, subcutaneous fat may be considerably depleted. An enlarged liver, eruptive xanthomas on the flexor surface of the limbs and on the buttocks, and lipemia retinalis indicate that chronic insulin deficiency has resulted in chylomicronemia, with

circulating triglycerides elevated usually to over 2000 mg/dL.

2. Type 2 diabetes—While many patients with type 2 diabetes present with increased urination and thirst, many others have an insidious onset of hyperglycemia and are asymptomatic initially. This is particularly true in obese patients, whose diabetes may be detected only after glycosuria or hyperglycemia is noted during routine laboratory studies. Occasionally, type 2 patients may present with evidence of neuropathic or cardiovascular complications because of occult disease present for some time prior to diagnosis. Chronic skin infections are common. Generalized pruritus and symptoms of vaginitis are frequently the initial complaints of women. Diabetes should be suspected in women with chronic candidal vulvovaginitis as well as in those who have delivered large babies (> 9 lb, or 4.1 kg) or have had polyhydramnios, preeclampsia, or unexplained fetal losses.

Obese diabetics may have any variety of fat distribution; however, diabetes seems to be more often associated in both men and women with localization of fat deposits on the upper segment of the body (particularly the abdomen, chest, neck, and face) and relatively less fat on the appendages, which may be quite muscular. Standardized tables of waist-to-hip ratio indicate that ratios of "greater than 0.9" in men and "greater than 0.8" in women are associated with an increased risk of diabetes in obese subjects. Mild hypertension is often present in obese diabetics.

B. Laboratory Findings

1. Urinalysis—

a. Glucosuria—A specific and convenient method to detect glucosuria is the paper strip impregnated with glucose oxidase and a chromogen system (Clinistix, Diastix), which is sensitive to as little as 0.1% glucose in urine. Diastix can be directly applied to the urinary stream, and differing color responses of the indicator strip reflect glucose concentration.

A normal renal threshold for glucose as well as reliable bladder emptying is essential for interpretation.

b. Ketonuria—Qualitative detection of ketone bodies can be accomplished by nitroprusside tests (Acetest or Ketostix). Although these tests do not detect β -hydroxybutyric acid, which lacks a ketone group, the semiquantitative estimation of ketonuria thus obtained is nonetheless usually adequate for clinical purposes.

2. Blood testing procedures—

a. Glucose tolerance test—

*(1) Methodology and normal fasting glucose—*Plasma or serum from venous blood samples has the advantage over whole blood of providing values for glucose that are independent of hematocrit and that reflect the glucose concentration to which body tissues are exposed. For these reasons, and because plasma and serum are more readily measured on automated equipment, they are used in most laboratories. If serum is used or if plasma is collected from tubes that lack an agent to block glucose metabolism (such as fluoride), samples should be refrigerated and separated within 1 hour after collection.

*(2) Criteria for laboratory confirmation of diabetes mellitus—*If the fasting plasma glucose level is 126 mg/dL or higher on more than one occasion, further evaluation of the patient with a glucose challenge is unnecessary. However, when fasting plasma glucose is less than 126 mg/dL in suspected cases, a standardized oral glucose tolerance test may be done ([Table 27-4](#)).

For proper evaluation of the test, the subjects should be normally active and free from acute illness. Medications that may impair glucose tolerance include diuretics, contraceptive drugs, glucocorticoids, niacin, and phenytoin.

Because of difficulties in interpreting oral glucose tolerance tests and the lack of standards related to aging, these tests are being replaced by documentation of fasting hyperglycemia.

Since fasting plasma glucose is known to increase with aging, clinicians should be more tolerant of slight abnormalities of fasting glucose values in older people (over 70 years of age) and not deprive patients of occasional sugar-containing snacks when symptoms are not evident. However, an occasional elderly patient may benefit from the diagnosis of mild diabetes in that macular edema may be detected earlier and laser treatment initiated before vision deteriorates permanently.

b. Glycated hemoglobin (hemoglobin A_{1c}) measurements—Glycated hemoglobin is abnormally high in diabetics with chronic hyperglycemia and reflects their metabolic control. It is produced by nonenzymatic condensation of glucose molecules with free amino groups on the globin component of hemoglobin. The higher the prevailing ambient levels of blood glucose, the higher will be the level of glycated hemoglobin.

The major form of glycohemoglobin is termed hemoglobin A_{1c}, which normally comprises only 4-6% of the total hemoglobin. The remaining glycohemoglobins (2-4% of the total) consist of phosphorylated glucose or fructose and are termed hemoglobin A_{1a} and hemoglobin A_{1b}. Some laboratories measure the sum of these three glycohemoglobins and report it as hemoglobin A₁, but more laboratories are converting to the more intricate but highly specific HbA_{1c} assay. There are now monoclonal immunoassays for measuring HbA_{1c}. Machines based on this technology can be used in clinicians' offices. They use capillary blood and give a result in about 9 minutes, allowing immediate feedback to the patients regarding their glycemic control.

Since glycohemoglobins circulate within red blood cells whose life span lasts up to 120 days, they generally reflect the state of glycemia over the preceding 8-12 weeks, thereby providing an improved method of assessing diabetic control. Measurements should be made in patients with either type of diabetes mellitus at 3- to 4-month intervals so that adjustments in therapy can be made if glycohemoglobin is either subnormal or if it is more than 2% above the upper limits of normal for a particular laboratory. In patients monitoring their own blood glucose levels, glycohemoglobin values provide a valuable check on the accuracy of monitoring. In patients who do not monitor their own blood glucose levels, glycohemoglobin values are essential for adjusting therapy. Use of glycohemoglobin for screening is controversial. Sensitivity in detecting known diabetes cases by hemoglobin A_{1c} measurements is only 85%, indicating that diabetes cannot be excluded by a normal value. On the other hand, elevated hemoglobin A_{1c} assays are fairly specific (91%) in identifying the presence of diabetes.

Occasionally, fluctuations in hemoglobin A₁ are due to an acutely generated, reversible, intermediary (aldimine-linked) product that can falsely elevate glycohemoglobins when measured with "short-cut" chromatographic methods. This can be eliminated by using specific HPLC methods that detect HbA_{1c} or by dialysis of the hemolysate before chromatography. When hemoglobin variants are present, such as negatively charged hemoglobin F, acetylated hemoglobin from high-dose aspirin therapy, or carbamoylated hemoglobin produced by the complexing of urea with hemoglobin in uremia, falsely high "hemoglobin A₁" values are obtained with commonly used chromatographic methods. In the presence of positively charged hemoglobin variants such as hemoglobin S or C, or when the life span of red blood cells is reduced by increased hemolysis or hemorrhage, falsely low values for "hemoglobin A₁" result.

c. Serum fructosamine—Serum fructosamine is formed by nonenzymatic glycosylation of serum proteins (predominantly albumin). Since serum albumin has a much shorter half-life than hemoglobin, serum fructosamine generally reflects the state of glycemic control for only the preceding 2 weeks. Reductions in serum albumin (eg, nephrotic state or hepatic disease) will lower the serum fructosamine value. When abnormal hemoglobins or hemolytic states affect the interpretation of glycohemoglobin or when a narrower time frame is required, such as for ascertaining glycemic control at the time of conception in a diabetic woman who has recently become pregnant, serum fructosamine assays offer some advantage. Normal values vary in relation to the serum albumin concentration and are 1.5-2.4 mmol/L when the serum albumin level is 5 g/dL.

d. Self-monitoring of blood glucose—Capillary blood glucose measurements performed by patients themselves, as outpatients, are extremely useful. In type 1 patients in whom "tight" metabolic control is attempted, they are indispensable. A portable battery-operated glucometer provides a digital readout of the intensity of color developed when glucose oxidase paper strips are exposed to a drop of capillary blood for up to 45 seconds. A large number of blood glucose meters are now available. All are accurate, but they vary with regard to speed, convenience, size of blood samples required, and cost. Popular models include those manufactured by LifeScan (One Touch), Bayer Corporation (Glucometer Elite, DEX), Roche Diagnostics (Accu-Chek), Abbott Laboratories (ExacTech, Precision), and Home Diagnostics (Prestige). One Touch Ultra, for example, requires only 0.3 mL of blood and gives a result in 5 seconds—and illustrates how there has been continued progress in this technologic area. Various glucometers appeal to a particular consumer need and are relatively inexpensive, ranging from \$50.00 to \$100.00 each. The more expensive models compute blood glucose averages and can be attached to printers for data records and graph production. Test strips remain a major expense, costing 50-75 cents apiece. In self-monitoring of blood glucose, patients must prick a finger with a 28-gauge lancet (Monolet, Ames Co.), which can be facilitated by a small plastic trigger device such as an Autolet (Ames Co.), SoftClix (Boehringer-Mannheim), or Penlet (Lifescan, Inc.). When used for multiple patients, as in a clinic, physician's office, or hospital ward, disposable finger-rest platforms are required to avoid inadvertent transmission of blood-borne viral diseases. Some meters such as the FreeStyle (Therasense) have been approved for measuring glucose in blood samples obtained at alternative sites such as the forearm and thigh. There is, however, a 5- to 20-minute lag in the glucose response on the arm with respect to the glucose response on the finger. Forearm blood glucose measurements could therefore result in a delay in detection of rapidly developing hypoglycemia.

The accuracy of data obtained by glucose monitoring requires education of the patient in sampling and measuring procedures as well as in proper calibration of the

instruments. Bedside glucose monitoring in a hospital setting requires rigorous quality control programs and certification of personnel to avoid errors.

e. Continuous glucose monitoring systems—Two continuous glucose monitoring systems are currently available for clinical use. The system manufactured by MiniMed Medtronic involves inserting a subcutaneous sensor (rather like an insulin pump cannula) that measures glucose concentrations in the interstitial fluid for 72 hours. The glucose values are not available for evaluation at time of measurement—the data are downloaded to a computer in a physician's office after collection. The other system ("GlucoWatch") measures glucose in interstitial fluid extracted through intact skin by applying a low electric current (reverse iontophoresis). This process can cause local skin irritation, and sweating distorts the glucose measurement. Both systems require calibration with finger blood glucose measurements. The main value of these systems appears to be in identifying episodes of asymptomatic hypoglycemia, especially at night.

3. Lipoprotein abnormalities in diabetes—Circulating lipoproteins are just as dependent on insulin as is the plasma glucose. In type 1 diabetes, moderately deficient control of hyperglycemia is associated with only a slight elevation of LDL cholesterol and serum triglycerides and little if any change in HDL cholesterol. Once the hyperglycemia is corrected, lipoprotein levels are generally normal. However, in obese patients with type 2 diabetes, a distinct "diabetic dyslipidemia" is characteristic of the insulin resistance syndrome. Its features are a high serum triglyceride level (300-400 mg/dL), a low HDL cholesterol (less than 30 mg/dL), and a qualitative change in LDL particles, producing a smaller dense particle whose membrane carries supranormal amounts of free cholesterol. These smaller dense LDL particles are more susceptible to oxidation, which renders them more atherogenic. Since a low HDL cholesterol is a major feature predisposing to macrovascular disease, the term "dyslipidemia" has preempted the term "hyperlipidemia," which mainly denoted the elevated triglycerides. Measures designed to correct the obesity and hyperglycemia, such as exercise, diet, and hypoglycemic therapy, are the treatment of choice for diabetic dyslipidemia, and in occasional patients in whom normal weight was achieved, all features of the lipoprotein abnormalities cleared. Since primary disorders of lipid metabolism may coexist with diabetes, persistence of lipid abnormalities after restoration of normal weight and blood glucose should prompt a diagnostic workup and possible pharmacotherapy of the lipid disorder. [Chapter 28](#) discusses these matters in detail.

Differential Diagnosis

A. Hyperglycemia Secondary to Other Causes

([Table 27-5](#).) Secondary hyperglycemia has been associated with various disorders of insulin target tissues (liver, muscle, and adipose tissue). Other secondary causes of carbohydrate intolerance include endocrine disorders—often specific endocrine tumors—associated with excess production of growth hormone, glucocorticoids, catecholamines, glucagon, or somatostatin. In the first four situations, peripheral responsiveness to insulin is impaired. With excess of glucocorticoids, catecholamines, or glucagon, increased hepatic output of glucose is a contributory factor; in the case of catecholamines, decreased insulin release is an additional factor in producing carbohydrate intolerance, and with excess somatostatin production it is the major factor.

A rare syndrome of extreme insulin resistance associated with acanthosis nigricans afflicts either young women with androgenic features as well as insulin receptor mutations or older people, mostly women, in whom a circulating immunoglobulin binds to insulin receptors and reduces their affinity to insulin.

Medications such as diuretics, phenytoin, niacin, and high-dose glucocorticoids can produce hyperglycemia that is reversible once the drugs are discontinued or when diuretic-induced hypokalemia is corrected. Chronic pancreatitis or subtotal pancreatectomy reduces the number of functioning B cells and can result in a metabolic derangement very similar to that of genetic type 1 diabetes except that a concomitant reduction in pancreatic A cells may reduce glucagon secretion so that relatively lower doses of insulin replacement are needed. Insulin-dependent diabetes is occasionally associated with Addison's disease and autoimmune thyroiditis (**Schmidt's syndrome**, or **polyglandular failure syndrome**). This occurs more commonly in women and represents an autoimmune disorder in which there are circulating antibodies to adrenocortical and thyroid tissue, thyroglobulin, and gastric parietal cells.

B. Nondiabetic Glycosuria

Nondiabetic glycosuria (renal glycosuria) is a benign asymptomatic condition wherein glucose appears in the urine despite a normal amount of glucose in the blood, either basally or during a glucose tolerance test. Its cause may vary from an autosomally transmitted genetic disorder to one associated with dysfunction of the proximal renal tubule (Fanconi's syndrome, chronic renal failure), or it may merely be a consequence of the increased load of glucose presented to the tubules by the elevated glomerular filtration rate during pregnancy. As many as 50% of pregnant women normally have demonstrable sugar in the urine, especially during the third and fourth months. This sugar is practically always glucose except during the late weeks of pregnancy, when lactose may be present.

Goals of Treatment of Diabetes

Diabetes mellitus requires ongoing medical care as well as patient and family education both to prevent acute illness and to reduce the risk of long-term complications. The Diabetes Control and Complications Trial of type 1 diabetes and the United Kingdom Prospective Diabetes Study of type 2 diabetes (see below) both indicate that the therapeutic objective is to restore known metabolic derangements toward normal in order to prevent and delay progression of diabetic complications.

Clinical Trials in Type 1 Diabetes

A. Diabetes Prevention Trial-1 (DPT-1)

This NIH-sponsored multicenter study was designed to determine whether the development of type 1 diabetes could be prevented or delayed by immune intervention therapy. Daily low-dose insulin injections were administered for up to 8 years in first-degree relatives of type 1 diabetics who were selected as being at high risk for development of type 1 diabetes because of detectable islet cell antibodies and reduced early-insulin release. Unfortunately, this immune intervention failed to affect the onset of type 1 diabetes as compared with a randomized untreated group. A related study is still in progress using oral insulin in lower-risk first-degree relatives who have islet cell antibodies but whose early-insulin release remains intact.

B. The Diabetes Control and Complications Trial (DCCT)

A long-term therapeutic study involving 1441 type 1 patients reported that "near" normalization of blood glucose resulted in a delay in the onset and a major slowing of the progression of established microvascular and neuropathic complications of diabetes during a follow-up period of up to 10 years. Multiple insulin injections (66%) or insulin pumps (34%) were used in the intensively treated group, who were trained to modify their therapy in response to frequent glucose monitoring. The conventionally treated groups used no more than two insulin injections, and clinical well-being was the goal with no attempt to modify management based on HbA_{1c} determinations or the glucose results.

In one-half of the subjects, a mean hemoglobin A_{1c} of 7.2% (normal: < 6%) and a mean blood glucose of 155 mg/dL were achieved using intensive therapy, while in the conventionally treated group HbA_{1c} averaged 8.9% with an average blood glucose of 225 mg/dL. Over the study period, which averaged 7 years, there was an approximately 60% reduction in risk between the two groups in regard to diabetic retinopathy, nephropathy, and neuropathy. Intensively treated patients had a threefold greater risk of serious hypoglycemia as well as a greater tendency toward weight gain. However, there were no deaths definitely attributable to hypoglycemia in any subjects in the DCCT study, and no evidence of posthypoglycemic cognitive damage was detected.

Reinterpretation of the published data from the DCCT trial suggests that "moderate" glycemic control (HbA_{1c} no higher than 2% above the upper limits of normal) rather than "tight" control was just as beneficial in reducing complications while producing fewer episodes of severe hypoglycemia. This implies that adjusting therapeutic glycemic goals a bit higher than those of the DCCT should retain the benefits of intensive insulin therapy at a somewhat lower risk.

The general consensus of the American Diabetes Association is that intensive insulin therapy associated with comprehensive self-management training should become standard therapy in type 1 patients after the age of puberty. Exceptions include those with advanced renal disease and the elderly, since in these groups the detrimental risks of hypoglycemia outweigh the benefits of tight glycemic control.

While patients with type 2 were not studied in the DCCT, the eye, kidney, and nerve abnormalities are quite similar in both types of diabetes, and it is likely that similar underlying mechanisms apply. Several important differences, however, must be considered. Since type 2 patients are generally an older population with a high incidence of macrovascular disease, an episode of severe hypoglycemia entails much greater risk than it would in younger type 1 patients of the DCCT. Moreover, weight gain may be much greater in obese type 2 patients in whom intensive insulin therapy is attempted. These risks take on greater relevance in older type 2 patients, who have a relatively lower prevalence of microangiopathy than type 1 patients and in whom prevention of macrovascular disease over the long term is much less likely to influence morbidity and mortality because of greater consequences of their macrovascular disease.

To address the issues raised by the DCCT findings as well as a previous concern that sulfonylureas may *increase* cardiovascular deaths, as reported in 1970 by the University Group Diabetes Program, randomized clinical trials of intensive therapy have been conducted in patients with type 2 diabetes—as summarized below

C. Immune Intervention Trials in New-Onset Type 1 Diabetes

At the time of diagnosis of type 1 diabetes, patients still have significant B cell function. This explains why soon after diagnosis patients go into a partial clinical remission ("honeymoon") requiring little or no insulin. This clinical remission is short-lived, however, and eventually patients lose all B cell function and have more labile glucose control. Attempts have been made to prolong this partial clinical remission using drugs such as cyclosporine, azathioprine, prednisone, and antithymocyte globulin. These drugs have had limited efficacy, and there are concerns about toxicity and the need for continuous treatment.

Newer agents that may induce immune tolerance and appear to have few side effects have been used in new-onset type 1 patients. Two small studies, one with a heat shock protein peptide (DiaPep277) and another with an anti-CD3 antibody, have demonstrated that these agents can preserve endogenous insulin production. Larger phase 2 clinical trials are currently in progress.

Clinical Trials in Type 2 Diabetes

A. The Diabetes Prevention Program (DPP)

This is a randomized clinical trial in 3234 overweight men and women aged 25-85 years who showed impaired glucose tolerance. Preliminary results indicate that intervention with a low-fat diet and 150 minutes of moderate exercise (equivalent to a brisk walk) per week reduces the risk of progression to type 2 diabetes by 58% as compared with a matched control group.

Another arm of this trial demonstrated that use of 850 mg of metformin twice daily reduced the risk of developing type 2 diabetes by 31%, but this intervention was relatively ineffective in those who were either less obese or in the older age group.

With the demonstration that intervention can be successful in preventing progression to diabetes in these subjects, a recommendation has been made to change the terminology from the less comprehensible "impaired glucose tolerance" to "prediabetes." The latter is a term which the public can better understand and thus respond to by implementing healthier diet and exercise habits.

B. The Veterans Administration Cooperative Study

This investigation involved 153 obese men who were moderately insulin-resistant and who were followed for only 27 months. Intensive insulin treatment resulted in mean HbA_{1c} differences from conventional insulin treatment (7.2% versus 9.5%) that were comparable to those reported from the Kumamoto Study. However, a difference in cardiovascular outcome in this study has prompted some concern. While conventional insulin therapy resulted in 26 total cardiovascular events, there were 35 total cardiovascular events in the intensively treated group. This difference in the relatively small population was not statistically significant, but when the total events were broken down to *major* events (myocardial infarction, stroke, cardiovascular death, congestive heart failure, or amputation), the 18 major events in the group treated intensively with insulin were reported to be statistically greater ($P = .04$) than the ten major events occurring with conventional treatment. While this difference may be a chance consequence of studying too few patients for too short a time, it raises the possibility that insulin-resistant patients with visceral obesity and long-standing type 2 diabetes may develop a greater risk of serious cardiovascular mishap when intensively treated with high doses of insulin. At the end of the study, 64% of the intensively treated group were either receiving (1) an average of 113 units of insulin per day when only two injections per day were used or (2) a mean dosage of 133 units per day when multiple injections were used. Unfortunately, the UKPDS (see below), which did not discern any effect of intensive therapy on cardiovascular outcomes, does not resolve the concern generated by the Veterans Administration Study since their patient population consisted of newly diagnosed diabetic patients in whom the obese subgroup seemed to be less insulin-resistant, requiring a median insulin dose for intensive therapy of only 60 units per day by the twelfth year of the study.

C. The United Kingdom Prospective Diabetes Study (UKPDS)

This study began in 1977 as a multicenter clinical trial designed to establish, in type 2 diabetic patients, whether the risk of macrovascular or microvascular complications could be reduced by intensive blood glucose control with oral hypoglycemic agents or insulin and whether any particular therapy was of advantage. Newly diagnosed type 2 diabetic patients aged 25-65 years were recruited between 1977 and 1991, and a total of 3867 were studied over 10 years. The median age at baseline was 54 years; 44% were overweight ($> 120\%$ over ideal weight); and baseline HbA_{1c} was 9.1%. Therapies were randomized to include a control group on diet alone and separate groups intensively treated with either insulin, chlorpropamide, glyburide, or glipizide. Metformin was included as a randomization option in a subgroup of 342 overweight patients, and much later in the study an additional subgroup of both normal-weight and overweight patients who were responding unsatisfactorily to sulfonylurea therapy were randomized to either continue on their sulfonylurea therapy alone or to have metformin combined with it.

In 1987, an additional modification was made to evaluate whether tight control of blood pressure with stepwise antihypertensive therapy would prevent macrovascular and microvascular complications in 758 hypertensive patients among this UKPDS population compared with 390 of them whose blood pressure was treated less intensively. The tight control group was randomly assigned to treatment with either an angiotensin-converting enzyme (ACE) inhibitor (captopril) or a beta-blocker (atenolol). Both drugs were stepped up to maximum dosages of 100 mg/d and then, if blood pressure remained higher than the target level of $< 150/85$ mm Hg, more drugs were added in the following stepwise sequence: a diuretic, slow-release nifedipine, methyldopa, and prazosin—until the target level of tight control was achieved. In the control group, hypertension was conventionally treated to achieve target levels $< 180/105$ mm Hg, but these patients were not prescribed either ACE inhibitors or beta-blockers.

Intensive glycemic therapy in the entire group of 3897 newly diagnosed type 2 diabetic patients followed over 10 years showed the following: Intensive treatment with either sulfonylureas, metformin, combinations of those two, or insulin achieved mean HbA_{1c} levels of 7%. This level of glycemic control decreases the risk of microvascular complications (retinopathy and nephropathy) in comparison with conventional therapy (mostly diet alone), which achieved mean levels of HbA_{1c} of 7.9%. Weight gain occurred in intensively treated patients except when metformin was used as monotherapy. No cardiovascular benefit and no adverse cardiovascular outcomes were noted regardless of the therapeutic agent. Hypoglycemic reactions occurred in the intensive treatment groups, but only one death from hypoglycemia was documented during 27,000 patient-years of intensive therapy.

When therapeutic subgroups were analyzed, some unexpected and paradoxical results were noted. Among the obese patients, intensive treatment with insulin or sulfonylureas did not reduce microvascular complications compared with diet therapy alone. This was in contrast to the significant benefit of intensive therapy with these drugs in the total group. Furthermore, intensive therapy with metformin was more beneficial in obese persons than diet alone as regards less myocardial infarctions, strokes, and diabetes-related deaths, but there was no significant reduction by metformin of diabetic microvascular complications as compared with the diet group. Moreover, in the subgroup of obese and nonobese patients in whom metformin was added to sulfonylurea failures, rather than showing a benefit, there was a 96% *increase* in diabetes-related deaths compared with the matched cohort of patients with unsatisfactory glycemic control on sulfonylureas who remained on their sulfonylurea therapy. Chlorpropamide also came out poorly on subgroup analysis in that those receiving it as intensive therapy did less well as regards progression to retinopathy than those conventionally treated with diet.

Intensive antihypertensive therapy to a mean of 144/82 mm Hg had beneficial effects on microvascular disease as well as on all diabetes-related end points, including virtually all cardiovascular outcomes, in comparison with looser control at a mean of 154/87 mm Hg. In fact, the advantage of reducing hypertension by this amount was substantially more impressive than the benefit achieved by improving the degree of glycemic control from a mean HbA_{1c} of 7.9% to 7%. More than half of the patients needed two or more drugs for adequate therapy of their hypertension, and there was no demonstrable advantage of ACE inhibitor therapy over therapy with beta-blockers with regard to diabetes end points. Use of a calcium channel blocker added to both treatment groups appeared to be safe over the long term in this diabetic population despite some controversy in the recent literature about its safety in diabetics.

Implications of the UKPDS

It appears that glycemic control to levels of HbA_{1c} to 7% shows benefit in reducing total diabetes end points, including a 25% reduction in microvascular disease as compared with HbA_{1c} levels of 7.9%. This reassures those who have questioned whether the value of intensive therapy, so convincingly shown by the DCCT in type 1 diabetes, can safely be extrapolated to older patients with type 2 diabetes. It also argues against the concept of a "threshold" of glycemic control since in this group there was a benefit from this modest reduction of HbA_{1c} below 7.9% whereas in the DCCT a threshold was suggested in that further benefit was less apparent at HbA_{1c} levels below 8%.

Because of the complexity of the overall design in which many of the original therapy groups received additional medications to achieve glycemic goals but remained assigned to their group, statistical analysis may have been compromised by these multiple crossovers. For instance, in the diet group that was used as a control for all the drug treatment groups, only 58% of their total "patient-years" were actually drug-free while the remainder consisted of nonintensive therapy with various hypoglycemic drug regimens to avoid unacceptable hyperglycemia. This probably partly explains why the mean HbA_{1c} for this group was only 7.9% on "diet alone" therapy for over 10 years. In view of these crossovers within treatment groups, caution is suggested regarding several subgroup analyses that are controversial. These include the implication that metformin was superior to insulin or sulfonylureas in reducing diabetes-related end points in obese patients compared with diet therapy even though all three treatment groups achieved the same degree of glycemic control. Conversely, the finding of excess mortality in the subgroup of patients receiving combination therapy with metformin and sulfonylureas need not necessarily preclude this combination in patients doing poorly on sulfonylureas alone, though it certainly indicates a need for clarification of this important question.

Probably the most striking implication of the UKPDS is the benefit to the *hypertensive* type 2 diabetic patient of intensive control of blood pressure. There was no demonstrable advantage of ACE inhibitor therapy on outcome despite a number of short-term reports in smaller populations, implying that these drugs have special efficacy in reducing glomerular pressure beyond their general antihypertensive effects. Moreover, slow-release nifedipine showed no evidence of cardiac toxicity in this study despite some previous reports claiming that calcium channel blockers may be hazardous in patients with diabetes. Finally, the greater benefit in diabetes end points from antihypertensive than from antihyperglycemic treatments may be that the difference between the mean blood pressures achieved (144/82 mm Hg versus 154/87 mm Hg) is therapeutically more influential than the slight difference in HbA_{1c} (7% versus 7.9%). Greater hyperglycemia in the control group would most likely have rectified this discrepancy in outcomes. At present, the American Diabetes Association recommends vigorous treatment of both hyperglycemia and hypertension

when they occur with an expectation that reductions in microvascular and cardiovascular outcomes will be additive.

Treatment Regimens

A. Diet

A well-balanced, nutritious diet remains a fundamental element of therapy. However, in more than half of cases, diabetic patients fail to follow their diet. In prescribing a diet, it is important to relate dietary objectives to the type of diabetes. In obese patients with mild hyperglycemia, the major goal of diet therapy is weight reduction by caloric restriction. Thus, there is less need for exchange lists, emphasis on timing of meals, or periodic snacks, all of which are so essential in the treatment of insulin-requiring nonobese diabetics. This type of patient represents the most frequent challenge for the clinician. Weight reduction is an elusive goal that can only be achieved by close supervision and education of the obese patient. See [Chapter 29](#) for dietary management of obesity.

1. Revised ADA recommendations—The American Diabetes Association releases an annual position statement on medical nutrition therapy that replaces the calculated ADA diet formula of the past with suggestions for an individually tailored dietary prescription based on metabolic, nutritional, and lifestyle requirements. They contend that the concept of one diet for "diabetes" and the prescription of an "ADA diet" no longer can apply to both major types of diabetes. In their recommendations for persons with type 2 diabetes, the 55-60% carbohydrate content of previous diets has been reduced considerably because of the tendency of high carbohydrate intake to cause hyperglycemia, hypertriglyceridemia, and a lowered HDL cholesterol. In obese type 2 patients, glucose and lipid goals join weight loss as the focus of therapy. These patients are advised to limit their carbohydrate content by substituting noncholesterologenic monounsaturated oils such as olive oil, rapeseed (canola) oil, or the oils in nuts and avocados. This maneuver is also indicated in type 1 patients on intensive insulin regimens in whom near-normoglycemic control is less achievable on higher carbohydrate diets. They should be taught "carbohydrate counting" so they can administer 1 unit of regular insulin or insulin lispro for each 10 or 15 g of carbohydrate eaten at a meal. In these patients, the ratio of carbohydrate to fat will vary among individuals in relation to their glycemic responses, insulin regimens, and exercise pattern.

The current recommendations for both types of diabetes continue to limit cholesterol to 300 mg daily and advise a daily protein intake of 10-20% of total calories. They suggest that saturated fat be no higher than 8-9% of total calories with a similar proportion of polyunsaturated fat and that the remainder of caloric needs be made up of an individualized ratio of monounsaturated fat and of carbohydrate containing 20-35 g of dietary fiber. Poultry, veal, and fish continue to be recommended as a substitute for red meats for keeping saturated fat content low. The present ADA position statement proffers no evidence that reducing protein intake below 10% of intake (about 0.8 g/kg/d) is of any benefit in patients with nephropathy and renal impairment, and doing so may be detrimental.

Exchange lists for meal planning can be obtained from the American Diabetes Association and its affiliate associations or from the American Dietetic Association, 216 W. Jackson Blvd., Chicago, IL 60606 (312-899-0040). Their Internet address is <http://www.eatright.org>.

2. Dietary fiber—Plant components such as cellulose, gum, and pectin are indigestible by humans and are termed dietary "fiber." Insoluble fibers such as cellulose or hemicellulose, as found in bran, tend to increase intestinal transit and may have beneficial effects on colonic function. In contrast, soluble fibers such as gums and pectins, as found in beans, oatmeal, or apple skin, tend to retard nutrient absorption rates so that glucose absorption is slower and hyperglycemia may be slightly diminished. Although its recommendations do not include insoluble fiber supplements such as added bran, the ADA recommends food such as oatmeal, cereals, and beans with relatively high soluble fiber content as staple components of the diet in diabetics. High soluble fiber content in the diet may also have a favorable effect on blood cholesterol levels.

3. Artificial sweeteners—Aspartame (NutraSweet) has proved to be a popular sweetener for diabetic patients. It consists of two amino acids (aspartic acid and phenylalanine) that combine to produce a nutritive sweetener 180 times as sweet as sucrose. A major limitation is that it cannot be used in baking or cooking because of its lability to heat.

The nonnutritive sweetener saccharin continues to be available in certain foods and beverages despite warnings by the FDA about its potential long-term carcinogenicity to the bladder. The latest position statement of the ADA concludes that all nonnutritive sweeteners that have been approved by the FDA (such as aspartame and saccharin) are safe for consumption by all people with diabetes. Two other nonnutritive sweeteners have been approved by the FDA as safe for general use: sucralose (Splenda) and acesulfame potassium (Sunett, Sweet One, DiabetiSweet). These are both highly stable and, in contrast to aspartame, can be used in cooking and baking.

Nutritive sweeteners such as sorbitol and fructose have increased in popularity. Except for acute diarrhea induced by ingestion of large amounts of sorbitol-containing foods, their relative risk has yet to be established. Fructose represents a "natural" sugar substance that is a highly effective sweetener which induces only slight increases in plasma glucose levels. However, because of potential adverse effects of large amounts of fructose (up to 20% of total calories) on raising serum cholesterol and LDL cholesterol, the ADA feels it may have no overall advantage as a sweetening agent in the diabetic diet. This does not preclude, however, ingestion of fructose-containing fruits and vegetables or fructose-sweetened foods in moderation.

B. Oral Drugs for Treating Hyperglycemia

([Tables 27-6](#), [27-7](#), and [27-8](#).) The drugs for treating type 2 diabetes fall into three categories: (1) Drugs that primarily stimulate insulin secretion: Sulfonylureas remain the most widely prescribed drugs for treating hyperglycemia. The meglitinide analog repaglinide and the D-phenylalanine derivative nateglinide also bind the sulfonylurea receptor and stimulate insulin secretion. (2) Drugs that alter insulin action: Metformin works primarily in the liver. The thiazolidinediones appear to have their main effect on skeletal muscle and adipose tissue. (3) Drugs that principally affect absorption of glucose: The α -glucosidase inhibitors acarbose and miglitol are such currently available drugs.

1. Drugs that stimulate insulin secretion—

a. Sulfonylureas—The primary mechanism of action of the sulfonylureas is to stimulate insulin release from pancreatic B cells. Specific receptors on the surface of pancreatic B cells bind sulfonylureas in the rank order of their insulinotropic potency (glyburide with the greatest affinity and tolbutamide with the least affinity). It has been shown that activation of these receptors closes potassium channels, resulting in depolarization of the B cell. This depolarized state permits calcium to enter the cell and actively promote insulin release

Sulfonylureas are not indicated for use in type 1 diabetes patients since these drugs require functioning pancreatic B cells to produce their effect on blood glucose. These drugs are used in patients with type 2 diabetes, in whom acute administration improves the early phase of insulin release that is refractory to acute glucose stimulation. Sulfonylureas are generally contraindicated in patients with hepatic or renal impairment. Idiosyncratic reactions are rare, with skin rashes or hematologic toxicity (leukopenia, thrombocytopenia) occurring in less than 0.1% of users.

(1) *First-generation sulfonylureas (tolbutamide, tolazamide, acetohexamide, chlorpropamide)—***Tolbutamide** is supplied as 500-mg tablets. It is rapidly oxidized in the liver to inactive metabolites, and its approximate duration of effect is relatively short (6-10 hours). Tolbutamide is probably best administered in divided doses (eg, 500 mg before each meal and at bedtime); however, some patients require only one or two tablets daily with a maximum dose of 3000 mg/d. Because of its short duration of action, which is independent of renal function, tolbutamide is probably the safest sulfonylurea to use if liver function is normal. Prolonged hypoglycemia has been reported rarely with tolbutamide, mostly in patients receiving certain antibacterial sulfonamides (sulfisoxazole), phenylbutazone for arthralgias, or the oral azole antifungal drugs to treat candidiasis. These drugs apparently compete with tolbutamide for oxidative enzyme systems in the liver, resulting in maintenance of high levels of unmetabolized, active sulfonylurea in the circulation.

Tolazamide is supplied in tablets of 100, 250, and 500 mg. It has a longer duration of action than tolbutamide, lasting up to 20 hours, with maximal hypoglycemic effect occurring between the fourth and fourteenth hours. It is often effective, as are other longer-acting sulfonylureas also, when tolbutamide fails to correct prebreakfast hyperglycemia. Tolazamide is metabolized to several compounds that retain hypoglycemic effects. If more than 500 mg/d is required, the dose should be divided and given twice daily. Doses larger than 1000 mg daily do not improve the degree of glycemic control.

Acetohexamide and chlorpropamide are now rarely used. Chlorpropamide has a prolonged biologic effect, and severe hypoglycemia can occur especially in the elderly as their renal clearance declines with aging. Its other side effects include alcohol-induced flushing and hyponatremia due its effect on vasopressin secretion and action.

(2) *Second-generation sulfonylureas (glyburide, glipizide, glimepiride)—*Glyburide, glipizide, and glimepiride are 100-200 times more potent than tolbutamide. These drugs should be used with caution in patients with cardiovascular disease or in elderly patients, in whom prolonged hypoglycemia would be especially dangerous.

Glyburide is available in 1.25-mg, 2.5-mg, and 5-mg tablets. The usual starting dose is 2.5 mg/d, and the average maintenance dose is 5-10 mg/d given as a single morning dose; maintenance doses higher than 20 mg/d are not recommended. Some reports suggest that 10 mg is a maximum daily therapeutic dose, with 15-20 mg having no additional benefit in poor responders and doses over 20 mg actually worsening hyperglycemia. Glyburide is metabolized in the liver into products with hypoglycemic activity, which probably explains why assays specific for the unmetabolized compound suggest a plasma half-life of only 1-2 hours, yet the biologic effects of glyburide are clearly persistent 24 hours after a single morning dose in diabetic patients. Glyburide is unique among sulfonylureas in that it not only binds to the pancreatic B cell membrane sulfonylurea receptor but also becomes sequestered within the B cell. This may also contribute to its prolonged biologic effect despite its relatively short circulating half-life. A "Press Tab" formulation of "micronized" glyburide—easy to divide in half with slight pressure if necessary—is available in tablet sizes of 1.5 mg, 3 mg, and 6 mg.

Glyburide has few adverse effects other than its potential for causing hypoglycemia, which at times can be prolonged. Flushing has rarely been reported after ethanol ingestion. It does not cause water retention, as chlorpropamide does, but rather slightly enhances free water clearance. Glyburide is absolutely contraindicated in the presence of hepatic impairment and should not be used in patients with renal insufficiency, in elderly patients, or in those who would be put at serious risk from an episode of hypoglycemia.

Glipizide is available in 5-mg and 10-mg tablets. For maximum effect in reducing postprandial hyperglycemia, this agent should be ingested 30 minutes before meals, since rapid absorption is delayed when the drug is taken with food. The recommended starting dose is 5 mg/d, with up to 15 mg/d given as a single daily dose before breakfast. When higher daily doses are required, they should be divided and given before meals. The maximum dose recommended by the manufacturer is 40 mg/d, though doses above 10-15 mg probably provide little additional benefit in poor responders and may even be less effective than smaller doses.

At least 90% of glipizide is metabolized in the liver to inactive products, and 10% is excreted unchanged in the urine. Glipizide therapy is therefore contraindicated in patients with hepatic or renal impairment, who would be at high risk for hypoglycemia, but because of its lower potency and shorter duration of action it is preferable to glyburide in elderly patients. Glipizide has also been marketed as Glucotrol-XL in 5-mg and 10-mg tablets. It provides extended release during transit through the gastrointestinal tract with greater effectiveness in lowering prebreakfast hyperglycemia than the shorter-duration immediate-release standard glipizide tablets. However, this formulation appears to have sacrificed its lower propensity for severe hypoglycemia compared with longer-acting glyburide without showing any demonstrable therapeutic advantages over glyburide.

Glimepiride is given once daily as monotherapy or in combination with insulin to lower blood glucose in diabetes patients who cannot control their glucose level through diet and exercise. Glimepiride achieves blood glucose lowering with the lowest dose of any sulfonylurea compound and this tends to increase its cost-effectiveness. A single daily dose of 1 mg/d has been shown to be effective, and the maximal recommended dose is 8 mg. It has a long duration of action with a pharmacodynamic half-life of 5 hours, allowing once-daily administration, which improves compliance. It is completely metabolized by the liver to relatively inactive metabolic products.

b. Meglitinide analogs—Repaglinide is structurally similar to glyburide but lacks the sulfonic acid-urea moiety. It acts by binding to the sulfonylurea receptor and closing the ATP-sensitive potassium channel. It is rapidly absorbed from the intestine and then undergoes complete metabolism in the liver to inactive biliary products, giving it a plasma half-life of less than 1 hour. The drug therefore causes a brief but rapid pulse of insulin. The starting dose is 0.5 mg three times a day 15 minutes before each meal. The dose can be titrated to a maximal daily dose of 16 mg. Like the sulfonylureas, repaglinide can be used in combination with metformin. Hypoglycemia is the main side effect. In clinical trials, when the drug was compared with a long-duration sulfonylurea (glyburide), there was a trend toward less hypoglycemia. Like the sulfonylureas also, repaglinide causes weight gain. Metabolism is by cytochrome P450 3A4 isoenzyme, and other drugs that induce or inhibit this isoenzyme may increase or inhibit (respectively) the metabolism of repaglinide. The drug may be useful in patients with renal impairment or in the elderly. It remains to be shown that this drug has significant advantages over short-acting sulfonylureas.

c. D-Phenylalanine derivative—Nateglinide stimulates insulin secretion by binding to the sulfonylurea receptor and closing the ATP-sensitive potassium channel. This compound is rapidly absorbed from the intestine, reaching peak plasma levels within 1 hour. It is metabolized in the liver and has a plasma half-life of about 1.5 hours. Like repaglinide, it causes a brief rapid pulse of insulin, and when given before a meal it reduces the postprandial rise in blood glucose. The drug is available as 60-mg and 120-mg tablets. The 60-mg dose is used in patients who have mild elevations in HbA_{1c}. For most patients, the recommended starting and maintenance dose is 120 mg three times a day before meals. Like the other insulin secretagogues, its main side effects are hypoglycemia and weight gain. This drug has been approved for use either alone or in combination with metformin.

2. Drugs that alter insulin action—

a. Metformin—Metformin (1,1-dimethylbiguanide hydrochloride) is used in the treatment of patients with type 2 diabetes, either alone or in conjunction with other oral agents or insulin. The exact mechanism of action remains unclear. It reduces both the fasting level of blood glucose and the degree of postprandial hyperglycemia in patients with type 2 diabetes but has no effect on fasting blood glucose in normal subjects. Metformin is particularly effective in reducing hepatic gluconeogenesis by interfering with lactate oxidation and uptake by the liver. Other proposed mechanisms include a slowing down of gastrointestinal absorption of glucose and increased glucose uptake by skeletal muscle, which have been reported in some but not all clinical studies. Because of its very high concentration in intestinal cells after oral administration, metformin increases glucose to lactate turnover, which may account for a reduction in hyperglycemia.

Metformin has a half-life of 11/2-3 hours, is not bound to plasma proteins, and is not metabolized in humans, being excreted unchanged by the kidneys.

Metformin may be used as an adjunct to diet for the control of hyperglycemia and its associated symptomatology in patients with type 2 diabetes, particularly those who are obese or are not responding optimally to maximal doses of sulfonylureas. A side benefit of metformin therapy is its tendency to improve both fasting and postprandial hyperglycemia and hypertriglyceridemia in obese diabetics without the weight gain associated with insulin or sulfonylurea therapy. Metformin is not indicated for patients with type 1 diabetes and is contraindicated in diabetics with serum creatinine levels of 1.5 mg/dL or higher, hepatic insufficiency, alcoholism, or a propensity to develop tissue hypoxia.

Metformin is dispensed as 500-mg, 850-mg, and 1000-mg tablets. A 500-mg extended-release preparation is also available. Although the maximal dosage is 2.55 g, little benefit is seen above a total dose of 2000 mg. It is important to begin with a low dose and increase the dosage very gradually in divided doses—taken with meals—to reduce minor gastrointestinal upsets. A common schedule would be one 500-mg tablet three times a day with meals or one 850-mg or 1000-mg tablet twice daily at breakfast and dinner. One to four tablets of the extended-release preparation can be given once a day.

The most frequent side effects of metformin are gastrointestinal symptoms (anorexia, nausea, vomiting, abdominal discomfort, diarrhea), which occur in up to 20% of patients. These effects are dose-related, tend to occur at onset of therapy, and often are transient. However, in 3-5% of patients, therapy may have to be discontinued because of persistent diarrheal discomfort.

Hypoglycemia does not occur with therapeutic doses of metformin, which permits its description as a "euglycemic" or "antihyperglycemic" drug rather than an oral hypoglycemic agent. Dermatologic or hematologic toxicity is rare.

Lactic acidosis has been reported as a side effect but is uncommon with metformin in contrast to phenformin. While therapeutic doses of metformin reduce lactate uptake by the liver, serum lactate levels rise only minimally if at all, since other organs such as the kidney can remove the slight excess. However, if tissue hypoxia occurs, the metformin-treated patient is at higher risk for lactic acidosis due to compromised lactate removal. Similarly, when renal function deteriorates, affecting not only lactate removal by the kidney but also metformin excretion, plasma levels of metformin rise far above the therapeutic range and block hepatic uptake enough to provoke lactic acidosis without associated increases in lactic acid production. Almost all reported cases have involved subjects with associated risk factors that should have contraindicated its use (renal, hepatic, or cardiorespiratory insufficiency, alcoholism, advanced age). Acute renal failure can occur rarely in certain patients receiving radiocontrast agents. Metformin therapy should therefore be temporarily halted on the day of the test and for 2 days following injection of radiocontrast agents to avoid potential lactic acidosis if renal failure occurs.

b. Thiazolidinediones—Drugs of this newer class of antihyperglycemic agents sensitize peripheral tissues to insulin. They bind a nuclear receptor called peroxisome proliferator-activated receptor gamma (PPAR-?) and affect the expression of a number of genes and regulate the release of the adipokines—resistin and adiponectin—from adipocytes. Adiponectin secretion is stimulated, which sensitizes tissues to the effects of insulin, and resistin secretion is inhibited, which reduces insulin resistance. Observed effects of thiazolidinediones include increased glucose transporter expression (GLUT 1 and GLUT 4), decreased free fatty acid levels, decreased hepatic glucose output, and increased differentiation of preadipocytes into adipocytes. Like the biguanides, this class of drugs does not cause hypoglycemia.

Troglitazone was the first drug in this class to go into widespread clinical use. Unfortunately, about 1.9% of patients taking this drug developed elevations in liver enzymes greater than three times normal, which resolved when the drug was stopped. Liver failure, however, occurred if the drug was continued—at least 90 cases have been reported, and 63 of these patients have died. The drug has therefore been withdrawn from clinical use.

Two other drugs in the same class are available for clinical use: rosiglitazone and pioglitazone. Both are effective as monotherapy and in combination with sulfonylureas or metformin. However, at present, only pioglitazone is approved by the FDA for use in combination with insulin. This is because in two clinical trials with 611 type 2 diabetic patients over a 26-week period, rosiglitazone in combination with insulin caused more congestive heart failure and other cardiovascular events than did insulin alone. Fluid retention has been invoked as the reason for this adverse effect of rosiglitazone when combined with insulin. When used as monotherapy, these drugs lower HbA_{1c} by about 1 or 2 percentage points. When used in combination with insulin, they can result in a 30-50% reduction in insulin dosage, and some patients can come off insulin completely. The combination of a thiazolidinedione and metformin has the advantage of not causing hypoglycemia. Patients inadequately managed on sulfonylureas can do well on a combination of sulfonylurea and rosiglitazone or pioglitazone. About 25% of patients in clinical trials fail to respond to these drugs, presumably because they are significantly insulinopenic.

Rosiglitazone therapy is associated with increases in total cholesterol, LDL cholesterol (15%), and HDL cholesterol (10%). There is reduction in free fatty acids of about 8-15%. The changes in triglycerides were generally not different from placebo. The increase in the LDL cholesterol need not necessarily be detrimental—studies with

troglitazone showed that there is a shift from the atherogenic small dense LDL particles to larger, less dense LDL particles. Pioglitazone in clinical trials lowered triglycerides (9%) and increased HDL cholesterol (15%) but did not cause a consistent change in total cholesterol and LDL cholesterol levels. A prospective randomized comparison of the metabolic effects of pioglitazone and rosiglitazone on patients who had previously been on troglitazone showed similar effects on HbA_{1c} and weight gain. Pioglitazone-treated subjects, however, had lower total cholesterol, LDL cholesterol, and triglycerides when compared with rosiglitazone. Anemia occurs in 4% of patients treated with these drugs, but this effect may be due to a dilutional effect of increased plasma volume rather than a reduction in red cell mass. Weight gain occurs especially when the drug is combined with a sulfonylurea or insulin. It is believed that this class of drugs might increase proliferation of subcutaneous preadipocytes, thereby increasing target cell responsiveness to insulin. This would make the drugs of particular benefit for patients with syndrome X.

The dosage of rosiglitazone is 4-8 mg daily and of pioglitazone 15-45 mg daily, and the drugs do not have to be taken with food. Rosiglitazone is primarily metabolized by the CYP 2C8 isoenzyme and unlike troglitazone does not appear to affect the CYP 3A4 isoenzyme and has no significant clinical effect on oral contraceptives. Pioglitazone is metabolized by CYP 2C8 and CYP 3A4. The pharmacokinetics of coadministration of pioglitazone and oral contraceptives has not been evaluated.

These two agents have so far not (unlike troglitazone) caused drug-induced hepatotoxicity. The FDA has, however, recommended that patients should not initiate drug therapy if the ALT is 2.5 times greater than the upper limit of normal. Obviously, caution should be used in initiation of therapy in patients with even mild ALT elevations. Liver function tests should be performed once every 2 months for the first year and periodically thereafter.

3. Drugs that affect absorption of glucose—Alpha-glucosidase inhibitors competitively inhibit the α -glucosidase enzymes in the gut that digest dietary starch and sucrose. Two of these drugs—acarbose and miglitol—are available for clinical use. Both are potent inhibitors of glucoamylase, α -amylase, and sucrase but have less effect on isomaltase and hardly any on trehalase and lactase. Acarbose binds 1000 times more avidly to the intestinal disaccharidases than do products of carbohydrate digestion or sucrose. A fundamental difference between acarbose and miglitol is in their absorption. Acarbose has the molecular mass and structural features of a tetrasaccharide, and very little (about 2%) crosses the microvillar membrane. Miglitol, however, has a structural similarity with glucose and is absorbable. Both drugs delay the absorption of carbohydrate and lower postprandial glycemic excursion.

a. Acarbose—Acarbose is available as 50-mg and 100-mg tablets. The recommended starting dose of acarbose is 50 mg twice daily, gradually increasing to 100 mg three times daily. For maximal benefit on postprandial hyperglycemia, acarbose should be given with the first mouthful of food ingested. In diabetic patients, it reduces postprandial hyperglycemia by 30-50%, and its overall effect is to lower the HbA_{1c} by 0.5-1%.

The principal adverse effect, seen in 20-30% of patients, is flatulence. This is caused by undigested carbohydrate reaching the lower bowel, where gases are produced by bacterial flora. In 3% of cases, troublesome diarrhea occurs. This gastrointestinal discomfort tends to discourage excessive carbohydrate consumption and promotes improved compliance of type 2 patients with their diet prescriptions. When acarbose is given alone, there is no risk of hypoglycemia. However, if combined with insulin or sulfonylureas, it might increase the risk of hypoglycemia from these agents. A slight rise in hepatic aminotransferases has been noted in clinical trials with acarbose (5% versus 2% in placebo controls, and particularly with doses > 300 mg/d). The levels generally return to normal on stopping the drug.

In the UKPDS, approximately 2000 patients on diet, sulfonylurea, metformin, or insulin therapy were randomized to acarbose or placebo therapy. By 3 years, 60% of the patients had discontinued the drug, mostly because of gastrointestinal symptoms. If one looked only at the 40% who remained on the drug, they had an 0.5% lower HbA_{1c} compared with placebo.

b. Miglitol—Miglitol is similar to acarbose in terms of its clinical effects. It is indicated for use in diet- or sulfonylurea-treated patients with type 2 diabetes. Therapy is initiated at the lowest effective dosage of 25 mg three times a day. The usual maintenance dose is 50 mg three times a day, though some patients may benefit from increasing the dose to 100 mg three times a day. Gastrointestinal side effects occur as with acarbose. The drug is not metabolized and is excreted unchanged by the kidney. Theoretically, absorbable α -glucosidase inhibitors could induce a deficiency of one or more of the α -glucosidases involved in cellular glycogen metabolism and biosynthesis of glycoproteins. This does not occur in practice because, unlike the intestinal mucosa, which sees a high concentration of the drug, the blood level is 200-fold to 1000-fold lower than the concentration needed to inhibit intracellular α -glucosidases. Miglitol should not be used in renal failure, when its clearance would be impaired.

4. Drug combinations—A glyburide and metformin combination (Glucovance) is available in dose forms of 1.25 mg/250 mg, 2.5 mg/500 mg, and 5 mg/500 mg. A rosiglitazone and metformin combination (Avandamet) is available in dose forms of 1 mg/500 mg, 2 mg/500 mg, and 4 mg/500 mg. These drug combinations, however, limit the clinician's ability to optimally adjust dosage of the individual drugs and for that reason are of questionable usefulness.

5. Safety of the oral hypoglycemic agents—The United Kingdom Prospective Diabetes Study of type 2 diabetes has put to rest previous concerns regarding the safety of sulfonylureas. It did not confirm any cardiovascular hazard among over 1500 patients treated intensively with sulfonylureas for over 10 years, compared with a comparable number who received either insulin or diet therapy. Analysis of a subgroup of obese patients receiving metformin also showed no hazard and even a slight reduction in cardiovascular deaths compared with conventional therapy.

The currently available thiazolidinediones have not to date exhibited the idiosyncratic hepatotoxicity seen with troglitazone. Lactic acidosis from metformin (see above) is quite rare and probably not a major problem with its use in the absence of major risk factors such as impaired renal or hepatic disease or conditions predisposing to hypoxia.

C. Insulin

Insulin is indicated for type 1 diabetes as well as for type 2 diabetic patients with insulinopenia whose hyperglycemia does not respond to diet therapy either alone or combined with oral hypoglycemic drugs.

With the development of highly purified human insulin preparations, immunogenicity has been markedly reduced, thereby decreasing the incidence of therapeutic complications such as insulin allergy, immune insulin resistance, and localized lipoatrophy at the injection site. However, the problem of achieving optimal insulin delivery remains unsolved with the present state of technology. It has not been possible to reproduce the physiologic patterns of intraportal insulin secretion with subcutaneous injections of soluble or longer-acting insulin suspensions. Even so, with the help of appropriate modifications of diet and exercise and careful monitoring of capillary blood glucose levels at home, it has often been possible to achieve acceptable control of blood glucose by using various mixtures of short- and longer-acting insulins injected at least twice daily or portable insulin infusion pumps.

1. Characteristics of available insulin preparations—Commercial insulin preparations differ with respect to the animal species from which they are obtained, their purity and solubility, and the time of onset and duration of their biologic action. As many as 17 different formulations of insulin are available in the United States.

a. Species of insulin—Human insulin is produced by recombinant DNA techniques (biosynthetic human insulin) as Humulin (Eli Lilly) and as Novolin (Novo Nordisk). It is dispensed as either regular (R), NPH (N), lente (L), or ultralente (U) formulations (see [Table 27-9](#)). Three analogs of human insulin—two rapidly acting (insulin lispro, insulin aspart) and one very long-acting (insulin glargine)—are now available for clinical use (see below). A limited supply of monospecies pork insulin (Iletin II) remains available for use in certain patients who may benefit from the slightly more prolonged and sustained effect of animal insulin compared with human insulin. The cost of human insulin is slightly less than the cost of purified pork insulin.

b. Purity of insulin—"Purified" insulin is defined by FDA regulations as the degree of purity wherein proinsulin contamination is less than 10 ppm, whether extracted from animal pancreas or produced from biosynthetic proinsulin. All human insulin and pork insulin products of Novo Nordisk and Eli Lilly presently available contain less than 10 ppm of proinsulin and are labeled as "purified." These purified insulins seem to preserve their potency quite well, so that refrigeration is recommended but not crucial. During travel, reserve supplies of insulin can thus be readily transported for weeks without losing potency if protected from extremes of heat or cold.

c. Concentration of insulin—At present, insulins in the United States are available in a concentration of 100 units/mL (U100), and all are dispensed in 10-mL vials. With the popularity of "low-dose" (0.5- or 0.3-mL) disposable insulin syringes, U100 can be measured with acceptable accuracy in doses as low as 1-2 units. For use in rare cases of severe insulin resistance in which large quantities of insulin are required, U500 regular human insulin (Humulin R) is available from Eli Lilly.

2. Insulin preparations—([Table 27-9](#).) Four principal types of insulins are available: (1) ultra-short-acting, with very rapid onset and short duration; (2) short-acting, with rapid onset of action; (3) intermediate-acting; and (4) long-acting, with slow onset of action ([Table 27-9](#) and [Figure 27-1](#)). Ultra-short-acting and short-acting insulins are dispensed as clear solutions at neutral pH and contain small amounts of zinc to improve their stability and shelf life. The long-acting insulin analog insulin glargine is also dispensed as a clear solution but at acidic pH. Other intermediate-acting and long-acting insulins are dispensed as turbid suspensions at neutral pH with either protamine in phosphate buffer (NPH insulin) or varying concentrations of zinc in acetate buffer (ultralente and lente insulins). The ultra-short-acting, intermediate-acting, and long-acting insulins are designed for subcutaneous administration only, while regular insulin can also be given intravenously.

a. Ultra-short-acting insulin—Insulin lispro (Humalog) is an insulin analog produced by recombinant technology, wherein two amino acids near the carboxyl terminal of the B chain have been reversed in position: Proline at position B28 has been moved to B29 and lysine has been moved from B29 to B28. Insulin aspart (Novolog) is a single substitution of proline by aspartic acid at position B28. These changes result in these two analogs having less tendency to form hexamers, in contrast to human insulin. When injected subcutaneously, the analogs quickly dissociate into monomers and are absorbed very rapidly, reaching peak serum values in as soon as 1 hour—in contrast to regular human insulin, whose hexamers require considerably more time to dissociate and become absorbed. The amino acid changes in these

analogs do not interfere with their binding to the insulin receptor, with the circulating half-life, or with their immunogenicity, which are all identical with those of human regular insulin.

Clinical trials have demonstrated that the optimal times of preprandial subcutaneous injection of comparable doses of the ultra-short-acting insulin and analogs and of regular human insulin are 20 minutes and 60 minutes, respectively, before the meal. While this ultrarapid onset of action has been welcomed as a great convenience by diabetic patients who object to waiting as long as 60 minutes after injecting regular human insulin before they can begin their meal, patients must be taught to ingest adequate absorbable carbohydrate early in the meal to avoid hypoglycemia during the meal. Another desirable feature of insulin lispro is that its duration of action remains at about 4 hours irrespective of dosage. This contrasts with regular insulin, whose duration of action is prolonged when larger doses are used.

b. Short-acting insulin—Regular insulin is a short-acting soluble crystalline zinc insulin whose effect appears within 30 minutes after subcutaneous injection and lasts 5-7 hours when usual quantities are administered. Intravenous infusions of regular insulin are particularly useful in the treatment of diabetic ketoacidosis and during the perioperative management of insulin-requiring diabetics. When intravenous insulin is needed for hyperglycemic emergencies, the ultra-short-acting insulin analogs have no advantage over regular human insulin, which is instantly converted to the monomeric form when given intravenously. Regular insulin is indicated when the subcutaneous insulin requirement is changing rapidly, such as after surgery or during acute infections—although the ultra-short-acting analogs may be preferable in these situations.

Aggregation of insulin solutions that cause clogging of tubing in insulin infusion pumps appears to be reduced by use of phosphate-buffered insulins. Novo Nordisk's Velosulin human insulin is a buffered regular insulin approved by the FDA for use in insulin pumps. The ultra-short-acting insulins are also commonly used in pumps. In a double-blind crossover study comparing insulin lispro with regular insulin in insulin pumps, subjects while using insulin lispro had lower HbA_{1c} values and improved postprandial glucose control with the same frequency of hypoglycemia. Insulin aspart has been approved by the FDA for use in insulin pumps. The concern remains that in the event of pump failure, users of the ultra-short-acting insulins will have more rapid onset of hyperglycemia and ketosis.

c. Intermediate-acting insulins—Lente insulin is a mixture of 30% semilente (an amorphous precipitate of insulin with zinc ions) with 70% ultralente insulin (an insoluble crystal of zinc and insulin). Its onset of action is delayed for up to 2 hours ([Figure 27-1](#)), and because its duration of action often is less than 24 hours (with a range of 18-24 hours), most patients require at least two injections daily to maintain a sustained insulin effect. Lente insulin has its peak effect in most patients between 8 and 12 hours, but individual variations in peak response time must be considered when interpreting unusual or unexpected patterns of glycemic responses in individual patients. While lente insulin is the most widely used of the lente series, particularly in conjunction with regular insulin, there has recently been a resurgence of use of ultralente in combination with multiple injections of rapid-acting insulin (regular insulin or insulin lispro) as a means of attempting optimal control in type 1 patients.

NPH (neutral protamine Hagedorn or isophane) insulin is an intermediate-acting insulin whose onset of action is delayed by combining 2 parts soluble crystalline zinc insulin with 1 part protamine zinc insulin. This produces equivalent amounts of insulin and protamine, so that neither is present in an uncomplexed form ("isophane").

The onset and duration of action of NPH insulin are comparable to those of lente insulin ([Figure 27-1](#)); it is usually mixed with regular insulin and given at least twice daily for insulin replacement in type 1 patients. Occasional vials of NPH insulin have tended to show unusual clumping of their contents or "frosting" of the container, with considerable loss of bioactivity. This instability is rare and occurs less frequently if NPH human insulin is refrigerated when not in use and if bottles are discarded after 1 month of use.

d. Long-acting insulins—Humulin ultralente is a crystalline insulin whose duration of action is less than that of the previously available beef ultralente. It is generally recommended that the daily dose be split into two equal doses given 12 hours apart. Its peak is less than that of NPH insulin, and it is often used to provide basal coverage while the short-acting insulins are used to cover the glucose rise associated with meals.

Insulin glargine is an insulin analog in which the asparagine at position 21 of the A chain of the human insulin molecule is replaced by glycine and two arginines are added to the carboxyl terminal of the B chain. The arginines raise the isoelectric point of the molecule closer to neutral, making it more soluble in an acidic environment. In contrast, human insulin has an isoelectric point of pH 5.4. Insulin glargine is a clear insulin which, when injected into the neutral pH environment of the subcutaneous tissue, forms microprecipitates that slowly release the insulin into the circulation. It lasts for about 24 hours without any pronounced peaks and is given once a day to provide basal coverage. This insulin cannot be mixed with the other human insulins because of its acidic pH. When this insulin was given as a single injection at bedtime to type 1 patients, fasting hyperglycemia was better controlled when compared with bedtime NPH insulin. The clinical trials also suggest that there may be less nocturnal hypoglycemia with this insulin when compared with NPH insulin.

In one clinical trial involving type 2 patients, insulin glargine was associated with a slightly higher progression of retinopathy when compared with NPH insulin. The frequency was 7.5% with the analog and 2.7% with the NPH. This finding, however, was not seen in other clinical trials with this analog. Insulin glargine does have a sixfold greater affinity for IGF-1 receptor compared with the human insulin. There has also been a report that insulin glargine had increased mitogenicity compared with human insulin in a human osteosarcoma cell line. The significance of these observations is not yet clear.

e. Mixtures of insulin—Since intermediate insulins require several hours to reach adequate therapeutic levels, their use in type 1 patients requires supplements of regular or lispro insulin preprandially. It is well established that insulin mixtures containing increased proportions of lente to regular insulins may retard the rapid action of admixed regular insulin. The excess zinc in lente insulin binds the soluble insulin and partially blunts its action, particularly when a relatively small proportion of regular insulin is mixed with lente (eg, 1 part regular to 11/2 or more parts lente). NPH preparations do not contain excess protamine and so do not delay absorption of admixed regular insulin. They are therefore preferable to lente when mixtures of intermediate and regular insulins are prescribed. For convenience, regular and NPH insulin may be mixed together in the same syringe and injected subcutaneously in split dosage before breakfast and supper. It is recommended that the regular insulin be withdrawn first, then the NPH insulin. No attempt should be made to mix the insulins in the syringe, and the injection is preferably given immediately after loading the syringe. Stable premixed insulins (70% NPH and 30% regular or 50% of each) are available as a convenience to patients who have difficulty mixing insulin because of visual problems or impairment of manual dexterity.

With increasing use of ultra-short-acting insulin lispro as a popular and convenient preprandial insulin, it has become evident that combination with a more sustained insulin is essential to maintain postabsorptive glycemic control. It has been demonstrated that insulin lispro can be acutely mixed with either NPH or ultralente insulin without affecting its rapid absorption. There are no data on mixing insulin aspart with lente or ultralente insulins. Premixed preparations of lispro and NPH insulins are unstable because of exchange of insulin lispro with the human insulin in the protamine complex. Consequently, the soluble component becomes over time a mixture of regular and insulin lispro at varying ratios. In an attempt to remedy this, an intermediate insulin composed of isophane complexes of protamine with insulin lispro was developed called NPL (neutral protamine lispro). This insulin has the same duration of action as NPH insulin. Premixed combinations of NPL and insulin lispro (eg, 75:25, 50:50, and 25:75 of NPL:insulin lispro) have been tested. The 75% NPL:25% insulin lispro mixture (Humalog Mix 75/25) is available for clinical use. Similarly, a 70% insulin aspart protamine/30% insulin aspart (NovoMix 30) is now available. These new mixtures have more rapid onset of glucose-lowering activity compared with the 70% NPH/30% regular human insulin mixture, and they can therefore be given within 15 minutes of starting a meal. It remains to be shown that these new mixtures have any other clinical advantage over the usual 70% NPH/30% regular mixture.

Since insulin lispro resists hexamer formation at pharmacologic concentrations, it appears to resist precipitation by high concentrations of zinc and thus cannot be used to make a lente or ultralente formulation. However, this lack of precipitation by zinc allows it to be mixed with any of the lente series—in contrast to regular insulin, which tends to be precipitated by the excess zinc in the lente series when mixed prior to injection.

3. Methods of insulin administration—

a. Insulin syringes and needles—Plastic disposable syringes are available in 1-mL, 0.5-mL, and 0.3-mL sizes. The "low-dose" 0.3-mL syringes have become increasingly popular, because diabetics generally should not take more than 30 units of insulin in a single injection except in rare instances of extreme insulin resistance. Two lengths of needles are available: short (8 mm) and long (12.7 mm). Long needles are preferable in obese patients to reduce variability of insulin absorption. Ultrafine needles as small as 30 gauge reduce the pain of injections. "Disposable" syringes may be reused until blunting of the needle occurs (usually after three to five injections). Sterility adequate to avoid infection with reuse appears to be maintained by recapping syringes between uses. Cleansing the needle with alcohol may not be desirable since it can dissolve the silicone coating and can increase the pain of skin puncturing.

Any part of the body covered by loose skin can be used, such as the abdomen, thighs, upper arms, flanks, and upper buttocks. Preparation with alcohol is no longer required prior to injection as long as the skin is clean. Rotation of sites continues to be recommended to avoid delayed absorption when fibrosis or lipohypertrophy occurs from repeated use of a single site. However, considerable variability of absorption rates from different sites, particularly with exercise, may contribute to the instability of glycemic control in certain type 1 patients if injection sites are rotated too frequently in different areas of the body. Consequently, it is best to limit injection sites to a single region of the body and rotate sites within that region. The abdomen is recommended for subcutaneous injections, since regular insulin has been shown to absorb more rapidly from there than from other subcutaneous sites. The effect of anatomic regions appears to be much less pronounced with the analog insulins.

b. Insulin pen injector devices—Insulin pens eliminate the need for carrying insulin vials and syringes. Cartridges of insulin lispro, insulin aspart, regular insulin, NPH insulin, and 70% NPH/30% regular insulin are available for reusable pens (Novo Nordisk and Becton Dickinson pens). Disposable prefilled pens are also available for insulin lispro, NPH, 70% NPH/30% regular, 75% NPL/25% insulin lispro, and 70% insulin aspart protamine/30% insulin aspart. Thirty-one gauge needles for these pens

make injections almost painless.

c. Insulin pumps—In the United States, Mini- Med, Disetronic, Animas, and Deltec Cozmo insulin infusion pumps are available for subcutaneous delivery of insulin. These pumps are small (about the size of a pager) and very easy to program. They offer many features, including the ability to set a number of different basal rates throughout the 24 hours and to adjust the time over which bolus doses are given. They also are able to detect pressure build-up if the catheter is kinked. Improvements have also been made in the infusion sets. The catheter connecting the insulin reservoir to the subcutaneous cannula can be disconnected, allowing the patient to remove the pump temporarily (eg, for bathing). The great advantage of continuous subcutaneous insulin infusion (CSII) is that it allows for establishment of a basal profile tailored to the patient. The patient therefore is able to eat with less regard to timing because the basal insulin infusion should maintain constant blood glucose between meals.

CSII therapy is appropriate for patients who are motivated, mechanically inclined, educated about diabetes (diet, insulin action, treatment of hypo- and hyperglycemia), and willing to monitor their blood glucose four to six times a day. Known complications of CSII include ketoacidosis, which can occur when insulin delivery is interrupted, and skin infections. Another disadvantage is its cost and the time demanded of physicians and staff in initiating therapy.

d. Inhaled insulin—A novel method for delivering preprandial insulin by inhalation has been reported. A 12-week study in type 1 patients showed that inhaled insulin is as efficacious as subcutaneously delivered insulin without additional side effects. Patients required 300-400 units of insulin a day, since only 10% of the inhaled insulin is bioavailable. Studies are in progress to determine whether adequate glycemic control can be sustained with inhaled insulin and whether long-term use affects pulmonary tissues.

D. Transplantation

Pancreas transplantation at the time of renal transplantation is becoming more widely accepted. Patients undergoing simultaneous pancreas and kidney transplantation have an 85% chance of pancreatic graft survival and a 92% chance of renal graft survival after 1 year. Solitary pancreatic transplantation in the absence of a need for renal transplantation should be considered only in those rare patients who fail all other insulin therapeutic approaches and who have frequent severe hypoglycemia or who have life-threatening complications related to their lack of metabolic control.

Islet cell transplantation is a minimally invasive procedure, and investigators in Edmonton, Canada, have reported insulin independence in a small number of patients with type 1 diabetes who underwent this procedure. Using islets from multiple donors and steroid-free immunosuppression, percutaneous transhepatic portal vein transplantation of islets has been achieved in over 20 subjects. All were able to achieve insulin independence, in some cases for more than 2 years of follow-up. All patients had complete correction of severe hypoglycemic reactions, leading to a marked improvement in overall quality of life. All patients continue to have persistent detectable levels of C peptide. Despite these remarkable advances achieved by the Edmonton group, wide application of this procedure for the treatment of type 1 diabetes is limited by the dependence on multiple donors and the requirement for potent long-term immunotherapy.

E. Aspirin Therapy

A dose of 81-325 mg of enteric-coated aspirin given once daily has been shown to effectively inhibit thromboxane synthesis by platelets and reduce the risk of diabetic atherothrombosis without increasing risks of either vitreous or gastrointestinal hemorrhage. Since diabetic patients have up to a fourfold increase in risk of dying from cardiovascular disease, the use of low-dose enteric-coated aspirin is recommended in diabetic adults with evident macrovascular disease or in those with increased cardiovascular risk factors. Contraindications for aspirin therapy are patients with aspirin allergy, bleeding tendency, recent gastrointestinal bleeding, or active hepatic disease.

General Considerations in Treatment of Diabetes

Insulin-treated patients with diabetes can have a full and satisfying life. However, "free" diets and unrestricted activity are still not advised. Until new methods of insulin replacement are developed that provide more normal patterns of insulin delivery in response to metabolic demands, multiple feedings with carbohydrate counting will continue to be recommended, and certain occupations potentially hazardous to the patient or others will continue to be prohibited because of risks due to hypoglycemia. The American Diabetic Association can act as a patient advocate in case of employment questions.

Exercise increases the effectiveness of insulin, and moderate exercise is an excellent means of improving utilization of fat and carbohydrate in diabetic patients. A judicious balance of the size and frequency of meals with moderate regular exercise can often stabilize the insulin dosage in diabetics who tend to slip out of control easily. Strenuous exercise can precipitate hypoglycemia in an unprepared patient, and diabetics must therefore be taught to reduce their insulin dosage in anticipation of strenuous activity or to take supplemental carbohydrate. Injection of insulin into a site farthest away from the muscles most involved in exercise may help ameliorate exercise-induced hypoglycemia, since insulin injected in the proximity of exercising muscle may be more rapidly mobilized.

All diabetic patients must receive adequate instruction on personal hygiene, especially with regard to care of the feet (see Box 27-1), skin, and teeth. All infections (especially pyogenic ones) provoke the release of high levels of insulin antagonists such as catecholamines or glucagon and thus bring about a marked increase in insulin requirements. Supplemental regular insulin is often required to correct hyperglycemia during infection.

INSTRUCTIONS IN THE CARE OF THE FEET FOR PERSONS WITH DIABETES MELLITUS OR VASCULAR DISTURBANCES

Hygiene of the Feet

- (1) Wash feet daily with mild soap and lukewarm water.
Dry thoroughly between the toes by pressure.
Do not rub vigorously, as this is apt to break the delicate skin.
- (2) When feet are thoroughly dry, rub well with vegetable oil to keep them soft, prevent excess friction, remove scales, and prevent dryness. Care must be taken to prevent foot tenderness.
- (3) If the feet become too soft and tender, rub them with alcohol about once a week.
- (4) When rubbing the feet, always rub upward from the tips of the toes. If varicose veins are present, massage the feet very gently; never massage the legs.
- (5) If the toenails are brittle and dry, soften them by soaking for one-half hour each night in lukewarm water containing 1 tbsp of powdered sodium borate (borax) per quart. Follow this by rubbing around the nails with vegetable oil. Clean around the nails with an orangewood stick. If the nails become too long, file them with an emery board. File them straight across and no shorter than the underlying soft tissues of the toe. Never cut the corners of the nails. (The podiatrist should be informed if a patient has diabetes.)
- (6) Wear low-heeled shoes of soft leather that fit the shape of the feet correctly. The shoes should have wide toes that will cause no pressure, fit close in the arch, and grip the heels snugly. Wear new shoes one-half hour only on the first day and increase by 1 hour each day following. Wear thick, warm, loose stockings.

Treatment of Corns & Calluses

- (1) Corns and calluses are due to friction and pressure, most often from improperly fitted shoes and stockings. Wear shoes that fit properly and cause no friction or pressure.
- (2) To remove excess calluses or corns, soak the feet in lukewarm (not hot) water, using a mild soap, for about 10 minutes and then rub off the excess tissue with a towel or file. Do not tear it off. Under no circumstances must the skin become irritated.

- (3) Do not cut corns or calluses. If they need attention it is safer to see a podiatrist.
- (4) Prevent callus formation under the ball of the foot (a) by exercise, such as curling and stretching the toes several times a day; (b) by finishing each step on the toes and not on the ball of the foot; and (c) by wearing shoes that are not too short and that do not have high heels.

Aids in Treatment of Impaired Circulation (Cold Feet)

- (1) Never use tobacco in any form. Tobacco contracts blood vessels and so reduces circulation.
- (2) Keep warm. Wear warm stockings and other clothing. Cold contracts blood vessels and reduces circulation.
- (3) Do not wear circular garters, which compress blood vessels and reduce blood flow.
- (4) Do not sit with the legs crossed. This may compress the leg arteries and shut off the blood supply to the feet.
- (5) If the weight of the bedclothes is uncomfortable, place a pillow under the covers at the foot of the bed.
- (6) Do not apply any medication to the feet without directions from a physician. Some medicines are too strong for feet with poor circulation.
- (7) Do not apply heat in the form of hot water, hot water bottles, or heating pads without a physician's consent. Even moderate heat can injure the skin if circulation is poor.
- (8) If the feet are moist or the patient has a tendency to develop athlete's foot, a prophylactic dusting powder should be used on the feet and in shoes and stockings daily. Change shoes and stockings at least daily or oftener.

Treatment of Abrasions of the Skin

- (1) Proper first-aid treatment is of the utmost importance even in apparently minor injuries. Consult a physician immediately for any redness, blistering, pain, or swelling. Any break in the skin may become ulcerous or gangrenous unless properly treated by a physician.
- (2) Dermatophytosis (athlete's foot), which begins with peeling and itching between the toes or discoloration or thickening of the toenails, should be treated immediately by a physician or podiatrist.
- (3) Avoid strong irritating antiseptics such as tincture of iodine.
- (4) As soon as possible after any injury, cover the area with sterile gauze, which may be purchased at drugstores. Only fine paper tape or cellulose tape should be used on the skin if adhesive retention of the gauze is required.
- (5) Elevate and, as much as possible until recovery, avoid using the foot

Steps in the Management of the Diabetic Patient

A. Diagnostic Examination

Any features of the clinical picture that suggest end-organ insensitivity to insulin, such as visceral obesity, must be identified. The family history should document not only the incidence of diabetes in other members of the family but also the age at onset, whether it was associated with obesity, and whether insulin was required. Other factors that increase cardiac risk, such as smoking history, presence of hypertension or hyperlipidemia, or oral contraceptive pill use, should be recorded.

Laboratory diagnosis should document fasting plasma glucose levels above 126 mg/dL or postprandial values consistently above 200 mg/dL and whether ketonuria accompanies the glycosuria. A glycohemoglobin measurement is useful for assessing the effectiveness of future therapy. Some flexibility of clinical judgment is appropriate when diagnosing diabetes mellitus in the elderly patient with borderline hyperglycemia.

Baseline values include fasting plasma triglycerides, total cholesterol and HDL-cholesterol, electrocardiography, renal function studies, peripheral pulses, and neurologic, podiatric, and ophthalmologic examinations to help guide future assessments.

B. Patient Education (Self-Management Training)

Since diabetes is a lifelong disorder, education of the patient and the family is probably the most important obligation of the clinician who provides initial care. The best persons to manage a disease that is affected so markedly by daily fluctuations in environmental stress, exercise, diet, and infections are the patients themselves and their families. The "teaching curriculum" should include explanations by the physician or nurse of the nature of diabetes and its potential acute and chronic hazards and how they can be recognized early and prevented or treated. Self-monitoring of blood glucose should be emphasized, especially in insulin-requiring diabetic patients, and instructions must be given on proper testing and recording of data. Patients should be provided with algorithms they can use to adjust the timing and quantity of their insulin dose, food, and exercise in response to measured blood glucose values. The targets for blood glucose control should be elevated appropriately in elderly patients since they have the greatest risk if subjected to hypoglycemia and the least long-term benefit from more rigid glycemic control. Advice on personal hygiene, including detailed instructions on foot care, as well as individual instruction on diet and specific hypoglycemic therapy, should be provided. Patients should be told about community agencies, such as Diabetes Association chapters, that can serve as a continuing source of instruction. Finally, vigorous efforts should be made to persuade new diabetics who smoke to give up the habit, since large vessel peripheral vascular disease and debilitating retinopathy are less common in nonsmoking diabetic patients.

C. Initial Therapy

Treatment must be individualized on the basis of the type of diabetes and specific needs of each patient. However, certain general principles of management can be outlined for hyperglycemic states of different types.

1. Type 2 diabetes—

a. The obese type 2 patient—The most common type of diabetic patient is obese, is non-insulin-dependent, and has hyperglycemia because of insensitivity to normal or elevated circulating levels of insulin.

(1) Weight reduction—Treatment is directed toward achieving weight reduction, and prescribing a diet is only one means to this end. Behavior modification to achieve adherence to the diet—as well as increased physical activity to expend energy—is also required. Cure can be achieved by reducing adipose stores, with consequent restoration of tissue sensitivity to insulin, but weight reduction is hard to achieve and even more difficult to maintain with our current therapies. The presence of diabetes with its added risk factors may motivate the obese diabetic to greater efforts to lose weight. (See also [Chapter 29](#).)

(2) Hypoglycemic agents—Neither insulin nor sulfonylureas are indicated for long-term use in the obese patient with *mild* diabetes. The weight reduction program can be upset by real or imagined hypoglycemic reactions when insulin therapy or sulfonylureas are used and weight gain is a frequent complication. Monotherapy with α -glucosidase inhibitors or metformin may be useful in the obese patient with mild diabetes if pharmacotherapy is required since they are not associated with weight gain or drug-induced hypoglycemia.

If metformin therapy (combined with a weight reduction regimen) is inadequate to control symptoms of hyperglycemia (eg, nocturia, blurred vision, or candidal vulvovaginitis), then a thiazolidinedione or a sulfonylurea should be added. Some individuals may require metformin, a thiazolidinedione, *and* a sulfonylurea to achieve adequate glycemic control. Insulin therapy should be instituted if the combination of these three drugs fails to restore euglycemia. Weight-reducing interventions should continue and may allow for simplification of this regimen in the future.

b. The nonobese type 2 patient—In the nonobese diabetic, mild to severe hyperglycemia is usually due to refractoriness of B cells to glucose stimulation. Treatment depends on whether insulinopenia is mild (type 2 or mild type 1 in partial remission) or severe, with ketoacidosis.

(1). *Diet therapy*—If hyperglycemia is mild, normal metabolic control can occasionally be restored by means of multiple feedings of a diet limited in simple sugars and with a caloric content sufficient to maintain ideal weight. Restriction of saturated fats and cholesterol is also strongly advised.

(2) *Oral hypoglycemic agents*—When diet therapy in nonketotic type 2 patients is not sufficient to correct hyperglycemia, a trial of sulfonylureas is often successful in reducing the glycohemoglobin concentration below 9.5%. Once the dosage of one of the more potent sulfonylureas reaches the upper recommended limit in a compliant patient without maintaining fasting blood glucose below 140 mg/dL during the day, combination therapy with metformin (up to 1000 mg twice daily) or a thiazolidinedione—or both—should be tried. When the patient fails the combination of these three drugs, insulin therapy is indicated.

c. Treatment of type 2 diabetes with insulin—When the combination of metformin, sulfonylurea, and a thiazolidinedione fails and type 2 patients require insulin, various insulin regimens may be effective. A single nighttime injection of NPH can be added and titrated to achieve target fasting blood glucose values while continuing daytime sulfonylurea therapy. If the patient does not achieve target glucose levels during the day, daytime insulin treatment can be initiated and the sulfonylurea discontinued. A convenient insulin regimen under these circumstances is a split dose of 70/30 NPH/regular mixture (or Humalog Mix 75/25 or NovoMix 30) before breakfast and before dinner. If this regimen fails to achieve satisfactory glycemic goals or is associated with unacceptable frequency of hypoglycemic episodes, then a more intensive regimen of multiple insulin injections can be instituted. Metformin principally reduces hepatic glucose output and the thiazolidinediones improve peripheral resistance, and it is a reasonable option to continue these drugs when insulin therapy is instituted. The drugs may permit the use of lower doses of insulin and simpler regimens.

2. Type 1 diabetes—Traditional once- or twice-daily insulin regimens are usually ineffective in type 1 patients without residual endogenous insulin. In these patients, information and counseling based on the findings of the DCCT (see above) should be provided about the advantages of taking multiple injections of insulin in conjunction with self-blood glucose monitoring. If near-normalization of blood glucose is attempted, at least three or four measurements of capillary blood glucose and three or four insulin injections are necessary.

A combination of ultra-short-acting insulin analogs and long-acting insulins (ultralente or insulin glargine) allows for more physiologic insulin replacement. The ultra-short-acting insulin analogs have been advocated as a safer and much more convenient alternative to regular human insulin for preprandial use. In a study comparing regular insulin with insulin lispro, daily insulin doses and hemoglobin A_{1c} levels were similar, but insulin lispro improved postprandial control, reduced hypoglycemic episodes, and improved patient convenience compared with regular insulin. However, because of their relatively short duration (no more than 3-4 hours), the ultra-short-acting insulin analogs need to be combined with longer-acting insulins to provide basal coverage and avoid hyperglycemia prior to the next meal. In addition to carbohydrate content of the meal, the effect of simultaneous fat ingestion must also be considered a factor in determining the ultra-fast-acting insulin dosage required to control the glycemic increment during and just after the meal. With low-carbohydrate content and high-fat intake, there is an increased risk of hypoglycemia from insulin lispro within 2 hours after the meal. [Table 27-10](#) illustrates some regimens that might be appropriate for a 70-kg person with type 1 diabetes eating meals providing standard carbohydrate intake and moderate to low fat content.

Since ultra-short-acting insulins reach peak serum levels so quickly after subcutaneous administration, smaller doses are generally required compared with regular human insulin. Multiple injections of NPH insulin (or twice-daily ultralente insulin) can be mixed in the same syringe as the insulin lispro or insulin aspart. Insulin glargine is usually given once in the evening to provide 24-hour coverage. This insulin *cannot be mixed* with any of the other insulins and must be given as a separate injection. There are occasional patients in whom insulin glargine does not seem to last for 24 hours, and in such cases it needs to be given twice a day.

Continuous subcutaneous insulin infusion (CSII) by portable battery-operated "open loop" devices currently provides the most flexible approach, allowing the setting of different basal rates throughout the 24 hours and permitting patients to delay or skip meals and vary meal size and composition. The dosage is usually based on providing 50% of the estimated insulin dose as basal and the remainder as intermittent boluses prior to meals. For example, a 70-kg man requiring 35 units of insulin per day may require a basal rate of 0.7 units per hour throughout the 24 hours with the exception of 3 AM to 8 AM, when 0.8 units per hour might be appropriate (for the dawn phenomenon). The meal bolus would depend on the carbohydrate content of the meal and the premeal blood glucose value. One unit per 15 g of carbohydrate plus 1 unit for 50 mg/dL of blood glucose above a target value (eg, 120 mg/dL) is a common starting point. Further adjustments to basal and bolus dosages would depend on the results of blood glucose monitoring. The majority of patients use the ultra-short-acting insulin analogs in the pumps. Patients using regular insulin should use the buffered insulin preparation (Velosulin) to minimize the risk of precipitation of the insulin in the pump tubing.

One of the more difficult therapeutic problems in managing patients with type 1 diabetes is determining the proper adjustment of insulin dose when the prebreakfast blood glucose level is high. Occasionally, the prebreakfast hyperglycemia is due to the Somogyi effect, in which nocturnal hypoglycemia leads to a surge of counterregulatory hormones to produce high blood glucose levels by 7 AM. However, a more common cause for prebreakfast hyperglycemia is the waning of circulating insulin levels by the morning. Also, the "dawn phenomenon"—reduced tissue sensitivity to insulin between 5 AM and 8 AM—is present in as many as 75% of type 1 patients and can aggravate the hyperglycemia.

[Table 27-11](#) shows that diagnosis of the cause of prebreakfast hyperglycemia can be facilitated by self-monitoring of blood glucose at 3 AM in addition to the usual bedtime and 7 AM measurements. This is required for only a few nights, and when a particular pattern emerges from monitoring blood glucose levels overnight, appropriate therapeutic measures can be taken. The Somogyi effect can be treated by eliminating the dose of intermediate insulin at dinnertime and giving it at a lower dosage at bedtime or by supplying more food at bedtime. When a waning insulin level is the cause, then either increasing the evening dose or shifting it from dinnertime to bedtime (or both) can be effective. A bedtime dose either of insulin glargine or of NPH insulin made from pork insulin provides more sustained overnight insulin levels than human NPH or human ultralente insulin and may be effective in managing refractory prebreakfast hyperglycemia. If this fails, insulin pump therapy may be required. When the dawn phenomenon alone is present, the dosage of intermediate insulin can be divided between dinnertime and bedtime; when insulin pumps are used, the basal infusion rate can be increased (eg, from 0.8 unit/h to 0.9 unit/h from 6 AM until breakfast).

Acceptable Levels of Glycemic Control

See above for a discussion of the Diabetes Control and Complications Trial (DCCT) and the United Kingdom Prospective Diabetes Study (UKPDS) and their implications for diabetes therapy. A reasonable aim of therapy is to approach normal glycemic excursions without provoking severe or frequent hypoglycemia. What has been considered "acceptable" control includes blood glucose levels of 90-130 mg/dL before meals and after an overnight fast, and levels no higher than 180 mg/dL 1 hour after meals and 150 mg/dL 2 hours after meals. Glycohemoglobin levels should be no higher than 1% above the upper limit of the normal range for any particular laboratory. It should be emphasized that the value of blood pressure control was as great as or greater than glycemic control in type 2 patients as regards microvascular as well as macrovascular complications.

Complications of Insulin Therapy

A. Hypoglycemia

Hypoglycemic reactions, the most common complication of insulin therapy, may result from delay in taking a meal or unusual physical exertion. With more type 1 patients attempting "tight" control, this complication has become even more frequent. In older diabetics, in those taking only longer-acting insulins, and often in those attempting to maintain euglycemia on infusion pumps, autonomic counterregulatory responses are less readily elicited during hypoglycemia, and central nervous system dysfunction may occur, ie, mental confusion, bizarre behavior, and ultimately coma. Even focal neurologic deficits mimicking stroke may be observed. More rapid development of hypoglycemia from the effects of regular insulin causes signs of autonomic hyperactivity, both sympathetic (tachycardia, palpitations, sweating, tremulousness) and parasympathetic (nausea, hunger), that may progress to coma and convulsions. Except for sweating, most of the sympathetic symptoms of hypoglycemia are blunted in patients receiving beta-blocking agents for angina or hypertension. Though not absolutely contraindicated, these drugs must be used with caution in insulin-requiring diabetics, and β_1 -selective blocking agents are preferred.

1. Altered awareness of hypoglycemia—Since autonomic responses correlate strongly with "awareness" of hypoglycemia, many poorly controlled diabetics—whose nervous systems have adapted to chronic hyperglycemia—may trigger adrenergic alarms at levels of blood glucose above the usual hypoglycemic range. Conversely, type 1 patients overtreated with insulin may be unaware of critically low levels of blood glucose because of an adaptive blunting of their alarm systems owing to repeated episodes of hypoglycemia. This has been shown to be reversible if higher average blood glucose levels are maintained in these patients to avoid recurrent hypoglycemia over a period of several weeks.

As evidenced by results of the DCCT, the risk of frequent severe hypoglycemic episodes is greatly increased when "normalization" of the blood glucose is attempted with presently available methods of insulin delivery, and this is independent of the species of insulin used. "Near normalization" is therefore a safer target for therapy to avoid hypoglycemic unawareness.

2. Lack of glucagon response in type 1—For unexplained reasons, patients with type 1 lose their glucagon responses to hypoglycemia (but not to amino acids in protein-containing meals) within a year or so after developing diabetes. These patients then rely predominantly on the sympathetic nervous system to counterregulate hypoglycemia and are at special risk in later years when aging, autonomic neuropathy, or frequent hypoglycemic episodes blunt their sympathetic responses.

3. Prevention and treatment of hypoglycemia—Because of the potential danger of insulin-induced reactions, the diabetic patient should carry packets of table sugar or a candy roll at all times for use at the onset of hypoglycemic symptoms. Tablets containing 3 g of glucose are available (Dextrosol). The educated patient soon learns to take the amount of glucose needed and avoids the excess that may occur with eating candy or drinking orange juice, causing very high hyperglycemia. An ampule of glucagon (1 mg) should be provided to every diabetic receiving insulin therapy, and family or friends should be instructed how to inject it intramuscularly in the event that the patient is unconscious or refuses food. An identification MedicAlert bracelet, necklace, or card in the wallet or purse should be carried by every diabetic receiving hypoglycemic drug therapy. The telephone number for the MedicAlert Foundation International in Turlock, California, is 800-ID-ALERT.

All of the manifestations of hypoglycemia are rapidly relieved by glucose administration. If more severe hypoglycemia has produced unconsciousness or stupor, the treatment is 50 mL of 50% glucose solution by rapid intravenous infusion. If intravenous therapy is not available, 1 mg of glucagon injected intramuscularly will usually restore the patient to consciousness within 15 minutes to permit ingestion of sugar. If the patient is stuporous and glucagon is not available, small amounts of honey or syrup or glucose gel (15 g) can be inserted within the buccal pouch, but, in general, oral feeding is contraindicated in unconscious patients. Rectal administration of syrup or honey (30 mL per 500 mL of warm water) has been effective.

B. Immunopathology of Insulin Therapy

At least five molecular classes of insulin antibodies are produced during the course of insulin therapy in diabetes, including IgA, IgD, IgE, IgG, and IgM. With the increased therapeutic use of purified pork and especially human insulin, the various immunopathologic syndromes such as insulin allergy, immune insulin resistance, and lipoatrophy have become quite rare since the titers and avidity of these induced antibodies are generally quite low. However, in parts of the world where less purified forms of beef insulin are still used, these disorders remain a clinical concern among some insulin-treated patients.

1. Insulin allergy—Insulin allergy, or immediate-type hypersensitivity, is a rare condition in which local or systemic urticaria is due to histamine release from tissue mast cells sensitized by adherence of anti-insulin IgE antibodies. In severe cases, anaphylaxis results. When only human insulin has been used from the onset of insulin therapy, insulin allergy is exceedingly rare. Antihistamines, corticosteroids, and even desensitization may be required, especially for systemic hypersensitivity. There have been case reports of successful use of insulin lispro in those rare patients who have a generalized allergy to human insulin or insulin resistance due to a high titer of insulin antibodies.

2. Immune insulin resistance—Most insulin-treated patients develop a low titer of circulating IgG anti-insulin antibodies that neutralize to a small extent the action of insulin. With the old animal insulins, a high titer of circulating antibodies sometimes developed, resulting in extremely high insulin requirements—often more than 200 units daily. This is now rarely seen with the switch to highly purified pork or human insulins and has not been reported with the analogs.

C. Lipodystrophy at Injection Sites

Atrophy of subcutaneous fatty tissue leading to disfiguring excavations and depressed areas may rarely occur at the site of injection. This complication results from an immune reaction, and it has become rarer with the development of pure insulin preparations. Injection of these preparations directly into the atrophic area often results in restoration of normal contours. Lipohypertrophy, on the other hand, is a consequence of the pharmacologic effects of insulin being deposited in the same location repeatedly. It can occur with purified insulins and is best treated with localized liposuction of the hypertrophic areas by an experienced plastic surgeon. Rotation of injection sites will prevent lipohypertrophy. There is a case report of a patient who had intractable lipohypertrophy with human insulin but no longer had the problem when he switched to insulin lispro.

Chronic Complications of Diabetes

Late clinical manifestations of diabetes mellitus include a number of pathologic changes that involve small and large blood vessels, cranial and peripheral nerves, the skin, and the lens of the eye. These lesions lead to hypertension, renal failure, blindness, autonomic and peripheral neuropathy, amputations of the lower extremities, myocardial infarction, and cerebrovascular accidents. These late manifestations correlate with the duration of the diabetic state subsequent to the onset of puberty. In type 1 diabetes, up to 40% of patients develop end-stage renal disease, compared with less than 20% of patients with type 2 diabetes. As regards proliferative retinopathy, it ultimately develops in both types of diabetes but has a slightly higher prevalence in type 1 patients (25% after 15 years' duration). In patients with type 1 diabetes, complications from end-stage renal disease are a major cause of death, whereas patients with type 2 diabetes are more likely to have macrovascular diseases leading to myocardial infarction and stroke as the main causes of death. Cigarette use adds significantly to the risk of both microvascular and macrovascular complications in diabetic patients.

A. Ocular Complications

1. Diabetic cataracts—Premature cataracts occur in diabetic patients and seem to correlate with both the duration of diabetes and the severity of chronic hyperglycemia. Nonglycosylation of lens protein is twice as high in diabetic patients as in age-matched nondiabetic persons and may contribute to the premature occurrence of cataracts.

2. Diabetic retinopathy—Three main categories exist: background, or "simple," retinopathy, consisting of microaneurysms, hemorrhages, exudates, and retinal edema; preproliferative retinopathy with arteriolar ischemia manifested as cotton-wool spots (small infarcted areas of retina); and proliferative, or "malignant," retinopathy, consisting of newly formed vessels. Proliferative retinopathy is a leading cause of blindness in the United States, particularly since it increases the risk of retinal detachment. Vision-threatening retinopathy virtually never appears in type 1 patients in the first 3-5 years of diabetes or before puberty. Up to 20% of patients with type 2 diabetes have retinopathy at the time of diagnosis. Annual consultation with an ophthalmologist should be arranged for patients who have had type 1 diabetes for more than 3-5 years and for all patients with type 2 diabetes, because many were probably diabetic for an extensive period of time before diagnosis. Patients with any macular edema, severe nonproliferative retinopathy, or any proliferative retinopathy require the care of an ophthalmologist. Extensive "scatter" xenon or argon photocoagulation and focal treatment of new vessels reduce severe visual loss in those cases in which proliferative retinopathy is associated with recent vitreous hemorrhages or in which extensive new vessels are located on or near the optic disk. Macular edema, which is more common than proliferative retinopathy in patients with type 2 diabetes (up to 20% prevalence), has a guarded prognosis, but it has also responded to scatter therapy with improvement in visual acuity if detected early. Avoiding tobacco use and correction of associated hypertension are important therapeutic measures in the management of diabetic retinopathy. There is no contraindication to using aspirin in patients with proliferative retinopathy.

3. Glaucoma—Glaucoma occurs in approximately 6% of persons with diabetes. It is responsive to the usual therapy for open-angle disease. Neovascularization of the iris in diabetics can predispose to closed-angle glaucoma, but this is relatively uncommon except after cataract extraction, when growth of new vessels has been known to progress rapidly, involving the angle of the iris and obstructing outflow.

B. Diabetic Nephropathy

As many as 4000 cases of end-stage renal disease occur each year among diabetic people in the United States. This is about one-third of all patients being treated for end-stage renal disease and represents a considerable national health expense.

The cumulative incidence of nephropathy differs between the two major types of diabetes. Patients with type 1 diabetes have a 30-40% chance of having nephropathy after 20 years—in contrast to the much lower frequency in type 2 diabetes patients, in whom only about 15-20% develop clinical renal disease. However, since there are many more individuals affected with type 2 diabetes, end-stage renal disease is much more prevalent in type 2 than in type 1 diabetes in the United States and especially throughout the rest of the world. Improved glycemic control and more effective therapeutic measures to correct hypertension—and with the beneficial effects of angiotensin-converting enzyme inhibitors—can reduce the development of end-stage renal disease among diabetics.

Diabetic nephropathy is initially manifested by proteinuria; subsequently, as kidney function declines, urea and creatinine accumulate in the blood.

1. Microalbuminuria—Sensitive radioimmunoassay methods of detecting small amounts of urinary albumin have permitted detection of microgram concentrations—in contrast to the less sensitive dipstick strips, whose minimal detection limit is 0.3-0.5%. Conventional 24-hour urine collections, in addition to being inconvenient for patients, also show wide variability of albumin excretion, since several factors such as sustained erect posture, dietary protein, and exercise tend to increase albumin excretion rates. For these reasons, a timed overnight urine collection or albumin-creatinine ratio in an early morning spot urine collected upon awakening is preferable. Normal subjects excrete less than 15 ug/min during overnight urine collections; values of 20 ug/min or higher are considered to represent abnormal microalbuminuria. In the early morning spot urine, a ratio of albumin (ug/L) to creatinine (mg/L) of < 30 ug/mg creatinine is normal, and a ratio of 30-300 ug/mg creatinine suggests abnormal microalbuminuria. At least two of three timed overnight or early morning spot urine collections over a 3- to 6-month period should be abnormal before a diagnosis of microalbuminuria is justified.

Subsequent renal failure can be predicted by persistent urinary albumin excretion rates exceeding 30 ug/min. Increased microalbuminuria correlates with increased levels of blood pressure and increased LDL cholesterol, and this may explain why increased proteinuria in diabetic patients is associated with an increase in cardiovascular deaths even in the absence of renal failure. Glycemic control as well as a low-protein diet (0.8 g/kg/d) may reduce both the hyperfiltration and the elevated microalbuminuria in patients in the early stages of diabetes and those with incipient diabetic nephropathy. Antihypertensive therapy also decreases microalbuminuria. Evidence from some studies—but not the UKPDS—supports a specific role for ACE inhibitors in reducing intraglomerular pressure in addition to their lowering of systemic hypertension. An ACE inhibitor (captopril, 50 mg twice daily) in normotensive diabetics impedes progression to proteinuria and prevents the increase in albumin excretion rate. Since microalbuminuria has been shown to correlate with elevated *nocturnal* systolic blood pressure, it is possible that "normotensive" diabetic patients with microalbuminuria have slightly elevated systolic blood pressure during sleep which is lowered during antihypertensive therapy. This action may contribute to the reported efficacy of ACE inhibitor drugs in reducing microalbuminuria in "normotensive" patients.

2. Progressive diabetic nephropathy—Progressive diabetic nephropathy consists of proteinuria of varying severity occasionally leading to nephrotic syndrome with hypoalbuminemia, edema, and an increase in circulating LDL cholesterol as well as progressive azotemia. In contrast to all other renal disorders, the proteinuria associated with diabetic nephropathy does not diminish with progressive renal failure (patients continue to excrete 10-11 g daily as creatinine clearance diminishes). As renal failure progresses, there is an elevation in the renal threshold at which glycosuria appears.

Hypertension develops with progressive renal involvement, and coronary and cerebral atherosclerosis seems to be accelerated. Approximately two-thirds of adult patients with diabetes have hypertension. Once diabetic nephropathy has progressed to the stage of hypertension, proteinuria, or early renal failure, glycemic control is not beneficial in influencing its course. In this circumstance, antihypertensive medications, including ACE inhibitors, and restriction of dietary protein to 0.8 g/kg body weight per day are recommended. ACE inhibitors have been shown to protect against deterioration in renal function in type 1 diabetic patients with clinical nephropathy. This beneficial effect appears to be due to improved glomerular hemodynamics that cannot be explained only by the antihypertensive action of these drugs. Captopril (25 mg three times daily) has shown a 50% reduction in the risk of the combined end points of death, dialysis, and transplantation in type 1 subjects with diabetic nephropathy and clinical proteinuria. During initiation of ACE-inhibitor therapy, an increment in serum creatinine greater than 2 mg/dL due to a rapid fall in intraglomerular pressure—or the occurrence of persistent hyperkalemia (above 6 meq/L) due to hyporeninemic hypoaldosteronism—is an indication to stop this medication.

Dialysis has been of limited value in the long-term treatment of renal failure due to diabetic nephropathy. At present, experience in renal transplantation—especially from related donors—is more promising and is the treatment of choice in cases where there are no contraindications such as severe cardiovascular disease.

C. Gangrene of the Feet

The incidence of gangrene of the feet in diabetics is 20 times the incidence in matched controls. The factors responsible for its development are ischemia, peripheral neuropathy, and secondary infection. Occlusive vascular disease involves both microangiopathy and atherosclerosis of large and medium-sized arteries. Cigarette smoking should be avoided, and prevention of foot disease should be emphasized, since treatment is difficult once ulceration and gangrene have developed. Patients should be examined with a 10-g Semmes-Weinstein monofilament to ensure that protective sensation is intact. If it is not, cushioned socks, athletic shoes, and special foot care are needed since insensitive feet are at high risk for development of neuropathic ulcers. Patients should be instructed to inspect their feet daily for reddened areas, blisters, abrasions, or lacerations (see Instructions in the Care of the Feet). Clinicians should inspect the feet at each visit and instruct patients as necessary on filing calluses with an emery board, cutting toenails straight across, not walking barefoot, and avoiding tight shoes. When an uncomplicated neuropathic ulcer is present and blood flow is not impaired, consultation with a podiatrist or orthopedist is recommended. Cholesterol-lowering agents are useful as adjunctive therapy when early ischemic signs are detected. If blood supply is diminished or absent, patients with foot ulcers should be referred to an appropriate specialist (vascular or orthopedic surgeon). When chronic foot ulcers are refractory to standard debridement and antibiotics, platelet-derived growth factor (Regranex) should be considered for local application. Special custom-built shoes are usually required to redistribute weight evenly over an insensitive foot when it has been deformed by surgery or asymptomatic fractures (Charcot's joint). Amputation of the lower extremities is sometimes required, but appropriate prophylactic foot care has greatly reduced its frequency.

Nonselective beta-blockers are relatively contraindicated in patients with ischemic foot ulcers, because these drugs may potentially reduce peripheral blood flow.

D. Diabetic Neuropathy

Peripheral and autonomic neuropathy, the two most common chronic complications of diabetes, are poorly understood.

1. Peripheral neuropathy—

a. Distal symmetric polyneuropathy—This is the most common form of diabetic peripheral neuropathy where loss of function appears in a stocking-glove pattern and is due to an axonal neuropathic process. Sensory involvement usually occurs first and is generally bilateral, symmetric, and associated with dulled perception of vibration, pain, and temperature, particularly in the lower extremities. At times, discomfort of the lower extremities can be incapacitating. Both motor and sensory nerve conduction are delayed in peripheral nerves, and ankle jerks may be absent. In most cases, motor weakness is mild and confined to the most distal intrinsic muscles of the hands and feet. Long-term complications of diabetic polyneuropathy include insensitivity of the feet, leading to repeated "silent" trauma that predisposes to neuropathic plantar ulcers or deformities of the feet secondary to multiple "silent" fractures (Charcot's joint).

b. Isolated peripheral neuropathy—Involvement of the distribution of only one nerve ("mononeuropathy") or of several nerves ("mononeuropathy multiplex") is characterized by sudden onset with subsequent recovery of all or most of the function. This neuropathology has been attributed to vascular ischemia or traumatic damage. Femoral and cranial nerves are commonly involved, and motor abnormalities predominate. These can result in sudden onset of diplopia due to ophthalmoplegia or in acute pain and weakness of thigh muscles (diabetic amyotrophy). Spontaneous resolution of these ischemic neuropathies generally occurs in 6-12 weeks. In more severe cases with extensive atrophy of limb musculature, this disorder has been termed "malignant cachexia" and mimics the end stages of advanced neoplasia, particularly when depression produces anorexia and weight loss. With this more severe manifestation of diabetic amyotrophy, recovery of muscle function may only be partial.

c. Painful diabetic neuropathy—Hypersensitivity to light touch and occasionally severe "burning" pain, particularly at night, can become physically and emotionally disabling. Amitriptyline, 25-75 mg at bedtime, has been recommended for pain associated with diabetic neuropathy. Dramatic relief has often resulted within 48-72 hours. This rapid response is in contrast to the 2 or 3 weeks required for an antidepressive effect. Patients often attribute benefit to their having a full night's sleep after amitriptyline compared to many previously sleepless nights occasioned by neuropathic pain. Mild to moderate morning drowsiness is a side effect that generally improves with time or can be lessened by giving the medication several hours before bedtime. This drug should not be continued if improvement has not occurred after 5 days of therapy. Desipramine in doses of 25-150 mg/d seems to have the same efficacy as amitriptyline. Gabapentin (900-1800 mg/d in three divided doses) has also been shown to be effective in the treatment of painful neuropathy and should be tried if the tricyclic drugs prove ineffective. There has also been interest in use of the antiarrhythmic drug mexiletine for this purpose in doses of up to 10 mg/kg/d. Capsaicin, a topical irritant, has been found to be effective in reducing local nerve pain; it is dispensed as a cream (Zostrix 0.025%, Zostrix-HP 0.075%) to be rubbed into the skin over the painful region two to four times daily. Gloves should be used for application since hand contamination could result in discomfort if the cream comes in contact with eyes or sensitive areas such as the genitalia.

2. Autonomic neuropathy—With autonomic neuropathy, there is evidence of postural hypotension, decreased cardiovascular response to Valsalva's maneuver, gastroparesis, alternating bouts of diarrhea (particularly nocturnal) and constipation, inability to empty the bladder, and impotence. Gastroparesis should be considered in type 1 diabetic patients who develop unexpected fluctuations and variability in their blood glucose levels after meals. Impotence due to neuropathy differs from psychogenic impotence in that the latter may be intermittent (erections occur under special circumstances), whereas diabetic impotence is usually persistent; aortoiliac occlusive disease may contribute to this problem.

a. Management of autonomic neuropathy—There is no consistently effective treatment for diabetic autonomic neuropathy. Metoclopramide has been of some help in treating diabetic gastroparesis over the short term, but its effectiveness seems to diminish over time. It is a dopamine antagonist that has central antiemetic effects as well as a cholinergic action to facilitate gastric emptying. It can be given intravenously (10 mg three or four times a day, 30 minutes before meals and at bedtime) or orally (20 mg of liquid metoclopramide) before breakfast and dinner. Drowsiness, restlessness, fatigue, and lassitude are common adverse effects. Tardive dyskinesia and extrapyramidal effects also occur. Because it has caused life-threatening cardiac arrhythmias, including 80 deaths, cisapride has been withdrawn from use in the United States. Erythromycin appears to bind to motilin receptors in the stomach and has been found to improve gastric emptying in doses of 250 mg three times daily. Diarrhea associated with autonomic neuropathy has occasionally responded to broad-spectrum antibiotic therapy, though it often undergoes spontaneous remission. Refractory diabetic diarrhea is often associated with impaired sphincter control and fecal incontinence. Therapy with loperamide, 4-8 mg daily, or diphenoxylate with atropine, two tablets up to four times a day, may provide relief. In more severe cases, tincture of paregoric or codeine (60-mg tablets) may be required to reduce the frequency of diarrhea and improve the consistency of the stools. Clonidine has been reported to lessen diabetic diarrhea, but its tendency to lower blood pressure in these patients who already have autonomic neuropathy and some orthostatic hypotension often limits its usefulness. Constipation usually responds to stimulant laxatives such as senna. Bethanechol in doses of 10-50 mg three times a day has occasionally improved emptying of the atonic urinary bladder. Catheter decompression of the distended bladder has been reported to improve its function, and considerable benefit has been reported after surgical severing of the internal vesicle sphincter. Mineralocorticoid therapy with fludrocortisone, 0.2- 0.3 mg/d, and elastic stockings or pressure suits have reportedly been of some help in patients with orthostatic hypotension occurring as a result of loss of postural reflexes.

b. Management of erectile dysfunction—There are medical, mechanical, and surgical treatments available for treatment of erectile dysfunction. Penile erection depends on relaxation of the smooth muscle in the arteries of the corpus cavernosum, and this is mediated by nitric oxide-induced cyclic 3',5'-guanosine monophosphate (cGMP) formation. Sildenafil (Viagra) is a selective inhibitor of cGMP-specific phosphodiesterase type 5. In response to sexual stimulation, there is local release of nitric oxide and cGMP production, and sildenafil, by inhibiting the breakdown of cGMP, improves the ability to attain and maintain an erection. The recommended dose for most patients is one 50 mg tablet taken approximately 1 hour before sexual activity. The peak effect is at 1.5-2 hours, with some effect persisting for 4 hours. Patients with diabetes mellitus using sildenafil reported 50-60% improvement in erectile function. The maximum recommended dose is 100 mg. In clinical trials, only a few adverse effects have been reported—transient mild headache, flushing, dyspepsia, and some altered color vision, particularly with the 100-mg dose. There was no priapism or increase in libido. Because of sildenafil's potentiation of the hypotensive effects of nitrates, its use is contraindicated in patients who are concurrently using organic nitrates in any form. Following its approval and release, a number of deaths have resulted from its use in men with active cardiovascular disease. The FDA has mandated a warning label change in the package insert, advising caution for men who have suffered a heart attack, stroke, or life-threatening arrhythmia within the previous 6 months; men who have resting hypotension or hypertension; and men who have a history of cardiac failure or have

unstable angina.

Intracorporeal injection of vasoactive drugs causes penile engorgement and erection. Drugs most commonly used include papaverine alone, papaverine with phentolamine, and alprostadil (prostaglandin E₁). Alprostadil injections are relatively painless, but careful instruction is essential to prevent local trauma, priapism, and fibrosis. Intraurethral pellets of alprostadil avoid the problem of injection of the drug.

External vacuum therapy (Erec-Aid System) is a nonsurgical treatment consisting of a suction chamber operated by a hand pump that creates a vacuum around the penis. This draws blood into the penis to produce an erection which is maintained by a specially designed tension ring inserted around the base of the penis and which can be kept in place for up to 20-30 minutes. While this method is generally effective, its cumbersome nature limits its appeal.

In view of the recent development of nonsurgical approaches to therapy of erectile dysfunction, resort to surgical implants of penile prostheses is becoming less common.

E. Skin and Mucous Membrane Complications

Chronic pyogenic infections of the skin may occur, especially in poorly controlled diabetic patients. Eruptive xanthomas can result from hypertriglyceridemia, associated with poor glycemic control. An unusual lesion termed **necrobiosis lipoidica diabetorum** is usually located over the anterior surfaces of the legs or the dorsal surfaces of the ankles. They are oval or irregularly shaped plaques with demarcated borders and a glistening yellow surface and occur in women two to four times more frequently than in men.

"Shin spots" are not uncommon in adult diabetics. They are brownish, rounded, painless atrophic lesions of the skin in the pretibial area. Candidal infection can produce erythema and edema of intertriginous areas below the breasts, in the axillas, and between the fingers. It causes vulvovaginitis in most chronically uncontrolled diabetic women with persistent glucosuria and is a frequent cause of pruritus.

While antifungal creams containing miconazole or clotrimazole offer immediate relief of vulvovaginitis, recurrence is frequent unless glucosuria is reduced.

F. Special Situations

1. Insulin replacement during surgery—A recent prospective trial reported that aggressive treatment of hyperglycemia (blood glucose > 110 mg/dL) in surgical ICU patients reduced mortality and morbidity. Only a minority of subjects in this study (204 of 1548) had a diagnosis of diabetes preoperatively, and so it seems that hyperglycemia per se (and not complications of diabetes) was an important cause of postoperative complications. Keeping blood glucose values as close to normal as possible is therefore the goal in the postsurgical patient *in the intensive care unit*. When surgical patients leave the intensive care unit, target glucose values between 100 mg/dL and 200 mg/dL may be appropriate, though this view is based on clinical observations rather than conclusive evidence. During major surgery and in the immediate recovery period in patients with type 1 diabetes—and in most patients with type 2 diabetes—5% dextrose in physiologic saline containing 20 meq of potassium chloride should be infused intravenously at a rate of 100-200 mL/h with regular human insulin (25 units/250 mL 0.9% saline) into the intravenous tubing at a rate of 1-3 units/h. The patient's blood glucose should be monitored every hour initially and the rates of insulin or dextrose adjusted to maintain blood glucose values between 80 mg/dL and 110 mg/dL in the intensive care unit and 100-200 mg/dL on the wards.

Type 2 patients facing minor surgical procedures not requiring general anesthesia who have previously been controlled on oral agents or diet alone do not generally require insulin infusions. Glucose-containing solutions should be avoided during surgery in these patients, and blood glucose levels should be monitored every 4 hours. Regular human insulin or insulin lispro should be administered subcutaneously if needed to maintain blood glucose below 200 mg/dL (see [Chapter 2](#)).

2. Pregnancy and the diabetic patient—Several features distinguish the management of diabetics during pregnancy from the general therapy of diabetes. These include the following: (1) Oral hypoglycemic agents are contraindicated. (2) Weight reduction is not advised, since fetal nutrition can be adversely affected. (3) Intensive insulin therapy with frequent self-monitoring of blood glucose is generally recommended to improve the likelihood of having healthy normal babies. Every effort should be made, utilizing multiple injections of insulin or a continuous infusion of insulin by pump, to maintain near-normalization of fasting and preprandial blood glucose values while avoiding hypoglycemia. Glycohemoglobin should be maintained in the normal range.

Since many diabetic pregnancies persist beyond the expected term—or because the infants are usually large and hydramnios may be present—it has been suggested that pregnancy be terminated early (at 37-38 weeks), especially if glycemic control during pregnancy has been inadequate (eg, glycohemoglobin > 10%). There is a present trend away from elective cesarean section and toward induction of labor.

See [Chapter 18](#) for further details.

Prognosis

The Diabetes Control and Complications Trial (DCCT) showed that the previously poor prognosis for as many as 40% of patients with type 1 diabetes is markedly improved by optimal care. DCCT participants were generally young and highly motivated and were cared for in academic centers by skilled diabetes educators and endocrinologists who were able to provide more attention and services than are usually available. Improved training of primary care providers may be beneficial.

For type 2 diabetes, the UKPDS documented a reduction in microvascular disease with glycemic control, though this was not apparent in the obese subgroup. Cardiovascular outcomes were not improved by glycemic control, though among hypertensive patients antihypertensive therapy showed benefit in reducing the number of adverse cardiovascular complications as well as in reducing the occurrence of microvascular disease. In those with visceral obesity, its successful management remains a major challenge in the attempt to achieve appropriate control of hyperglycemia, hypertension, and dyslipidemia. Once safe and effective methods are devised to prevent or manage obesity, the prognosis of type 2 diabetes with its high cardiovascular risks should improve considerably.

In addition to poorly understood genetic factors relating to differences in individual susceptibility to development of long-term complications of hyperglycemia, it is clear that in both types of diabetes, the diabetic patient's intelligence, motivation, and awareness of the potential complications of the disease contribute significantly to the ultimate outcome.

■ DIABETIC COMA

Coma may be due to a variety of causes not directly related to diabetes. Certain causes directly related to diabetes require differentiation: (1) Hypoglycemic coma resulting from excessive doses of insulin or oral hypoglycemic agents. (2) Hyperglycemic coma associated with either severe insulin deficiency (diabetic ketoacidosis) or mild to moderate insulin deficiency (hyperglycemic hyperosmolar state). (3) Lactic acidosis associated with diabetes, particularly in diabetics stricken with severe infections or with cardiovascular collapse.

DIABETIC KETOACIDOSIS

Essentials of Diagnosis

- Hyperglycemia > 250 mg/dL.
- Acidosis with blood pH < 7.3.
- Serum bicarbonate < 15 meq/L.
- Serum positive for ketones.

General Considerations

Diabetic ketoacidosis may be the initial manifestation of type 1 diabetes or may result from increased insulin requirements in type 1 diabetes patients during the course of infection, trauma, myocardial infarction, or surgery. It is a life-threatening medical emergency with a mortality rate just under 5% in individuals under 40 years of age, but with a more serious prognosis in the elderly, who have mortality rates over 20%. The National Data Group report an annual incidence of five to eight episodes of diabetic ketoacidosis per 1000 diabetic subjects. Type 2 diabetics may develop ketoacidosis under severe stress such as sepsis or trauma. Diabetic ketoacidosis has been found to be one of the more common serious complications of insulin pump therapy, occurring in approximately 1 per 80 patient-months of treatment. Many patients who monitor capillary blood glucose regularly ignore urine ketone measurements, which would signal the possibility of insulin leakage or pump failure before serious illness develops. Poor compliance is one of the most common causes of diabetic ketoacidosis, particularly when episodes are recurrent.

Clinical Findings

A. Symptoms and Signs

The appearance of diabetic ketoacidotic coma is usually preceded by a day or more of polyuria and polydipsia associated with marked fatigue, nausea and vomiting, and, finally, mental stupor that can progress to coma. On physical examination, evidence of dehydration in a stuporous patient with rapid deep breathing and a "fruity" breath odor of acetone would strongly suggest the diagnosis. Hypotension with tachycardia indicates profound fluid and electrolyte depletion, and mild hypothermia is usually present. Abdominal pain and even tenderness may be present in the absence of abdominal disease. Conversely, cholecystitis or pancreatitis may occur with minimal symptoms and signs.

B. Laboratory Findings

(Table 27-12.) Glycosuria of 4+ and strong ketonuria with hyperglycemia, ketonemia, low arterial blood pH, and low plasma bicarbonate are typical of diabetic ketoacidosis. Serum potassium is often elevated despite total body potassium depletion resulting from protracted polyuria or vomiting. Elevation of serum amylase is common but often represents salivary as well as pancreatic amylase. Thus, in this setting, an elevated serum amylase is not specific for acute pancreatitis. Serum lipase may be useful if the diagnosis of acute pancreatitis is being seriously considered. Azotemia may be a better indicator of renal status than serum creatinine, since multichannel chemical analysis of serum creatinine (SMA-6) is falsely elevated by nonspecific chromogenicity of keto acids and glucose. Most laboratories, however, now routinely eliminate this interference. Leukocytosis as high as 25,000/uL with a left shift may occur with or without associated infection. The presence of an elevated or even a normal temperature would suggest the presence of an infection, since patients with diabetic ketoacidosis are generally hypothermic if uninfected.

Complications

The two major metabolic aberrations of diabetic ketoacidosis are hyperglycemia and ketoacidemia, both due to insulin lack associated with hyperglucagonemia as well as elevated levels of other stress hormones such as catecholamines, cortisol, and growth hormone.

A. Hyperglycemia

Hyperglycemia results from increased hepatic production of glucose as well as diminished glucose uptake by peripheral tissues. Hepatic glucose output is a consequence of increased gluconeogenesis resulting from insulinopenia as well as from an associated hyperglucagonemia. When serum hyperosmolality exceeds 320-330 mosm/L, central nervous system depression or coma may ensue. Coma in a diabetic patient with a lower osmolality should prompt a search for cause of coma other than hyperosmolality.

B. Ketoacidemia

Ketoacidemia represents the effect of insulin lack at multiple enzyme loci. Insulin lack associated with elevated levels of growth hormone, catecholamines, and glucagon contributes to an increase in lipolysis from adipose tissue and in hepatic ketogenesis. In addition, there is evidence that reduced ketolysis by insulin-deficient peripheral tissues contributes to the ketoacidemia. The only true "keto" acid present is acetoacetic acid, which, along with its by-product acetone, is measured by nitroprusside reagents (Acetest and Ketostix). The sensitivity for acetone, however, is poor, requiring over 10 mmol, which is seldom reached in the plasma of ketoacidotic subjects—although this detectable concentration is readily achieved in urine. Thus, in the plasma of ketotic patients, only acetoacetate is measured by these reagents. The more prevalent β-hydroxybutyric acid has no ketone group and is therefore not detected by conventional nitroprusside tests. This takes on special

importance in the presence of circulatory collapse during diabetic ketoacidosis, wherein an increase in lactic acid can shift the redox state to increase β -hydroxybutyric acid at the expense of the readily detectable acetoacetic acid. Bedside diagnostic reagents would then be unreliable, suggesting no ketonemia in cases where β -hydroxybutyric acid is a major factor in producing the acidosis. A combined glucose and ketone meter (Precision, Medisense) that is able to measure blood betahydroxybutyrate concentration on capillary blood is available.

Treatment

A. Prevention

Education of diabetic patients to recognize the early symptoms and signs of ketoacidosis has done a great deal to prevent severe acidosis. Urine ketones should be measured in patients with signs of infection or in insulin pump-treated patients when capillary blood glucose is unexpectedly and persistently high. When heavy ketonuria and glycosuria persist on several successive examinations, supplemental regular insulin should be administered and liquid foods such as lightly salted tomato juice and broth should be ingested to replenish fluids and electrolytes. The patient should be instructed to contact the physician if ketonuria persists, and especially if vomiting develops or if appropriate adjustment of the infusion rate on an insulin pump does not correct the hyperglycemia and ketonuria. In juvenile-onset diabetics, particularly in the teen years, recurrent episodes of severe ketoacidosis often indicate poor compliance with the insulin regimen, and these patients will require intensive family counseling.

B. Emergency Measures

If ketosis is severe, the patient should be placed in the hospital for correction of the hyperosmolality as well as the ketoacidemia. An intensive care unit or, at the least, a step-down unit is preferable for more severe cases.

1. Therapeutic flow sheet—One of the most important steps in initiating therapy is to start a flow sheet listing vital signs and the time sequence of diagnostic laboratory values in relation to therapeutic maneuvers. Indices of the metabolic defects include urine glucose and ketones as well as arterial pH, plasma glucose, acetone, bicarbonate, serum urea nitrogen, and electrolytes. Serum osmolality should be measured or estimated and tabulated during the course of therapy.

A convenient method of estimating effective serum osmolality is as follows (normal values in humans are 280-300 mosm/kg):

$$\text{mosm/kg} = 2[\text{Na}^+] + \frac{\text{Glucose (mg/dL)}}{18}$$

These calculated estimates are usually 10-20 mosm/kg lower than values measured by standard cryoscopic techniques in patients with diabetic coma. Urea is freely permeable across cell membranes and therefore not included in calculations of effective serum osmolality. One physician should be responsible for maintaining this therapeutic flow sheet and prescribing therapy. An indwelling urinary catheter is required in all comatose patients but should be avoided if possible in a fully cooperative diabetic because of the risk of introducing bladder infection. Fluid intake and output should be recorded. Gastric intubation is recommended in the comatose patient to correct the commonly associated gastric dilatation that may lead to vomiting and aspiration. The patient should not receive sedatives or narcotics.

2. Insulin replacement—Only regular insulin should be used initially in all cases of severe ketoacidosis, and it should be given immediately after the diagnosis is established. Regular insulin can be given in a loading dose of 0.15 unit/kg as an intravenous bolus to prime the tissue insulin receptors. Following the initial bolus, doses of insulin as low as 0.1 unit/kg/h are continuously infused or given hourly as an intramuscular injection; this is sufficient to replace the insulin deficit in most patients. Replacement of insulin deficiency helps correct the acidosis by reducing the flux of fatty acids to the liver, reducing ketone production by the liver, and also improving removal of ketones from the blood. Insulin treatment reduces the hyperosmolality by reducing the hyperglycemia. It accomplishes this by increasing removal of glucose through peripheral utilization as well as by decreasing production of glucose by the liver. This latter effect is accomplished by direct inhibition of gluconeogenesis and glycogenolysis, as well as by lowered amino acid flux from muscle to liver and reduced hyperglucagonemia.

The insulin dose should be "piggy-backed" into the fluid line so the rate of fluid replacement can be changed without altering the insulin delivery rate. If the plasma glucose level fails to fall at least 10% in the first hour, a repeat loading dose is recommended. The availability of bedside glucometers and of laboratory instruments for rapid and accurate glucose analysis (Beckman or Yellow Springs glucose analyzer) has contributed much to achieving optimal insulin replacement. Rarely, a patient with immune insulin resistance is encountered, and this requires doubling the insulin dose every 2-4 hours if hyperglycemia does not improve after the first two doses of insulin.

3. Fluid replacement—In most patients, the fluid deficit is 4-5 L. Initially, 0.9% saline solution is the solution of choice to help reexpand the contracted vascular volume and should be started in the emergency room as soon as the diagnosis is established. The saline should be infused rapidly to provide 1 L/h over the first 1-2 hours. After the first 2 L of fluid have been given, the intravenous infusion should be at the rate of 300-400 mL/h. Use 0.9 % ("normal") saline unless the serum sodium is greater than 150 meq/L, when 0.45% ("half normal") saline solution should be used. The volume status should be very carefully monitored. Failure to give enough volume replacement (at least 3-4 L in 8 hours) to restore normal perfusion is one of the most serious therapeutic shortcomings adversely influencing satisfactory recovery. Excessive fluid replacement (more than 5 L in 8 hours) may contribute to acute respiratory distress syndrome or cerebral edema. When blood glucose falls to approximately 250 mg/dL, the fluids should be changed to a 5% glucose solution to maintain serum glucose in the range of 250-300 mg/dL. This will prevent the development of hypoglycemia and will also reduce the likelihood of cerebral edema, which could result from too rapid decline of blood glucose. Intensive insulin therapy should be continued until the ketoacidosis is corrected.

4. Sodium bicarbonate—The use of sodium bicarbonate in management of diabetic ketoacidosis has been questioned since clinical benefit was not demonstrated in one prospective randomized trial and because of the following potentially harmful consequences: (1) development of hypokalemia from rapid shift of potassium into cells if the acidosis is overcorrected, (2) tissue anoxia from reduced dissociation of oxygen from hemoglobin when acidosis is rapidly reversed (leftward shift of the oxygen dissociation curve), and (3) cerebral acidosis resulting from lowering of cerebrospinal fluid pH. It must be emphasized, however, that these considerations are less important when severe acidosis exists. It is therefore recommended that bicarbonate be administered to diabetic patients in ketoacidosis if the arterial blood pH is 7.0 or less, with careful monitoring to prevent overcorrection. One or two ampules of sodium bicarbonate (one ampule contains 44 meq/50 mL) should be added to 1 L of 0.45% saline. (**Note:** Addition of sodium bicarbonate to 0.9% saline would produce a markedly hypertonic solution that could aggravate the hyperosmolar state already present.) This should be administered rapidly (over the first hour). It can be repeated until the arterial pH reaches 7.1, but *it should not be given if the pH is 7.1 or greater* since additional bicarbonate would increase the risk of rebound metabolic alkalosis as ketones are metabolized. Alkalosis shifts potassium from serum into cells, which could precipitate a fatal cardiac arrhythmia.

5. Potassium—Total body potassium loss from polyuria and vomiting may be as high as 200 meq. However, because of shifts of potassium from cells into the extracellular space as a consequence of acidosis, serum potassium is usually normal to slightly elevated prior to institution of treatment. As the acidosis is corrected, potassium flows back into the cells, and hypokalemia can develop if potassium replacement is not instituted. If the patient is not uremic and has an adequate urine output, potassium chloride in doses of 10-30 meq/h should be infused during the second and third hours after beginning therapy as soon as the acidosis starts to resolve. Replacement should be started sooner if the initial serum potassium is inappropriately normal or low and should be delayed if serum potassium fails to respond to initial therapy and remains above 5 meq/L, as in cases of renal insufficiency. An ECG can be of help in monitoring the patient's potassium status: High peaked T waves are a sign of hyperkalemia, and flattened T waves with U waves are a sign of hypokalemia. Foods high in potassium content should be prescribed when the patient has recovered sufficiently to take food orally. Tomato juice has 14 meq of potassium per 240 mL, and a medium-sized banana provides about 10 meq.

6. Phosphate—Phosphate replacement is seldom required in treating diabetic ketoacidosis. However, if severe hypophosphatemia of less than 1 mg/dL (< 0.32 mmol/L) develops during insulin therapy, a small amount of phosphate can be replaced per hour as the potassium salt. Correction of hypophosphatemia helps to restore the buffering capacity of the plasma, thereby facilitating renal excretion of hydrogen. It also corrects the impaired oxygen dissociation from hemoglobin by regenerating 2,3-diphosphoglycerate. However, three randomized studies in which phosphate was replaced in only half of a group of patients with diabetic ketoacidosis did not show any apparent clinical benefit from phosphate administration. Moreover, attempts to use the phosphate salt of potassium as the sole means of replacing potassium have led to a number of reported cases of severe hypocalcemia with tetany. To minimize the risk of inducing tetany from too-rapid replacement of phosphate, the average deficit of 40-50 mmol of phosphate should be replaced intravenously at a rate *no greater than 3-4 mmol/h* in a 60-70-kg person. A stock solution (Abbott) provides a mixture of 1.12 g KH_2PO_4 and 1.18 g K_2HPO_4 in a 5-mL single-dose vial (this equals 22 mmol of potassium and 15 mmol of phosphate). One-half of this vial (2.5 mL) should be added to 1 L of either 0.45% saline or 5% dextrose in water. Two liters of this solution, infused at a rate of 400 mL/h, will correct the phosphate deficit at the optimal rate of 3 mmol/h while providing 4.4 meq of potassium per hour. (Additional potassium should be administered as potassium chloride to provide a total of 10-30 meq of potassium per hour, as noted above.) If the serum phosphate remains below 2.5 mg/dL after this infusion, a repeat 5-hour infusion can be given.

7. Hyperchloremic acidosis during therapy—Because of the considerable loss of keto acids in the urine during the initial phase of therapy, substrate for subsequent regeneration of bicarbonate is lost and correction of the total bicarbonate deficit is hampered. A portion of the bicarbonate deficit is replaced with chloride ions infused in large amounts as saline to correct the dehydration. In most patients, as the ketoacidosis clears during insulin replacement, a hyperchloremic, low-bicarbonate pattern emerges with a normal anion gap. This is a relatively benign condition that reverses itself over the subsequent 12-24 hours once intravenous saline is no longer being administered.

8. Treatment of associated infection—Antibiotics are prescribed as indicated. Cholecystitis and pyelonephritis may be particularly severe in these patients.

Prognosis

The frequency of deaths due to diabetic ketoacidosis has been dramatically reduced by improved therapy of young diabetics, but this complication remains a significant risk in the aged and in patients in profound coma in whom treatment has been delayed. Acute myocardial infarction and infarction of the bowel following prolonged hypotension worsen the outlook. A serious prognostic sign is renal failure, and prior kidney dysfunction worsens the prognosis considerably because the kidney plays a key role in compensating for massive pH and electrolyte abnormalities. Cerebral edema has been reported to occur rarely as metabolic deficits return to normal. This is best prevented by avoiding sudden reversal of marked hyperglycemia. Maintaining glycemic levels of 200-300 mg/dL for the initial 24 hours after correction of severe hyperglycemia reduces this risk.

Kitabchi AE et al: Management of hyperglycemic crises in patients with diabetes. Diabetes Care 2001;24:131. [PMID: 11194218]

HYPERGLYCEMIC HYPEROSMOLAR STATE

Essentials of Diagnosis

- Hyperglycemia > 600 mg/dL.
- Serum osmolality > 310 mosm/kg.
- No acidosis; blood pH above 7.3.
- Serum bicarbonate > 15 meq/L.
- Normal anion gap (< 14 meq/L).

General Considerations

This second most common form of hyperglycemic coma is characterized by severe hyperglycemia in the absence of significant ketosis, with hyperosmolality and dehydration. It occurs in patients with mild or occult diabetes, and most patients are at least middle-aged to elderly. Accurate figures are not available as to its true incidence, but from data on hospital discharges it is rarer than diabetic ketoacidosis even in older age groups. Lethargy and confusion develop as serum osmolality exceeds 310 mosm/kg, and coma can occur if osmolality exceeds 320-330 mosm/kg. A committee of the American Diabetes Association has recommended replacing the previous name of this disorder (hyperglycemic, hyperosmolar, nonketotic coma) with the consensus term hyperglycemic hyperosmolar state. Underlying renal insufficiency or congestive heart failure is common, and the presence of either worsens the prognosis. A precipitating event such as infection, myocardial infarction, stroke, or recent operation is often present. Certain drugs such as phenytoin, diazoxide, glucocorticoids, and diuretics have been implicated in its pathogenesis, as have procedures associated with glucose loading such as peritoneal dialysis.

Pathogenesis

A partial or relative insulin deficiency may initiate the syndrome by reducing glucose utilization of muscle, fat, and liver while inducing hyperglucagonemia and increasing hepatic glucose output. With massive glycosuria, obligatory water loss ensues. If a patient is unable to maintain adequate fluid intake because of an associated acute or chronic illness or has suffered excessive fluid loss, marked dehydration results. As plasma volume contracts, renal insufficiency develops, and the resultant limitation of renal glucose loss leads to increasingly higher blood glucose concentrations. Severe hyperosmolality develops that causes mental confusion and finally coma. It is not clear why ketosis is virtually absent under these conditions of insulin insufficiency, although reduced levels of growth hormone may be a factor, along with portal vein insulin concentrations sufficient to restrain ketogenesis.

Clinical Findings

A. Symptoms and Signs

Onset may be insidious over a period of days or weeks, with weakness, polyuria, and polydipsia. The lack of features of ketoacidosis may retard recognition of the syndrome and delay therapy until dehydration becomes more profound than in ketoacidosis. Reduced intake of fluid is not an uncommon historical feature, due to either inappropriate lack of thirst, nausea, or inaccessibility of fluids to elderly, bedridden patients. Lethargy and confusion develop, progressing to convulsions and deep coma. Physical examination confirms the presence of profound dehydration in a lethargic or comatose patient without Kussmaul respirations.

B. Laboratory Findings

Severe hyperglycemia is present, with blood glucose values ranging from 600 to 2400 mg/dL. In mild cases, where dehydration is less severe, dilutional hyponatremia as well as urinary sodium losses may reduce serum sodium to 120-125 meq/L, which protects to some extent against extreme hyperosmolality. However, as dehydration progresses, serum sodium can exceed 140 meq/L, producing serum osmolality readings of 330-440 mosm/kg. Ketosis and acidosis are usually absent or mild. Prerenal azotemia is the rule, with serum urea nitrogen elevations over 100 mg/dL being typical.

Treatment

A. Saline

Fluid replacement is of paramount importance in treating nonketotic hyperglycemic coma. The onset of hyperosmolality is more insidious in elderly people without ketosis than in younger individuals with high serum ketone levels, which provide earlier indicators of severe illness (vomiting, rapid deep breathing, acetone odor, etc). Consequently, diagnosis and treatment are often delayed until fluid deficit has reached levels of 6-10 L.

If hypovolemia is present as evidenced by hypotension and oliguria, fluid therapy should be initiated with 0.9% saline. In all other cases, 0.45% saline appears to be preferable as the initial replacement solution because the body fluids of these patients are markedly hyperosmolar. As much as 4-6 L of fluid may be required in the first 8-10 hours. Careful monitoring of the patient is required for proper sodium and water replacement. Once blood glucose reaches 250 mg/dL, fluid replacement should include 5% dextrose in either water, 0.45% saline solution, or 0.9% saline solution. The rate of dextrose infusion should be adjusted to maintain glycemic levels of 250-300 mg/dL in order to reduce the risk of cerebral edema. An important end point of fluid therapy is to restore urine output to 50 mL/h or more.

B. Insulin

Less insulin may be required to reduce the hyperglycemia in nonketotic patients as compared to those with diabetic ketoacidotic coma. In fact, fluid replacement alone can reduce hyperglycemia considerably by correcting the hypovolemia, which then increases both glomerular filtration and renal excretion of glucose. An initial dose of 0.15 unit/kg is followed by an insulin infusion of 1-2 units/h which is titrated to lower blood glucose levels by 50-70 mg/dL per hour.

C. Potassium

With the absence of acidosis, there may be no initial hyperkalemia unless associated renal failure is present. This results in less severe total potassium depletion than in diabetic ketoacidosis, and less potassium replacement is therefore needed. However, because initial serum potassium is usually not elevated and because it declines rapidly as a result of insulin's effect on driving potassium intracellularly, it has been recommended that potassium replacement be initiated earlier than in ketotic patients, assuming that no renal insufficiency or oliguria is present. Potassium chloride (10 meq/L) can be added to the initial bottle of fluids administered if the patient's serum potassium is not elevated.

D. Phosphate

If severe hypophosphatemia (serum phosphate < 1 mg/dL [< 0.32 mmol/L]) develops during insulin therapy, phosphate replacement can be given as described for ketoacidotic patients (at 3 mmol/h).

Prognosis

The overall mortality rate of hyperglycemic, hyperosmolar, nonketotic coma is more than ten times that of diabetic ketoacidosis, chiefly because of its higher incidence in older patients, who may have compromised cardiovascular systems or associated major illnesses and whose dehydration is often excessive because of delays in recognition and treatment. (When patients are matched for age, the prognoses of these two hyperglycemic emergencies are reasonably comparable.) When prompt therapy is instituted, the mortality rate can be reduced from nearly 50% to that related to the severity of coexistent disorders.

Hyperglycemic crises in patients with diabetes mellitus. Diabetes Care 2001;24:154. [PMID: 11221603]

Trence DL et al: Hyperglycemic crisis in diabetes mellitus type 2. Endocrinol Metab Clin North Am 2001;30:817. [PMID: 11727401]

LACTIC ACIDOSIS

Essentials of Diagnosis

- Severe acidosis with hyperventilation.
- Blood pH below 7.30.
- Serum bicarbonate < 15 meq/L.
- Anion gap > 15 meq/L.
- Absent serum ketones.
- Serum lactate > 5 mmol/L.

General Considerations

Lactic acidosis is characterized by accumulation of excess lactic acid in the blood. Normally, the principal sources of this acid are the erythrocytes (which lack enzymes for aerobic oxidation), skeletal muscle, skin, and brain. Conversion of lactic acid to glucose and its oxidation principally by the liver but also by the kidneys represent the chief pathways for its removal. Overproduction of lactic acid (tissue hypoxia), deficient removal (hepatic failure), or both (circulatory collapse) can cause accumulation. Lactic acidosis is not uncommon in any severely ill patient suffering from cardiac decompensation, respiratory or hepatic failure, septicemia, or infarction of bowel or extremities. With the discontinuance of phenformin therapy in the United States, lactic acidosis in patients with diabetes mellitus has become uncommon but occasionally occurs in metformin-treated patients (see above) and it still must be considered in the acidotic diabetic, especially if the patient is seriously ill.

Clinical Findings

A. Symptoms and Signs

The main clinical feature of lactic acidosis is marked hyperventilation. When lactic acidosis is secondary to tissue hypoxia or vascular collapse, the clinical presentation is variable, being that of the prevailing catastrophic illness. However, in the idiopathic, or spontaneous, variety, the onset is rapid (usually over a few hours), blood pressure is normal, peripheral circulation is good, and there is no cyanosis.

B. Laboratory Findings

Plasma bicarbonate and blood pH are quite low, indicating the presence of severe metabolic acidosis. Ketones are usually absent from plasma and urine or at least not prominent. The first clue may be a high anion gap (serum sodium minus the sum of chloride and bicarbonate anions [in meq/L] should be no greater than 15). A higher value indicates the existence of an abnormal compartment of anions. If this cannot be clinically explained by an excess of keto acids (diabetes), inorganic acids (uremia), or anions from drug overdosage (salicylates, methyl alcohol, ethylene glycol), then lactic acidosis is probably the correct diagnosis. (See [Chapter 21](#) also.) In the absence of azotemia, hyperphosphatemia may be a clue to the presence of lactic acidosis for reasons that are not clear. The diagnosis is confirmed by demonstrating, in a sample of blood that is promptly chilled and separated, a plasma lactic acid concentration of 5 mmol/L or higher (values as high as 30 mmol/L have been reported). Normal plasma values average 1 mmol/L, with a normal lactate/pyruvate ratio of 10:1. This ratio is greatly exceeded in lactic acidosis.*

*In collecting samples, it is essential to rapidly chill and separate the blood in order to remove red cells, whose continued glycolysis at room temperature is a common source of error in reports of high plasma lactate. Frozen plasma remains stable for subsequent assay.

Treatment

Aggressive treatment of the precipitating cause of lactic acidosis is the main component of therapy, such as ensuring adequate oxygenation and vascular perfusion of tissues. Empirical antibiotic coverage for sepsis should be given after culture samples are obtained in any patient in whom the cause of the lactic acidosis is not apparent.

Alkalinization with intravenous sodium bicarbonate to keep the pH above 7.2 has been recommended by some in the emergency treatment of lactic acidosis; as much as 2000 meq in 24 hours has been used. However, there is no evidence that the mortality rate is favorably affected by administering bicarbonate, and its use remains controversial. Hemodialysis may be useful in cases where large sodium loads are poorly tolerated.

Prognosis

The mortality rate of spontaneous lactic acidosis is high. The prognosis in most cases is that of the primary disorder that produced the lactic acidosis.

■ THE HYPOGLYCEMIC STATES

Spontaneous hypoglycemia in adults is of two principal types: fasting and postprandial. Symptoms begin at plasma glucose levels in the range of 60 mg/dL and impairment of brain function at approximately 50 mg/dL. Fasting hypoglycemia is often subacute or chronic and usually presents with neuroglycopenia as its principal manifestation; postprandial hypoglycemia is relatively acute and is often heralded by symptoms of neurogenic autonomic discharge (sweating, palpitations, anxiety, tremulousness).

Differential Diagnosis ([Table 27-13](#))

Fasting hypoglycemia may occur in certain endocrine disorders, such as hypopituitarism, Addison's disease, or myxedema; in disorders related to liver malfunction, such as acute alcoholism or liver failure; and in instances of renal failure, particularly in patients requiring dialysis. These conditions are usually obvious, with hypoglycemia being only a secondary feature. When fasting hypoglycemia is a primary manifestation developing in adults without apparent endocrine disorders or inborn metabolic diseases from childhood, the principal diagnostic possibilities include (1) hyperinsulinism, due to either pancreatic B cell tumors or surreptitious administration of insulin (or sulfonylureas), and (2) hypoglycemia due to non-insulin-producing extrapancreatic tumors.

Postprandial (reactive) hypoglycemia may be classified as early (within 2-3 hours after a meal) or late (3-5 hours after eating). Early, or alimentary, hypoglycemia occurs when there is a rapid discharge of ingested carbohydrate into the small bowel followed by rapid glucose absorption and hyperinsulinism. It may be seen after gastrointestinal surgery and is particularly associated with the dumping syndrome after gastrectomy. In some cases, it is functional and may represent overactivity of the parasympathetic nervous system mediated via the vagus nerve. Rarely, it results from defective counterregulatory responses such as deficiencies of growth hormone, glucagon, cortisol, or autonomic responses.

Alcohol-related hypoglycemia is due to hepatic glycogen depletion combined with alcohol-mediated inhibition of gluconeogenesis. It is most common in malnourished alcohol abusers but can occur in anyone who is unable to ingest food after an acute alcoholic episode followed by gastritis and vomiting.

Immunopathologic hypoglycemia is an extremely rare condition in which anti-insulin antibodies or antibodies to insulin receptors develop spontaneously. In the former case, the mechanism appears to relate to increasing dissociation of insulin from circulating pools of bound insulin. When antibodies to insulin receptors are found, most patients do not have hypoglycemia but rather severe insulin-resistant diabetes and acanthosis nigricans. However, during the course of the disease in these patients, certain anti-insulin receptor antibodies with agonist activity mimicking insulin action may develop, producing severe hypoglycemia.

Factitious hypoglycemia is self-induced hypoglycemia due to surreptitious administration of insulin or sulfonylureas.

HYPOGLYCEMIA DUE TO PANCREATIC B CELL TUMORS

Fasting hypoglycemia in an otherwise healthy, well-nourished adult is rare, and is most commonly due to an adenoma of the islets of Langerhans. Ninety percent of such tumors are single and benign, but multiple adenomas can occur as well as malignant tumors with functional metastases. Adenomas may be familial, and multiple adenomas have been found in conjunction with tumors of the parathyroids and pituitary (multiple endocrine neoplasia type 1 [MEN 1]).

Clinical Findings

A. Symptoms and Signs

The most important prerequisite to diagnosing an insulinoma is simply to consider it, particularly in relatively healthy-appearing persons who have fasting hypoglycemia

associated with some degree of central nervous system dysfunction such as confusion or abnormal behavior. A delay in diagnosis can result in unnecessary treatment for psychomotor epilepsy or psychiatric disorders and may cause irreversible brain damage. In long-standing cases, obesity can result as a consequence of overeating to relieve symptoms.

Whipple's triad is characteristic of hypoglycemia regardless of the cause. It consists of (1) a history of hypoglycemic symptoms, (2) an associated fasting blood glucose of 40 mg/dL or less, and (3) immediate recovery upon administration of glucose. The hypoglycemic symptoms in insulinoma often develop in the early morning or after missing a meal. Occasionally, they occur after exercise. They typically begin with evidence of central nervous system glucose lack and can include blurred vision or diplopia, headache, feelings of detachment, slurred speech, and weakness. Personality and mental changes vary from anxiety to psychotic behavior, and neurologic deterioration can result in convulsions or coma. Sweating and palpitations may not occur.

Hypoglycemic unawareness is very common in patients with insulinoma. They adapt to chronic hypoglycemia by increasing their efficiency in transporting glucose across the blood-brain barrier, which masks awareness that their blood glucose is approaching critically low levels. Counterregulatory hormonal responses as well as neurogenic symptoms such as tremor, sweating, and palpitations are therefore blunted during hypoglycemia. If lack of these warning symptoms prevents recognition of the need to eat to correct the problem, patients can lapse into severe hypoglycemic coma. However, symptoms and normal hormone responses during experimental insulin-induced hypoglycemia have been shown to be restored after successful surgical removal of the insulinoma. Presumably with return of euglycemia, adaptive effects on glucose transport into the brain are corrected and thresholds of counterregulatory responses and neurogenic autonomic symptoms are therefore restored to normal.

B. Laboratory Findings

B cell adenomas do not reduce secretion in the presence of hypoglycemia, and the critical diagnostic test is to demonstrate inappropriately elevated serum insulin levels at a time when hypoglycemia is present. A reliable serum insulin level of 6 uU/mL or more in the presence of blood glucose values below 40 mg/dL is diagnostic of inappropriate hyperinsulinism. Other causes of hyperinsulinemic hypoglycemia must be considered, including factitious administration of insulin or sulfonylureas. An elevated circulating proinsulin level (above 0.2 ng/mL) in the presence of fasting hypoglycemia is characteristic of most B cell adenomas and does not occur in factitious hyperinsulinism.

In patients with epigastric distress, a history of renal stones, or menstrual or erectile dysfunction, a serum calcium, gastrin, or prolactin level may be useful in screening for MEN 1 associated with insulinoma.

C. Diagnostic Tests

1. Prolonged fasting—Prolonged fasting under hospital supervision until hypoglycemia is documented is probably the most dependable means of establishing the diagnosis, especially in men. In 30% of patients with insulinoma, the blood glucose levels often drop below 40 mg/dL after an overnight fast, but some patients require up to 72 hours to develop symptomatic hypoglycemia. However, the term "72-hour fast" is actually a misnomer in most cases since the fast should be immediately terminated as soon as symptoms appear and laboratory confirmation of hypoglycemia is available. In normal male subjects, the blood glucose does not fall below 55-60 mg/dL during a 3-day fast. In contrast, in normal premenopausal women who have fasted for only 24 hours, the plasma glucose may fall normally to such an extent that it can reach values as low as 35 mg/dL. In these cases, however, the women are not symptomatic, presumably owing to the development of sufficient ketonemia to supply energy needs to the brain. Insulinoma patients, on the other hand, become symptomatic when plasma glucose drops to subnormal levels, since inappropriate insulin secretion restricts ketone formation. Moreover, the demonstration of a nonsuppressed insulin level (= 6 uU/mL) in the presence of hypoglycemia suggests the diagnosis of insulinoma. If hypoglycemia does not develop in a male patient after fasting for up to 72 hours—and particularly when this prolonged fast is terminated with a period of moderate exercise—insulinoma must be considered an unlikely diagnosis. A suggested protocol for the supervised fast is shown in [Table 27-14](#).

2. Proinsulin determinations—In contrast to normal subjects, whose proinsulin concentration is less than 20% of the total immunoreactive insulin, most patients with insulinoma have elevated levels of proinsulin representing 30-90% of total immunoreactive insulin. While absolute proinsulin measurements may be elevated in other conditions besides insulinoma (such as in insulin-resistant states), an increased percentage of proinsulin-like components in relation to total insulin immunoreactivity is more specific for insulinoma. However, since this assay of the "percent proinsulin" requires laborious methodology to separate serum protein components, its usefulness is limited. Absolute proinsulin levels are more readily measured, and their specificity increases as plasma glucose falls during a supervised fast. If the laboratory diagnosis is not evident using insulin levels, it may be helpful to find that serum proinsulin fails to suppress below 0.2 ng/mL in the presence of hypoglycemia.

3. Stimulation tests—Stimulation with pancreatic B cell secretagogues such as tolbutamide, glucagon, or leucine is generally not needed in most cases if basal insulin is found to be nonsuppressible and therefore inappropriately elevated during fasting hypoglycemia.

Intravenous glucagon (1 mg over 1 minute) can be useful in patients with "borderline" fasting inappropriate hyperinsulinism. A serum insulin rise above baseline of 200 uU/mL or more at 5 and 10 minutes strongly suggests insulinoma, although poorly differentiated tumors may not respond. Glucagon has the advantage over tolbutamide of correcting rather than provoking hypoglycemia during stimulation testing and is diagnostic in 60-70% of patients with insulinoma. False-negative results can occur if the tumor is poorly differentiated and agranular.

D. Preoperative Localization of B Cell Tumors

Radiographic and arteriographic techniques are seldom helpful in localizing insulinomas preoperatively owing to the small size of most of these tumors (averaging 1.5 cm in diameter in one large series). These methods are often positive only when the tumor is large enough to be easily visualized or palpated intraoperatively.

Currently, there is a growing consensus among experts in this field that present techniques for preoperative localization are of limited usefulness and should be replaced by careful intraoperative ultrasonography and palpation by a surgeon experienced in insulinoma surgery. This approach has a success rate of over 90% in recent surveys and is the sole localizing approach relied upon by many centers, though a CT scan or MRI can be useful to screen for hepatic metastases from a malignant islet cell tumor.

When the insulinoma is not found at the initial surgery, three localization methods are available prior to reoperation. (1) The least invasive is a kinetic MRI with multiple imaging during gadolinium injection, but its accuracy for small tumors is no better than 40%. (2) Percutaneous transhepatic pancreatic vein catheterization with insulin assay can also be useful for localizing small insulinomas with about 70% reliability. However, this technique is not widely available, is invasive and expensive, and is associated with considerable discomfort and some risk to the patient. (3) A more acceptable and currently favored modification correlates imaging from selective arteriography of segments of the pancreas with simultaneous hepatic vein sampling for insulin during a bolus of intra-arterial calcium delivered selectively to these same pancreatic segments. Calcium has been found to be a secretagogue only for insulinomas and not for normal islet tissue, so that a rise in hepatic insulin concentration indicates segmental localization of an insulinoma. Furthermore, this technique may provide data which are particularly helpful when multiple insulinomas are suspected, as in patients with coexisting pituitary or parathyroid adenomas or in rare instances of pancreatic hyperplasia due to nesidioblastosis.

Treatment

A. Surgical Measures

It is imperative that the surgeon be convinced that the diagnosis of insulinoma has been unequivocally made by clinical and laboratory findings. Only then should surgery be considered, as there is no justification for exploratory operation—just as there is none for the use of current localization techniques as a preoperative diagnostic tool. Resection by a surgeon with previous experience in removing pancreatic B cell tumors is the treatment of choice. In patients with a single benign adenoma 90-95% have a successful cure at the first surgical attempt when intraoperative ultrasound is used by a skilled surgeon. Blood glucose should be monitored throughout surgery, and 10% dextrose in water should be infused at a rate of 100 mL/h or faster. In cases where the diagnosis has been established but no adenoma is located after careful palpation and use of intraoperative ultrasound, it is no longer advisable to blindly resect the body and tail of the pancreas, since a nonpalpable tumor missed by ultrasound is most likely embedded within the fleshy head of the pancreas that is left behind with subtotal resections. Most surgeons prefer to close the incision and schedule a selective arterial calcium stimulation with hepatic venous sampling to locate the tumor site prior to a repeat operation. Laparoscopy using ultrasound and enucleation has been successful with a single tumor of the body or tail of the pancreas, but open surgery remains necessary for tumors in the head of the pancreas.

B. Diet and Medical Therapy

In patients with inoperable functioning islet cell carcinoma and in approximately 5-10% of MEN 1 cases when subtotal removal of the pancreas has failed to produce cure, reliance on frequent feedings is necessary. Since most tumors are not responsive to glucose, carbohydrate feedings every 2-3 hours are usually effective in preventing hypoglycemia, although obesity may become a problem. Glucagon should be available for emergency use as indicated in the discussion of treatment of diabetes, but its beneficial effect may be diminished by a concomitant stimulation of insulin release from the tumor. Diazoxide, 300-600 mg daily orally in two or three divided doses, is the treatment of choice. Hydrochlorothiazide, 25-50 mg daily, should also be prescribed to counteract the sodium retention and edema secondary to diazoxide therapy as well as to potentiate its hyperglycemic effect. If patients are unable to tolerate diazoxide because of gastrointestinal upset, hirsutism, or edema, the calcium channel blocker verapamil may be beneficial in view of its inhibitory effect on insulin release from insulinoma cells. Octreotide, a potent long-acting synthetic octapeptide analog of somatostatin, has been used to inhibit release of hormones from a number of endocrine tumors. A dose of 50 ug of octreotide injected subcutaneously twice daily has been tried in cases where surgery failed to remove the source of hyperinsulinism. However, its effectiveness is limited since its affinity for somatostatin receptors of the pancreatic B cell is very much less than for those of the anterior pituitary somatotrophs for which it was originally designed as

treatment for acromegaly. When hypoglycemia persists after attempted surgical removal of the insulinoma and if diazoxide or verapamil is poorly tolerated or ineffective, multiple small feedings may be the only recourse until more selective somatostatin receptor agonists are available. Streptozocin can decrease insulin secretion in islet cell carcinomas, and effective doses have been delivered via selective arterial catheter so that the undue renal toxicity that characterized early experience is less of a problem.

Prognosis

When insulinoma is diagnosed early and cured surgically, complete recovery is likely, although brain damage following prolonged severe hypoglycemia is not reversible. A significant increase in survival rate has been shown in streptozocin-treated patients with islet cell carcinoma, with reduction in tumor mass as well as decreased hyperinsulinism.

HYPOGLYCEMIA DUE TO EXTRAPANCREATIC TUMORS

These rare causes of hypoglycemia include mesenchymal tumors such as retroperitoneal sarcomas, hepatocellular carcinomas, adrenocortical carcinomas, and miscellaneous epithelial-type tumors. The tumors are frequently large and readily palpated or visualized on CT scans or MRI.

The expression and release of an incompletely processed insulin-like growth factor-2 (IGF-2) has provided the best explanation for the clinical manifestations of hypoglycemia in these cases. A larger immature form of the IGF-2 molecule is released which binds to a carrier protein but not to an acid-labile component of serum which inactivates normal IGF-2. This immature IGF-2 complex therefore remains active and binds to insulin receptors in muscle to promote glucose transport and to insulin receptors in liver and kidney to reduce glucose output. It also binds to receptors for IGF-1 in the pancreatic B cell to inhibit insulin secretion. Serum levels of IGF-2 may be increased but often are "normal" in quantity, despite the presence of the immature, higher-molecular-weight form of IGF-2, which can only be detected by special laboratory techniques. Laboratory diagnosis depends upon documenting fasting hypoglycemia associated with undetectable serum insulin levels.

The prognosis for these tumors is generally poor, and surgical removal should be attempted when feasible. Dietary management of the hypoglycemia is the mainstay of medical treatment, since diazoxide is usually ineffective.

Le Roith D: Tumor-induced hypoglycemia. N Engl J Med 1999;341:757. [\[PMID: 10471466\]](#)

POSTPRANDIAL HYPOGLYCEMIA (REACTIVE HYPOGLYCEMIA)

Postgastrectomy Alimentary Hypoglycemia

Reactive hypoglycemia following gastrectomy is a consequence of hyperinsulinism resulting from rapid gastric emptying of ingested food. Symptoms result from adrenergic hyperactivity in response to the hypoglycemia. Treatment consists of more frequent feedings with smaller portions of less rapidly assimilated carbohydrate combined with more slowly absorbed fat and protein.

Functional Alimentary Hypoglycemia

This syndrome is classified as functional when no postsurgical explanation exists for the presence of early alimentary type reactive hypoglycemia. It is most often associated with chronic fatigue, anxiety, irritability, weakness, poor concentration, decreased libido, headaches, hunger after meals, and tremulousness. However, most patients with these symptoms do not have hypoglycemia after a mixed meal. (See Chronic Fatigue Syndrome in [Chapter 1](#).)

Indiscriminate use and overinterpretation of glucose tolerance tests have led to an unfortunate tendency to overdiagnose functional hypoglycemia. As many as one-third or more of normal subjects have blood glucose levels as low as 40-50 mg/dL with or without symptoms during a 4-hour glucose tolerance test. Accordingly, to increase diagnostic reliability, hypoglycemia should preferably be documented during a spontaneous symptomatic episode accompanying routine daily activity, with clinical improvement following feeding. Oral glucose tolerance tests are overly sensitive and mixed meals are relatively insensitive in detecting postprandial reactive hypoglycemia. It has been shown that a high-carbohydrate breakfast has proved useful in differentiating persons with postprandial reactive hypoglycemia from normal controls. The test resulted in reactive hypoglycemia to levels below 59 mg/dL in 47% of 38 subjects, in contrast to only 2.2% of the 43 controls. This test was found to be much more sensitive than a standard mixed meal, which was also given to these two groups.

In patients with documented postprandial hypoglycemia on a functional basis, there is no harm and occasional benefit in reducing the proportion of carbohydrate in the diet while increasing the frequency and reducing the size of meals. Support and mild sedation should be the mainstays of therapy, with dietary manipulation only an adjunct.

Late Hypoglycemia (Occult Diabetes)

This condition is characterized by a delay in early insulin release from pancreatic B cells, resulting in initial exaggeration of hyperglycemia during a glucose tolerance test. In response to this hyperglycemia, an exaggerated insulin release produces a late hypoglycemia 4-5 hours after ingestion of glucose. These patients are usually quite different from those with early hypoglycemia occurring 2-3 hours after glucose ingestion, often being obese and frequently having a family history of diabetes mellitus.

In obese patients, treatment is directed at weight reduction to achieve ideal weight. Like all patients with postprandial hypoglycemia, regardless of cause, these patients often respond to reduced carbohydrate intake with multiple, spaced, small feedings. They should be considered potential diabetics and advised to have periodic medical evaluations.

Service FJ: Diagnostic approach to adults with hypoglycemic disorders. Endocrinol Metab Clin North Am 1999;28:519. [\[PMID: 10500929\]](#)

ALCOHOL-RELATED HYPOGLYCEMIA

Fasting Hypoglycemia after Ethanol

During the postabsorptive state, normal plasma glucose is maintained by hepatic glucose output derived from both glycogenolysis and gluconeogenesis. With prolonged starvation, glycogen reserves become depleted within 18-24 hours and hepatic glucose output becomes totally dependent on gluconeogenesis. Under these circumstances, a blood concentration of ethanol as low as 45 mg/dL can induce profound hypoglycemia by blocking gluconeogenesis. Neuroglycopenia in a patient whose breath smells of alcohol may be mistaken for alcoholic stupor. Prevention consists of adequate food intake during ethanol ingestion. Therapy consists of glucose administration to replenish glycogen stores until gluconeogenesis resumes.

Postethanol Reactive Hypoglycemia

When sugar-containing soft drinks are used as mixers to dilute alcohol in beverages (gin and tonic, rum and cola), there seems to be a greater insulin release than when the soft drink alone is ingested and a tendency for more of a late hypoglycemic overswing to occur 3-4 hours later. Prevention would consist of avoiding sugar mixers while ingesting alcohol and ensuring supplementary food intake to provide sustained absorption.

FACTITIOUS HYPOGLYCEMIA

Factitious hypoglycemia may be difficult to document. A suspicion of self-induced hypoglycemia is supported when the patient is associated with the health professions or has access to insulin or sulfonylurea drugs taken by a diabetic member of the family. The triad of hypoglycemia, high immunoreactive insulin, and suppressed plasma C peptide immunoreactivity is pathognomonic of exogenous insulin administration. Demonstration of circulating insulin antibodies supports this diagnosis in suspected cases. When sulfonylureas are suspected as a cause of factitious hypoglycemia, a plasma level of these drugs to detect their presence may be required to distinguish laboratory findings from those of insulinoma. Unfortunately, the newer sulfonylurea, glimepiride, and other insulinotropic hypoglycemic drugs like repaglinide and nateglinide are not detected in the standard assays for sulfonylureas.

IMMUNOPATHOLOGIC HYPOGLYCEMIA

This rare cause of hypoglycemia, documented in isolated case reports, may occur as two distinct disorders: one associated with spontaneous development of circulating anti-insulin antibodies and another associated with antibodies to insulin receptors, in which the antibodies apparently have agonist capabilities. This latter disorder is extremely rare, having been documented in no more than five cases. However, development of anti-insulin antibodies has been reported in over 200 patients most of whom were being treated with methimazole for thyrotoxicosis. In Western countries, 23 cases have been reported and include patients with a lupus-like syndrome or with various paraproteinemias. The hypoglycemia occurs 3-4 hours after meals following an initial postprandial hyperglycemic phase that is due to the antibodies interfering with the exit of insulin from the plasma to reach its target tissues. Later, after most of the meal is absorbed, inappropriate high levels of insulin dissociate from this antibody-bound compartment, resulting in hypoglycemia.

Redmon JB et al: Autoimmune hypoglycemia. Endocrinol Metab Clin North Am 1999;28:603. [\[PMID: 10500933\]](#)

PENTAMIDINE-INDUCED HYPOGLYCEMIA

Ten to 20 percent of patients receiving pentamidine for *Pneumocystis jiroveci* pneumonia develop symptomatic hypoglycemia, particularly when the drug is administered intravenously. This apparently is due to lytic destruction of pancreatic B cells, causing acute hyperinsulinemia and hypoglycemia. It is later followed by insulinopenia and hyperglycemia, which occasionally is persistent. Since other drugs have been found to be as effective in treating pneumocystis pneumonia, pentamidine administration and its hypoglycemic sequelae are less frequently encountered

Chlorpropamide (Diabinese) ²	100 and 250 mg	0.1-0.5 g as single dose	24-72 hours	\$0.61/250 mg	\$36.60
Glyburide (DiaBeta, Micronase)	1.25, 2.5, and 5 mg	1.25-20 mg as single dose or in 2 divided doses	Up to 24 hours	\$0.78/5 mg	\$93.60
(Glynase)	1.5, 3, and 6 mg	1.5-18 mg as single dose or in 2 divided doses	Up to 24 hours	\$1.07/6 mg	\$96.30
Glipizide (Glucotrol)	5 and 10 mg	2.5-40 mg as single dose or in 2 divided doses on an empty stomach	6-12 hours	\$0.59/10 mg	\$70.80
(Glucotrol XL)	5 and 10 mg	Up to 20 or 30 mg daily as a single dose	Up to 24 hours	\$0.75/10 mg	\$67.50
Glimeperide (Amaryl)	1, 2, and 4 mg	1-4 mg as single dose	Up to 24 hours	\$1.02/4 mg	\$30.60
Meglitinide analogs					
Repaglinide (Prandin)	0.5, 1, and 2 mg	4 mg in two divided doses given 15 minutes before breakfast and dinner	3 hours	\$0.98/2 mg	\$58.80
D-Phenylalanine derivative					
Nateglinide (Starlix)	60 mg and 120 mg	60 mg or 120 mg 3 times a day before meals	1.5 hours	\$1.05/60 mg; \$1.09/120 mg	\$98.10

¹Cost to pharmacist (average wholesale price, generic when possible) for maximum dosage listed. Source: *Drug Topics Red Book*, May 2003; Vol. 22, No. 5.

²There has been a decline in use of these formulations. In the case of chlorpropamide, the decline is due to its numerous side effects (see text).

Table 27-10. Examples of intensive insulin regimens using insulin lispro or insulin aspart and ultralente, NPH, or insulin glargine in a 70 kg man with type 1 diabetes.^{1,2,3}

	Pre-Breakfast	Pre-Lunch	Pre-Dinner	At Bedtime
Insulin lispro or aspart	5 units	4 units	6 units	—
Ultralente insulin	8 units	—	8 units	—
	OR			
Insulin lispro or aspart	5 units	4 units	6 units	—
NPH insulin	3 units	3 units	2 units	8-14 units
Insulin lispro or aspart	5 units	4 units	6 units	—
Insulin glargine	—	—	—	15-16 units

¹Assumes that patient is consuming approximately 75 g carbohydrate at breakfast, 60 g at lunch and 90 g at dinner.

²The dose of insulin lispro or insulin aspart can be raised by 1 or 2 units if extra carbohydrate (15-30 g) is ingested or if premeal blood glucose is > 170 mg/dL. Insulin lispro or insulin aspart can be mixed in the same syringe with ultralente or NPH insulin.

³Insulin glargine cannot be mixed with any of the available insulins and must be given as a separate injection.

Table 27-13. Common causes of hypoglycemia in adults.¹

Fasting hypoglycemia

- Hyperinsulinism
- Pancreatic B cell tumor
- Surreptitious administration of insulin or sulfonylureas
- Extrapancreatic tumors

Postprandial (reactive) hypoglycemia

- Early hypoglycemia (alimentary)

Postgastrectomy

Functional (increased vagal tone)

- Late hypoglycemia (occult diabetes)

Delayed insulin release due to B cell dysfunction

- Counterregulatory deficiency
- Idiopathic

Alcohol-related hypoglycemia

Immunopathologic hypoglycemia

- Idiopathic anti-insulin antibodies (which release their bound insulin)
- Antibodies to insulin receptors (which act as agonists)

Pentamidine-induced hypoglycemia

¹In the absence of clinically obvious endocrine, renal, or hepatic disorders and exclusive of diabetes treated with hypoglycemic agents.

Table 27-14. Suggested hospital protocol for supervised fast in diagnosis of insulinoma.¹

- (1) Obtain baseline serum glucose, insulin, and C-peptide measurements at onset of fast and initiate reliable intravenous access with normal saline.
- (2) Permit only calorie-free and caffeine-free fluids and encourage activity.
- (3) Measure all voided urine for acetone.
- (4) Obtain capillary glucose measurements with a reflectance meter every 4 hours until values < 60 mg/dL are obtained. Then increase the frequency of fingersticks to each hour, and when capillary glucose value is < 49 mg/dL send a venous blood sample to the laboratory for serum glucose, insulin, and C-peptide measurements. Check frequently for manifestations of neuroglycopenia.
- (5) If symptoms of hypoglycemia occur or if a laboratory value of serum glucose is < 45 mg/dL, conclude the fast with a final blood sample for serum glucose, insulin, C-peptide, and sulfonylurea measurements. Intravenous glucose should then be administered (40-50 mL of 50% dextrose in water over 3-5 minutes through the intravenous access line) and administer calorie-containing liquids and food.

INTRODUCTION

For patients with known cardiovascular disease (secondary prevention), cholesterol lowering leads to a reduction in total mortality in men and women and in middle-aged patients and older patients. Among patients without cardiovascular disease (primary prevention), the data are less conclusive, with heart disease mortality and all-cause mortality differing among studies. Nonetheless, treatment algorithms have been designed to assist clinicians in selecting patients for cholesterol-lowering therapy based on their lipid levels and their overall risk of developing cardiovascular disease.

LIPIDS & LIPOPROTEINS

The two main lipids in blood are cholesterol and triglyceride. They are carried in lipoproteins, globular particles that also contain proteins known as apoproteins. Cholesterol is an essential element of all animal cell membranes and forms the backbone of steroid hormones and bile acids; triglycerides are important in transferring energy from food into cells. Why lipids are deposited into the walls of large and medium-sized arteries—an event with potentially lethal consequences—is not known.

Lipoproteins are usually classified on the basis of density, which is determined by the amounts of triglyceride (which makes them less dense) and apoproteins (which makes them more dense). The least dense particles, known as chylomicrons, are normally found in the blood only after fat-containing foods have been eaten. They rise as a creamy layer when nonfasting serum is allowed to stand. The other lipoproteins are suspended in serum and must be separated using a centrifuge. The densest (and smallest) family of particles consists mainly of apoproteins and cholesterol and are called high-density lipoproteins (HDL). Somewhat less dense are the low-density lipoproteins (LDL). Least dense are the large, very-low-density lipoproteins (VLDL), consisting mainly of triglyceride. In fasting serum, most of the cholesterol is carried on LDL particles and is therefore referred to as LDL cholesterol; most of the triglyceride is found in VLDL particles. Specific apoproteins are associated with each lipoprotein class.

Chylomicrons are made in the gut and travel via the portal vein into the liver and via the thoracic duct into the circulation. They are normally completely metabolized, transferring energy from food into muscle and fat cells. The liver manufactures VLDL particles from its own stores of fat and carbohydrate. VLDL particles transfer triglyceride to cells; after losing enough, they eventually become LDL particles, which provide cholesterol for cellular needs. Excess LDL particles are taken up by the liver, and the cholesterol they contain is then excreted into the bile. HDL particles are made in the liver and intestine and appear to facilitate the transfer of apoproteins among lipoproteins. They also participate in reverse cholesterol transport, either by transferring cholesterol into other lipoproteins or directly into the liver.

LIPOPROTEINS & ATHEROGENESIS
